Representation of the sample values by a binary code, although straightforward and intuitively satisfying, is not always the best course to follow. For example, large values are represented by the same number of bits as smaller values, and this may not be the best road to follow since smaller values may be more probable than the larger values. Two methods for representing more probable values of the samples may be employed: (1) nonuniform **quantization** and (2) compression of the signal to be sampled and quantized followed by subsequent expansion at the receiver, referred to as **companding**. The objective is to compress the signal before sampling and quantization such that the dynamic range is increased with very little loss in

TABLE 12.8 Sample Values and Binary Representations for the Waveform of Fig. 12.49(b).

5	155	10011011	10101101

terms of signal to quantization noise power ratio. One such compressor characteristic is called the μ -**law compressor**, which is described by the input-output characteristic (Couch, 1990)

$$y(x) = V \operatorname{sgn}(x) \frac{\ln \left[1 + \frac{\mu|x|}{V} \right]}{\ln(1 + \mu)} \quad (12.57)$$

where V is the maximum input signal amplitude, μ is a parameter, and

$$\operatorname{sgn}(x) = \begin{cases} 1, & x > 0 \\ 0, & x = 0 \\ -1, & x < 0 \end{cases} \quad (12.58)$$

The value $\mu = 255$ is used in the telephone system in the U.S. At the receiving end, the samples are put through a nonlinearity which is the inverse of Eq. (12.57).

Companders are an attempt at minimizing the error in representing a waveform in terms of quantized samples based on a fixed wordlength. Another approach at minimizing the average number of bits per sample is to use a variable length code. The optimum variable wordlength code for independent samples is called a **Huffman code** after its inventor (Blahut, 1990). It is an algorithm for obtaining the minimum average number of bits per sample based on the probability distribution of the samples, with the lower probability samples being assigned the most number of bits and the most probable sample values being assigned the least number of bits. The process of encoding samples at a source is called **source encoding** and can be viewed as removing redundancy from the source output. Another type of encoding, called **channel encoding** or *error correction encoding*, adds redundancy in terms of extra bits appended to each encoded sample so that errors can be corrected at the reception point.

12.4.4 Baseband Digital Pulse Modulation

After the samples have been quantized, they are transmitted through a channel, received, and converted back to their approximate original form. The reason for the modifier “approximate” is that they will invariably suffer some degradation from noise and channel-induced distortion. This will be explored shortly. It is first important to point out that transmission does not necessarily mean to a remote location. For example, storage of data on a computer hard disk and retrieval may happen in the same physical location.

The question at hand is in what format, hereafter called modulation, should the quantized samples be placed for faithful transmission through the channel and subsequent reproduction? The answer depends on the channel. In the case of magnetic recording media, low-frequency response of the medium and recording and pickup heads is poor, so a type of modulation must be used that minimizes the low-frequency content of the signal being recorded. A myriad of formats is possible. We will discuss only a few. In Fig. 12.50, several possible formats are shown.

The first is called **nonreturn-to-zero (NRZ)** polar because the waveform does not return to zero during each signaling interval, but switches from $+V$ to $-V$, or vice versa at the end of each signaling interval (NRZ unipolar uses the levels V and 0). NRZ-mark (also called differentially encoded) represents a data 1 by no change of level and a data 0 by a change of level as shown in Fig. 12.50(b). **Unipolar return-to-zero (URZ)** format, shown in Fig. 12.50(b), returns to zero in each signaling interval. Since bandwidth is inversely proportional to pulse duration, it is apparent that URZ requires twice the bandwidth that NRZ does. Another point about URZ is that it has a nonzero DC component, whereas this is usually not the case for NRZ unless there are more 1s than 0s present in the data or vice versa. An advantage of URZ over NRZ is that a pulse transition is guaranteed in each signaling interval whereas this is not the case for NRZ. Thus, in cases where there are long strings of 1s or 0s, it may be difficult to synchronize the receiver to the starting and stopping times of each pulse in the case of NRZ. A very important modulation format from synchronization considerations is NRZ-mark, also known as **differential encoding**, where an initial reference bit is chosen and a subsequent 1 is encoded as no change from the reference and a 0 is encoded as a change. After the initial reference bit, the current bit serves as a reference for the next bit, etc.

FIGURE 12.50 Various baseband modulation formats: (a) nonreturn-to-zero change, (b) differentially encoded NRZ-mark), (c) return-to-zero, (d) split phase.

An example of this modulation format is shown in Fig. 12.50(b). Another baseband data modulation format that guarantees a transition in each signaling interval and does not have a DC component is known as Manchester, biphas, or **split phase**, which is illustrated in Fig. 12.50(d). It is produced by doing a logical OR of the data clock with an NRZ-formatted signal. The result is a + to – transition for a logic 1, and a – to + zero crossing for a logic 0. Several other data formats have been proposed and employed in the past, but we will consider only these.

An important consideration of any data format is its **bandwidth occupancy**. It can be shown (Ziemer and Tranter, 2002) that NRZ-polar has the power spectral density $[\text{sinc}(z) = \sin(\pi z)/(\pi z)]$

$$S_{\text{NRZ}}(f) = V^2 T_b \text{sinc}^2(T_b f) \tag{12.59}$$

whereas URZ format has the power spectrum

$$S_{\text{RZ}}(f) = \frac{V^2 T_b}{16} \text{sinc}^2\left(\frac{T_b f}{2}\right) + \frac{V^2}{16} \sum_{\substack{m=-\infty \\ m \text{ odd}}}^{\infty} \frac{4}{(\pi m)^2} \delta\left(f - \frac{m}{T_b}\right) + \frac{V^2}{16} \delta(f) \tag{12.60}$$

where the delta function at $f = 0$ reflects the nonzero DC level of the unipolar return-to-zero format. On the other hand, differentially encoded (NRZ-mark) and split phase are formats with zero DC level. The power spectral density of the former is the same as for NRZ, and that of the latter is

$$S_{\text{SP}}(f) = V^2 T_b \text{sinc}^2\left(\frac{T_b f}{2}\right) \sin^2\left(\frac{\pi T_b f}{2}\right) \tag{12.61}$$

FIGURE 12.51 Power spectra for baseband modulation formats: (a) nonreturn-to-zero, (b) unipolar return-to-zero, (c) split phase. (Amplitudes of pulse trains scaled to have unit energy.)

The total average power in each case is obtained by integrating the power spectrum over $-\infty < f < \infty$. Spectra for NRZ, URZ, and split phase are plotted in Fig. 12.51, where it is noted that nonreturn-to-zero occupies half the bandwidth of URZ and split phase.

Of the four modulation formats discussed, NRZ and URZ assume zero memory between pulses, and differentially encoded and split phase have memory imposed between pulses. Split phase has zero power density at $f = 0$ with the result that its bandwidth is double that of nonreturn-to-zero. In a sense, the zero power density at $f = 0$ is obtained in the case of split phase by imposing a particular type of memory between pulses. More general memory structures are used between pulses for applications such as magnetic recording. These can be classified as **line codes**. It is beyond the scope of this chapter to go into this subject here. A simple example is provided by assuming a square pulse function of width T_b for each bit, but with successive pulse multipliers related by $a_k = A_k - A_{k-1}$ where $A_k = \pm 1$ represent the bit value in signaling interval k . Thus the multiplier for pulse k can assume the values 2 ($A_k = 1$ and $A_{k-1} = -1$), 0 ($A_k = 1$ and $A_{k-1} = 1$), or -2 ($A_k = -1$ and $A_{k-1} = 1$). The power spectral density of this pulse modulation format can be shown to be (Ziemer and Tranter, 2002)

$$S_{DC}(f) = 4V^2 T_b \text{sinc}^2(T_b f) \sin^2(\pi T_b f) \tag{12.62}$$

Such pulse modulation is referred to as *dicode*. If the original bit stream is precoded with differential encoding, it is referred to as *duobinary*, a modulation scheme that was invented by Lender (1966).

Before leaving the subject of pulse modulation formats, we discuss one more principle involved in choosing pulse shapes with bandwidth occupancy in mind, known as **Nyquist's pulse-shaping criterion**. The idea is to find pulse shapes $p(t)$, with bandlimited spectra, that have the zero **intersymbol-interference**

property, given by

$$p(nT_b) = \begin{cases} 1, & n = 0 \\ 0, & n \neq 0 \end{cases} \tag{12.63}$$

The condition (12.63) says that if the output of the transmitter/channel/receiver filter cascade is of the form

$$x_{\text{rec}}(t) = V \sum_{k=-\infty}^{\infty} a_k p(t - kT_b) \tag{12.64}$$

where a_k represent the bit values (± 1), then sampling at intervals of T_b ensures that a given pulse sample is not influenced by preceding or following pulses. This is referred to as zero intersymbol interference. Nyquist's pulse shaping criterion states that Eq. (12.64) holds if the Fourier transform of $p(t)$, $P(f)$, satisfies

$$\sum_{k=-\infty}^{\infty} P\left(f + \frac{k}{T_b}\right) = T_b, \quad |f| \leq \frac{1}{2T_b} \tag{12.65}$$

One pulse family that has this property is that family having **raised-cosine spectra**. This pulse shape family is given by

$$p(t) = \frac{\cos 2\pi\beta t}{1 - (4\beta t)^2} \text{sinc}(t/T_b) \tag{12.66}$$

which has the spectrum

$$P(f) = \begin{cases} T_b, & |f| \leq \frac{1}{2T_b} - \beta \\ \frac{T_b}{2} \left[1 + \cos\left(\frac{\pi(|f| - 1/(2T_b) + \beta)}{2\beta}\right) \right], & \frac{1}{2T_b} - \beta < |f| \leq \frac{1}{2T_b} + \beta \\ 0, & |f| > \frac{1}{2T_b} + \beta \end{cases} \tag{12.67}$$

The parameter β determines the bandwidth of the pulse spectrum and its rate of decrease to zero. This pulse shape family and the corresponding spectra are shown in Fig. 12.52.

12.4.5 Detection of Pulse Modulation Formats

With no dependency between signaling pulses, the optimum detection scheme for a digitally modulated pulse train in additive white Gaussian noise (AWGN) is to pass the received pulse train plus noise through a filter matched to the basic signaling pulse, sample the output at the time of the peak output signal, and compare this sample with a suitably chosen threshold. A **matched filter** has impulse response proportional to the time reverse of the signal to which it is matched. It can be shown that the matched filtering and sampling of a signal is equivalent to correlating the received signal plus noise with a replica of the basic pulse shape, sampling, and threshold comparison. These two basic detector structures are shown in Fig. 12.53(a) and Fig. 12.53(b). For a rectangular pulse shape, the **correlation receiver** is equivalent to integrating the pulse being detected over its width, sampling at the end of the pulse, and comparing with a threshold. This receiver structure, called an **integrate-and-dump detector**, is shown in Fig. 12.53(c). NRZ pulse modulation fits this description, and it can be shown that the average probability of making an error in detecting NRZ using this procedure is given by

$$P_E = Q\left(\sqrt{\frac{2E_b}{N_0}}\right), \quad \text{NRZ} \tag{12.68}$$

where

$$Q(x) = \int_x^{\infty} \frac{\exp(-u^2/2)}{\sqrt{2\pi}} du \tag{12.69}$$

FIGURE 12.52 The raised cosine family of (a) pulse shapes and (b) spectra.

FIGURE 12.53 Detectors for pulse modulated signals: (a) matched filter, (b) correlation, (c) integrate-and-dump for square-pulse signals.

is the so-called Q -function, N_0 is the one-sided noise power spectrum level, and $E_b = V^2 T_b$ is the energy in the pulse.

Since URZ has half the pulse width of NRZ, we scale the amplitude by $2^{1/2}$ relative to NRZ in order to do a comparison on an equal energy basis. However, since the level zero is used to represent a logic 0 (as opposed to $-V$ for NRZ), its performance is a factor of two worse than that of NRZ, with the result for the **probability of error** being

$$P_E = Q\left(\sqrt{\frac{E_b}{N_0}}\right), \quad \text{URZ} \tag{12.70}$$

where E_b is now the average bit energy. For differential encoding, essentially two bit errors result each time there is a bit error (the present bit serves as a reference for a succeeding bit) so that for a given E_b/N_0 the probability of error is double that of NRZ. This amounts to about a 0.8-dB shift on the E_b/N_0 axis in a plot of P_E vs. E_b/N_0 . Finally, detection of split phase is accomplished by the same detector as for NRZ with a multiplication by the clock preceding the detector. The probability of error is the same as for NRZ. The P_E results for these pulse modulation formats are plotted in Fig. 12.54 as a function of E_b/N_0 .

12.4.6 Analog Pulse Modulation

The concentration in this section has been on digital pulse modulation methods. Analog pulse modulation, whereby some attribute of a pulse is made to vary in a one-to-one correspondence with the signal samples,

FIGURE 12.54 Probability of error curves for NRZ, URZ, and differentially encoded data formats.

is not as important now as it once was. The main types of analog pulse modulation are pulse amplitude, pulse width, and pulse position modulation. (Ziemer and Tranter, 2002).

Defining Terms

Aliasing: Distortion arising from the representation of a signal by its samples due to too low a sampling rate relative to the signal bandwidth.

Analog-to-digital (A/D) conversion: The process of approximating an analog sample in terms of a finite-precision number, usually in binary form.

Bandwidth occupancy: The amount of bandwidth in Hz occupied by a signal. Quite often, an approximate measure must be used because the total bandwidth extent of typical signals is infinite.

Binary representation: Representation of sample values in terms of a binary number.

Channel encoding: The process of appending redundant bits onto the digital information sent through a channel with the goal of being able to correct errors at the receiver.

Companding: The process of compressing a signal in amplitude before A/D conversion and then expanding it after digital-to-analog conversion. The purpose is to get more resolution for small and moderate sample values and less at large amplitudes. Without quantization, companding would result in no waveform distortion.

Correlation receiver: A receiver structure that correlates received signal plus noise with replicas of the possible received signal shapes. It is completely equivalent in terms of performance to the matched filter receiver.

Differential encoding (NRZ-mark): The process of encoding a bit stream using the present bit as a reference for the following bit, with a 1 encoded as a change from the reference and a 0 encoded as no change.

Flat top sampling: Sampling in which the sampling pulses hold the value of the signal being sampled for a short period of time.

Gray code: A particular binary number representation in which only one bit changes in going from one level to an adjacent level.

Huffman code: A variable-length source code that optimally represents lower probability samples with long codewords and higher probability samples with short codewords so as to minimize overall average codeword length.

Integrate-and-dump detector: A form of the matched filter or correlation detector that is specialized to rectangular signal shapes. Thus, the correlation operation reduces to an integration of the signal interval.

Intersymbol interference: Interference from preceding or succeeding pulses being smeared into a pulse of interest during a sampling process, usually at the receiver.

Line codes: Codes that utilize memory between pulses to control spectral shape, among other reasons. *Dicode* and *duobinary* are early examples of such encoding techniques.

Matched filter: A fixed, linear filter that maximizes peak signal-to-rms noise ratio. Its impulse response is the time reverse of the signal.

μ -Law compressor: A particular compressor characteristic (see *companding*) used in telephone representation of speech signals.

Natural sampling: Sampling that can be modeled as multiplication of a periodic rectangular-pulse sampling waveform by the signal to be sampled. During the sampling times, the sample values follow the shape of the signal being sampled.

Nonreturn-to-zero: A pulse modulation format where ones are represented by a constant positive level for a time period called the bit period and zeros by minus that constant level for the same period. Thus, the pulse representation never returns to zero.

Nyquist's pulse-shaping criterion: A condition placed on the spectrum of a pulse shape function that guarantees zero intersymbol interference when samples are taken at a proper sampling rate.

Probability of error: A measure of performance for a digital receiver. Over a long string of received symbols (signals), it is approximately the ratio of the number of symbols received erroneously divided by the total number.

Pulse modulation: A process whereby information is impressed on a pulse train carrier for transmission through a channel.

Quantization: One of the steps in A/D conversion whereby samples assuming a continuum of values are approximated by finite-precision values.

Raised-cosine spectra: The spectrum of one family of pulses that obeys Nyquist's pulse-shaping criterion.

Sampling Theorem: One of several theorems, the most common of which is called the low-pass sampling theorem and says that a low-pass bandlimited signal of bandwidth W Hz may be represented in terms of samples taken periodically at a minimum rate of $2W$ per second.

Source code: Any coding technique to represent the output of a source, usually with the objective of minimizing the average wordlength.

Split phase: A pulse modulating format that amounts to nonreturn-to-zero multiplied by the data clock, which assumes ± 1 values (also called Manchester or biphase).

Time-division multiplexing: Interlacing pulse samples from different sources in time so that they can be transmitted through a common channel.

Unipolar return-to-zero: A pulse modulation format wherein ones are represented by a positive pulse level during the first-half of the bit period and zero during the last-half and zeros are represented by a zero level.

Wordlength: As pertaining to A/D conversion, the number of digits, usually bits, used to represent a sample.

12.5 Digital Modulation

Rodger E. Ziemer

12.5.1 Introduction

Digital modulation is necessary before digital data can be transmitted through a bandpass channel. Examples of such channels are microwave line of sight, satellite, optical fiber, and cellular mobile radio. Modulation is the process of varying some attribute of a carrier waveform, such as amplitude, phase, or frequency, in accordance with the message to be transmitted. In the case of digital modulation, the message sequence is a stream of digits, quite often binary valued. In the simplest case, this parameter variation is on a symbol-by-symbol basis (zero memory), and the carrier parameters that can be varied are amplitude (**amplitude-shift keying (ASK)**), phase (**phase-shift keying (PSK)**), or frequency (**frequency-shift keying (FSK)**). So-called higher order modulation schemes impose memory over several symbol periods. Modulation techniques can be classified as **binary** or **M-ary** depending on whether one of two possible **signals** or $M > 2$ signals per signaling interval can be sent. If the latter, and if the source digits are binary, it is clear that several bits must be grouped together in order to make up an M -ary word. Another classification for digital modulation techniques is **coherent** vs. **noncoherent**, depending on whether a reference carrier at the receiver coherent with the received carrier is necessary for demodulation (coherent) or not (noncoherent).

12.5.2 Detection of Binary Signals in Additive White Gaussian Noise

Binary, Coherent Modulation Schemes

The simplest possible digital communications system is one which transmits a sequence of binary symbols represented for convenience by $\{0, 1\}$ from a transmitter to a receiver over a channel that degrades the transmitted signal with **additive white Gaussian noise (AWGN)** of two-sided spectral density $N_0/2$. The transmitted binary symbols are associated with two signaling waveforms, denoted as $s_1(t)$ and $s_2(t)$, defined to exist over the time interval $(0, T_b)$. (The symbol T_b will be used to denote **bit period**. Later, T_s will be used to denote **symbol period** when signaling schemes that select from more than two possible transmitted signals are discussed). One of these signals is transmitted each T_b seconds so that the information transmission rate is $R_b = 1/T_b$ binary symbols (bits) per second (b/s). During signaling interval k , the transmitter associates a symbol, such as a 1, with $s_1(t - kT_b)$ and the other symbol, a 0, with $s_2(t - kT_b)$. The receiver is assumed to have perfect knowledge of both $s_1(t)$ and $s_2(t)$, including the precise time at which they could be received and the probability that they were transmitted, assumed to be equally likely, but the receiver does not know which signal was, in fact, transmitted. During each T_b -signaling interval, the receiver observes the signaling waveform contaminated in AWGN and processes this information so as to minimize the probability of making an error.

It can be shown (Ziemer and Tranter, 2002; Wozencraft and Jacobs, 1965; Blahut, 1990; Proakis, 2002) that the minimum probability of error is achieved when the receiver guesses the transmitted signal to be that signal which, given the received signal plus noise waveform, was most likely to have been transmitted. Such a receiver is called a **maximum-likelihood receiver**. For equally likely binary symbols transmitted in AWGN, it can be shown (Ziemer and Tranter, 2002) that the minimum **probability of error** is

$$P_E = Q[\sqrt{z(1 - R_{12})}] \quad (12.71)$$

where

$$Q(x) = \int_x^\infty \frac{e^{-u^2/2}}{\sqrt{2\pi}} du \quad (12.72)$$

is the Q function. The quantities z and R_{12} are defined as

$$z = \frac{E_1 + E_2}{2N_0} = \frac{E_b}{N_0} \quad (12.73)$$

and

$$R_{12} = \frac{\sqrt{E_1 E_2}}{E_b} \rho_{12} \tag{12.74}$$

in which $E_i, i = 1, 2$, is the energy of signal i defined as

$$E_i = \int_0^{T_b} |s_i(t)|^2 dt \tag{12.75}$$

and $E_b = (E_1 + E_2)/2$ is the average signal energy. The parameter ρ_{12} is the normalized **correlation coefficient** between signals, which is given by

$$\rho_{12} = \frac{1}{\sqrt{E_1 E_2}} \int_0^{T_b} s_1(t) s_2(t) dt \tag{12.76}$$

If $R_{12} = 0$, the signaling scheme is said to be **orthogonal**, whereas if $R_{12} = -1$, the signaling scheme is said to be **antipodal**. An example of the former is coherent, binary FSK and an example of the latter is binary PSK. The probability of error is shown in Fig. 12.55 as a function of $z = E_b/N_0$ in decibels for these two cases.

FIGURE 12.55 Probability of error for orthogonal (solid curve) and antipodal (dashed curve) signaling.

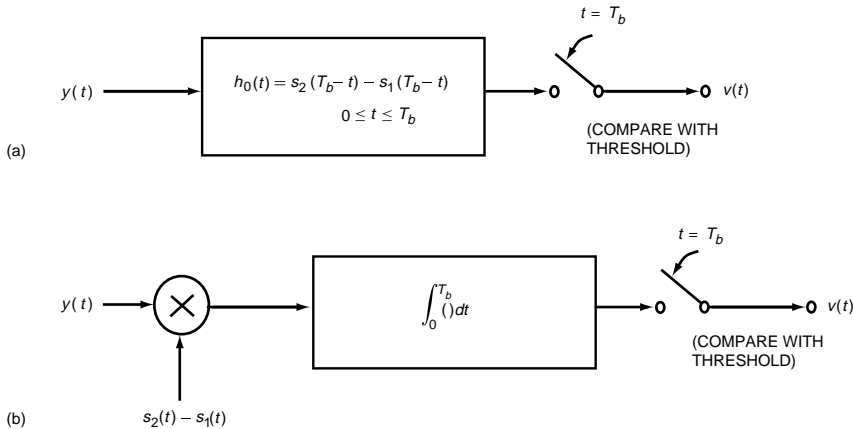

FIGURE 12.56 Implementations of the minimum probability of error receiver for binary signal reception: (a) matched filter, (b) correlator.

The receiver for these binary signaling schemes can have one of two equivalently performing structures—a **matched filter implementation** and a **correlator implementation**. A block diagram for the matched filter receiver is shown in Fig. 12.56(a), and is seen to consist of a matched filter followed by a sampler, which samples the output of the matched filter at the end of each T_b -s signaling interval, and a threshold comparator. A matched filter for any signal has an impulse response that is the shifted time reverse of the signal. Since we are dealing with two signals in this case, the matched filter is matched to the *difference* of the two signals and has impulse response

$$h(t) = s_2(T_b - t) - s_1(T_b - t), \quad 0 \leq t \leq T_b \quad (12.77)$$

A block diagram for the correlator receiver is shown in Fig. 12.56(b), and consists of a correlation operation with the difference of the two signals, followed by a sampler and threshold comparison. The correlator consists of the multiplier and integrator cascade.

For equally probable signals, the comparator threshold is set at

$$k = \frac{1}{2}(s_{o1}(T_b) + s_{o2}(T_b)) \quad (12.78)$$

where $s_{o1}(T_b)$ and $s_{o2}(T_b)$ are the output signals from the matched filter at the sampling instant corresponding to $s_1(t)$ and $s_2(t)$, respectively, at its input. The threshold simplifies to (Ziemer and Tranter, 2002)

$$k = \frac{1}{2}(E_2 - E_1) \quad (12.79)$$

Several special cases of interest in the binary signaling hierarchy are listed in [Table 12.9](#), along with the thresholds and correlation coefficients in each case.

Binary, Noncoherent Modulation Schemes

In situations where it is difficult to maintain phase stability, for example in fading channels, it is useful to employ modulation schemes that do not require the acquisition of a reference signal at the receiver that is in phase coherence with the received carrier. ASK and FSK are two modulation schemes that lend themselves well to noncoherent detection. Receivers for detection of ASK and FSK noncoherently are shown in [Fig. 12.57](#).

TABLE 12.9 Characteristics of Coherent Binary Digital Modulation Schemes

Name	Signal	Threshold Eq (12.78)	Signal Corr. Coeff., R_{12}
Antipodal baseband ^a signaling	$s_{1,2}(t) = \pm \sqrt{\frac{E_b}{T_b}}, \quad 0 \leq t \leq T_b$ $s_1(t) = 0$	0	-1
Amplitude-shift keying	$s_2(t) = \sqrt{\frac{4E_b}{T_b}} \cos(\omega_c t)$	$E_2/2$	0
(Binary) phase-shift keying (PSK)	$s_{1,2}(t) = \sqrt{\frac{2E_b}{T_b}} \sin(\omega_c t \pm \cos^{-1} m), \quad 0 \leq t \leq T_b$ where $ m \leq 1$ is the modulation index	0	$2m^2 - 1$
Biphase-shift keying (BPSK)	$s_{1,2}(t) = \pm \sqrt{\frac{2E_b}{T_b}} \cos(\omega_c t), \quad 0 \leq t \leq T_b$	0	-1
Frequency-shift keying (FSK)	$s_1(t) = \sqrt{2E_b/T_b} \cos(\omega_c t)$ $s_2(t) = \sqrt{2E_b/T_b} \cos[(\omega_c + \Delta\omega)t]$ $\Delta\omega = \pi \times \text{integer}/T_b$	0	0

^aIn all cases, E_b is the average signal energy per bit, E_1 is the energy of signal 1, and E_2 is the energy of signal 2. All signalling schemes except antipodal baseband are referred to as coherent, because the carrier phase must be known at the receiver to implement the matched or correlator detector.

For noncoherent reception of binary ASK, the error probability for large signal-to-noise ratios is well approximated by (Ziemer and Tranter, 2002)

$$P_E \cong \frac{1}{2} e^{-z/2}, \quad z \gg 1 \text{ (noncoherent ASK)} \tag{12.80}$$

where $z = E_b/N_0$ as before. For noncoherent detection of binary FSK, the probability of error is exactly given by (Ziemer and Tranter, 2002)

$$P_E = \frac{1}{2} e^{-z/2} \text{ (noncoherent FSK)} \tag{12.81}$$

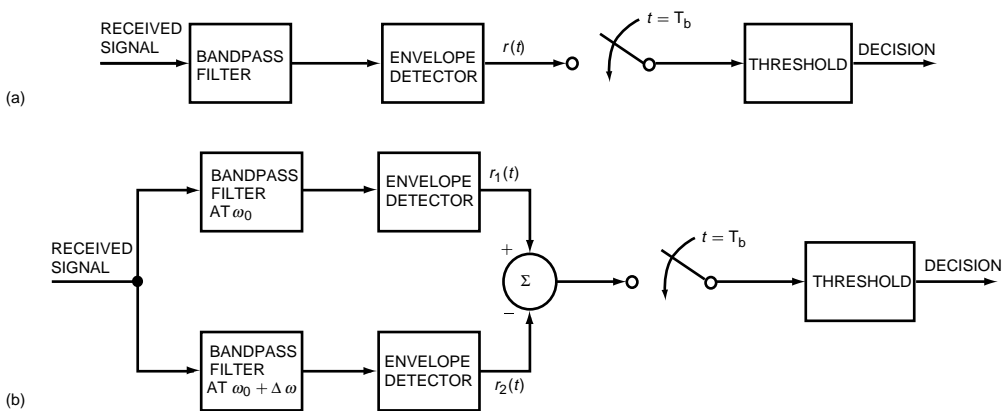

FIGURE 12.57 Receivers for noncoherent detection of binary signals: (a) ASK, (b) FSK.

TABLE 12.10 An Example Illustrating the Differential Encoding Process

Message sequence:	1	0	0	1	1	1	0
Encoded sequence:	1	1	0	1	1	1	0
Transmitted phase radians:	0	0	π	0	0	0	π

Thus, both perform the same for large signal-to-noise ratios. To compare this with coherent detection of FSK, the asymptotic approximation for the Q function given by

$$Q(x) = \frac{e^{-x^2/2}}{\sqrt{2\pi}x}, \quad x \gg 1 \tag{12.82}$$

is employed. Application of this to Eq. (12.71) with $R_{12} = 0$ gives

$$P_E = \frac{e^{-z/2}}{\sqrt{2\pi}z}, \quad z \gg 1 \text{ (coherent FSK)} \tag{12.83}$$

Since the dominant behavior comes through the exponent in Eq. (12.83) it follows that coherent and noncoherent FSK have very nearly the same error probability performance at large signal-to-noise ratios, with coherent FSK slightly better due to the $z^{-1/2}$ in the denominator of Eq. (12.83).

There is one other binary modulation scheme which is, in a sense, noncoherent. It is **differentially coherent PSK (DPSK)**, in which the phase of the preceding bit interval is used as a reference for the current bit interval. This technique depends on the channel being stable enough so that phase changes due to channel perturbations from a given bit interval to the succeeding one are inconsequential. It also depends on there being a known phase relationship from one bit interval to the next. This is ensured by differentially encoding the bits before phase modulation at the transmitter. **Differential encoding** is illustrated in Table 12.10. An arbitrary reference bit is chosen to start the process off. In Table 12.10 a 1 has been chosen. For each bit of the encoded sequence, the present bit is used as a reference for the following bit in the sequence. A 0 in the message sequence is encoded as a transition from the state of the reference bit to the opposite state in the encoded message sequence; a 1 is encoded as no change of state. Using these rules, it is seen that the encoded sequence shown in Table 12.10 results.

Block diagrams of two possible receiver structures for DPSK are shown in Fig. 12.58. The first is suboptimum, but relatively simple to implement. The second is the optimum receiver for DPSK in AWGN.

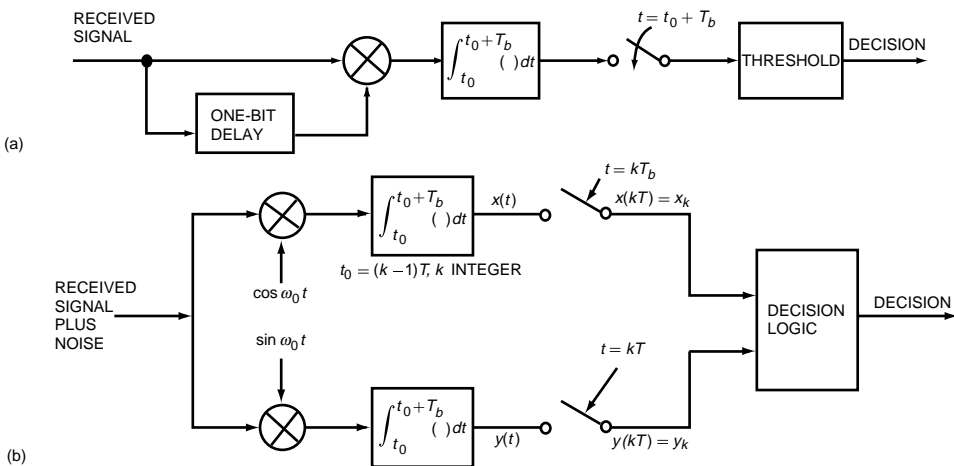

FIGURE 12.58 Receiver block diagrams for detection of DPSK: (a) suboptimum, (b) optimum.

FIGURE 12.59 Comparison of error probabilities for BPSK, DPSK, coherent FSK, and noncoherent FSK.

Its probability of error performance can be shown to be (Ziemer and Tranter, 2002)

$$P_E = \frac{1}{2}e^{-z} \text{ (DPSK)} \tag{12.84}$$

This can be compared with BPSK by again making use of the asymptotic approximation for the Q function given by Eq. (12.82) in Eq. (12.71) with $R_{12} = -1$ to give the following approximate result for BPSK for large signal-to-noise ratios:

$$P_E = \frac{e^{-z}}{2\sqrt{\pi z}}, \quad z \gg 1 \text{ (BPSK)} \tag{12.85}$$

The exponential behavior for DPSK and BPSK is the same for large z ; BPSK is slightly better due to the factor $z^{-1/2}$ in Eq. (12.85). Error probabilities for BPSK, DPSK, coherent binary FSK, and noncoherent binary FSK are compared in Fig. 12.59. It is seen that less than 1 dB of degradation results in going from coherent to noncoherent detection at $P_E = 10^{-6}$.

Bandwidth Efficiency

The error probability as a function of E_b/N_0 for a given modulation scheme tells only half of the story, and is often referred to as a measure of its **power efficiency**. Also important is its **bandwidth efficiency**, defined to be the ratio of the bandwidth required to accept a given data rate divided by the data rate.

TABLE 12.11 Bandwidth Efficiencies for Binary Modulation Schemes

Modulation Type	Bandwidth Efficiency, b/s/Hz
Rectangular pulse baseband	1
ASK, PSK, BPSK, DPSK	0.5
Coherent FSK	0.4
Noncoherent FSK	0.25

For example, it is well known from Fourier theory that the spectrum of a rectangular pulse of duration T is

$$S(f) = AT \operatorname{sinc}(fT) \quad (12.86)$$

where $\operatorname{sinc}(x) = \sin(\pi x)/(\pi x)$.

When used to modulate a cosinusoid of frequency f_c , the spectrum of the rectangular pulse is centered around the carrier frequency, f_c

$$S_m(f) = \frac{AT}{2} \{ \operatorname{sinc}((f - f_c)T) + \operatorname{sinc}((f + f_c)T) \} \quad (12.87)$$

The bandwidth of the main lobe of the magnitude of this spectrum is

$$B_{\text{RF}} = \frac{2}{T} \text{ Hz} \quad (12.88)$$

Since ASK and PSK involve square-pulse modulated sinusoidal carriers, this is the null-to-null main lobe bandwidth for these modulation schemes with T replaced by T_b . For coherent FSK, note that the minimum frequency spacing between cosinusoidal bursts at frequencies f_c and $f_c + \Delta f$ is $1/2T_b$ Hz in order to maintain orthogonality of the two signals. The first null of the sinc function at frequency f_c must have $1/T_b$ Hz below it, and the one at frequency $f_c + \Delta f$ must have $1/T_b$ Hz above it, giving a total bandwidth for FSK of

$$B_{\text{FSK}} = \frac{2.5}{T_b} \text{ Hz} \quad (12.89)$$

For noncoherent FSK, the frequency spacing between tones should be $2/T_b$ to allow separation at the receiver by filtering. Allowing the additional $1/T_b$ on either side due to the sinc-function spectrum for each tone, the total bandwidth required for noncoherent FSK is

$$B_{\text{NFSK}} = \frac{4}{T_b} \text{ Hz} \quad (12.90)$$

Since $1/T_b$ is the data rate R_b in b/s, the bandwidth efficiencies, defined as the b/s per hertz of bandwidth, of the various modulation schemes considered are as given in Table 12.11.

12.5.3 Detection of M -ary Signals in Additive White Gaussian Noise

Signal Detection in Geometric Terms

It is useful to view digital data transmission in geometric terms for several reasons. First, it provides a general framework that makes the analysis of several types of digital data transmission methods easier, particularly M -ary systems. Second, it provides an insight into the digital data transmission problem that allows one to see intuitively the power-bandwidth tradeoffs possible. Third, it suggests ways to improve upon standard modulation schemes. The mathematical basis for the geometric approach is known as signal

space (Hilbert space in mathematical literature) theory. The first book to use this approach in the U.S. was Wozencraft and Jacobs (1965), which was based, in part, on earlier work by the Russian Kotelnikov (1960). An early paper in the literature approaching signal detection from a geometric standpoint is Arthurs and Dym (1962). An overview of signal space concepts is given next.

The Gram--Schmidt Procedure

Given a finite set of signals, denoted $s_i(t)$, $i = 1, 2, \dots, M$ for $0 \leq t \leq T_s$, it is possible to find an orthonormal basis set in terms of which all signals in the set can be represented. (Because more than two possible signals can be sent during each signaling interval, the parameter T_s will now be used to denote the signaling, or *symbol, interval*). The procedure is known as the **Gram--Schmidt procedure**, and is easy to describe once some notation is defined. (For the most part, signals will be real. However, it is sometimes convenient to represent signals as phasors or complex exponentials). The **scalar product** of two signals, u and v , defined over the interval $(0, T_s)$, is defined as

$$(u, v) = \int_0^{T_s} u(t)v^*(t)dt \tag{12.91}$$

and the **norm** of a signal is defined as

$$\|u\| = \sqrt{(u, u)} \tag{12.92}$$

In terms of this notation, the Gram--Schmidt procedure is as follows:

1. Set $v_1(t) = s_1(t)$ and define the first orthonormal basis function as

$$\phi_1(t) = \frac{v_1(t)}{\|v_1\|} \tag{12.93}$$

2. Set $v_2(t) = s_2(t) - (s_2, \phi_1)\phi_1(t)$ and let the second orthonormal basis function be

$$\phi_2(t) = \frac{v_2(t)}{\|v_2\|} \tag{12.94}$$

3. Set $v_3(t) = s_3(t) - (s_3, \phi_2)\phi_2(t) - (s_3, \phi_1)\phi_1(t)$ and let the next orthonormal basis function be

$$\phi_3(t) = \frac{v_3(t)}{\|v_3\|} \tag{12.95}$$

4. Continue until all signals have been used. If one or more of the steps yield $v_j(t)$ for which $\|v_j(t)\| = 0$, omit these from consideration so that a set of $K \leq M$ orthonormal functions is obtained. This is called a *basis set*.

Using the orthonormal basis set thus obtained, an arbitrary signal in the original set of signals can be represented as

$$s_j(t) = \sum_{i=1}^K S_{ij}\phi_i(t), \quad j = 1, 2, \dots, M \tag{12.96}$$

where

$$S_{ij} = (s_j, \phi_i) = \int_0^{T_s} S_j(t)\phi_i^*(t)dt \tag{12.97}$$

With this procedure, any signal of the set can be represented as a point in a signal space (the coordinates of $s_j(t)$ are $S_{1j}, S_{2j}, \dots, S_{Kj}$). The representation of the signal in this space will be referred to as the signal vector. Thus, the signal detection problem can be viewed geometrically. This is discussed in the following subsection.

Geometric View of Signal Detection

Given a set of M signals as discussed, an M -ary digital communication system selects one of them with equal likelihood each contiguous T_s -s interval and sends it through a channel in which AWGN of two-sided spectral density $N_0/2$ is added. Letting the noise be represented by $n(t)$ and supposing that the j th signal is transmitted, the coordinates of the noisy received signal, here called the components of the data vector, are

$$Z_i = S_{ij} + N_i, \quad i = 1, 2, \dots, K \text{ (signal } j \text{ transmitted)} \tag{12.98}$$

where

$$N_i = (n, \phi_i) = \int_0^{T_s} n(t)\phi_i^*(t)dt \tag{12.99}$$

Schematic diagrams of two receiver front ends that can be used to compute the coordinates of the data vector are shown in Fig. 12.60. The first is called the **correlator implementation**, and the second is called the **matched filter implementation**. Because the noise components are linear transformations of a Gaussian random process, they are also Gaussian, and can be shown to have zero means and covariances

$$\text{cov}(N_i, N_j) = E\{N_i N_j\} = \frac{N_0}{2} \delta_{ij} \tag{12.100}$$

where δ_{ij} is the Kronecker delta, which is zero for the indices equal and zero otherwise. Consequently, the signal coordinates (12.96) are Gaussian with means S_{ij} , zero covariances, and variances of $N_0/2$. Thus,

FIGURE 12.60 Receiver configurations for computing data vector components: (a) correlator realization, (b) matched filter realization.

given signal $s_j(t)$ was sent, the joint conditional probability density function of the received data vector components is

$$p[z_1, z_2, \dots, z_k | s_j(t)] = (\pi N_0)^{-K/2} \exp \left\{ -\frac{1}{N_0} \sum_{i=1}^K (z_i - s_{ij})^2 \right\}, \quad j = 1, 2, \dots, M \quad (12.101)$$

A reasonable strategy for deciding on the signal that was sent is to choose the most likely, that is, if each signal is transmitted with equal probability, maximize the conditional probability density function (12.101) by choosing the appropriate signal vector, which can also be shown equivalent to minimizing the average probability of error (Wozencraft and Jacobs, 1965). Given the form of Eq. (12.101), this is accomplished by minimizing its exponent. Minimizing the exponent is equivalent to minimizing the sum of the squares of the differences between the components of the received data vector and those of the signal vector, that is, choosing the signal point that is closest in Euclidian distance to the received data point. This is illustrated in the following specific examples.

M-ary Phase-Shift Keying (MPSK)

Consider MPSK for which the signal set is

$$s_i(t) = \sqrt{\frac{2E_s}{T_s}} \cos \left[2\pi \left(f_c t + \frac{i-1}{M} \right) \right], \quad 0 \leq t \leq T_s; i = 1, 2, \dots, M \quad (12.102)$$

where E_s is the signal energy, T_s is the signal duration, and f_c is the carrier frequency in hertz. An $M = 4$ MPSK system is referred to as **quadrphase-shift keying (QPSK)**. The Gram–Schmidt procedure could be used to find the orthonormal basis set for expanding this signal set, but it is easier to expand Eq. (12.101) using trigonometric identities as

$$\begin{aligned} s_i(t) &= \sqrt{E_s} \left[\cos \left(\frac{2\pi(i-1)}{M} \right) \sqrt{\frac{2}{T_s}} \cos \omega_c t - \sin \left(\frac{2\pi(i-1)}{M} \right) \sqrt{\frac{2}{T_s}} \sin \omega_c t \right] \\ &= \sqrt{E_s} \left[\cos \left(\frac{2\pi(i-1)}{M} \right) \phi_1(t) - \sin \left(\frac{2\pi(i-1)}{M} \right) \phi_2(t) \right] \end{aligned} \quad (12.103)$$

$0 \leq t \leq T_s; i = 1, 2, \dots, M$

where $\omega_c = 2\pi f_c$, and it follows that

$$\phi_1(t) = \sqrt{\frac{2}{T_s}} \cos \omega_c t, \quad 0 \leq t \leq T_s \quad \text{and} \quad \phi_2(t) = \sqrt{\frac{2}{T_s}} \sin \omega_c t, \quad 0 \leq t \leq T_s \quad (12.104)$$

Note that in this case $K = 2 \leq M$. A signal space diagram is shown in Fig. 12.61(a) (only the i th signal point is shown). The best decision strategy, as discussed, chooses the signal point in signal space closest in **Euclidian distance** to the received data point. This is accomplished in Fig. 12.61(a) by dividing the signal space up into pie-shaped decision regions associated with each signal point. If the received data point lands in a given region, the decision is made that the corresponding signal was transmitted. The probability of error is the probability that, given a certain signal was transmitted, the noise causes the data vector to land outside of the corresponding decision region. The **probability of symbol error** P_s can be upper and lower bounded by (Peterson, Ziemer, and Borth, 1995)

$$Q \left(\sqrt{\frac{2E_s}{N_0}} \sin \frac{\pi}{M} \right) \leq P_s \leq 2Q \left(\sqrt{\frac{2E_s}{N_0}} \sin \frac{\pi}{M} \right) \quad (12.105)$$

which is obtained by considering two half-planes above and below the wedge corresponding to the i th signal as shown in Fig. 12.61(b) and Fig. 12.61(c). The upper bound is very tight for M moderately large, a fact which follows by comparing the areas of the plane with one wedge excluded in Fig. 12.61(a) with the area of the two half-planes in Fig. 12.61(b) and Fig. 12.61(c). Probability of error curves will be shown later.

FIGURE 12.61 Signal space diagrams for MPSK: (a) diagram showing typical transmitted signal point with decision region; (b) and (c) half-planes for bounding the error probability. The probability of error is greater than the probability of the received data vector falling into one half-plane, but less than the probability of it falling into either one of both half-planes.

Coherent M-ary Frequency-Shift Keying (CMFSK)

The signal set for this modulation scheme is given by

$$s_i(t) = \sqrt{\frac{2E_s}{T_s}} \cos\{2\pi [f_c + (i - 1)\Delta f]t\}, \quad 0 \leq t \leq T_s, i = 1, 2, \dots, M \tag{12.106}$$

where f_c is the lowest tone frequency and Δf is the frequency spacing between tones, both in hertz. The orthonormal basis function set for this modulation scheme is

$$s_i(t) = \sqrt{\frac{2}{T_s}} \cos\{2\pi [f_c + (i - 1)\Delta f]t\}, \quad 0 \leq t \leq T_s, i = 1, 2, \dots, M \tag{12.107}$$

Note that the signal space is M dimensional as opposed to two dimensional for the case of MPSK. A signal space diagram for $M = 3$ is shown in Fig. 12.62. For moderately large M , the symbol error probability can be tightly upper bounded by (Peterson, Ziemer, and Borth, 1995)

$$P_s \leq (M - 1)Q\left(\sqrt{\frac{E_s}{N_0}}\right) \tag{12.108}$$

Curves showing bit error probability as a function of signal-to-noise ratio will be presented later.

M-ary Quadrature-Amplitude-Shift Keying (MQASK)

The M -ary **quadrature-amplitude-shift keying** (MQASK) modulation scheme uses the two-dimensional space of MPSK, but with multiple amplitudes. Many such two-dimensional configurations have been considered, but only a simple rectangular grid of signal points will be considered here. The signal set can be expressed as

$$s_i(t) = \sqrt{\frac{2}{T_s}}(A_i \cos \omega_c t + B_i \sin \omega_c t), \quad 0 \leq t \leq T_s \tag{12.109}$$

FIGURE 12.62 Signal space showing the possible transmitted signal points and decision boundaries for coherent 3-ary FSK

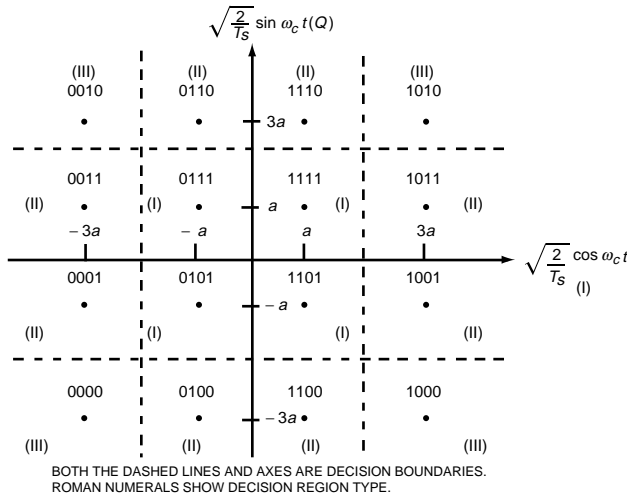

FIGURE 12.63 Signal space diagram for 16-ary QASK.

where ω_c is the carrier frequency in radians per second, and A_i and B_i are amplitudes taking on the values

$$A_i, B_i = \pm a, \pm 3a, \dots, \pm \sqrt{M}a \tag{12.110}$$

where M is assumed to be a power of 4. The parameter a can be related to the average signal energy by

$$a = \sqrt{\frac{3E_s}{2(M-1)}} \tag{12.111}$$

A signal space diagram is shown in Fig. 12.63 for $M = 16$ with optimum partitioning of the decision regions. Each signal point is labeled with a Roman numeral I, II, or III. For the type I regions, the probability of correct reception is

$$P(C | I) = \left[1 - 2Q \left(\sqrt{\frac{2a^2}{N_0}} \right) \right]^2 \tag{12.112}$$

For the type II regions, the probability of correct reception is

$$P(C | II) = \left[1 - 2Q \left(\sqrt{\frac{2a^2}{N_0}} \right) \right] \left[1 - Q \left(\sqrt{\frac{2a^2}{N_0}} \right) \right] \tag{12.113}$$

and for the type III regions, it is

$$P(C | III) = \left[1 - Q \left(\sqrt{\frac{2a^2}{N_0}} \right) \right]^2 \tag{12.114}$$

In terms of these probabilities, the probability of symbol error is (Peterson, Ziemer, and Both, 1995)

$$P_s = 1 - \frac{1}{M} \left[(\sqrt{M} - 2)^2 P(C | I) + 4(\sqrt{M} - 2) P(C | II) + 4P(C | III) \right] \tag{12.115}$$

Bit error probability plots will be provided later.

Differentially Coherent Phase-Shift Keying (DPSK)

DPSK discussed earlier can be generalized to more than two phases. Suppose that the transmitted carrier phase for symbol interval $n-1$ is α_{n-1} and the desired symbol phase for interval n is β_n , which is assumed to take on a multiple of $2\pi/M$ rad. If it is desired to send the particular symbol (phase) $\beta_n = \Phi$, then the transmitted phase at interval n , α_n , is

$$\alpha_n = \alpha_{n-1} + \Phi \tag{12.116}$$

where α_{n-1} is the transmitted phase in interval $n - 1$. Suppose that the phases detected corresponding to α_{n-1} and α_n are $\theta_{n-1} = \alpha_{n-1} + \gamma$ and $\theta_n = \alpha_n + \gamma$, respectively, where γ is the unknown phase shift introduced by the channel. The first stage of the receiver is a phase discriminator, which detects θ_n . From the previous decision interval, it is assumed that θ_{n-1} is available, so the receiver forms the difference

$$\begin{aligned} \theta_n - \theta_{n-1} &= (\alpha_n + \gamma) - (\alpha_{n-1} + \gamma) = \alpha_n - \alpha_{n-1} \\ &= \alpha_{n-1} + \Phi - \alpha_{n-1} = \Phi \end{aligned} \tag{12.117}$$

where no noise is assumed. In the presence of noise, the receiver must decide which $2\pi/M$ region $\theta_n - \theta_{n-1}$ falls into; hopefully, in this example, this is the region centered on Φ . Thus, a correct decision will be made at the receiver when

$$\Phi - \frac{\pi}{M} < \theta_n - \theta_{n-1} \leq \Phi + \frac{\pi}{M} \tag{12.118}$$

A receiver block diagram implementing this decision strategy is shown in Fig. 12.64. The error probability can be bounded by (Prabhu, 1982)

$$P_1 \leq P_s \leq 2P_1 \tag{12.119}$$

where P_1 is upper and lower bounded by

$$\begin{aligned} P_1 &\leq \frac{\pi}{2} \frac{\cos\left(\frac{\pi}{2M}\right)}{\sqrt{\cos(\pi/M)}} Q\left[2\sqrt{\frac{E_s}{N_0}} \sin\left(\frac{\pi}{2M}\right)\right] \\ P_1 &\geq \frac{1}{2} \frac{\cos\left(\frac{\pi}{2M}\right)}{\sqrt{\cos(\pi/M)}} \left[1 - 2Q\left(\pi\sqrt{\frac{E_s}{N_0}} \sin\left(\frac{\pi}{M}\right)\right)\right] Q\left[2\sqrt{\frac{E_s}{N_0}} \sin\left(\frac{\pi}{2M}\right)\right] \end{aligned} \tag{12.120}$$

Noncoherent M-ary FSK

The signal set for noncoherent MFSK can be expressed as

$$s_i(t) = \sqrt{\frac{2E_s}{T_s}} \cos(\omega_i t + \alpha), \quad 0 \leq t \leq T_s; i = 1, 2, \dots, M \tag{12.121}$$

where ω_i is the radian frequency of the i th signal, E_s is the symbol energy, T_s is the symbol duration, and α is the unknown phase, which is modeled as a uniformly distributed random variable in $(0, 2\pi)$. The

FIGURE 12.64 Block diagram for an M -ary differential PSK receiver.

signal space is $2M$ dimensional and can be defined by the basis functions

$$\left. \begin{aligned} \phi_{xi}(t) &= \sqrt{\frac{2}{T_s}} \cos \omega_i t \\ \phi_{yi}(t) &= \sqrt{\frac{2}{T_s}} \sin \omega_i t \end{aligned} \right\}, \quad 0 \leq t \leq T_s; i = 1, 2, \dots, M \quad (12.122)$$

A fairly lengthy derivation (Peterson, Ziemer, and Borth, 1995) results in the symbol error probability expression

$$P_s = \sum_{k=1}^{M-1} \binom{M-1}{k} \frac{(-1)^k}{k+1} \exp\left(-\frac{k}{k+1} \frac{E_s}{N_0}\right) \quad (12.123)$$

which reduces to the result for binary noncoherent FSK for $M = 2$. The optimum receiver is an extension of Fig. 12.57 with a parallel set of in-phase and quadrature filters and envelope detectors for each possible transmitted signal.

12.5.4 Comparison of Modulation Schemes

Bandwidth Efficiency

There are several ways to compare bandwidth of M -ary digital modulation schemes. One way is to compute out-of-band power as a function of bandwidth of an ideal brick wall filter. This requires integration of the power spectrum of the various modulation schemes being compared. The basis for bandwidth comparison used here will be the bandwidth required for the mainlobe of the signal spectrum, which makes for somewhat simpler computation without undue loss of accuracy. For example, replacing T by the symbol duration, T_s , in Eq. (12.87), the radio-frequency bandwidth of the mainlobe of a modulation scheme, which uses a single modulated frequency to transmit the information, such as M -ary PSK, M -ary DPSK, or QASK, is

$$B_{RF} = \frac{2}{T_s} = 2R_s \text{ Hz} \quad (12.124)$$

where R_s is the symbol rate. However, for an M -ary modulation scheme, the symbol duration is related to the bit duration by

$$T_s = T_b \log_2 M = \frac{\log_2 M}{R_b} \quad (12.125)$$

Thus, the bandwidth in terms of bit rate for such modulation schemes is

$$B_{RF} = \frac{2R_b}{\log_2 M} \text{ (MPSK, MDPSK, MQASK)} \quad (12.126)$$

Now the ratio of bit rate to required bandwidth is called the bandwidth efficiency of a modulation scheme. In the case at hand, the bandwidth efficiency is

$$\text{bandwidth efficiency} = \frac{R_b}{B_{RF}} = 0.5 \log_2 M \text{ (MPSK, MDPSK, MQASK)} \quad (12.127)$$

For schemes using multiple frequencies to transmit the information such as M -ary FSK, a more general approach is used. Each symbol is represented by a different frequency. For coherent M -ary FSK, the minimum separation per frequency required to maintain orthogonality is $1/2T_s$ Hz. The two outside frequencies use $1/T_s$ Hz for the half of the mainlobe on the left and right of the composite spectrum. The $M - 2$ interior frequencies require a minimum separation of $1/2T_s$ Hz (there are actually $M - 1$ interior slots)

for a total RF bandwidth of

$$B_{\text{RF}} = \frac{1}{T_s} + \frac{M-1}{2T_s} + \frac{1}{T_s} = \frac{M+3}{2T_s} \text{ (coherent MFSK)} \quad (12.128)$$

Substitution of Eq. (12.125) gives a bandwidth efficiency of

$$\text{bandwidth efficiency} = \frac{R_b}{B_{\text{RF}}} = \frac{2 \log_2 M}{M+3} \text{ (coherent MFSK)} \quad (12.129)$$

For noncoherent MFSK, the minimum separation of the frequencies used to represent the symbols is taken as $2/T_s$ Hz for a total RF bandwidth of

$$B_{\text{RF}} = \frac{1}{T_s} + \frac{2(M-1)}{T_s} + \frac{1}{T_s} = \frac{2M}{T_s} \text{ (noncoherent MFSK)} \quad (12.130)$$

with a bandwidth efficiency of

$$\text{bandwidth efficiency} = \frac{R_b}{B_{\text{RF}}} = \frac{\log_2 M}{2M} \text{ (noncoherent MFSK)} \quad (12.131)$$

A comparison of Eq. (12.127) with Eq. (12.129) and (12.131) shows that the bandwidth efficiency of MPSK and MQASK *increases* with M whereas the bandwidth efficiency of MFSK *decreases* with M . This can be attributed to the dimensionality of the signal space staying constant with M for the former modulation schemes, whereas it increases with M for the latter. A comparison of bandwidth efficiencies for the various modulation schemes considered in this chapter is given in Table 12.12.

Power Efficiency

The power efficiency of a modulation method is indicated by the value of E_b/N_0 required to yield a desired bit error probability, such as 10^{-6} . This being the case, it is necessary to convert from symbol error probability to bit error probability and from E_s/N_0 to E_b/N_0 for M -ary modulation schemes. The latter is straightforward since the difference between symbol energy and bit energy is symbol duration vs. bit duration, which are related by

$$T_s = T_b \log_2 M \quad (12.132)$$

giving

$$\frac{E_b}{N_0} = \frac{1}{\log_2 M} \frac{E_s}{N_0} \quad (12.133)$$

Conversion between symbol error probability and bit error probability is somewhat more complicated. First, considering two-dimensional modulation schemes such as MPSK and MQASK, it is assumed that

TABLE 12.12 Comparison of Bandwidth Efficiencies for Various Modulation Methods

M	MPSK, MDPSK, MQASK ^a	Coherent MFSK	Noncoherent MFSK
2	0.5	0.400	0.250
4	1.0	0.571	0.250
8	1.5	0.545	0.188
16	2.0	0.421	0.125
32	2.5	0.286	0.078
64	3.0	0.179	0.047

^aFor MQASK, only values of M of a power of four are applicable.

the most probable errors are those in favor of adjacent signal points and that encoding is used that results in a single bit change in going from one signal point to an adjacent one (i.e., Gray encoding). Since there are $\log_2 M$ bits per symbol, the result is that bit error probability is approximately related to symbol error probability by

$$P_s = \frac{P_b}{\log_2 M} \tag{12.134}$$

Finally, consider MFSK for which each symbol occupies a separate dimension in the signal space. Thus, all symbol errors are equally probable, which means that each symbol error occurs with probability $P_s/(M - 1)$. Suppose that for a given symbol error k bits are in error. There are

$$\binom{\log_2 M}{k}$$

ways that this can happen, since each symbol represents $\log_2 M$ bits. This gives the average number of bit errors per symbol error as

$$\text{Ave. no. of bit errors per symbol error} = \sum_{k=1}^{\log_2 M} k \binom{\log_2 M}{k} \frac{P_s}{M-1} = \frac{M \log_2 M}{2(M-1)} \tag{12.135}$$

Since there are a total of $\log_2 M$ bits per symbol, the average bit error probability in terms of symbol error probability is

$$P_b = \frac{M}{2(M-1)} P_s \tag{12.136}$$

The various modulation schemes considered in this section are compared on the basis of bit error probability versus E_b/N_0 in Fig. 12.65 to Fig. 12.69.

FIGURE 12.65 Bit error probability vs. E_b/N_0 for coherent M -ary PSK.

FIGURE 12.66 Bit error probability vs. E_b/N_0 for coherent M -ary FSK.

Other Important Types of Digital Modulation Schemes

There are many other important digital modulation formats that have not been discussed here. In this section, several of these will be mentioned with appropriate references given so that the reader will have a place to start to learn more about them.

A modulation scheme related to QPSK is **offset QPSK** (OQPSK) (Ziemer and Tranter, 2002). This modulation format is produced by allowing only $\pm 90^\circ$ phase changes in a QPSK format. Furthermore,

FIGURE 12.67 Bit error probability vs. E_b/N_0 for coherent M -ary QASK.

FIGURE 12.68 Bit error probability vs. E_b/N_0 for M -ary DPSK.

the phase changes can take place at multiples of a half-symbol interval, or a bit period. The reason for limiting phase changes to $\pm 90^\circ$ is to prevent the large envelope deviations that occur when QPSK is filtered to limit sidelobe power, and then regrowth of the sidelobes after amplitude limiting is used to produce a constant-envelope signal. This is typically encountered in satellite communications where, due to power efficiency considerations, hard limiting repeaters are used in the satellite communications system.

FIGURE 12.69 Bit error probability vs. E_b/N_0 for noncoherent M -ary FSK.

Another modulation scheme closely related to QPSK and OQPSK is **minimum shift keying (MSK)** (Ziemer and Tranter, 2002), which can be produced from OQPSK by weighting the inphase and quadrature components of the baseband OQPSK signal with half-sinusoids. As with OQPSK, this is a further attempt at producing a modulated signal with spectrum that has less sidelobe power than BPSK, QPSK, or OQPSK and behaves well when filtered and limited. With MSK, there are no abrupt phase changes, but rather, the phase changes linearly over the symbol interval.

Many different forms of MSK have been proposed and investigated over the years. One form is **Gaussian-filtered MSK (GMSK)**, where the baseband data is filtered by a filter having a Gaussian-shaped transfer function at the baseband before modulating the carrier (Murota, 1981). GMSK is another attempt at producing a signal spectrum that is compact around the carrier and having low envelope deviation of the modulated carrier. It has been adopted by the European community for second-generation cellular-mobile communication systems.

A modulation scheme that is related to 8-PSK is **$\pi/4$ -differential QPSK ($\pi/4$ -DQPSK)** (Peterson, Ziemer). It is essentially an 8-PSK format with differential encoding where, from a given phase state, only phase shifts of $\pm\pi/4$ or $\pm3\pi/4$ are allowed. It has been adopted as the modulation format for one North American standard for second-generation cellular-mobile radio. The other adopted standard uses direct-sequence spread-spectrum modulation.

A whole host of modulation schemes may be grouped under the heading **continuous-phase modulation (CPM)** (Sklar, 1988). These modulation formats employ continuous phase trajectories over one or more symbols to get from one phase to the next in response to input data changes. MSK and GMSK are special cases of CPM. CPM schemes are employed in an attempt to simultaneously improve power and bandwidth efficiency.

A class of modulation that is important for military and cellular radio communications is spread spectrum (Peterson, Ziemer, and Borth, 1995). Spread spectrum modulation is any modulation format that utilizes a transmission bandwidth much wider than that required to transmit the message signal itself, independent of the message signal bandwidth. It can be categorized several ways. The two most common types of spread spectrum modulation are **direct-sequence spread spectrum (DSSS)** and **frequency-hop spread spectrum (FHSS)**. In the former type, the modulated signal spectrum is spread by multiplication with a pseudonoise binary code, which changes state several times during a symbol interval. In the latter type, the spectrum is spread by hopping the modulated signal spectrum about in a pseudorandom manner. The code that is used for spreading at the transmitter is known at the receiver. Thus, it is possible to despread the received signal at the receiver once the receiver's code is synchronized with the spreading coding on the received signal. Spread spectrum modulation is used for several reasons. Among these are to hide the modulated signal from an enemy interceptor, to lower the susceptibility of jamming by an unfriendly or unintentional source, to combat multipath, to provide multiple access capability for the modulation scheme, and to provide a means for range measurement. An example of the latter application is the **global positioning system (GPS)**.

12.5.5 Higher Order Modulation Schemes

Error Correction Coding Fundamentals

The previously discussed modulation schemes had dependency between signaling elements only over one signaling element. There are advantages to providing memory over several signaling elements from the standpoint of error correction. Historically, the first way that this was accomplished was to encode the data (usually binary) by adding redundant symbols for error correction and use the encoded symbol stream to modulate the carrier. The ratio of information symbols to total encoded symbols is referred to as the **code rate**. At the receiver, demodulation was accomplished followed by decoding. The latter operation allowed some channel-induced errors to be corrected. Since redundant symbols are added at the transmitter, it is necessary to use a larger bandwidth by a factor of one over the code rate than if no encoding is employed in order to keep the same information rate through the channel with coding as without coding. Thus, the signal-to-noise ratio is smaller by a factor of the code rate with coding than without coding,

and the raw bit error probability is higher. Since the code can correct errors, however, this compensates partially for the higher raw bit error probability to a degree. If the code is powerful enough, the overall bit error probability through the channel is lower with coding than without. Usually, this depends on the signal-to-noise ratio: for small values of the signal-to-noise ratio, the compensation by coding is not enough, and the overall bit error probability is higher with coding than without; for sufficiently large values of the signal-to-noise ratio, the error correction capability of the code more than makes up for the higher raw bit error probability, and a lower overall error probability is obtained. The **coding gain** is defined as the ratio of the signal-to-noise ratios without and with coding, or if they are expressed in decibels, the difference between the signal-to-noise ratios without and with coding, at a given bit error probability.

There are two widely used types of coding: **block** and **convolutional**. We will discuss these assuming that binary data is used. For block coding, the information bits are taken a block at a time (k of them) and correction bits are added to the block to make an overall block of length n . The ratio k/n is the code rate in this case. The trick is to introduce dependencies between the bits in the blocks of length n so that error correction can be accomplished at the receiver. The field of block coding dates back to work by Shannon in the late 1940s, and many powerful block codes are now available with efficient decoding techniques to make them implementable. Examples are Hamming, Bose–Chaudhuri–Hocquenghem (BCH), and Golay codes for binary codes; a nonbinary family of codes that is very powerful is the Reed–Solomon codes, which are used in compact disc audio technology. Depending on the code rate and the code used, block codes can provide coding gains from less than 1 to 10 or more dB at a probability of bit error of 10^{-6} .

A second class of error correction codes are convolutional codes. A simple convolutional encoder is shown in block diagram form in Fig. 12.70. It consists of a shift register and two or more modulo-2 adders to combine the input bit and bits residing in the shift register. It is assumed that a clock synchronizes the shifting of the bits into and down the shift register. When a new bit is shifted into the first stage of the shift register, all former bits in the shift register ripple to the right. In this case, the raw data is fed into the shift register bit-by-bit and the outputs of the modulo-2 adders are sampled in turn after each bit is fed in. Since two encoded bits are obtained for each input bit, this is a rate- $\frac{1}{2}$ convolutional encoder. If there were three modulo-2 adders for the bits in the shift register, a rate- $\frac{1}{3}$ code would result. Code rates greater than $\frac{1}{2}$ can be achieved by deleting bits periodically at the output of the encoder. This process is called **puncturing**. At the decoder, arbitrary symbols are inserted at each puncturing time (the period of the puncturing is known at the decoder, but the values of the punctured symbols are, of course, not known) and the decoder treats the arbitrarily inserted bit as a possible error. Convolutional codes have been in existence since the 1960s. A very efficient decoding method for convolutional codes is called the **Viterbi algorithm**, which was invented by Andrew Viterbi in the late 1960s. We will not present this algorithm in detail here, but the reader is referred to the references (Peterson, Ziemer, and Borth, 1995). The performance of convolutional

FIGURE 12.70 A rate- $\frac{1}{2}$, constraint length 3 convolutional encoder.

codes depends on the number of stages in the shift register (the number of stages plus 1 is called the **constraint length** of the code), the code rate, and whether hard or soft decisions are fed into the decoder. A **hard decision** is a definite 1–0 decision at the output of the detector; a **soft decision** is a quantized version of the detector output before a hard decision is made. Coding gains for convolutional codes range from a few decibels to 6 or 7 dB at a probability of error of 10^{-6} for soft decisions, constraint lengths of 8 or 9, and rates of $\frac{1}{2}$ or $\frac{1}{3}$. The higher the rate of a punctured code (i.e., the closer the rate is to 1), the less coding gain yielded by puncturing. Code rates close to 1 can be achieved by methods other than puncturing.

In closing, we note that coding used in conjunction with modulation always expands the required transmission bandwidth by the inverse of the code rate, assuming the overall bit rate is kept constant. In other words, power efficiency goes up but bandwidth efficiency goes down with use of a well-designed code.

Trellis-Coded Modulation

In attempting to simultaneously conserve power and bandwidth, Ungerboeck (1987) in the 1970s began to look at ways to combine coding and modulation. His solution was to use coding in conjunction with M -ary modulation to increase the minimum Euclidian distance between those signal points that are most likely to be confused without increasing the average power or bandwidth over an uncoded scheme transmitting the same number of bits per second. The technique is called **trellis-coded modulation (TCM)**. An example will illustrate the procedure.

In the example, we wish to compare a TCM system and a QPSK system operating at the same data rates and, hence, the same bandwidths. Since the QPSK system transmits 2 b per signal phase, we can keep that same data rate with the TCM system by employing an 8-PSK modulator, which carries 3 b per signal phase, in conjunction with a convolutional encoder that produces three encoded symbols for every two input data bits (i.e., a rate $\frac{2}{3}$ encoder). Figure 12.71 shows a way in which code symbols can be associated with signal phases. This technique, called **set partitioning**, is carried out according to the following rules: (1) All code triples from the encoder differing by one code symbol are assigned the maximum possible Euclidian distance in encoded phase points; (2) All other possibilities are assigned the next to largest possible Euclidian distance.

To decode the TCM signal, the received signal plus noise in each signaling interval is correlated with each possible signal/code combination; a search for the closest symbol combination is made by means of a Viterbi algorithm using the sums of these correlations as the metric in the algorithm (i.e., Euclidian

FIGURE 12.71 A set partitioning scheme to assign code symbols to M -ary signal points in order to maximize Euclidian distance between signal points.

distance). With the level of this chapter, the reader is encouraged to consult the references for the details of the decoding procedure (Ziemer and Tranter, 2002; Blahut, 1990; Proakis, 1995). Using this procedure, it can be shown that a coding gain results in going from the QPSK system to the combined coded/8-PSK system at *no increase in bandwidth*. In fact, for the system considered here, Ungerboeck has shown that an asymptotic (i.e., in the limit of small bit error probabilities) coding gain in excess of 3.5 dB results. More powerful codes and larger phase shifts result in asymptotic coding gains of over 5.5 dB. Viterbi et al. (1989) has discussed the use of rate $\frac{1}{2}$, constraint length 7 convolutional codes, for which VLSI circuit implementations are available at a low cost, to provide various coding gains using puncturing and MPSK.

Defining Terms

Additive white Gaussian noise (AWGN): Noise that is additive to the signal having a constant power spectrum over all frequencies and Gaussian amplitude distribution.

Amplitude-shift keying (ASK): A signaling scheme whereby the digital data modulates the amplitude of a carrier.

Antipodal signaling: A signaling scheme which represents the digital data as plus (logic 1) or minus (logic 0) a basic pulse shape.

Bandwidth efficiency: The ratio of bit rate to bandwidth occupied for a digital modulation scheme. Technically, it is dimensionless, but it is usually given the dimensions of bits/second/hertz.

Binary signaling: Any signaling scheme where the number of possible signals sent during any given signaling interval is two.

Bit period: The symbol duration for a binary signaling scheme.

Block code: Any encoding scheme that encodes the information symbols block-by-block by adding a fixed number of error correction symbols to a fixed block length of information symbols.

Code rate: The ratio of the number of information bits into to encoded symbols out of a coder corresponding to those input bits.

Coding gain: The amount of improvement in E_b/N_0 at a specified probability of bit error provided by a coding scheme.

Coherent modulation: Any modulation technique that requires a reference at the receiver which is phase coherent with the received modulated carrier signal for demodulation.

Constraint length: The number of shift register stages plus one for a convolutional encoder. It is also the span of information symbols that determines the error correction symbols for a convolutional code.

Continuous-phase modulation (CPM): Any phase modulation scheme where the phase changes continuously over one or more symbol intervals in response to a change of state of the input data.

Convolutional code: Any encoding scheme that encodes a sliding window of information symbols by means of a shift register and two or more modulo-2 adders for the bits in the shift register that are sampled to produce the encoded output.

Correlation coefficient: A measure of the similarity between two signals normalized to a maximum absolute value of 1. If the correlation coefficient of two signals is zero, they are called orthogonal; if -1 , they are called antipodal.

Correlator implementation: A receiver implementation that multiplies the incoming signal plus noise during any given signaling interval by a replica of each possible signal transmitted, integrates over the signaling interval, and uses these data for determining the transmitted signal.

Differential encoding: A coding scheme that compares the present differentially encoded bit with the next data bit; if a 1, the next encoded bit is the same as the reference, whereas if a 0, the next encoded bit is opposite the reference.

Differentially coherent PSK (DPSK): The result of using a differentially encoded bit stream to phase-shift key a carrier.

Digital modulation: The variation of some attribute of a carrier, such as amplitude, phase, or frequency, in a one-to-one correspondence with a message taking on a discrete set of values.

Direct-sequence spread-spectrum (DSSS): A modulation scheme employing a transmission bandwidth much wider than that required for the message signal, where the additional spectral spreading is

achieved by multiplication with a binary pseudonoise code having many state changes per data symbol.

Euclidian distance: The length of the vector that is the difference of two other vectors in signal space; forms the Euclidian distance between the points defined by these vectors.

Frequency-hop spread-spectrum (FHSS): A modulation scheme employing a transmission bandwidth much wider than that required for the message signal, where the additional spectral spreading is achieved by hopping the modulated signal spectrum pseudorandomly in frequency.

Frequency-shift keying (FSK): A signaling scheme whereby the digital data modulates the frequency of a carrier.

Gaussian MSK (GMSK): MSK in which the baseband signal has been filtered with a filter having a Gaussian-shaped amplitude response before carrier modulation.

Global positioning system: A system consisting of 24 satellites spaced around the Earth with precise timing sources and emitting DSSS signals, at least four of which can be acquired by a receiver simultaneously in order to determine the position of the platform on which the receiver is located.

Gram–Schmidt procedure: An algorithm for obtaining a set of orthonormal functions from a set of signals.

Hard decision: The process of making a definite 1–0 decision at the output of a detector, usually in conjunction with coding. Thus information is discarded before the decoding process.

M-ary signaling: Any signaling scheme where the number of possible signals sent during any given signaling interval is M ; binary signaling is a special case with $M = 2$. MPSK uses M phases of a sinusoidal carrier.

Matched filter implementation: A receiver implementation that has a parallel bank of matched filters as the first stage, one matched to each possible transmitted signal. A matched filter has an impulse response that is the time reverse of the signal to which it is matched.

Maximum-likelihood receiver: A receiver that bases its decisions on the probabilities of the received waveform given each possible transmitted signal.

Minimum-shift keying (MSK): OQPSK with the in-phase and quadrature baseband signal components weighted by half-sinusoids. The phase changes linearly over a bit interval.

Noncoherent modulation: Any modulation scheme not requiring a reference at the receiver in phase coherence with the received modulated signal in order to perform demodulation.

Norm: A function of a signal that is analogous to its length.

Offset quadriphase-shift keying (OQPSK): A QPSK scheme where phase shifts can be only $\pm\pi/2$ and can occur at half-symbol intervals.

Orthogonal signaling: Any signaling scheme that uses a signal set that have zero correlation coefficient between any pair of signals.

Phase-shift keying (PSK): A signaling scheme whereby the digital data modulates the phase of a carrier.

$\pi/4$ -differential quadriphase-shift keyed signaling ($\pi/4$ -DQPSK): A differentially coherent phase-shift keyed modulation scheme in which one of eight possible phases is transmitted each signaling interval, and in which the possible phase changes from the current phase is limited to $\pm\pi/4$ and $\pm3\pi/4$.

Power efficiency: The energy-per-bit over noise power spectral density (E_b/N_0) required to provide a given probability of bit error for a digital modulation scheme.

Probability of (bit) (symbol) error: The average number of symbol errors over a long string (ideally infinite) of transmitted signals for any digital modulation scheme. If expressed in terms of the number of bits per symbol, the probability of bit error results.

Puncturing: A method to increase the rate of a code, usually convolutional, by periodically deleting symbols from the encoded output. At the decoder, arbitrary symbols are inserted in the places the deleted symbols would have occupied, and the decoder corrects a large majority of these if necessary.

Quadrature-amplitude-shift keying (QASK): A digital modulation scheme in which both the phase and amplitude of the carrier takes on a set of values in one-to-one correspondence with the digital data to be transmitted.

Quadrature-phase-shift keying (QPSK): An MPSK (see M -ary signaling) system that utilizes four signals in the signal set distinguished by four phases 90° apart.

Scalar product: A function of two signals that is analogous to their inner or dot product in ordinary geometric terms.

Set partitioning: A procedure for implementing TCM encoding rules in order to maximize Euclidian distance between signal points.

Soft decisions: The use of detector outputs quantized to more than two levels (i.e., a 1 or a 0) to feed into a decoder with the intention of improving the coding gain over what is achievable with hard decisions.

Symbol period: The duration of the signaling element for an M -ary modulation scheme.

Trellis-coded modulation (TCM): The process of using convolutional codes of suitable rates in conjunction with M -ary modulation to achieve coding gain without bandwidth expansion.

Viterbi algorithm: An efficient algorithm for decoding convolutional codes, among other applications, that implements maximum likelihood estimation.

12.6 Spread Spectrum Systems

Kurt L. Kosbar and William H. Tranter

12.6.1 Why Use Spread Spectrum?

Radio communication systems are designed to move the information contained in a low-frequency message waveform through a channel that only passes high-frequency signals. High-frequency signals allow for channel assignment using frequency division multiplexing and allow signals to be radiated using antennas of reasonable size. The process referred to as *modulation* translates a low-frequency message signal to a high-frequency modulated signal. Modulation may be analog or digital. Examples of analog modulation are amplitude modulation (AM), frequency modulation (FM), and a variety of other formats such as phase modulation (PM), double sideband (DSB), single sideband (SSB), and VSB. A similar set of modulation formats were developed for digital data messages (Sklar, 1988) and examples include ASK, FSK, BPSK, QPSK, and MSK. All of these modulation techniques fall into a general class that we will call **narrow-band (NB) modulation** techniques since the result of the modulation process is a NB bandpass signal. If an analog message has a bandwidth of W Hz, or a digital source has a data rate of W bits/second, the output of a NB transmitter (modulator) will span a bandwidth of αW Hz. The exact bandwidth will depend on the choice of modulation and various system parameters, but in most cases of practical interest the transmitted bandwidth will be within an order of magnitude (a factor of 10) of W Hz. In other words, α will be less than 10 for most applications.

Since NB signals have a limited bandwidth, multiple users can share a band of the electromagnetic spectrum by using frequency division multiple access (FDMA). In this format, the available spectral space is divided into nonoverlapping segments, or channels, and each user is given exclusive use of one channel. The narrower the bandwidth of the transmitted signals, the more channels and users a given bandwidth can support. The architects of NB FDMA systems typically make a number of assumptions about the operating environment, including the following:

- Aside from the intended transmitter, there will be no other devices producing high-power signals within the allocated channel, that is, interference is negligible.
- Electronic devices in close proximity to the transmitter will not be adversely affected by the radiated signal.
- There is no need to conceal the existence of the transmitter.
- It should be easy to receive and demodulate the signal.
- The channel model will be fairly simple, such as an attenuation and a small amount of additive noise.
- Reflections or multipath problems will be insignificant.

These assumptions were quite reasonable during the early development of commercial FDMA systems since these systems used a relatively small number of high-power transmitters at fixed locations. Regulatory agencies such as the FCC carefully controlled the radiation patterns, power levels, location and frequency assignments of the transmitters to avoid interference.

Military users could not afford to use the same set of assumptions. An enemy may intentionally generate interfering signals to disrupt (jam) the communication link, or secretly intercept and demodulate the radiated signal (eavesdrop). Sometimes the transmitted message is of little interest, but detecting the presence and location of a transmitted signal may be very useful. More than one weapon system has been developed to locate and destroy a source of electromagnetic (EM) radiation. These difficulties lead designers to search for a modulation technique that would be very difficult to jam, easy for friendly users to demodulate, difficult for unfriendly users to demodulate, and difficult for enemies to detect the presence of a transmitter. The result of this research was a completely new class of modulation techniques now known as **spread spectrum (SS)** communications. As the name suggests, signals generated by SS modulators and transmitters cover a much wider frequency range than NB signals. The

TABLE 12.13 Similarity of Military and Commercial Problems

Military Problem	Commercial Problem
Hostile Jammers	<ul style="list-style-type: none"> • Electronic equipment that unintentionally radiates interfering signals. • New communication services must share bands with existing NB transmitters

New multiple access format	<ul style="list-style-type: none"> • New multiple access format

radiated bandwidth may be many orders of magnitude greater than the message bandwidth or message data rate.

Commercial communication system designers initially ignored SS techniques. Spread spectrum systems were considered exotic, expensive, and necessary only when hostile parties were attempting to jam or intercept the communication signal. This attitude toward SS techniques has changed within the past few decades for a number of reasons as outlined in [Sec. 12.6.7](#) to follow. Although military and commercial users have different motivations, the technical problems faced by these systems are very similar. Table 12.13 summarizes these similarities.

12.6.2 Jamming and Eavesdropping

Figure 12.72 is a high level block diagram that we will use throughout this section. The goal is to transmit data from the source, through the friendly transmitter and receiver to the authorized end user. We assume the designer has complete control over the friendly transmitter and receiver. The designer has little or no control over the design and operation of the two related systems that we call the jammer and the unauthorized receiver. In a military environment these devices may be operated by hostile parties. For commercial systems, the *jammer* is any piece of equipment that radiates EM signals, whereas the unauthorized receiver is any device that is susceptible to electromagnetic interference (EMI). If the friendly receiver link is operational even when the jammer is producing a high-power signal, we call the friendly system **jam resistant**. If the friendly receiver can demodulate the signal, but it is very difficult (or unlikely) that the

FIGURE 12.72 Communication system threats.

unauthorized receiver can do the same, we say the friendly system has a **low probability of intercept (LPI)**. Spread spectrum systems are both jam resistant and exhibit an LPI.

Jam resistance and LPI come at a cost. Spread spectrum systems are typically more complex, require greater bandwidth, and have lower message bandwidths and lower message data rates than NB systems. In spite of these drawbacks SS systems are attractive for some applications. Spread spectrum techniques provide the designer with a set of design tradeoffs that are unavailable with conventional NB systems.

The remainder of this section will discuss two fundamental SS modulation techniques: **frequency hopping (FHSS)** and **direct sequence (DSSS)**. After introducing the basic architecture of these SS systems, their performance in the face of interfering signals will be addressed. Designers accustomed to working with NB systems will notice an unfamiliar device in all SS systems. A pair of SS transmitters and receivers must synchronously generate pseudorandom waveforms called *spreading signals*.

12.6.3 Basic Spread Spectrum Techniques

Frequency Hopping

One of the simplest ways to disrupt a NB communication link is for a jammer to produce a high-power sinusoid near the friendly carrier frequency. The friendly system can obviously avoid this threat by switching to a new carrier frequency. If the new carrier is sufficiently far away from the jamming tone, the IF filters in the friendly receiver will remove the interfering signal. The selection of a new carrier frequency may be difficult for a variety of reasons. A truly hostile and intelligent jammer may monitor the friendly signal and intentionally shift the jamming frequency to match it. In a more benign setting, the friendly transmitter may be unaware of which frequencies are being jammed at the friendly receiver. A reverse link from the friendly receiver to the friendly transmitter would solve this problem, but increases system complexity. Even if the friendly link is not being jammed, the friendly transmitter will typically be unaware if the unauthorized receiver is able to demodulate the radiated signal.

Some of these problems can be overcome by quickly switching, or hopping, the friendly carrier frequency over a wide band. This is the fundamental concept behind frequency-hopped spread spectrum systems, as shown in Fig. 12.73. A number of excellent texts discuss this topic such as Sklar (1988); Peterson, Ziemer, and Borth (1995); and Simon et al. (1985). The system design is very similar to conventional NB systems. The only modification to the transmitter is that the conventional fixed frequency oscillator is replaced by a variable frequency oscillator that can change frequency very quickly under electronic control. In Fig. 12.73 the message source and variable frequency oscillator are fed into a DSB modulator (a simple multiplier), although any form of NB modulation can be used. The oscillator frequency used at any instant in time is

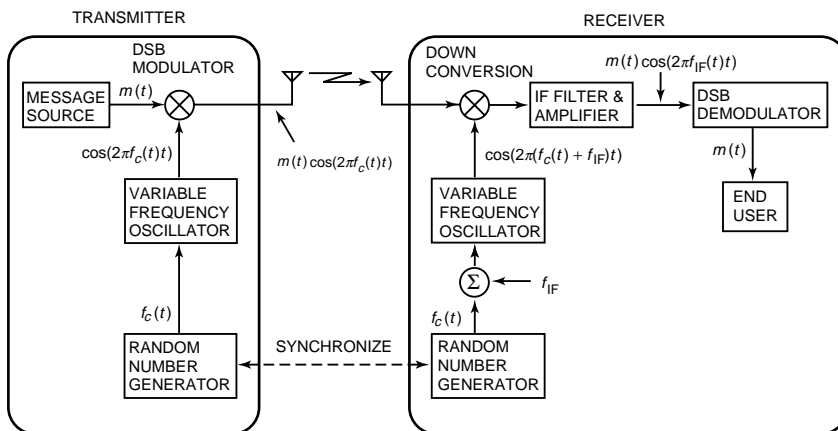

FIGURE 12.73 Frequency hopped spread spectrum system.

FIGURE 12.74 Sample hopping pattern for an FHSS system.

controlled by a pseudorandom number (PN) generator. A sample output of the PN generator output is shown in Fig. 12.74. Typically, the PN generator remains at each frequency for a fixed time interval called the *chip time*. At the end of the chip time, the transmitter will rapidly change to a new carrier frequency, selected at random by the PN generator, over the channel bandwidth. The transmitter and receiver use identical and synchronized PN generators. This ensures that the output of the receiver’s downconverter is always at the IF frequency, regardless of the carrier frequency. There are two classes of FHSS systems based on the chip time and the symbol time of the message source. In *fast hopping systems* the chip time is less than the symbol time, whereas the converse is true in a *slow hopping system*.

Frequency hopping accomplishes one of the major goals of an SS system: it makes it difficult to jam the transmitted signal over an extended time. If the hopping rate is sufficiently rapid, this system can also be immune to some multipath problems. However, FHSS signals are fairly easy to detect and demodulate. A spectrum analyzer or bank of energy detectors tuned to different frequency bands can detect the presence of an FHSS signal. Once the carrier frequency is located, a conventional receiver can demodulate the signal. There will be a processing delay from the time the friendly transmitter changes frequencies until the time the hostile receiver detects the change, but a delay line can store the signal long enough to permit demodulation. Frequency hopping is also only moderately successful at eliminating EMI. If the unauthorized receiver is an electronic device sensitive to a particular frequency range, it may see bursts of energy in the frequency band. In many cases short bursts of interference may be just as damaging as interference from a constant source.

Direct Sequence

Frequency hopped transmitters are easy to detect because at any given time they are radiating large amounts of energy in a limited bandwidth. For a system to have an LPI, it must continuously spread the transmitted power over a wide-frequency band. This will reduce the power spectral density (PSD) level and make the transmitted signal resemble background noise. An unauthorized or unintended receiver will only detect a slight increase in the noise floor, due to the presence of the signal, and will find it extremely difficult to demodulate the signal. Instantaneous frequency spreading can be accomplished by using the DSSS system shown in Fig. 12.75. The message is modulated using a conventional NB modulator at a fixed carrier frequency. Prior to transmission, the modulated signal is multiplied by a high-rate PN sequence. The chip time of the sequence is much less than the message symbol time, as shown in Fig. 12.76. Arbitrarily complex PN sequences can be used, but most systems of practical interest select the bilevel sequence ($c(t) = +1$ or -1). The DSSS receiver can strip the PN spreading code from the signal by multiplying the received signal by a locally produced replica of $c(t)$. When the code is a bilevel sequence, the output of the despreading

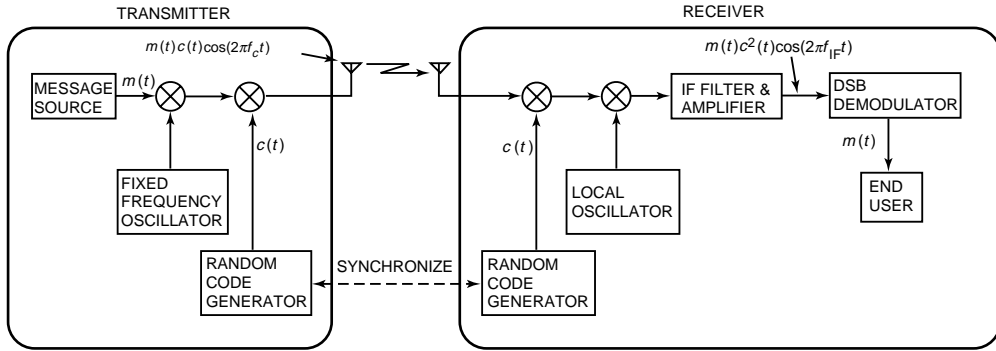

FIGURE 12.75 Direct sequence spread spectrum system.

multiplier is then

$$c^2(t)m(t) \cos(\omega_c t) = m(t) \cos(\omega_c t)$$

This despread signal can be demodulated by a conventional NB receiver.

The LPI characteristics of DSSS systems can be observed in the spectra of Fig. 12.76. Since the chip time of the PN generator is much less than the symbol time of the message source, the PN spectrum is much wider than the NB signal. From basic Fourier transform theory, we know that multiplication in time is equivalent to convolution in the frequency domain. Since the NB signal spectra is narrow compared to the spreading code, it will act almost the same as an impulse function. The result of the convolution will essentially be the PN spectrum shifted to the carrier frequency. This very wide bandwidth signal will resemble thermal noise over than bandwidth of the receiver.

12.6.4 Performance in Jamming Environments

Spread spectrum techniques are often used to improve the system performance when the received signal contains both the desired and interfering waveforms. The sensitivity of systems to a jamming waveform will depend on the modulation format and on the characteristics of the interference.

The jamming of a communication link is often viewed as a game. The transmitter can deliver a fixed amount of power S to the receiver, and the end user specifies a maximum allowable bit error rate (BER).

FIGURE 12.76 Direct sequence signals.

The jammer can deliver a signal with J watts of power to the friendly receiver and will try to force the BER above the acceptable level. An important parameter in these systems is the *jammer-to-signal ratio (JSR)*, J/S , which is often greater than unity. The jammer can always win this game by making J sufficiently large. Spread spectrum techniques can only increase the threshold where the jammer will eventually win the game. The change in the JSR level required for the jammer to win the game is called the *system processing gain*, and may be many orders of magnitude.

The jammer can use a wide variety of signals, including white Gaussian noise, bandlimited white Gaussian noise, pulsed noise, continuous tone, multiple tones, or a time-delayed copy of the transmitted signal (intentional multipath). A formidable adversary will be adept at observing the friendly signal and altering the jamming waveform to maximize the damage. The SS system designer should consider many jamming waveforms, to help minimize the chance the jammer will find one that is particularly effective. In a commercial environment, an electronic device may inadvertently act like a jammer by radiating one of these signals. Designers often analyze commercial systems in the same way as military systems because Murphy's law guarantees that an unintentional jammer will be just as effective as the most capable enemy jammer.

The Jammer Must Not Know the Spreading Code

A jammer can do a tremendous amount of damage if he knows the spreading format, carrier frequency, symbol rate, chip rate, and the spreading code used by the friendly system. Given all of this information, the jammer will be able to disrupt or eavesdrop on the SS link as effectively as a simple NB link. Designers and users of secure communication systems find it very difficult to keep the jammer from learning many of these system parameters. A conservative designer will assume the jammer has access to a complete description of the transmitter architecture. Somewhat surprisingly, a SS system can still be made secure by prohibiting the jammer from learning how to predict the output of the PN spreading code generator in real time. Even if the jammer knows the architecture of the PN generator, it is often impossible to predict the exact output without knowing the initial state of the generator (this requires a PN generator that is more complex than the simple *binary shift register (BSR)* generators discussed earlier). In the discussion that follows, we will assume the jammer knows all of the critical parameters of the friendly system *except* the exact sequence produced by the PN spreading code generator.

Additive White Gaussian Noise (AWGN) Jamming

One of the simplest ways to degrade the performance of any communication system is to raise the noise floor from N_0 to $N_0 + \Delta W/\text{Hz}$ over the entire band of the transmitted signal. This will lower the SNR at the receiver and degrade the performance of any communication system. For a NB system, the jamming power required to effect a change of $\Delta W/\text{Hz}$ over a band of W Hz is $\Delta W W$. In a SS system the transmitted bandwidth is $Y \gg W$ Hz, so to create the same change in the noise floor, the jammer must now produce Y/W times as much energy.

Continuous Wave (CW) Jammers

Another simple jamming signal is a sinusoidal tone, or continuous wave (CW) signal. This type of jammer produces a high-power sinusoid or other very narrow bandwidth waveform. Conventional NB transmitters often look like CW jammers to a SS signal. First consider the effect of a CW jammer on a DSSS system as shown in Fig. 12.77. The despreading mixer in the receiver collapses the DSSS signal back to a NB signal for processing by the IF filter. This mixer has the exact opposite effect on the jamming tone. It will multiply the CW signal by a high-rate PN code, effectively spreading it over a very wide bandwidth. Some of the jamming signal will still fall within the IF bandwidth, but the majority will fall well outside the passband of the IF filters, significantly decreasing the JSR at the demodulator.

The **processing gain** is the improvement in the JSR at the demodulator output compared to the JSR at the receiver antenna input. Nearly all of the friendly signal power passes through the IF filter, which has a bandwidth of approximately W Hz. Since the spreading code has a bandwidth of Y Hz, the jamming signal power will be spread over Y Hz. This means that the JSR at the IF output will be approximately

FIGURE 12.77 Response of a DSSS receiver to a jamming tone.

Y/W times less than the JSR at the antenna. There is a second, more subtle, benefit to DSSS receivers. Even though the jammer produced a continuous tone, the demodulator will see the interference as bandlimited white noise because of the multiplication by the spreading code. Most demodulators are designed under the assumption that the interference is white Gaussian noise. Nearly all jamming signals will look like white noise by the time they reach the demodulator output in these systems.

An FHSS system response to a CW jammer is slightly different and is summarized in Fig. 12.78. As the carrier frequency is hopped over a discrete set of frequencies, different frequency bands will be passed by the receiver's IF filter (recall that the local oscillator at the receiver will hop in the same pattern as the transmitter's oscillator). The shaded regions on the time/frequency graph represent the bands passed by the IF filter. During the majority of the hops the jamming tone (represented by the heavy line) will not be passed by the IF filter. When the jammer is lucky enough to hit the right frequency, all of the jammer energy is passed through the IF filter to the demodulator. During these chips, the data or message produced by the demodulator may be in error. There are many well-known error detection and correction techniques for dealing with errors, including the use of interleavers and error correcting codes. These devices are often used in FHSS systems.

To measure the jam resistance of a FHSS system, assume that the IF filter has a bandwidth of W Hz and the range of frequencies available to the system is Y Hz. If the jammer does not know the hopping pattern, the probability the signal will pass through the IF filter is W/Y , the reciprocal of the processing gain. The jammer will obviously be more successful if the jammer can determine the hopping pattern and make the corresponding change to the jamming frequency.

FIGURE 12.78 Sample hopping pattern for a FHSS system.

There are other techniques that receivers can use to combat CW jammers, particularly if the jammer uses a constant frequency. A narrow band exciser can be inserted before the despreading mixer. This device will actively search for powerful, narrow-band interference signals, then form a notch filter to remove the interfering signal. This will also remove a segment of the friendly signal, but may still improve overall system performance. A truly hostile jammer can defeat the exciser by hopping the jamming carrier frequency. These devices are much more useful in benign environments, such as when new commercial systems must share a band with existing NB transmitters.

Partial-Band Jammers

There are several jamming strategies between the two extremes of AWGN and CW jamming. Two possible alternatives are to send a collection of tones at different frequencies or transmit bandlimited AWGN that covers only a fraction of the friendly signal bandwidth. We will refer to both of these techniques as *partial-band jamming*. The advantage to partial-band jamming is most easily seen with FHSS systems. If a jammer can generate twice the power required to disable a NB demodulator, it would be foolish for the jammer to concentrate all of this power into a single tone. The jammer will be more successful by generating two lower power tones at widely differing frequencies. This will double the chance that the FHSS system will see an interfering signal and still guarantee the system will be disabled when it does see one of these tones. Depending on the JSR, the jammer may wish to generate more than two tones. For a given JSR, there will be an optimal number of tones the jammer should produce. If the jammer exceeds this optimal number, the power in each tone will become too small to effectively jam the friendly signal. There is a similar tradeoff with the bandwidth of a bandlimited AWGN jamming signal. It is well known that for a given JSR there is an optimal bandwidth that the jammer should use to increase the average BER to the extent possible.

There is typically little reason to use partial band jamming against DSSS systems. By spreading the jamming signal over a wider bandwidth, the jammer lowers the PSD of the jamming signal within the passband of the IF filter.

Pulse Jammers

In some cases the jammer has both an average power and peak power constraint. If the peak power limit is less stringent than the average power limit, the jammer may wish to deliver short bursts of interference rather than a constant signal. This type of jamming is also common in commercial systems, such as is found in computer local area networks, where each device may transmit a short burst of information and then remain silent for an extended time.

The exact analysis of pulse jammers can be rather difficult, and the analysis is dependent on a variety of parameters. Pulse jammers have the advantage that it is difficult for the friendly receiver to use an adaptive device to remove the jamming signal. Besides degrading demodulator performance, pulse jammers can disrupt a variety of support subsystems in the receiver. For example, pulse jammers can disrupt automatic gain control (AGC) systems. Most AGC subsystems use low-pass filters to find the average signal power. This means that when a pulse jammer is first turned on it can saturate the AGC amplifiers, although immediately after the end of the pulse the amplifier gains may be so low that the signal is lost due to quantizing noise or some other nonlinear distortion effect. Other devices sensitive to pulse jammers include carrier, symbol, and **code synchronization** devices.

Repeat-Back (Multipath) Jammers

Rather than generating a completely new waveform, some jammers prefer to intentionally introduce a multipath component. These jammers are reflective devices, where the friendly signal is received and then reflected or retransmitted in the direction of the receiver. In military systems the repeat-back jammer may be an active device; however, in commercial applications it is typically known as multipath interference. Multipath is a significant problem in urban areas where signals can reflect off buildings and in indoor wireless communication systems where high carrier frequencies make a host of structures and equipment effective reflectors of EM radiation.

Direct sequence SS systems can combat this type of interference effectively because the autocorrelation function of the spreading code is typically very small for time delays greater than one chip time. This means that the delayed signal will not be despread at the receiver, but will simply appear as another noise source at the despread output. To demonstrate this effect, assume that the received signal consists of the direct path signal and a reflected signal of equal strength but delayed by τ s. Therefore

$$r(t) = m(t) \cos(2\pi f_c t)c(t) + m(t) \cos(2\pi f_c (t - \tau))c(t - \tau)$$

and the output of the despreading mixer is

$$\begin{aligned} m(t) \cos(2\pi f_c t)c^2(t) + m(t) \cos(2\pi f_c (t - \tau))c(t - \tau)c(t) \\ = m(t) \cos(2\pi f_c t) + m(t) \cos(2\pi f_c (t - \tau))c(t - \tau)c(t) \end{aligned}$$

The second term will typically not despread because $c(t - \tau)c(t)$ will be a function of time. If τ is greater than a chip time, this product will resemble a PN sequence and be largely removed by the IF filter. This property will make DSSS receivers fairly insensitive to multipath interference as long as the differential delay between the main path and the multipath components is greater than a chip time. There will be some synchronization problems with these receivers, since it is important that the local PN reference is aligned to the strongest signal (usually the direct path) and not fooled into becoming synchronized with one of the multipath components.

Slow FHSS systems are sensitive to multipath jamming. The problem can sometimes be avoided by switching to a fast FHSS format. In a hostile environment, one can typically assume there is some minimum time difference between the main path and any multipath signal. This minimum time delay will be determined by calculating the difference in distance of the transmitter–jammer–receiver path over the transmitter–receiver direct path. If the chip time is less than the minimum time difference, the multipath jamming signal will always be at least one chip time behind the correct frequency. A judicious choice of hopping patterns will ensure that a jammer that is at least one chip time behind will seldom, if ever, be at a frequency that can cause interference. Of course, if the jammer is very close to the transmitter, it may be impossible to hop sufficiently fast. This may be the case for many indoor and urban communication systems. In these cases, the friendly users must simply use other NB techniques for dealing with the multipath problem, and FHSS will provide little assistance in overcoming the problem.

12.6.5 Random Number Generators

As we have seen, both FHSS and DSSS transmitters and receivers use random number generators, a device not typically found in NB systems. Frequency hopped SS systems use generators that produce integers, whereas DSSS systems typically use binary generators. Despite this difference, the underlying structure of the generators is very similar. The structure of the maximal length binary shift register generator is shown in [Fig. 12.79](#).

The BSR generator contains a series of D type flip-flops (F/F) all cycled by a common clock. The number of F/F in the shift register will vary depending on the application, but is typically between 10 and 100. The BSR generator also contains a series of modulo-two adders, or exclusive-OR gates. Figure 12.79 shows one XOR gate for each F/F, with a switch between the gate and the F/F. The designer of the generator must select the number of F/F in the BSR and which of the switches will be closed. Open switches will feed a logic 0 to the XOR gate, meaning that the gate is not needed. The designer (or user) must also select an appropriate clock frequency and the initial state of the BSR.

In many applications we would like the PN generator to produce a sequence that is unpredictable and never repeats. The BSR generator can come close to, but does not achieve, this ideal goal. The output of a sample BSR generator is shown in [Fig 12.80](#). Notice that the output seems to toggle randomly, but after 63 clock cycles the pattern repeats. Since BSR generators are finite state machines with no inputs, their outputs must be periodic. If the generator has N F/F, and each F/F can take on one of two states, the generator has only 2^N unique states. After no more than 2^N clock cycles, the generator must return to a

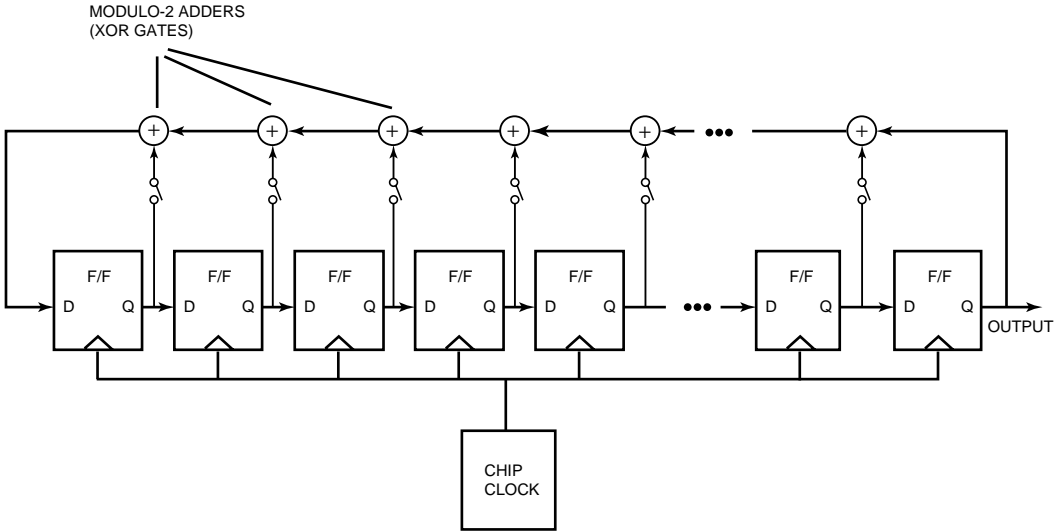

FIGURE 12.79 Binary shift register PN sequence generator.

state that it has already occupied, at which time the generator enters a loop it can never exit. The period of the generator will be determined by both N and the settings of the feedback switches. By carefully selecting the switch positions, the period of the output can reach a maximum of $2^N - 1$ clock cycles. Tables of optimal switch settings have been tabulated for various BSR lengths up to 89. Note that a $N = 89$ BSR generator clocked at 1 GHz will have a period of approximately 10^{10} years.

When the generator is first turned on the F/F must be set to predetermined states. For a BSR this may be any set of values agreed upon by the transmitter and receiver, except the all 0 state. A BSR initiated to all 0s will stay in that state forever. This set of initial values, along with the real-world time at which the generator is set to this state, is known as the PN generator **key**. Two identical SS systems (same carrier frequency, same modulation format) can share a common channel by simply using different keys. This format is called *code division multiple access (CDMA)* and is becoming popular in a variety of new communication systems.

The BSR generators discussed previously have one serious flaw: they are not secure. An intelligent enemy can determine the generator key and architecture after observing $2N$ output symbols. Secure communication systems must use more elaborate generators. Although the internal mechanism of secure generators vary, they will still be finite state machines that must be initialized by a key and have an output that is ultimately periodic.

Recall that FHSS systems require generators that produce integers. This is easily accomplished by increasing the clock rate of the BSR generator. An 8 state output can be produced by increasing the BSR

FIGURE 12.80 Typical PN generator output.

FIGURE 12.81 PN code synchronization subsystem.

clock by a factor of 3 and using the output of the last three F/F to generate a 3 bit number. This same strategy can be used to generate arbitrarily large integers.

12.6.6 Code Synchronization

All communication systems require synchronization in some form. In most cases the receiver needs a fairly accurate measure of the carrier frequency, and in digital communication systems the receiver often performs carrier phase synchronization and symbol synchronization. Besides these traditional synchronization tasks, SS systems must also synchronize the PN generators used at the transmitter and receiver since it is impossible for the receiver to demodulate the message without proper PN code synchronization. Pseudonoise code synchronization concerns may limit how rapidly a SS system be turned on and may also limit the minimum SNR at which the link can be maintained.

Code synchronization is divided into two separate tasks: initial timing acquisition and code tracking. Figure 12.81 is a high-level block diagram of a code synchronization system. The lock detector determines if the subsystem is in the acquisition or tracking mode. If the lock detector thinks the difference between the received and local PN codes exceeds a chip time, it will connect the acquisition device to the PN generator and inform the end user that the demodulated data is not valid. The acquisition device will reduce the timing error to approximately one chip time or less. At this point the lock detector will turn control of the PN generator over to the tracking device. This device further reduces the timing error and maintains it to within a small fraction of a chip time. The lock detector will constantly monitor the synchronization state. If at any time the timing error becomes large, the lock detector will switch control back to the acquisition device, causing the subsystem to reacquire the signal. Figure 12.81 is a conceptual block diagram only. The hardware that implements these functions is often shared between the different blocks.

Acquisition Devices

There are many acquisition strategies, but one of the simplest and most common is the serial search. Figure 12.82 illustrates a simple serial search device that uses a correlator and energy detector. Assume we are using a DSSS system where the received signal is

$$r(t) = m(t) \cos(2\pi f_c(t - \tau))c(t - \tau_1)$$

The cross correlator multiplies $r(t)$ by $c(t - \tau_2)$, and passes the result through a bandpass filter at the carrier frequency. If $\tau_1 = \tau_2$, the output of the multiplier will be $m(t) \cos(2\pi f_c(t - \tau))$, a NB signal that

FIGURE 12.82 Serial search acquisition device.

will pass through the IF filter. This will generate a large signal at the IF filter output, causing the energy detector to produce a large output voltage. If there is a large difference between τ_1 and τ_2 , the multiplier output will still have a PN code multiplying the NB signal. Very little of this wide-band signal will pass through the IF filter, and so the energy detector output will be quite small.

In sequential search acquisition, the PN generator is initiated with a key that is as close to the correct value as possible. The sweep generator forces the PN generator to sweep a wide range of timing offsets. Eventually one of these offsets will be within a chip time of the true offset, producing a significant output of the energy detector. The lock detector will sense the large energy detector output, halt the sweep generator, and turn control over to a tracking device. There are a variety of search patterns the sweep generator can use when hunting for the correct timing offset. Some of the more common sweep patterns are shown in Fig. 12.83.

FIGURE 12.83 Three common sweep strategies.

Tracking Devices

Once the acquisition device has placed the PN generator to within a chip time of the correct value, control is turned over to a code tracking device. *Delay-locked loops (DLL)* are frequently used for code tracking and are closely related the phase-locked loops (PLL) widely used in NB systems. The DLL can be used in a variety of configurations to track PN codes in FHSS and DSSS systems. The only DLL discussed in this section will be the noncoherent early/late DLL for DSSS code tracking. Figure 12.84 shows the basic components of the DLL are the PN sequence generator, two cross correlation arms, a loop filter, and a voltage controlled clock. These devices are analogous to the VCO, phase detector, and loop filter used in a conventional PLL.

The PN code generator in a DLL must be modified to produce both an early and late output. If the on-time output of the DLL is $c(t)$, then the early output will be $c(t + \Delta/2)$ and the late output will be $c(t - \Delta/2)$. The time difference Δ is under the control of the designer and is typically on the order of 0.5 to 1.0 chip times. Figure 12.85 shows the output of the early and late correlator arms for different timing errors. When the received PN code aligns with one of the locally generated references the received signal will be perfectly despread. This will produce a high-power, NB signal that will pass through the IF filter and be seen by the energy detector. As the timing error increases, the signal will be less perfectly despread,

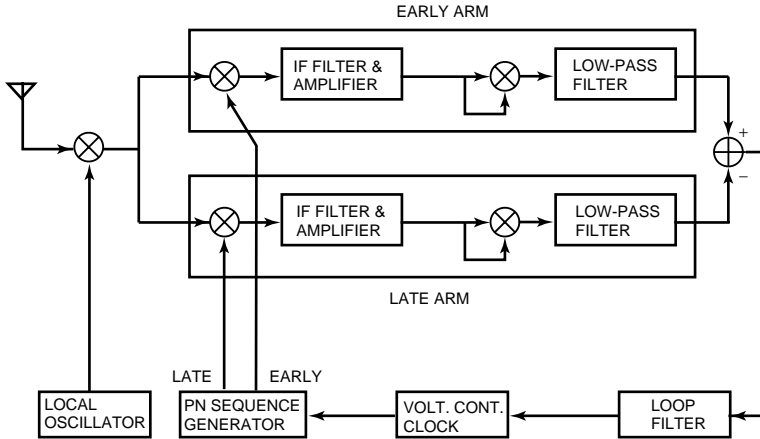

FIGURE 12.84 Noncoherent early/late DLL.

resulting in a lower amplitude NB signal. When the timing error exceeds one chip time, the signal will not be despread at all and the energy detector output will be negligible.

A useful error signal is generated by subtracting the output of the early and late cross-correlation arms. The average value of the summer output as a function of the timing error is called the *loop S-curve*. A sample S-curve is shown in Fig. 12.85. The signal produced by the summer will have a number of noise terms from thermal noise, jammers, and the so-called self-noise from the PN code. The loop filter will need to reduce these effects before passing the signal on to the voltage controlled clock.

The DLL S-curve is analogous to the sinusoidal phase detector characteristic of the PLL. In both cases the loops attempt to maintain a small timing error, keeping the error in the linear region of the S-curve of the phase discriminator characteristic. If the PLL error becomes large, the loop will cycle slip and attempt to relock on the next stable lock point. A large DLL timing error is more catastrophic. Once the timing error becomes large, the error term becomes negligible and the timing error will wander aimlessly. The lock detector will need to detect this large timing error and initiate a reacquisition cycle.

FIGURE 12.85 DLL timing waveforms.

12.6.7 Applications of Spread Spectrum Systems

An excellent tutorial paper on the theory of spread spectrum was published in 1992 (Pickholtz, Schilling, and Milstein). In this paper six characteristics of spread spectrum systems were identified. These were as follows:

- Antijamming
- Anti-interference
- Low probability of intercept
- Multiple user random access communications with selective addressing capability
- High-resolution ranging
- Accurate universal timing

Over the past decade spread spectrum systems have matured significantly. The operating characteristics of these systems are becoming better understood. In addition, dramatic advances in the technology for implementing SS systems allows them to be fabricated using a small number of integrated circuits. In addition, current SS systems provide much better performance, higher carrier frequencies, and higher data rates than those of just a few years ago. Although the basic list of characteristics remain unchanged, there has been a shift from military to commercial applications (Schilling et al., 1995).

The previous pages discussed in some detail the antijamming, anti-interference, and low probability of intercept characteristics of spread spectrum systems. In this section we look at several applications, especially those arising from the multiple access characteristics.

Wireless Local Area Networks (LANs)

One important application of spread spectrum communication systems is in the implementation of wireless local area networks (LANs). The attraction of such networks is obvious. A computer with access to a wireless LAN is completely untethered and a hard (wired) connection to a network is unnecessary. Wireless LANs are clearly advantageous in a situation in which computers are highly mobile (roaming), such as with laptop computers being moved from office to office or from an office to a conference room. Each computer carries its own RF transmitter and receiver, and such a system becomes very practical if licensing requirements can be avoided.

For systems such as wireless LANs to operate without a FCC site license, the industrial, scientific, and medical (ISM) frequency bands were created. There are two such bands, 902–928 MHz and 2.400–2.484 GHz. The FCC requires that transmission on these bands must use either frequency hopping or direct sequence spread spectrum transmission. The more restrictive IEEE 802.11 standard, however, limits FHSS to the 2.400–2.484 GHz band, so that the lower frequency band is reserved for DSSS systems. FCC requirements also dictate certain parameters that influence the hopping pattern for FHSS systems. For example, the FCC dictates that in the 2.4-GHz frequency band, a FHSS transmitter must not spend more than 0.4 s in any one frequency slot every 30 s and that the transmitter must hop through at least 75 frequency slots in the frequency hopping pattern (Rigney, 1995).

Defining Terms

Code synchronization: Spread spectrum transmitters and receivers must synchronously generate identical pseudorandom sequences. Code synchronization is the act of bringing these two generators into alignment.

Direct sequence: A spread spectrum format where a narrow-band signal is multiplied by a high rate pseudonoise code prior to transmission.

Frequency hopping: A spread spectrum format where the frequency of the transmitted signal is rapidly changed in a pseudorandom pattern.

- Jam resistant systems:** Systems that can reliably transmit information even when interfering signals are present. The power in the interfering signal may be significantly greater than the power of the transmitted signal.
- Key:** A piece of data that describes the initial state of a pseudorandom generator. It can be difficult or impossible to determine the output of the generator if one does not know the key.
- Low probability of intercept:** The transmitted signal in some spread spectrum systems resembles background noise. It is difficult for unauthorized users to detect and demodulate these signals.
- Narrow-band modulation:** Any one of a variety of modulation techniques where the bandwidth of the transmitted signal is comparable with the bandwidth (or data rate) of the message. Common examples include AM, FM, PM, ASK, FSK, BPSK, MSK, and QPSK.
- Processing gain:** Jammers must use more power to disrupt a spread spectrum link than to disrupt a narrow-band link. The amount the jammer must increase power is known as the processing gain of the spread spectrum system.
- Pseudorandom noise:** A deterministic, but noiselike, waveform typically produced by a digital pseudorandom number generator. Two pseudorandom generators will generate identical waveforms if they are initialized with the same seed and clocked synchronously.
- Spread spectrum modulation:** A modulation format where the bandwidth of the transmitted signal is typically orders of magnitude wider than the bandwidth (or data rate) of the message. Common examples include frequency hopping (FHSS) and direct sequence (DSSS).

12.7 Digital Coding Schemes

Oktaý Alkin

12.7.1 Introduction

Two fundamental issues in assessing the performance of a digital communication system are:

- The reliability of the system in terms of accurately transmitting information from one point to another
- The rate at which information can be transmitted with an acceptable level of reliability

In an ideal communication system, information would be transmitted at an infinite rate with an infinite level of reliability. In reality, however, there are fundamental limitations affecting the performance of any communication system. No physical system is capable of responding to changes in an instantaneous manner, and the range of frequencies that a system could reliably handle is limited, thus leading to the concept of *bandwidth*. In addition, *random noise* affects any signal being transmitted through any communication medium. Finite bandwidth and additive random noise are two fundamental limitations that prevent us from achieving an infinite rate of transmission with infinite reliability, and a compromise must be found. What makes the problem even more challenging is the fact that the reliability and the rate of information transmission usually work against each other, that is, for a given system, a higher rate of transmission means a lower degree of reliability and vice versa. To affect the balance in our favor, we need to improve the efficiency and the robustness of the communication system. **Source coding** and **channel coding** are the means for accomplishing this task, and will be discussed in the following subsections. First, some background in **information theory** needs to be established.

Since we are concerned about transmitting information from one point to another, a mathematical means for measuring information is needed. Consider an information source that produces symbols from an alphabet

$$\mathcal{A} = \{a_0, a_1, \dots, a_{M-1}\} \quad (12.137)$$

with associated probabilities

$$\text{Prob}\{a_k\} = p_k, \quad k = 0, \dots, M-1 \quad (12.138)$$

subject to the constraints $p_k \geq 0$ for all k , and $\sum_{k=0}^{M-1} p_k = 1$. We will assume that the source generates symbols from the alphabet given in Eq. (12.138) at a rate of r symbols per second. We will further assume that subsequent symbols generated are statistically independent of each other. Such an information source is referred to as a *discrete memoryless source*. An example might be a digital computer or some kind of a data acquisition device.

If we were to observe the output of this information source for one symbol interval, our level of surprise after observing the symbol would depend on the probability of that symbol being generated. A symbol with low probability would cause a bigger surprise than a symbol with higher probability. Furthermore, if any symbol in the source alphabet has a probability of 1, observing that symbol would cause no surprise at all, and no information would be gained. Thus, it would intuitively make sense to associate the *amount of information* gained by observing a symbol with the *degree of surprise* caused by that observation. We will define the amount of information gained by observing the symbol a_k at the source output as

$$\begin{aligned} I(a_k) &= \log_2 \left(\frac{1}{p_k} \right) \\ &= -\log_2(p_k) \end{aligned} \quad (12.139)$$

expressed in *bits*. [Note in this context we are using the term *bit* as a unit of information. This should not be confused with the common use of this term in computer terminology as a *binary digit*. One *binary digit* does not necessarily contain one *bit of information*.]

Example 1

Consider a source that generates symbols from the alphabet $A = \{a_0, a_1\}$ with probabilities $p_0 = 0.7$ and $p_1 = 0.3$. If we observe the symbol a_0 at the source output, the information gained by this observation is

$$I(a_0) = -\log_2(0.7) = 0.5146 \text{ bits}$$

Similarly, the information gained after observing the symbol a_1 would be

$$I(a_1) = -\log_2(0.3) = 1.7370 \text{ bits}$$

To assess the efficiency of a source, we need to know the average amount of information expected to be gained from the observation of one source symbol. The **entropy** of a source is defined as

$$\begin{aligned} H(\mathcal{A}) &= E \{I(a_k)\} \\ &= -\sum_{k=0}^{M-1} p_k \log_2(p_k) \end{aligned} \quad (12.140)$$

and represents the expected amount of information per symbol. Note that entropy is a general characteristic of the source, and represents the expected average amount of information before an observation. Once the symbol is observed, the amount of information gained depends on the symbol, and can be computed as in example 1.

Example 2

Consider again the binary source in example 1. The entropy of the source is

$$\begin{aligned} H(\mathcal{A}) &= -0.7 \log_2(0.7) - 0.2 \log_2(0.2) \\ &= 0.8813 \text{ bits/symbol} \end{aligned}$$

Once an observation is made, the amount of information gained is either 0.5146 bits or 1.7370 bits depending on the symbol observed. If a large number of observations are made, however, the amount of information per symbol is expected to average around 0.8813 bits/symbol.

As the previous example illustrates, the entropy of a source is a function of only the symbol probabilities. For a binary source $p_1 = 1 - p_0$, and the entropy can be written as

$$H(\mathcal{A}) = -p_0 \log_2(p_0) - (1 - p_0) \log_2(1 - p_0) \quad (12.141)$$

A graph of $H(\mathcal{A})$ as a function of p_0 is given in Fig. 12.86. Note that the entropy is maximum when $p_0 = p_1 = 0.5$, that is, when the uncertainty of the symbol to be generated is maximum. If an information source generates symbols from an alphabet of M distinct symbols, it can be shown that the entropy is maximum if all symbols of the alphabet are equally likely, that is

$$p_0 = p_1 = \cdots = p_{M-1} = \frac{1}{M} \quad (12.142)$$

Example 3

Consider a discrete memoryless source that generates symbols from the alphabet

$$\mathcal{A} = \{a_0, a_1, a_2, a_3\} \quad (12.143)$$

FIGURE 12.86 Entropy of binary source as a function of p_0 .

with corresponding probabilities

$$P(a_0) = 0.50$$

$$P(a_1) = 0.30$$

$$P(a_2) = 0.15$$

$$P(a_3) = 0.05$$

If the output of the source is to be transmitted through a binary channel, it needs to be *encoded* in binary form. Let us assume that the following encoding scheme is used:

$$a_0 \Rightarrow 00$$

$$a_1 \Rightarrow 01$$

$$a_2 \Rightarrow 10$$

$$a_3 \Rightarrow 11$$

It can easily be shown that the entropy of this source is 1.6477 bits/symbol. All symbols are coded into 2-bits codewords.

Source Coding Theorem

Given a discrete memoryless source with entropy $H(\mathcal{A})$ and an average codeword length of L , it is possible to encode the output of the source in such a way that the resulting average codeword length can be made as close to the lower bound

$$L \geq H(\mathcal{A}) \quad (12.144)$$

as desired. Note that the theorem establishes a lower bound on L , and claims that it could be approached, however, we are not told how to accomplish this. Methods of source encoding will be the subject of the next subsection.

Example 4

Consider again the source in example 3. The average codeword length is significantly greater than the entropy of the source. Note that the symbol a_0 occurs with a higher probability than the other symbols, hence it would be wise to assign a shorter codeword to a_0 perhaps at the expense of longer codewords to some of the other symbols. Consider the alternative encoding scheme

$$a_0 \Rightarrow 0$$

$$a_1 \Rightarrow 10$$

$$a_2 \Rightarrow 110$$

$$a_3 \Rightarrow 111$$

It can be shown that the average codeword length for this case is 1.7 bits/symbol, significantly closer to the source entropy compared to the encoding scheme of example 3. Based on the source coding theorem, however, there is still room for further improvement, perhaps by using another coding scheme.

12.7.2 Source Coding

Examples 3 and 4 illustrate an important concept: The most intuitive coding scheme may not always be the most efficient. In example 3, each symbol was assigned a codeword of length 2. If N symbols are transmitted, the number of codewords to be transmitted would be $2N$. In example 4, symbols were assigned codewords of different lengths resulting in an average codeword length of 1.7. For large N , this would translate to about $1.7N$ codewords for the transmission of the same information. Thus, the coding scheme of example 4 allows us to get closer to the boundary set by the source coding theorem.

Most information sources generate signals that contain redundancies. For example, consider a page of text. If we want to code this text in binary so that it can be transmitted over a digital channel, we might opt for a scheme that assigns 7 bits to each symbol on the page including space and punctuation characters. (One example of such a coding scheme is American Standard Code for Information Interchange (ASCII).) If the page is set up to hold 60 rows with 80 characters in each line, transmitting a page of text would require transmitting 4,800 characters, or equivalently, 33,600 binary digits. It is very unlikely, however, that the page will contain 33,600 bits of information. Another example is a picture that is made up of pixels each of which represent one of 256 grayness levels. If we use a fixed coding scheme that assigns 8 binary digits to each pixel, a 100 by 100 picture of random patterns and a 100 by 100 picture that consists of only white pixels would both be coded into the same number of binary digits, although the latter has significantly less information than the former.

One simple method of source encoding is the *Huffman coding* technique, which is based on the idea of assigning a codeword to each symbol of the source alphabet such that the length of each codeword is approximately equal to the amount of information conveyed by that symbol. As a result, symbols with lower probabilities get longer codewords. Huffman coding is achieved through the following process:

- List source symbols in descending order of probabilities.
- Assign a binary-0 and a binary-1, respectively, to the last two symbols in the list.
- Combine the last two symbols in the list into a new symbol with its probability equal to the sum of two symbol probabilities.
- Reorder the list, and continue in this manner until only one symbol is left.
- Trace the binary assignments in reverse order to obtain the codeword for each symbol.

The following example should help clarify this procedure.

Example 5

Consider a discrete memoryless source that generates symbols from the alphabet

$$\mathcal{A} = \{a_0, a_1, a_2, a_3, a_4, a_5, a_6, a_7\} \quad (12.145)$$

with corresponding probabilities

$$P(a_0) = 0.46$$

$$P(a_1) = 0.18$$

$$P(a_2) = 0.12$$

$$P(a_3) = 0.08$$

$$P(a_4) = 0.07$$

$$P(a_5) = 0.04$$

$$P(a_6) = 0.03$$

$$P(a_7) = 0.02$$

Figure 12.87 illustrates the Huffman coding procedure for this source. Obtained codewords are

$$a_0 \Rightarrow 1$$

$$a_1 \Rightarrow 000$$

$$a_2 \Rightarrow 011$$

$$a_3 \Rightarrow 0010$$

$$a_4 \Rightarrow 0011$$

$$a_5 \Rightarrow 0101$$

$$a_6 \Rightarrow 01000$$

$$a_7 \Rightarrow 01001$$

FIGURE 12.87 Huffman coding algorithm.

A tree diagram for decoding a coded sequence of symbols is shown in Fig. 12.88.

It can easily be verified that the entropy of the source under consideration is 2.3382 bits/symbol, and the average codeword length using Huffman coding is 2.37 bits/symbol.

FIGURE 12.88 Huffman code tree for Example 5.

12.7.3 Forward Error Correction Coding

In the previous section, we discussed the need for removing redundancies from the message signal in order to increase efficiency in transmission. From an efficiency point of view, the ideal scenario would be to obtain an average wordlength that is numerically equal to the entropy of the source. From a practical perspective, however, this would make it impossible to detect or correct errors that may occur during transmission. Some redundancy must be added to the signal in a controlled manner to facilitate detection and correction of transmission errors. This is referred to as channel encoding.

A variety of techniques exists for detection and correction of errors. In this section, we will consider *linear block codes*. The term **block code** refers to the fact that the message signal is partitioned into blocks (codewords) of fixed length.

Let a codeword be represented as a vector in the form

$$T = (m_1 m_2 \cdots m_k c_1 c_2 \cdots c_{n-k})^T$$

where the leftmost k bits m_1, m_2, \dots, m_k are the message bits, and the following $n - k$ bits c_1, c_2, \dots, c_{n-k} are the parity bits added by the channel encoder. Parity bits are selected such that

$$h_{i,1}m_1 + h_{i,2}m_2 + \cdots + h_{i,k}m_k + c_i = 0 \quad i = 0, \dots, n - k \tag{12.146}$$

where additions are done in modulo-2. In matrix form, Eq. (12.146) can be written as

$$P T = 0 \tag{12.147}$$

where P is the *parity-check matrix* defined as

$$P = [H \ I_{n-k}] = \begin{bmatrix} h_{1,1} & h_{1,2} & \cdots & h_{1,k} & 1 & 0 & \cdots & 0 \\ h_{2,1} & h_{2,2} & \cdots & h_{2,k} & 0 & 1 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ h_{n-k,1} & h_{n-k,2} & \cdots & h_{n-k,k} & 0 & 0 & \cdots & 1 \end{bmatrix} \tag{12.148}$$

If the transmitted and received codewords are T and R , respectively, we can write

$$R = T + E \quad (12.149)$$

where E represents the transmission error(s) caused by the channel. Using Eq. (12.147) and Eq. (12.149) together, we obtain

$$\begin{aligned} S &= P T + P E \\ &= P E \end{aligned} \quad (12.150)$$

The vector S is called the *syndrome*. In the absence of any bit errors, the syndrome should be zero.

Now, let us assume that the vector E has a binary 1 in the i th position indicating a bit error, that is

$$E = (00 \dots, 1 \dots 0)$$

In this case, the syndrome would be identical to the i th column of the matrix parity-check matrix P . The following example illustrates this.

Example 6

The parity-check matrix for a particular code is

$$P = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \end{bmatrix}$$

If the bitstream 10011000 is received, the syndrome would be

$$S = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} 1 \\ 0 \\ 0 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

This is clearly identical to the fourth column of the parity-check matrix, and indicates a possible bit error in the fourth bit position. We can not be absolutely sure since this scheme only detects single bit errors. In the case of multiple bit errors, the syndrome would be the sum of corresponding columns of the parity-check matrix. For example, the situation may also indicate that bits 2 and 6 are in error. On the other hand, in most communication systems, the probability of having multiple bit errors within one codeword is significantly smaller than the probability of a single bit error.

The set of equations in Eq. (12.146) can also be written in the alternative form

$$h_{i,1}m_1 + h_{i,2}m_2 + \dots + h_{i,k}m_k = c_i \quad i = 0, \dots, n - k \quad (12.151)$$

or in matrix form as

$$\begin{bmatrix} h_{1,1} & h_{1,2} & \dots & h_{1,k} \\ h_{2,1} & h_{2,2} & \dots & h_{2,k} \\ \dots & & & \\ \dots & & & \\ h_{n-k,1} & h_{n-k,2} & \dots & h_{n-k,k} \end{bmatrix} \cdot \begin{bmatrix} m_1 \\ m_2 \\ \dots \\ m_k \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ \dots \\ c_{n-k} \end{bmatrix} \tag{12.152}$$

Based on Eq. (12.152), a *generator matrix* can be constructed as

$$\mathbf{G} = [\mathbf{I}_{n-k} \mathbf{H}] = \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \dots & & & \\ \dots & & & \\ 0 & 0 & \dots & 1 \\ h_{1,1} & h_{1,2} & \dots & h_{1,k} \\ h_{2,1} & h_{2,2} & \dots & h_{2,k} \\ \dots & & & \\ \dots & & & \\ h_{n-k,1} & h_{n-k,2} & \dots & h_{n-k,k} \end{bmatrix} \tag{12.153}$$

so that codewords can be obtained from message bit sequences as

$$\mathbf{T} = \mathbf{G} \mathbf{M} \tag{12.154}$$

Defining Terms

- Block codes:** Error detecting codes that are obtained by appending special bits to data bits.
- Channel coding:** Adding redundancy into information in a controlled manner to facilitate detection and possible correction of errors that may occur during transmission.
- Entropy:** Average information gained per symbol by observing the output of an information source.
- Error correcting codes:** Codes that are added to data for locating erroneous bits and correcting them at the receiver end.
- Information theory:** The mathematical theory that deals with quantifying and statistically analyzing information.
- Source coding:** Encoding the output of an information source to remove redundancy.

12.8 Audio Compression Techniques

Fred Wylie

12.8.1 Introduction

The transmission and storage of digital signals present difficulties to professional audio users due to the large and expensive circuit bandwidth and computer storage space required to cope with such a signal. The CD and DAT formats, real-time 16-bit linear *pulse code modulation* (**PCM**) processes, each transfers data at 1.411 Mb/s for stereo and require circuit bandwidth of at least 700 kHz to avoid distorting the digital signal during transmission. In practice, additional overhead bits are added to the signal for channel coding, synchronization, and error correction, and this increases the bandwidth demands yet again. The commonly quoted bandwidth figure for distribution and transmission circuits is 1.5 MHz. Compare this with the requirement for two separate 20-kHz circuits to distribute the same stereo audio in its analog format. The mathematics quickly demonstrate that it would take around 630 megabytes of computer storage space to hold the contents of a single 60-min stereo CD or DAT tape.

The general result is that it is too costly and complex to fully implement a 16-bit linear PCM infrastructure, except over very short distances and within studio areas.

12.8.2 Digital Audio Data Compression

Significant developments in high speed digital signal processing (**DSP**) hardware have resulted in a number of alternative real-time, or in reality, near instantaneous digital compression coding systems offering sizeable reductions in data rates. These rates require significantly lower bandwidths for transmission and occupy less computer storage space and yet subjectively still deliver high quality audio.

Applications

Digital audio data compression systems are currently in use throughout the world with many applications. For broadcast telecommunications this includes RF studio transmitter links (**STL**) and other fixed digital cable links and satellite-based outside broadcast links; all of which can be adapted by selecting different data rates for either speech or high-quality music. New eras of broadcasting unfold with the introduction of digital audio broadcasting (**DAB**) and high-definition television (**HDTV**), both of which will use audio data reduction techniques.

Data compression can be used to increase the capacity of numerous audio storage products such as hard and magneto-optical (**MO**) disk-based digital audio recorders and work stations. A modest compression ratio of 4:1 enables a 1-h stereo CD to be stored on 160 megabyte (**MB**) of disk space and to store some 30 s of full bandwidth stereo on a 1.44 MB, 3¹/₂-in floppy diskette. Cinema audiences are now being offered virtual audio splendor with audio surround systems incorporating data compression.

Definition of Real-Time Data Compression

Real-time data compression is the reduction of the bit rate of linear PCM with a minimum of processing delay and imperceptible loss of quality, either from signal distortion or injected noise.

Analog audio transmission requires fixed input and output bandwidths, and this implies that in a real-time compression system the quality, bandwidth, and distortion/noise level of both the original and the decoded output sound should not be subjectively different, thus giving the appearance of a lossless and real-time process.

Without exception all real-time bit rate reduction systems can be referred to as *lossy*. In other words the digital audio signal at the output is not identical to the input signal PCM data stream. However, some *adaptive differential pulse code modulation* (**ADPCM**) compression algorithms are to all intents and purposes lossless by losing as little as 2% of the original signal and others are in the *adaptive pulse code modulation* (**APCM**) or transform family of algorithms, which remove around 80% of the original signal.

A common application of data compression, which illustrates lossless compression, is the fax machine. This requires a variable bandwidth and some statistical knowledge of the incoming data. A blank page is processed much more quickly than a complicated page, the feed speed dynamically changing as the text detail changes. This adjusts the bandwidth of the scanner input to maintain a fixed 9600 Bd (9.6 kb/s) rate into the telecom line.

Redundancy and Irrelevancy

A complex linear PCM signal contains a great deal of information, some of which the human ear cannot hear and can, therefore, be deemed to be irrelevant. The same signal, depending on its complexity, contains information that is highly predictable and, therefore, can be made redundant.

Redundancy, measurable and quantifiable, can be removed in the coder and replaced again in the decoder, a process often referred to as statistical compression. On the other hand, *irrelevancy*, referred to as perceptual coding, once removed from the signal cannot be replaced and is irretrievably lost. This is entirely a subjective process with each proprietary algorithm using a different psychoacoustic model.

Critically perceived signals, such as pure tones, are high in redundancy and low in irrelevancy. They compress quite easily, almost totally a statistical compression process. Conversely, noncritically perceived signals, such as complex audio or noisy signals, are low in redundancy but high in irrelevancy. These compress easily in the perceptual coder but with the total loss of all of the irrelevancy content.

Human Auditory System

The sensitivity of the human ear is biased toward the lower end of the audible frequency spectrum, around 3 kHz. At 50 Hz, the bottom end of the spectrum, and 17 kHz, at the top end, the sensitivity of the ear is down by approximately 50 dB relative to that at 3 kHz (see Fig. 12.89). Additionally, there are very few audio signals, music or speech based, that carry fundamental frequencies above 4 kHz. Taking advantage of these characteristics of the ear, the structure of audible sounds and the redundancy content of the PCM signal is the basis used by the designers of the ADPCM or *predictive* range of compression algorithms.

Another well-known feature of the hearing process is that loud sounds will mask out quieter sounds at a similar or near frequency. This compares with the action of an automatic gain control, turning the gain down when subjected to loud sounds, thus making quieter sounds less likely to be heard. For example

FIGURE 12.89 Frequency response of the human ear.

FIGURE 12.90 Masking effect of high-level sound.

(see Fig. 12.90), with a 1 kHz tone level of 70 dB it would require levels of greater than 40 dB at 750 Hz and 2 kHz for those frequencies to be heard. The ear also exercises a degree of temporal masking, being exceptionally tolerant of sharp transient sounds.

It is by mimicking these additional psychoacoustic features of the human ear and identifying the irrelevancy content of the PCM signal that the APCM, or *transform* range of low bit rate algorithms operate, adopting the principle that if the ear is unable to hear the sound then there is no point in transmitting it in the first place.

Quantization

Quantization is the process of converting an analog signal to its representative digital format or, as in the case with compression, the requantizing of an already converted signal. It is the limiting of a finite level measurement of a signal sample to a specific preset integer value. This means that the *actual* level of the sample may be greater or smaller than the preset *reference* level it is being compared with. The difference between these two levels is called the quantization error, and is compounded in the decoded signal as *quantization noise*.

Therefore, quantization noise will be injected into the audio signal after any A/D and D/A conversion, the level of that noise being governed by the bit allocation associated with the coding process, that is, the number of bits allocated to represent the level of each sample taken of the analog signal. For linear PCM the bit allocation is 16, and, therefore, the level of each audio sample will be compared with one of 2^{16} or 65,536 discrete levels or steps.

Compression or bit rate reduction of the PCM signal leads to the re-quantizing of that already quantized signal, and this will unavoidably inject further quantization noise. It has always been good operating procedure to restrict the number of A/D and D/A conversions in an audio chain. Nothing has changed, and now the number of compression stages should also be kept to a minimum and, additionally, the bit rate of these stages should be set as high as is practical. Put another way, the compression ratio should be as low as possible.

Sooner or later after a finite number of A/D and D/A conversions and passes of compression coding, of whatever ilk, the accumulation of quantization noise and other unpredictable signal degradations will eventually break through the noise/signal threshold, will be interpreted as part of the audio signal, processed as such, and will be heard.

Therefore, when considering using compression it is crucial to first select a compression coder–decoder (**codec**) best suited for the specific purpose, anticipating the possibility or requirement for any further

compression. Second, retain as far as possible the signal in the PCM format between any further stages of compression, signal routing, or distribution. The latter may not be very practical, and additional D/A and A/D conversions between stages may be unavoidable.

Sampling Frequency and Bit Rate

The bit rate of a digital signal is defined by

$$\text{sampling frequency} \times \text{bit resolution} \times \text{no. of audio channels}$$

The rules regarding the selection of a sampling frequency are based on Nyquist's theorem, which states that the rate must be at least twice the highest audible frequency required at the analog output of the decoder. In particular, this ensures that the lower sideband of the sampling frequency does not encroach into the wanted base band audio. Objectionable and audible aliasing effects would occur if the two bands should overlap. In practice, the sampling rate is set slightly above twice the highest audible frequency, which makes the filter designs less complex and less expensive.

In the case of a stereo CD, with the audio signal having been sampled at 44.1 kHz, produces audio bandwidths of approximately 20 kHz for each channel. The resulting audio bit rate is $44.1 \text{ kHz} \times 16 \times 2 = 1.411 \text{ M b/s}$. Similarly, an FM stereo broadcaster would generate a PCM signal of 1.024 Mb/s ($32 \text{ kHz} \times 16 \times 2$) to deliver 15 kHz stereo audio.

Why 44.1-kHz Sampling

The unique 44.1-kHz sampling frequency used in the CD is historical. The early digital stereo audio recordings were made on VHS video recorders using the Sony F1 format. The equipment would only record a video signal with line sync signals; therefore, the digital audio signal had to be reformatted to resemble a video signal. Three 16-bit PCM words were carried on each active line of the video signal, whether NTSC or PAL, and quite remarkably, even with these differing line and picture standards a common sampling frequency of 44.1 kHz produced 20-kHz stereo audio on both systems.

Compression Ratio

Compression algorithms come with differing and often selectable bit rates related to a combination of sampling frequency and compressed bits per PCM sample (compression ratio). For example, a compression ratio of 6:1 can be translated as 2.66 b/PCM sample and with a sampling frequency of 48 kHz produces a bit rate of $(2.66 \times 48 \text{ kHz}) = 128 \text{ kb/s}$ per mono channel capable of delivering greater than 20-kHz audio bandwidth.

The same FM stereo broadcaster distributing a linear PCM signal at 1.024-Mb/s bit rate would have the option of using a compression coder offering a modest 4:1 compression ratio and the same sampling frequency of 32 kHz. The coding process would generate a new reduced output bit rate of 256 kb/s (for stereo), and this when subsequently decoded would produce the same 15-kHz bandwidth audio.

Higher compression ratios up to 18:1 can reduce the PCM bit rate even further. This may be satisfactory for the final delivery of audio or the capture of a single shot audio but if further compression is anticipated, even at lower compression ratios, then this more aggressive compression may render the signal more vulnerable to noise and distortion breakthrough and in the case of a stereo signal may, alter the stereo image, depending on the program content.

The misuse of compression can lead to difficulties, particularly with tandem or multiple passes, and bandwidths or noise floors defined by an earlier stage of aggressive compression cannot be subsequently improved by later less aggressive stages.

12.8.3 Processing and Propagation Delay

Compression coding is not a wholly real time but a near instantaneous process and, with any of today's popular algorithms, will introduce processing delay. This delaying of the output audio with reference to the input can range from a few milliseconds in some codecs to tens of milliseconds in others. This can be

a crucial factor in the selection of a codec for a two-way interview or interactive applications where delays in excess of 20 ms can be problematical. In a one-way audio capture or delivery application the delay is of no consequence.

Propagation delay is unavoidable and is due to the length of the satellite, extremely long terrestrial circuit paths, or mixes of both. A 1000-km totally digital telecommunication path in full duplex mode has a propagation delay of 3 ms in each direction, and this is comparable with two people in a conversation while standing approximately 1 m apart. Whether in a short or long haul two-way hook-up, it is clear that the introduction of a compression codec with a long processing delay will have a dramatic effect.

History of Data Compression

It was in the early 1960s that data compression was first used by two Consultative Committees for International Telegraph and Telephone (CCITT) G711 compliant systems: A law in Europe and μ law in the U.S. The sampling frequency was 8 kHz and the then 12-bit PCM format was reduced to 8 b, delivering an audio bandwidth of 4 kHz at a bit rate of 64 kb/s, ideal for telephone speech. Eventually, 64 kb/s was adopted as the bit rate for a single ISDN B, basic rate telecommunication channel.

The unique NICAM system was developed by the British Broadcasting Corporation (BBC) during the 1970s to make more efficient use of its leased transmitter and interstudio communications network, which was carrying linear PCM signals and distributing channels of audio in mono and stereo. NICAM reduces a 32-kHz sampled, 14-bit linear signal down to 10 b, a modest compression. The technique analyzes 1-ms blocks of 32 PCM samples and compresses them into one of five ranges, depending on the amplitude of the largest sample in the block and signaled by a 3-bit scale factor word. Some of the most significant and least significant bits (MSBs or LSBs) of each digital word are discarded depending on which range the block is allocated. Nicam 3, with 338 kb/s allocated to each 15-kHz audio channel enables 24 audio channels to be distributed in the same carrier bandwidth where previously only 13 linear channels could be accommodated, an 80% increase.

12.8.4 Modern Compression Techniques

Common compression formats are based on

- *Predictive* or ADPCM time-domain coding
- *Transform* or APCM frequency-domain coding.

It is in their approach to dealing with the redundancy and irrelevancy of the PCM signal that these techniques differ.

Subband coding variations of both of these techniques figure highly within the audio industry. The present range of popular algorithms process the PCM signal in narrow discrete frequency bands, splitting the frequency range of the signal into 2, 4, 32, 256, 576, or 1024 subbands, dependent on the system being used. The bit allocation is then either dynamically adapted or fixed, for each subband. In doing so the frequency-domain redundancies within the audio signals can be exploited, allowing for a reduction in the coded bit rate, compared to PCM, for a given signal fidelity. Since the signal energies in each subband are unequal at any instant in time this will also lead to spectral redundancies. By altering the short-term coding resolution in each band, according to the energy of the subband signal the quantization noise can be reduced across all bands. This process compares favorably with the noise characteristics of a PCM coder performing at the same overall bit rate.

On its own, subband coding incorporating PCM in each band is capable of providing an improvement in performance compared with that of full band PCM coding, both being fed with the same complex, constant level input signal. This improvement or gain is defined as the ratio of the variations in quantization errors generated in each case while both are operating at the same transmission data rate. The gain increases as the number of subbands increases and varies with the extent of the complexity of the input signal. [Figure 12.91](#) illustrates the variation of subband gain with the number of subbands for four essentially stationary, but differing, complex audio signals.

FIGURE 12.91 Variation of subband gain with the number of subbands.

In the practical implementations of compression codecs a number of factors tend to limit the number of subbands employed. First, the level variation of normal audio signals leads to an averaging of the energy across bands and a reduction in the coding gain. The coding or processing delay and computational complexity are two further problems that must also be addressed.

The key issue in the analysis of a subband framework is in determining the likely improvement associated with high-quality audio and in also determining the relationships between that gain, the number of subbands, and the response of the filter bank used to create those subbands.

12.8.5 Subband ADPCM Coding

G722 was the first commercial quality compression algorithm in this category and was approved by the CCITT in the mid-1970s. Although originally designed to compress 14-bit PCM sampled at 16 kHz, it is still very much in use for 16-bit PCM, 7-kHz bandwidth, speech only applications. The algorithm processes the PCM signal in 2 subbands with 6-bit resolution for the 50 Hz–4 kHz subband, and 2 b for the other 4–7 kHz subband.

Apart from subband coding the other key components of the subband ADPCM algorithm, which collectively achieve compression, are

- Linear prediction
- Adaptive quantization

Linear Prediction

Any reduction in potential gain from the use of just four subbands can be compensated for by linear prediction, which aims to remove spectral redundancies remaining in the subbands. With the inclusion of linear prediction, the total performance of the coder can easily match the subband gain associated with the use of many more subbands, without resorting to an increase in filter complexity or coding delay.

Redundancy is removed by subtracting a predicted signal, derived from coder lookup tables, from the incoming subband signal. This action creates a difference signal, which is then requantized. If the prediction is accurate enough, then the magnitude of the difference or error signal will be quite small, much less than the original subband signal. This allows the bit allocation to be effectively reduced. The degree to which the subband signal is attenuated is termed the *prediction gain* and represents an improvement in the coded S/N ratio compared with linear PCM.

FIGURE 12.92 Subband gain with and without prediction.

In the decoder, a signal, identical to that predicted and removed in the coder and similarly derived from lookup tables, is added back again to the now decoded error or difference signal. This enables the reconstruction of the original linear PCM signal with a minimal loss of information.

The success of linear predictive coding is highly dependent on the predictability or correlation of the subband signals. Prediction gain is reduced in the higher subbands and for most musical instruments the gain is mainly in the first two bands. For the trombone signal the 4-band coder with prediction is seen to give comparable gain to a 64-band coder without prediction. (See Fig. 12.92.)

Adaptive Quantization

Audio exhibits relatively slowly varying energy fluctuations with respect to time, and adaptive quantization exploits this feature by dynamically adjusting the quantizer step size to match the level of the incoming signal. This is a continuous process and provides an almost constant and optimal signal/quantization noise ratio across the operating range of the quantizer.

Time-domain algorithms implicitly model the hearing process and indirectly exploit a degree of irrelevancy by accepting that the human ear is less sensitive at higher frequencies. This is achieved in the subband derivative by allocating more bits to the lower frequency bands. This is the only application of psychoacoustics exercised in ADPCM. All of the information contained in the PCM signal is processed, audible or not; no attempt is made to remove irrelevant information.

12.8.6 Subband APCM Coding

The APCM or transform processor acts in a similar fashion to the automatic gain control in the ear, continually adjusting in response to the dynamics of the incoming audio signal at all frequencies.

Transform coding takes a time block of signal and analyzes it for frequency, energy, and identification of the irrelevancy content. Again, to exploit the spectral response of the ear, the frequency spectrum of the signal is divided into a number of subbands and the most important criteria is coded with a bias toward the more sensitive low frequencies. At the same time, using psychoacoustic masking techniques, those frequencies that it is assumed will be masked by the ear are also identified and removed. Therefore, the data generated describe the frequency content and the energy level at those frequencies, with more bits being allocated to the higher energy frequencies than to those with lower energy.

The larger the time block of signal being analyzed the better the frequency resolution will be and the greater the amount of irrelevancy identified. The penalty, however, is an increase in coding delay and a decrease in temporal resolution. A balance has been struck with advances in perceptual coding techniques and psychoacoustic modeling leading to increased efficiency.

This hybrid arrangement of working with time-domain subbands and simultaneously carrying out a spectral analysis can be achieved by using a dynamic bit allocation process for each subband.

Additionally, some of these systems exploit the significant redundancy between stereo channels by a technique known as joint stereo coding. Once the common information between left and right channels of a stereo signal has been identified it is only coded once, thus reducing the bit rate demands yet again.

Each of the subbands has its own defined masking threshold. The output data from each of the filtered subbands is requantized with just enough bit resolution to maintain adequate headroom between the quantization noise and the masking threshold for each band. In more complex coders, for example, ISO/MPEG layer 3, any spare bit capacity is utilized by those subbands with the greater need for increased masking threshold separation.

It is the maintenance of these signal to masking threshold ratios that is crucial if further compression is contemplated in any post production or onward transmission process. In extremis, one of the limits for data compression is reached when the quantization noise rises above the masking threshold and is detected as part of the wanted audio, processed as such, and is then heard. Out of limits harmonic and phase distortion are other limiting factors.

Defining Terms

ADPCM: Adaptive differential pulse code modulation.

APCM: Adaptive pulse code modulation.

ASPEC: Adaptive spectral perceptual entropy coding.

ATC: Adaptive transform coding.

ATRAC: Adaptive transform acoustic coding.

BER: Bit error rate.

CCITT: Consultative committee for international telephone and telegraph.

CODEC: Coder-decoder.

CRC: Cyclic redundancy code.

DAB: Digital audio broadcasting.

DCC: Digital compact cassette.

DSP: Digital signal processor.

EBU: European broadcasting union.

FFT: Fast fourier transform.

HDTV: High-definition television.

ISDN: Integrated services digital network.

ISO: International Standards Organisation.

ITU: International Telecommunications Union.

MB: Megabyte.

MD: MiniDisc.

MDCT: Modified discrete cosine transform.

MO: Magneto-optical.

MPAC: Multichannel perceptual audio coding.

MPEG: Moving Pictures Experts Group.

MSB: Most significant bit.

MUSICAM: Masking pattern universal subband integrated coding and multiplexing.

NICAM: Near instantaneously companded audio multiplex.

PAC: Perceptual audio coding.

PASC: Precision adaptive subband coding.

PCM: Pulse code modulation.

PLCC: Plastic leadless chip carrier.

PSTN: Public switched telephone network.

QMF: Quadrature mirror filter.

RAM: Random access memory.

ROM: Read only memory.

SCFSI: Scale factor select information.

SEDAT: Spectrum efficient digital audio technology.

SMR: Signal-to-mask ratio.

STL: Studio to transmitter link.

12.9 Aural Noise Reduction Systems

William J.J. Roberts and Yariv Ephraim

12.9.1 Introduction

There are many examples of voice and aural systems that have to battle with the detrimental effects of noise. Pay phones are often located in noisy environments, such as airports and near busy streets. Air-ground communications suffer from both loud cockpit noise and noise introduced by the communications channel. Long-distance communications suffer primarily from the noise arising in the channel. Cellular telephone systems have to contend with noise introduced by traffic, wind, and other people talking. Hearing aid users must struggle with acoustic distortions due to reverberations in a room and ambient noise. The performance of speech recognition systems suffers greatly as noise is introduced into the system. Researchers have studied ways to reduce the effects of noise since the 1940s. In this presentation, we characterize the different types of noise, and review some of the techniques that are used to reduce the deleterious effects of noise. The techniques discussed will generally be those that have been useful to the problem of noise reduction of speech signals, but they may be applied to the noise reduction of other types of signals. The advantages and disadvantages of each technique will be discussed, and the assumptions, upon which each technique relies, will be stated. Some of the techniques require special circumstances such as two or more sensors, or the ability to gain access to the signal prior to its corruption by noise, and these circumstances will be listed where appropriate. Because of the limited number of references allowed in this publication, the references given will generally be of a tutorial nature and will not necessarily reflect the originators of a particular approach.

12.9.2 Noise Sources

Signals that interfere with a desired signal are referred to as *noise*. Noise may be deterministic in nature or it may be random in nature. An example of **deterministic noise** is the 50- or 60-Hz line hum due to the coupling between an audio system and any nearby power lines. **Random noise** includes thermal noise, due to the random thermal motion of charge carriers, and shot noise, due to the discrete nature of charge particles. Often noise can look like the clean signal itself. An example of this is a second competing speaker in a speech recognition system. This is a particularly odious type of noise as it is statistically similar to the clean signal itself. Typical noise sources include cafeterias, traffic, music, competitive speech, reverberations, and communication channels.

Noise can also be related in some manner to the clean signal. It may be independent of the clean signal or it may depend statistically on the clean signal. The noise can be additive, as in the case of a noisy communications channel, it may be multiplicative, as in the case of speckle in radar systems, or it may have some other relationship to the signal, such as convolutional reverberation noise.

The amount of noise in a signal can be characterized by the **signal-to-noise ratio (SNR)**, which is the ratio of the power of the signal to the power of the noise. The SNR is usually expressed in decibels.

Thermal noise is very well modeled by the Gaussian distribution implying that a histogram plot of thermal noise values looks somewhat like that of the normal or Gaussian distribution. This is a very important property as it permits this type of noise to be treated as a mathematical entity allowing the development of closed-form solutions. As with thermal noise there is a mathematical distribution that is useful in modeling speech. It is the **hidden Markov model (HMM)** and it is also mathematically tractable and is employed in many speech systems, see Rabiner (1989).

In this chapter, noise generally will be assumed to be uncorrelated with, and additive to, the signal. This assumption is not particularly restrictive and holds for many situations of interest. Generally the noise will also be assumed to be **white**. This is also not a restrictive assumption, since if the noise is not white it can always be made so with an appropriate linear transformation, see Van Trees (1968).

12.9.3 Performance Measures

Noise reduction systems are designed by optimizing a performance measure; however, in the case of speech, the most perceptually meaningful distortion measure is not known. Furthermore, measures correlated with speech perception are not easily quantified in mathematical terms. Hence, mathematically tractable measures are often used in designing noise reduction systems, and actual performance is evaluated on human listeners. Two aspects of the noisy speech signal that attempts are often made to improve are speech quality and intelligibility. Quality is a subjective measure, which is expressed in terms of how pleasant the signal sounds, or how much effort is required by the listeners in order to understand the message. Intelligibility, which is an objective criterion, measures the amount of information that a listener can extract from the signal. A given signal may be of high quality and low intelligibility or vice versa. The aspect of the signal to which we wish to devote the most attention depends on the application. High quality is generally preferred for telephone systems where intelligibility is already high. For an air-ground communications system, where mistakes may be disastrous, quality may be sacrificed for an improvement in intelligibility. The goal of speech enhancement for listening purposes may be expressed as that of maximum quality improvement without significant decreases in speech intelligibility.

The most mathematically tractable distortion measure is the *mean square error (MSE)*, originally proposed by Gauss in the late 1700s. Its utility for speech processing, however, has been questioned (Lim and Oppenheim, 1979). For example, changing the short-term phase of a speech signal may result in a signal that sounds very similar to the original but the MSE between the two signals could be very large.

A modification of the MSE criterion which allows some masking of the input noise has been found to be useful. Here the system is designed so that the spectrum of the residual noise is similar to that of the speech. This is illustrated in Fig. 12.93 for a typical spectrum of a vowel. This figure shows the shaped spectrum of the residual noise, as well as the spectrum of white noise with the same power. A system that results in this shaped noise provided higher SNR in the perceptually important spectral regions such as in the vicinity of the second and third formants, that is, the peaks in the spectral envelope of the signal. This allows spectral components of the noise in these regions to be fully or partially masked by the corresponding spectral components of the speech signal. This interesting phenomenon is explained by studies of the human aural system that suggest that humans may be more tolerant of a particular frequency of noise when there is a large-signal component near that frequency and correspondingly less tolerant of noise in frequency bands where the signal energy is low. The noise near the large-signal components is effectively masked by those components. Significant progress has been made in understanding and utilizing noise masking in designing speech processing systems (Jayant, Johnston, and Safranek, 1993).

FIGURE 12.93 Shaped noise spectra.

12.9.4 Configurations

The applied noise reduction technique for a particular situation depends on the physical configuration of the system. For instance, the clean signal may be available for preprocessing prior to its degradation by noise. Access to a reference noise source, recorded by a second microphone, may be available for cancellation of the main noise source. In many other situations, we are required to suppress noise from a noisy signal where neither reference to the noise nor access to the clean signal is possible. This is the most difficult situation and has been the subject of intensive research. To illustrate these concepts, consider a pilot communicating with a control tower. The control tower may be relatively noise free and thus the signal from the air-traffic controller may be preprocessed prior to being transmitted to the pilot. In the noisy cockpit, there will be a microphone to record the pilot's speech and if a second microphone is located such that it receives cockpit noise only, noise cancellation techniques are possible. Back in the control tower, however, only the noisy signal from the pilot is available for processing. Although all of these configurations are addressed in this chapter, the main thrust is toward the single microphone situation.

In some situations we may have training data allowing us to learn some statistical aspects of the speech signal. In this case, the learned statistics may be used in designing the noise reduction systems.

12.9.5 Accomplishments

The problem of noise reduction in speech has been an active area of research for over three decades, and numerous solutions with various degrees of success have been developed, see Lim and Oppenheim (1979), Ephraim (1992), and the references therein. Currently there are no noise reduction systems that achieve improvements in both quality and intelligibility for people with normal hearing and where intelligibility is measured by the DRT using nonsense syllables. However, many of the approaches to be described here yield significant improvements in quality with only some sacrifice in intelligibility. The *spectral subtraction* approach is perhaps the most successful as it is conceptually simple, easy to implement, and yields good results. Most techniques will result in quality improvement at high SNR; however, the problem of enhancing speech at low SNR remains unsolved. Noise reduction for speech coding and speech recognition has met with more success, and algorithms that improve both quality and intelligibility have been developed, see Juang (1991) and the references therein.

12.9.6 Techniques

Linear Filtering

If only the noisy signal is available, perhaps the most straightforward approach is to pass the degraded signal through a linear filter designed to suppress the noise without significantly affecting the clean signal. The linear term refers to the fact that the output is a linear function of the input. The linear constrain is made to make the mathematics tractable, and it often provides effective filters. If the system is operated in discrete time, and the filter is of finite impulse response (FIR), then the filter can be implemented as a matrix multiplication.

Consider the block diagram of Fig. 12.94. The output from the linear filter is used to provide an estimate of the desired response or clean signal. The estimation error is the difference between the estimate and the actual desired response.

Some considerations that are necessary in the design of the filter include whether the filter is finite duration impulse response or infinite duration impulse response (IIR). Also the choice of optimality criterion must be addressed. The design of such filters is in the domain of optimal filter design, the theory of which was pioneered by Norbet Wiener and Andrei Kolmogorove in the 1940s and extended by Kalman and others in the 1960s. Wiener's solution for the optimal linear estimate of a signal in the minimum MSE

FIGURE 12.94 The linear filtering problem.

sense requires the solution of an integral equation known as the *Wiener–Hopf equation*. The resulting linear filter is optimal in the minimum MSE sense for the case of Gaussian signals and additive Gaussian noise. Kalman’s solution requires description of speech in terms of a dynamic system and is also optimal in the minimum MSE sense. In both cases a priori information about the signal and noise, such as the spectra and the parameters of the dynamical system are required. Implementation of these classical solutions will require estimation from either the noisy data or from *training data*. Furthermore, these estimates will need to be periodically updated to accommodate the fact that speech is not strictly stationary.

Lim and Oppenheim (1979) question the effectiveness of Wiener filtering for speech due to the reliance on the mean squared error criterion. In Ephraim and Van Trees (1995), linear estimators that minimize signal distortion subject to a permissible noise energy or spectrum were designed. These estimators allow noise masking and have performed better than plain Wiener filtering techniques. They constitute Wiener filters with an adjustable noise spectrum or energy and were implemented using signal and noise statistics estimated from the noisy signal. The implementation of this approach using the signal subspace technique will be discussed in the following.

Spectral Subtraction

Spectral subtraction (Lim and Oppenheim, 1979) is currently the standard filtering approach for speech enhancement as it is simple, intuitive, easy to implement, and provides reasonable results. This approach operates on a frame by frame basis where each frame consists of 20–30 ms of speech samples. In the spectral subtraction method, the discrete Fourier transform (DFT) of the signal vector is computed, and those spectral components whose variance is smaller than that of the noise are nulled. The surviving spectral components are modified by a gain function. The resulting set of nulled and modified spectral components constitute the spectral components of the enhanced signal. The inverse DFT is applied to get the enhanced signal estimate. A block diagram of the spectral subtraction process is shown in Fig. 12.95.

The choice of gain function is motivated by different perceptual criteria. An often used criterion is the minimum MSE between spectral components of the clean signal and its estimate. The result is a Wiener gain function that constitutes the ratio of the variances of the clean and noisy spectral components. Since the Wiener gain factor was proved to be too mild, families of related gain factors have been used (Lim and Oppenheim, 1979), for instance

$$\alpha(k) = \left(\frac{|Z(k)|^a - bE\{V(k)^a\}}{|Z(k)|^a} \right)^c$$

Here $Z(k)$ and $V(k)$ denote the k th spectral components of the noisy signal and noise process, respectively, and $a > 0, b > 0, c > 0$. The Wiener gain function is obtained when $a = 2, b = 1, c = 1$.

The spectral subtraction approach is very popular as it is easy to implement, makes minimal assumptions about the signal and noise, and does not require training data. It results in reasonably clear enhanced signals; however, a major drawback is the residual noise has annoying tonal characteristics referred to as *musical noise*. This effect is due to the random nulling of the spectral components of the enhanced signal.

Many variations of spectral subtraction algorithms have been developed, see Lim and Oppenheim (1979), Ephraim (1992), and references therein. A notable approach was proposed by McAulay and Malpass (1980) who modified the basic estimator to take into account the fact that speech is not always present in

FIGURE 12.95 Block diagram of the spectral subtraction process.

the noisy observations. A weighted combination of the estimate for the clean signal given the noisy signal and the clean signal given that the noisy signal is noise only is applied. Since the optimal estimate of the clean signal given that the clean signal is absent is zero, the resulting estimator is simply the product of the estimator for the clean signal given that the signal is present and the posterior probability of the signal being present given the noisy signal. Significant improvement of the spectral subtraction estimator was achieved using this approach.

Signal Subspace Approaches

Another possible approach for speech enhancement is to utilize the existence of the **signal subspace** of speech signals (Ephraim and Van Trees, 1995). The signal subspace technique is motivated by the observation that sample clean speech covariance matrices have some eigenvalues that are practically zero. The implication of this fact is that K -dimensional speech vectors are confined to a *subspace* of the K -dimensional Euclidean space. The white noise covariance, however, has equal eigenvalues and, hence, noise vectors occupy the entire K dimension Euclidean space. Thus the vector space of the noisy signal can be decomposed into a signal plus noise subspace and a noise only subspace. Speech enhancement can be accomplished by removing the **noise subspace** and masking the remaining noise in the signal subspace.

The eigenvalues of the noisy speech are given by the addition of the eigenvalues of the clean speech and the eigenvalues of the noise. Thus a typical plot of the ordered noisy signal eigenvalues would look like Fig. 12.96.

FIGURE 12.96 Ordered noisy eigenvalues.

It can be shown that the eigenvectors corresponding to eigenvalues that are above the noise energy span the signal subspace. Thus, in theory, the signal subspace can be identified from eigendecomposition of the covariance matrix of the noisy signal using the noise variance. In practice these second-order statistics are not available, and they must be estimated from the noisy data. Hence, more sophisticated approaches must be used to identify the signal subspace, see Ephraim and Van Trees (1995).

If the noisy signal is projected onto the signal subspace, a least squares (LS) estimate is obtained. The projection can be accomplished by applying the *Karhunen–Loeve transform* (KLT) (Van Trees, 1968) to the noisy signal and nulling transform components obtained from eigenvectors in the noise subspace.

It is possible to further reduce the noise, at the expense of some signal distortion, by modifying the projected signal. If the linear estimate that minimizes signal distortion for a given spectrum of residual noise is used, then an estimator as shown in Fig. 12.97 results. Here $\alpha(k)$ represents the gain function applied to the k th spectral component. An example of a useful $\alpha(k)$ is given by

FIGURE 12.97 Block diagram of gain function modified KLT components.

$$\alpha(k) = \left(\frac{\lambda_y(k)}{\lambda_y(k) + \sigma_w^2} \right)^{\gamma/2}$$

where $\lambda_y(k)$ is the k th sample eigenvalue of the clean signal covariance as obtained by subtracting the noise variance σ_w^2 from the sample eigenvalue of the noisy signal covariance, and $\gamma \geq 1$ is an experimentally determined constant that determines the suppression level of the noise as well as the resulting signal distortion. If M denotes the signal subspace dimension then $\alpha(k) = 0$ for $k > M$. More aggressive noise suppression can be obtained by using $\alpha(k) = \exp\{-\gamma\sigma_w^2/\lambda_y(k)\}$.

A performance evaluation of the subspace technique appears in Ephraim and Van Trees (1995) where it was found that a majority of listeners preferred speech that had been processed with this techniques to speech process by spectral subtraction.

The signal subspace approach and the spectral subtraction approach are closely related (see Fig. 12.95 and Fig. 12.97). They mainly differ in the transform applied to the noisy signal. Spectral subtraction uses the DFT and the subspace approach uses the KLT. The conditions under which the DFT is equivalent to the KLT are known (Gray, 1977) and occur when the noisy signal covariance **matrix** is **circulant**. For this case spectral subtraction is a signal subspace approach and is optimal in the same sense as used in designing the filter of Fig. 12.97. If the speech in a given vector has a **Toeplitz** covariance **matrix**, that is, this vector may be a portion of a **stationary process**, then it can be shown that spectral subtraction estimates asymptotically coincides with the linear estimator of Fig. 12.97 if both use the Wiener gain function. In this case, spectral subtraction is an asymptotically optimal linear estimator in the minimum MSE sense.

The KLT depends on the second-order statistics of the noisy signal and is known to be computationally intensive. The DFT is computationally much less intensive and is a signal independent transformation.

The signal subspace has been the subject of intensive research in the statistical literature where approximations to the KLT, in the form of wavelet transforms, are being investigated. Under certain conditions, the wavelet transform was shown to be optimal in the minimax sense, see Donoho (1995).

Model-Based Approaches

Model-based speech enhancement utilizes a statistical model of the signal and noise to optimize a performance measure. For example, minimization of the MSE can be performed by implementing the conditional mean estimator. The models are estimated using training data. Empirical distributions or parametric models can be used. Using the sample distributions of the clean signal and noise to implement the conditional mean estimator is conceptually simple and can be shown to be asymptotically optimal (Porter and Boll, 1984). Since the conditional mean is a function of the noisy signal, however, the sample average must be calculated for each newly observed vector of the noisy signal.

Based on both theoretical knowledge and experimental observations, parametric models of the source and noise can be chosen. The model parameters are then estimated from training data. This method has some important advantages:

- If the model chosen accurately reflects the true underlying model for the data, then the chosen model will represent any sample function of the source and not just those in the training set. The sample densities of the training data only represents samples that are in the training set.
- Generally the chosen model has only a small number of parameters to estimate and, thus, the estimates can be expected to be reliable.
- If the chosen model is mathematically tractable, we can find closed-form expressions for the desired estimators.

The most popular statistical model for speech signals is the hidden Markov model, a tutorial on which can be found in Rabiner (1989). This model assumes that each speech vector is generated from a finite sequence of states, each of which is characterized by a Gaussian process with a given mean and covariance. Transitions from one state to another are made in a Markovian manner. Iterative algorithms are known for model training. This model has been used in Ephraim (1992) in designing speech enhancement systems. The major disadvantages of this technique are that its performance depends on statistical similarity between the training and test data and its implementation is computationally intensive.

Another example of a model based system is the one proposed by Ephraim and Malah (1984) in which the spectral components of speech and noise in a given vector are modeled as statistically independent Gaussian random variables. The variance of a given spectral component of the speech signal varies from frame to frame and is estimated from the noisy signal. Under these assumptions, the minimum MSE estimate of the short-time spectral amplitude is derived. This approach outperforms spectral subtraction as it provides enhanced signals with similar clarity but with drastically reduced musical noise.

Note that in these two techniques, speech is not assumed to be Gaussian but rather a mixture of Gaussian processes. In the HMM system, each mixture component has a fixed mean and covariance, whereas in the minimum MSE short-time spectral amplitude estimation system, the mean and variance are estimated from the noisy data.

Model based approaches made significant progress in the speech recognition and enhancement problems in the 1980s. A comprehensive treatment of this subject can be found in the tutorial paper by Ephraim (1992).

Signal Preprocessing

In some situations, such as when speech is generated in a clean environment and then transmitted to listeners in a noisy environment, the signal can be preprocessed to increase its robustness to noise (Lim and Oppenheim, 1979). The technique in Niederjohn and Grotelueschen (1976) is to first apply high-pass filtering to the clean signal, normalize the amplitude of the filtered signal so that it remains constant within a certain range, and finally restore the original power to the clean signal. These operations emphasize spectral and temporal components of the speech signal that are known to be important for understanding speech, such as consonants and spectral component in the vicinity of the second and third formants. This approach achieves significant improvement in the intelligibility of the noisy signal.

Adaptive Noise Cancellation

Adaptive noise canceling makes use of an auxiliary or reference input in addition to the noisy signal from the primary sensor. If a reference for the noise is desired, the auxiliary microphone is placed at a position in the noise field where the signal is weak or undetectable. This scheme operates on the basis of two main assumptions:

1. The signal and noise at the input to the primary sensor are uncorrelated.
2. The noise input to the reference sensor is correlated with the noise component at the primary input.

The reference signal is filtered to obtain an estimate of the noise, which is then subtracted from the primary sensor signal. As a result, the noise in the noisy signal is attenuated or eliminated by cancellation. The filtering of the reference signal is done adaptively allowing the filter parameters to be adjusted automatically according to the dynamics of the noise. The filter design may make little use of a priori knowledge of the signal. The filter parameters are adjusted based on the overall output of the noise canceler. Ordinarily, it is inadvisable to subtract noise from a received signal because of the possibility of a disastrous increase in the average power of the output noise. However, in circumstances where adaptive noise cancellation is appropriate, and proper provisions are made, levels of noise reduction may be achieved that are not attainable by other means (Widrow et al., 1975). An adaptive noise cancellation is illustrated in Fig. 12.98.

The most common filter adaptation algorithm is the *least-mean-square* (LMS) algorithm. The LMS algorithm adjusts the filter parameters in the opposite direction to the gradient of the squared amplitude

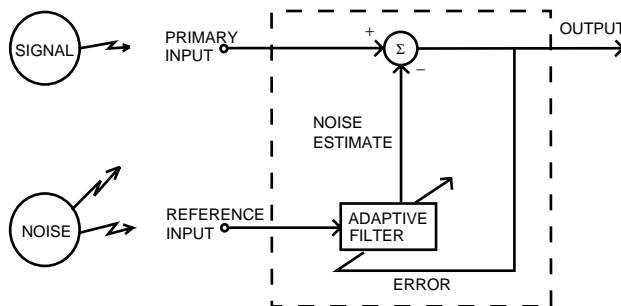

FIGURE 12.98 The adaptive noise cancellation concept.

FIGURE 12.99 Active noise cancellation scheme.

of the error signal. The LMS algorithm is simple and yields good performance when an appropriate noise reference exists.

In some applications the noise reference may be created from the main noisy signal. For example, if the noise is white, a delayed version of the noisy signal will decorrelate the noise and leave the signal in both inputs correlated. In this case, the signal may be predicted and subtracted from the primary input. The predicted signal is used as the signal estimate. The major limitation is its slow rate of convergence which adversely affects its usefulness in some applications of speech signals.

The earliest work on adaptive noise cancelers can be traced to the mid 1960s to Kelly of Bell Telephone Laboratories, who first proposed the use of an adaptive filter for echo cancellation of speech signals. Kelly's contribution is cited in the book by Haykin (1991). Widrow et al. (1975) extended the concept and built a device to cancel 60-Hz interference at the output of an electrocardiograph amplifier and recorder. Lim and Oppenheim (1979) discuss the use of adaptive noise cancellation on speech and find that, at some SNR, the technique actually decreases the intelligibility of the speech signal.

Active Noise Cancellation

In active noise cancellation, the noisy input signal is adaptively filtered to produce a signal that is supplied to a canceling microphone. The output from the canceling microphone destructively interferes with the noise (Oppenheim et al., 1994). A block diagram appears in Fig. 12.99.

The purpose of the error microphone is to measure the unwanted noise field after destructive interference. The adaptive filter takes this measurement and produces an estimate of the noise process, which is then used to adjust the filter parameters so as to improve the cancellation effect. In general, there may be a multiple error microphones producing an improved noise estimate; however, Oppenheim et al. (1994) presents a scheme using only a single input sensor. The approach is evaluated using both computer generated noise and with recordings of aircraft noise.

Comb Filtering

Comb filtering capitalizes on the periodicity of voiced speech signals. It uses **pitch** information to design a comb filter that passes the harmonics of the signal while rejecting noise between these harmonics. This and other related techniques are discussed in Lim and Oppenheim (1979). The main drawback with this approach is that accurate estimates of the voiced speech pitch are required and such estimates are difficult to obtain from noisy speech.

12.9.7 Comments

Some of the major approaches for noise reduction from speech signals were reviewed. Emphasis of the physical circumstances where each is applicable and the theoretical assumptions upon which each is based were considered. Aural noise reduction systems have been an active area of research for many decades. The theory of Wiener and Kolmogorov was advanced in the 1940s and has been applied for many different speech models since then. However, the utility of the MSE criterion upon which these methods are based has been questioned for speech. In addition, these methods require knowledge of the spectra of speech which, due to the fact that speech is not strictly stationary, are difficult to obtain. Thus approaches, which subscribe a parametric model to the speech signal, have arisen. The MSE criterion has also been applied in the spectral domain to yield the successful spectral subtraction technique. The theoretical justification for

spectral subtraction comes from considering the signal subspace of speech signals. Improved performance can be obtained in special circumstances where, for instance, separate noise only signals are available, or where the clean signal is available prior to its degradation by noise.

Defining Terms

Circulant matrix: A Toeplitz matrix in which every row beginning from the second is obtained from the preceding row through a cyclic shift.

Deterministic noise: Noise that is of known form but with one or more unknown parameters.

Hidden Markov model (HMM): A statistical model consisting of several subsources or states controlled by a Markovian process.

Noise subspace: A complimentary subspace to the signal subspace that contains noise only.

Pitch period: Fundamental period of periodic portions of speech.

Random noise: Noise that fluctuates in an unpredictable manner.

Signal subspace: A subspace of the Euclidean space R^K that contains both signal information and noise.

Signal-to-noise ratio (SNR): Ratio of the signal power to the noise power, usually expressed in decibels.

Stationary process: A process whose probability law does not change with time.

Toeplitz matrix: A matrix with all diagonal values equal.

White noise: Noise exhibiting a flat spectrum.

12.10 Video Compression Techniques

Gopal Lakhani

12.10.1 Demand for Video Compression

Virtually all applications of video and visual communication deal with enormous amount of data. Because of the volume of data, compression is an integral part of all video applications. A compression system reduces the volume of data by exploiting **spatial** and **temporal redundancies** and by eliminating the data, which cannot be displayed suitably by the associated display or imaging devices. Its main objective is to retain as little data as possible, but sufficient to reproduce the original images without causing much distortion.

A compression system consists of the following components:

- *Digitization, sampling, and segmentation*: Conversion of analog signals on a regular grid of picture elements; division of video input first into frames and then into blocks.
- *Redundancy reduction*: Decorrelation of data into fewer useful data using some invertible transformation techniques.
- *Entropy reduction*: Representation of digital data using fewer bits by dropping lesser significant information. This component causes distortion and it is the main contributor in *lossy* compression.
- *Entropy coding*: Assignment of codewords (bit strings) of shorter length to more likely image symbols and codewords of longer length to lesser likely symbols in order to minimize the average number of bits needed to code an image.

This section presents the core compression techniques of widely known video standards. The structure of this compression system is shown in [Fig. 12.100](#).

12.10.2 Video Image Representation

For the purpose of image processing, digitized video can be treated as a sequence of frames (*images*) with each frame represented as an array of picture elements (*pixels*). For color video, a pixel is represented by three primary components: red (*R*), green (*G*), and blue (*B*). For effective coding, the three color components are converted to another coordinate system, called *YUV*, where *Y* denotes the luminance (brightness), and *U* and *V*, called the *chrominance*, denote the strength and vividness of the color. This conversion is described as

$$Y = 0.3R + 0.6G + 0.1B$$

$$U = B - Y$$

$$V = R - Y$$

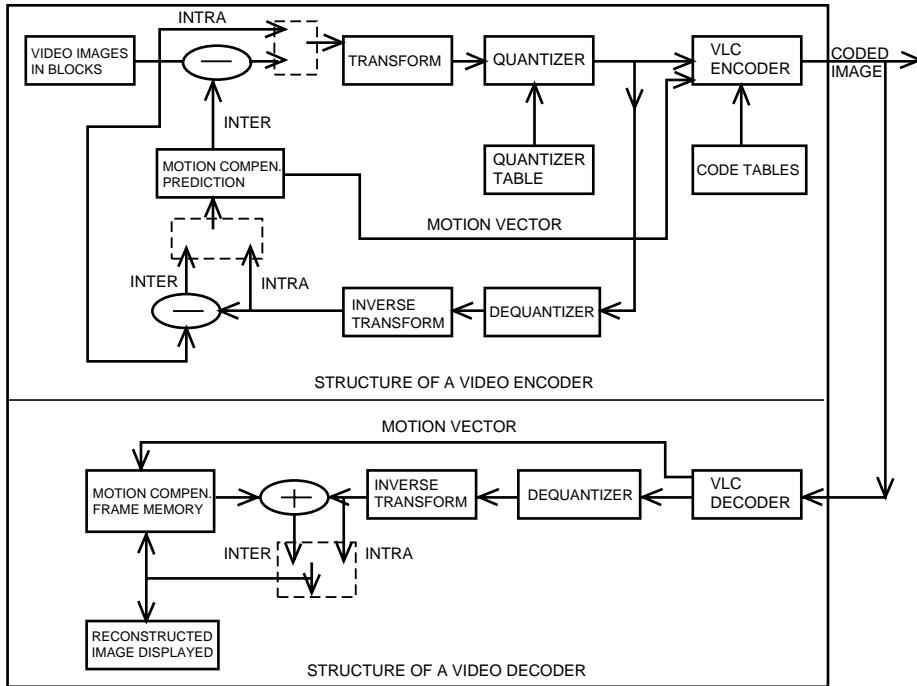

FIGURE 12.100 Structure of a typical coder and decoder.

A color coordinate system, followed in many compression standards, is *YCrCb*; the *Cr* and *Cb* components are obtained as follows:

$$Cr = (V/1.6) + 0.5$$

$$Cb = (U/2) + 0.5$$

There is a higher order of redundancy in the *Cr* and *Cb* components. A popular method is to subsample the chrominance components 2:1 along each dimension, resulting in 4 luminance values, but only one *Cr* and one *Cb* value for each 2×2 array of the image. The luminance component is divided into four components, labeled as *Y1*, *Y2*, *Y3*, and *Y4*. The subsampled *Cr* and *Cb* data is obtained by averaging the chrominance values of the four pixels in the array. Figure 12.101 shows this subsampling pattern. Thus, a region of 16×16 pixels of the original 24-b frame can be represented by four *Y* and one of each *Cr* and *Cb* blocks, each expressed as a 8×8 array of 8-b integers. This group of the six blocks is called the *minimum coded unit* (MCU) since these are stored and decoded together for efficient computing. A 352 pixels per

FIGURE 12.101 2:1 Subsampling of chrominance pixels.

line by 288 line frame can be segmented into 396 (22 × 18) MCUs. Note that this subsampling alone reduces the total size of the original data by one-half.

12.10.3 Scalar Quantization of Image Data

Scalar quantization is the process of mapping the input to a small number of output levels. Since the small number of levels can be coded using shorter codes, the code size of the image is reduced. The quantization and dequantization is performed according to the following equations:

$$\begin{aligned} \text{Quantization: } \hat{X} &= \text{round}\left(\frac{X}{Q}\right) \\ \text{Dequantization: } \bar{X} &= \hat{X} * Q \end{aligned}$$

In these equations, X denotes the input and Q is a quantizer step size. The coder codes \hat{X} as a representation of X . The difference, $X - \bar{X}$ is the loss due to quantization. A careful selection of quantizer steps is very important since it results in high compression, but at the same time it also introduces small losses in the reconstructed image.

12.10.4 Intraframe Compression Techniques

Before a frame is quantized, it is desirable to eliminate redundant data in the frame. There are many techniques for reducing the spatial redundancy, but by far, **DPCM** and **discrete cosine transformation-(DCT-)** based coding are the most widely used techniques for intraframe compression. (Rabbani and Jones (1991) discuss many image compression techniques. See Further Information.)

Differential Pulse Code Modulation (DPCM)

This compression method encodes the difference of the video signals (pulses). It can be applied for both the **intraframe** coding, which exploits the spatial redundancy, and the **interframe** coding, which exploits the temporal redundancy. In the intramode, the difference is formed between the values of two neighboring pixels of the same frame, and in the intermode, it is between the value of the same pixel on two consecutive frames. In either mode, the value of the target pixel is predicted using the reconstructed values of the previously coded neighboring pixels and this value is subtracted from the original value to form the differential image. The differential image is then quantized and encoded. Figure 12.102 presents the structure of a DPCM **codec**. Its computation is described in the following for intraframe coding.

FIGURE 12.102 DPCM system block diagram.

In Figure 12.102, X denotes the actual value of the target pixel and \hat{X} denotes the predicted value that the decoder would compute using some prechosen criterion. Here, e denotes the difference, $X - \hat{X}$, and \bar{e} denotes its quantized value, which when dequantized is denoted by \tilde{e} . In the coded image, X is represented by \bar{e} . During decompression, \bar{e} is decoded, and the reconstructed value \tilde{X} of X is obtained by adding \tilde{e} to \hat{X} . \tilde{X} is used to display X , which the coder also uses for all future use of X .

Effectiveness of DPCM depends on the prediction method. For intraframe coding, a common method is to use the values of three previously coded pixels A , B , and C , where A is immediate to the left of X , C is above X and B is above A . A simple predictor is $\hat{X} = A - B + C$, and a predictor based on some statistical derivation is $\hat{X} = 0.90A - 0.81B + 0.90C$.

DCT-Based Transform Coding

The main advantage of DCT is that it *decorrelates* the pixels (i.e., converts statistically dependent pixel values into independent coefficients) very efficiently, and in the process, it packs the signal energy of the image block onto a small number of coefficients. Another big advantage of using DCT is that a number of its fast implementations are available. Rao and Yip (1990) provide in-depth study of DCT for image compression. A block diagram of a DCT-based codec is shown in Fig. 12.103.

Let B denote the DCT matrix and B^T be its transpose. For 8×8 size image blocks, the matrix of B is defined by:

$$B(i, j) = 0.5C \cos\{2i\pi(2j + 1)/16\}$$

where row and column indices, i and j vary from 0 to 7, respectively, and

$$C = \begin{cases} 1/\sqrt{2} & \text{if } i = 0 \\ 1 & \text{otherwise} \end{cases}$$

Note that DCT is an orthogonal transformation and, therefore, $B^{-1} = B^T$.

Let f denote a 8×8 image block and F be its transformed block. Then f and F can be obtained from each other by applying the forward DCT (FDCT) and inverse DCT (IDCT), respectively, which are defined as

- FDCT: $F = BfB^T$
- IDCT: $f = B^T F B$

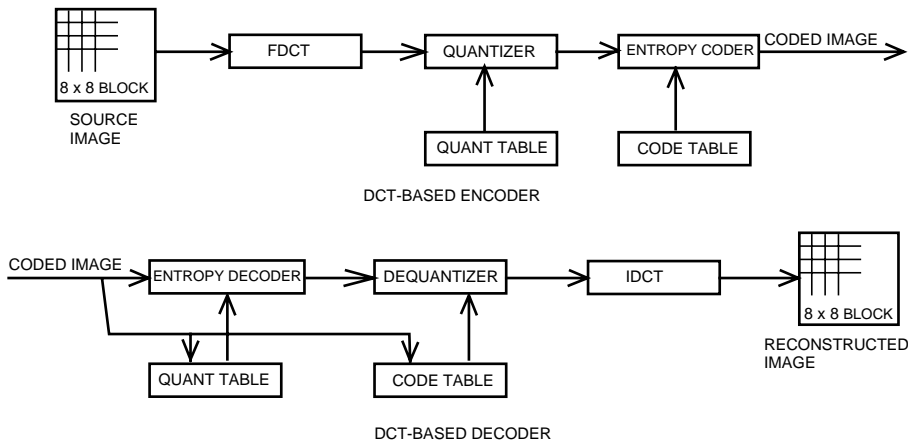

FIGURE 12.103 A block diagram of DCT-based image compression system.

To demonstrate effectiveness of DCT, Fig. 12.104 presents a complete example. It considers a luminance block f taken from a real image, the corresponding F , the block \mathcal{F} of DCT coefficients of f obtained by quantizing the elements of F by 16 uniformly, and the reconstructed image \hat{f} of f .

Note that all but five elements of F are very small, which signifies that DCT packs the signal energy onto a few coefficients and decorrelates the pixel values efficiently.

The element $F(0, 0)$ is called the *DC coefficient*, since it denotes the weighted average of the pixel values in the block, and the remaining elements are called *AC coefficients*, since each coefficient is a difference of weighted sum of pixels in various sub-blocks.

To encode only the nonzero elements of \mathcal{F} , a commonly used method is to scan the matrix in a zig-zag order and produce a list of pairs, each containing a run-length of zeros and the next nonzero DCT coefficient. The procedure is called the run-length encoder. For \mathcal{F} , the following list will be produced.

$$f = \begin{bmatrix} 85 & 86 & 87 & 89 & 91 & 92 & 94 & 94 \\ 96 & 96 & 96 & 95 & 95 & 94 & 94 & 94 \\ 113 & 111 & 109 & 105 & 101 & 98 & 95 & 94 \\ 126 & 124 & 119 & 114 & 108 & 102 & 98 & 96 \\ 130 & 128 & 124 & 118 & 112 & 107 & 102 & 100 \\ 125 & 124 & 121 & 117 & 114 & 110 & 108 & 106 \\ 115 & 115 & 114 & 114 & 113 & 113 & 113 & 112 \\ 107 & 108 & 109 & 111 & 113 & 114 & 116 & 116 \end{bmatrix}$$

$$F = \begin{bmatrix} 854 & 31 & 0 & 0 & 0 & 0 & -1 & 0 \\ -63 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -38 & -44 & 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}$$

$$\mathcal{F} = \begin{bmatrix} 53 & 2 & 0 & 0 & 0 & 0 & 0 & 0 \\ -4 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -2 & -3 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$\hat{f} = \begin{bmatrix} 84 & 85 & 87 & 89 & 91 & 93 & 94 & 94 \\ 95 & 95 & 95 & 95 & 94 & 94 & 94 & 93 \\ 112 & 110 & 108 & 104 & 100 & 96 & 93 & 92 \\ 125 & 123 & 118 & 112 & 106 & 100 & 95 & 93 \\ 130 & 127 & 123 & 117 & 110 & 104 & 100 & 97 \\ 125 & 123 & 120 & 116 & 112 & 109 & 106 & 104 \\ 114 & 114 & 114 & 113 & 113 & 113 & 112 & 112 \\ 107 & 107 & 109 & 111 & 113 & 115 & 116 & 117 \end{bmatrix}$$

FIGURE 12.104 An illustration of DCT computation.

$$(53)(0, 2)(0, -4)(0, -2)(4, -3)(0, 0)$$

(0, 0) is added to the list to denote the end of block (EOB).

This list is finally encoded in the form of bit strings using an entropy encoder, such as the Huffman or arithmetic coder, which have been widely used in data compression (Amsterdam, 1986).

The process of decompression is completely the reverse of the compression process. The coded bit strings are first decoded, and the dequantization is performed by multiplying each element by the chosen quantizer step. The resulting block is then inverse DCT transformed to obtain the reconstructed block. The difference e of f and \hat{f} denotes the loss due to compression. In the compression literature, the loss is expressed as the *root mean square error* (RMSE), and it is defined as

$$RMSE = \frac{1}{64} \sqrt{\sum_{i=0}^7 \sum_{j=0}^7 e^2(i, j)}$$

For f in Fig. 12.104, the RMSE is 0.047.

12.10.5 Interframe Coding

A simple method for interframe coding is to compute the difference of a frame with the previous frame and then apply the DCT-based method to code the difference image. This method exploits temporal redundancy, but is not very efficient, because pixels of difference images are poorly correlated and DCT does not compress uncorrelated data efficiently. To support this statement, results of a compression experiment are given in Table 12.14. A gray-level video sequence of 40 frames was compressed using an H.261 codec (Turletti, 1993). Table 12.14 gives percentage of nonzero elements at every stage of the compression. Here, 75% of the frames were interframe coded, and an overall compression ratio of 4.7:1 was achieved, which is by no standard adequate for video compression. For this reason, hybrid methods are used for interframe

TABLE 12.14 Compression Ratio for Intra- and Interframe Coding

Coding Mode	Nonzero Pixels	Nonzero DCT Coeff.	Nonzero Quant. Coeff.	Compression Ratio, bpp
Intra	99.99	25.44	10.50	1.32
Inter	92.68	53.93	18.90	1.85

coding (Naveen and Wood, 1994). The common theme of these methods is to consider motion in the video and code information pertaining to displacement of image blocks.

12.10.6 Motion Compensation

For the motion-compensated interframe coding, the target frame is divided into nonoverlapping, fixed-size blocks, and then each block is compared with blocks of the same size of some reference frame to find its best match. To limit the search, a small neighborhood is selected in the reference frame, and then a search is performed by stepwise translation of the target block. To reduce mathematical complexity, a simple block matching criterion, such as the mean of the absolute difference of pixels, is used to find a best matched block. The position of the best matched block determines the displacement of the target block, and its location is denoted by a (motion) vector. Block matching is computationally expensive and, therefore, a number of heuristics have been developed (Pirsh, Demassieux, and Gehrke, 1995; Naveen and Wood, 1994). A simple method, known as one-at-a-time search (OTS), is shown in Fig. 12.105. First the target block is moved along one direction and the best match is found, and then it is moved along the perpendicular direction to find the best match in that direction. Figure 12.106 shows the target frame in terms of the best match blocks in the reference frame. This much detail of the motion-compensated interframe codec is now sufficient to follow the diagram of Fig. 12.100.

12.10.7 H.261: A Videoconference Coding Standard

H.261 is a standard to describe the data organization of a low-bit rate visual communication over telephone lines. It is also known as $p \times 64$ kb/s codec, since it identifies the data rate of the communication, where p is between 1 and 30. It uses DCT and **variable length coding (VLC)** techniques for intraframe coding and an optional block-based motion compensated coding for interframe coding. The frame previous to the target frame is used for **motion compensation (MC)** prediction. The range of the motion vector is ± 15 pixels with integer values, and the size of blocks for matching is 16×16 .

H.261 describes the organization of the compressed bit stream, and not how it should be produced. The coded data is arranged in a hierarchical structure consisting of four layers, each with its own header and a number of data blocks. The input picture is partitioned into 8 lines by 8 pixels per line image blocks. The lowest layer containing the quantized transformed coefficients of image blocks is called the block layer.

FIGURE 12.105 A simplified search of a best matched block.

FIGURE 12.106 Motion compensated prediction.

The so-called *macroblock* (MB) contains four luminance *Y* and two chrominance *Cr* and *Cb* blocks. MBs pertaining to three rows of image blocks form a group of blocks (GOB). There are two picture size formats: *common intermediate format* (CIF) and quarter-CIF (QCIF). Figure 12.107 gives arrangement of various types of blocks for a CIF picture.

As expected, headers contain different information about the coded picture such as the location of blocks in the picture, method of coding, quantizer step size, and motion vectors. There are four types of coding

- Intra: transformed-quantized representation of the original input.
- Inter: the difference pixels with the previous frame; zero-motion vectors are not coded.
- Inter with MC: predicted residual with respect to the previous frame; the displacement (nonzero motion vector) is coded as part of the MB header; no specific method is recommended for block matching.
- Inter MC with filtering: the residual filtered by a predefined filter to reduce block artifacts, which occur routinely at low-bit rate coding.

12.10.8 MPEG: Standards for Audio and Video Compression

The Moving Photographic Expert Group (MPEG) set up international standards for compression of digital audio and video transmission at various bit rates. The first version, MPEG-1, was developed primarily for coding of video for digital storage media, for example, CD-ROM, at the rates of 1–1.5 Mb/s. The goal

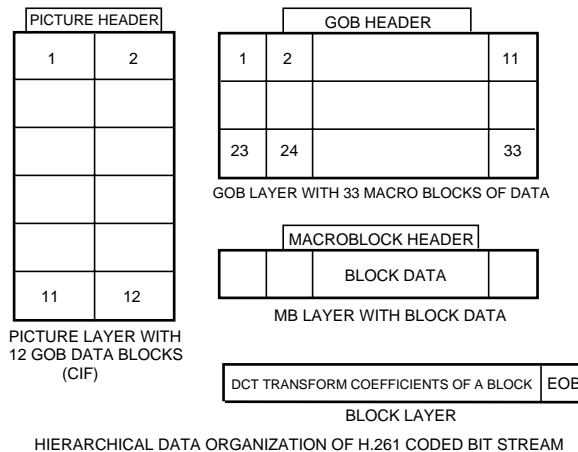

FIGURE 12.107 Organization of H.261 coded data.

of MPEG-2 was to describe coding of interleaved audio and video data at a much higher rate, such as 10 Mb/s, and is suitable for consumer electronics and telecommunication. An overview of the video coding of MPEG-1 is given next. A detailed block diagram of MPEG-1 codec is given in Fig. 12.108.

MPEG uses the **Joint Photographic Expert Group (JPEG)** standard for intraframe coding by first dividing each frame into 8×8 blocks, and then encoding each block independently compressed using

FIGURE 12.108 A typical MPEG-1 codec. (Source: Adapted from Arvind, R. et al. 1993. Images and video coding standards, p. 86. AT&T Technical J.)

FIGURE 12.109 Bidirectional prediction in MPEG coding.

the DCT-based method illustrated in Fig. 12.103. Interframe coding is based on MC prediction, but its implementation is far more complex than the one used in H.261. The main difference between the two standards is that MPEG allows bidirectional, temporal prediction. As usual, a block matching algorithm is used to find the best matched block, which can belong to either the past frame (i.e., forward prediction) or the future frame (i.e., backward prediction). In fact, the best matched block can be the average of two blocks, one from the previous and the other from the next frame of the target frame (i.e., interpolation). In any case, the placement of the best matched block(s) is used to determine the motion vector(s); blocks predicted on the basis of interpolation have two motion vectors. Frames that are bidirectionally predicted are never used themselves as reference frames.

Figure 12.109 shows a group of pictures of 14 frames with two different orderings. Pictures marked I are intraframe coded. A P-picture is predicted using the most recently encoded P or I picture in the sequence. A macroblock in a P picture can be coded using either the intraframe or the forward predicted method. A B-picture macroblock can be predicted using either or both of the previous or the next I and/or P pictures. To meet this requirement, the transmission order and display order of frames are different. The two orders are also shown in Fig. 12.109.

Like H.261, the MPEG coded bit stream is divided into several layers. The outermost layer, called *video sequence*, contains the basic global information, such as the size of frames, bit rate, and frame rate. GOP layer contains information on fast search and random access of the video data. A GOP can be of arbitrary length. The picture layer contains a coded frame. Its header contains the type I, P, B, and the position of the frame in the GOP. The next three layers are the *slice*, *macroblock*, and the *block layer*, which basically correspond to the GOB, MB, and block layers of H.261.

The size of the luminance and the chrominance components of the input picture recommended by the MPEG-1 standard are 360×240 and 180×120 , respectively, and the recommended frame rate for the coding of the NTSC-compatible television signal is 29.97 frames/s. MPEG uses blocks of size 16×16 for block matching, and the search is limited to an area of 31×31 .

Roughly speaking, the coding algorithms and prediction methods of MPEG-1 and MPEG-2 are very much the same, but MPEG-2 contains more features, such as interlaced video and scalability. In the interlaced video, a frame may be divided into fields such as one containing the odd numbered lines and other containing the even numbered lines of the picture. A block can be coded either in the frame mode, as in MPEG-1, or in the field mode to exploit the correlation between the two fields. Scalability allows coding for multiple-grade and multiple-bandwidth service.

Pirsch, Demassieux, and Gehrke (1995) provide numerous references on MPEG and relevant topics for further studies.

Defining Terms

Codec: Coder–decoder programs of a compression system.

Discrete cosine transformation (DCT): Decorrelates image data efficiently [Rao and Yip 1990].

DPCM: Predictive coding of differences of samples.

H.261: Recommendation of International Telegraph and Telephone Consultative Committee (CCITT) on low-bit videoconferencing on telephone lines (Liou, 1991).

Interframe: Encoding of a frame by predicting its elements from elements of the previous frame.

Intraframe: Encoding of a video frame by exploiting spatial redundancy within the frame.

Joint Photographic Expert Group (JPEG): Proposed standards for coding of still images (Wallace, 1991).

Motion compensation (MC): Coding of video segments considering their displacements in successive frames (Naveen and Wood, 1994).

Moving Photographic Expert Group (MPEG): Charged to develop standards for video coding for various audio/video applications (Gall, 1991).

Pulse code modulation (PCM): Sampling of continuous video signal and coding of samples. (Rabbani and Jones discuss basics of image techniques. See Further Information.)

Quantization: Dropping of the less significant bits of image values to gain higher compression.

Redundancies: (1) Spatial—correlation within a still image or a video frame data, (2) spectral—correlation between different color components of image elements, (3) temporal—correlation between successive frames of a video file.

Variable length coding (VLC): An entropy coding method (Amsterdam, 1986).

13.1 Antenna Principles

Pingjuan L. Werner, Anthony J. Ferraro, and Douglas H. Werner

13.1.1 Antenna Types

Antennas find extensive utilization in communication systems ranging from cellular telephone, television, radio, radar, and numerous other applications. An antenna is designed to launch an electromagnetic signal with desired characteristics; this could be direction of radiation, area of coverage, strength of emission, beamwidth, sidelobe levels, etc. Any metal structure carrying a time varying electrical current will radiate electromagnetic waves as dictated by the well established Maxwell equations. Antennas however are purposefully designed to radiate with certain specified characteristics.

Antenna types are numerous; generally a metallic structure such as wires or metal surfaces serve as the radiator. Simple configurations like a straight length of wire excited from a signal source at the center, for instance, is called a **dipole**. Dipoles can be grouped to form what is known as an *antenna array* for enhancing some characteristic like power gain. A wire curved into a closed circuit, like a circle, forms a simple **loop antenna**. On the other hand, certain useful antennas do not bear any resemblance to the wire types. For instance, the common satellite television receiving antenna is actually a paraboloidal reflector collecting and focusing the received electromagnetic signal to a feed antenna. Such an antenna is called an

FIGURE 13.1 Examples of different types of antennas: (a) dipole, (b) loop, (c) array, (d) patch, (e) pyramidal horn.

aperture. Antennas can either receive, or transmit, or be designed to do both. The *laws of reciprocity* allow the receiving characteristics to be defined from the transmitting characteristics.

Figure 13.1 depicts several common types of antennas. In Fig. 13.1(a), a half-wave dipole is shown oriented parallel to and above the Earth. The antenna length is adjusted to be near one-half of the emitted wavelength of the electromagnetic signal. If the frequency is changed, then the structure is no longer one half-wave in length, and all of the characteristics will change. One of the most important characteristics is the impedance that the center of the antenna, called the *feed-point*, presents to the signal source. A circular loop antenna is shown in Fig. 13.1(b). Like the dipole, the characteristics of the loop depend on whether the loop circumference is small or large compared to the signal wavelength. Figure 13.1(c) is an array of dipoles that are parallel to each other and spaced a fixed distance between individual elements. A typical *patch antenna* is shown in Fig. 13.1(d). The patch antenna is constructed from a rectangular sheet of metal on a substrate. The electrical properties of the substrate influence the characteristics of this antenna. Figure 13.1(e) is a *pyramidal electromagnetic horn* connected to a waveguide for delivering the excitation to the mouth of the horn. This is a type of aperture antenna in which a knowledge of the electromagnetic fields across the face of the mouth are used to calculate the electromagnetic fields radiated by the horn.

13.1.2 Antenna Bandwidth

Antennas can find use in systems that require narrow or large bandwidths depending on the intended application. Bandwidth is a measure of the frequency range over which a parameter, such as impedance, remains within a given tolerance. Dipoles, for example, by their nature are very narrow band.

For narrow-band antennas, the percent bandwidth can be written as

$$\frac{(f_U - f_L)}{f_C} \times 100 \quad (13.1)$$

where

- f_L = lowest useable frequency
- f_U = highest useable frequency
- f_C = center design frequency

In the case of a broadband antenna it is more convenient to express bandwidth as

$$\frac{f_U}{f_L} \quad (13.2)$$

One can arbitrarily define an antenna to be *broadband* if the impedance, for instance, does not change significantly over one octave ($f_U/f_L = 2$).

The design of a broadband antenna relies in part on the concept of a **frequency-independent** antenna. This is an idealized concept, but understanding of the theory can lead to practical applications. Broadband antennas are of the helical, biconical, spiral, and **log-periodic** types. Frequency independent antenna concepts are discussed later in this chapter. Some newer concepts employing the idea of fractals are also discussed for a new class of wideband antennas.

Narrow-band antennas can be made to operate over several frequency bands by adding resonant circuits in series with the antenna wire. Such traps allow a dipole to be used at several spot frequencies, but the dipole still has a narrow band around the central operating frequency in each band. Another technique for increasing the bandwidth of narrow-band antennas is to add parasitic elements, such as is done in the case of the open-sleeve antenna (Hall, 1992).

13.1.3 Antenna Parameters

Current Distribution

To calculate the characteristics of an antenna, the distribution of current on the elements must be known in advance. From the current distribution, the vector potential can be computed, and ultimately the electric field \mathbf{E} and magnetic field \mathbf{H} can be found. With this information, the radiation pattern, polarization, **directivity**, and other parameters can be described.

In the case of an aperture such as that shown in Fig. 13.1(e), the primary currents are flowing on the wave-guide and horn surfaces and are too difficult to find. In this case, the standard practice is to introduce what are known as *equivalent currents*. For the rectangular aperture at the mouth of the horn, equivalent electric and magnetic currents can be found from the equivalence principle so that the radiation from the equivalents is the same as from the primary currents. In any event, the current must be known before proceeding with the analysis of an antenna. Several techniques are available for determining the current distribution including transmission line approximations, the **method of moments (MoM)** and measurements.

The transmission line approximation looks at a center fed dipole, as in Fig. 13.1(a), as an open-circuited transmission line that has been opened up or fanned out. This interpretation suggests a sinusoidal current distribution with current nodes at the ends as shown in Fig. 13.2. The current distribution can be written as

FIGURE 13.2 Transmission line approximation for the current distribution of a center fed dipole.

$$\begin{aligned}
 I(z) &= I_m \sin \beta(h - z) \quad z > 0 \\
 I(z) &= I_m \sin \beta(h + z) \quad z < 0
 \end{aligned}
 \tag{13.3}$$

where

- β = propagation constant
- h = half-length of the center fed dipole
- z = distance measured along the dipole with the center as the origin
- I_m = maximum current that occurs along the wire.

Exact closed-form expressions for the fields may be derived based on the assumed sinusoidal current distribution of Eq. (13.3). The z component of the free space electric field intensity \mathbf{E} is given by

$$E_z = -j30I_m \left(\frac{e^{-j\beta R_1}}{R_1} + \frac{e^{-j\beta R_2}}{R_2} - 2 \cos(\beta h) \frac{e^{-j\beta r}}{r} \right)
 \tag{13.4}$$

where R_1 , R_2 , and r are as indicated in Fig. 13.2. The far-field radiation pattern is of primary interest for most practical antenna applications in communications. The far-field approximation is valid for very large values of r . In particular, using the sinusoidal current distribution given in Eq. (13.3), it can be shown that the corresponding far-zone θ component of the electric field is

$$E_{\theta} = \frac{60I_m}{r} \left[\frac{\cos(\beta h) - \cos(\beta h \cos \theta)}{\sin \theta} \right] e^{-j\beta r} \quad (13.5)$$

For preliminary investigations the sinusoidal distribution is useful. For more accurate analysis, however, the MoM is required. The MoM solves an integral equation for the current distribution required to satisfy the boundary conditions on the surface of the antenna wires. There are several user friendly software packages available for the analysis of complex antenna geometries.

The **Numerical Electromagnetics Code** (NEC-2) (Burke and Poggio, 1981) is an antenna simulation program for modeling wire-based antennas. NEC has many features that include

- Ability to handle wire arcs
- Coordinate transformations
- Generates cylindrical structures
- Scales all of the units
- Surface patches
- Many different ground types
- Networks integrated into the wires
- Generates patterns
- Computes far and near fields
- Computes efficiency

MININEC (Logan and Rockway, 1986) was originally written in order to allow antenna simulations to run on personal computers. ELNEC (Lewallen, 1993) was developed as a user friendly interface to MININEC. MININEC can perform near-field calculations, whereas ELNEC does not. A comparison of the current distribution for a one-half wave and a full-wave dipole using the MoM and the transmission line approximation is shown in Fig. 13.3. Agreement is quite good for the half-wave dipole; on the other hand, there are significant differences in the case of a full-wave dipole. Hence, the limited usefulness of the transmission line approximation is clearly demonstrated in Fig. 13.3(b).

Polarization

Antennas create a state of electromagnetic polarization generally described as *linear*, *circular* or *elliptical*. Figure 13.4(a) depicts a linear polarized electric field (vertical polarization in this case). This would result from one of the dipoles shown in Fig. 13.1(c). The polarization of the wave is related to the orientation of the antenna wire. The electric field in Fig. 13.4(a) oscillates up and down at the angular frequency ω .

FIGURE 13.3 Comparison of current distributions using the transmission line approximation (sinusoidal) and method of moments: (a) half-wave dipole, (b) full wave dipole.

FIGURE 13.4 Various wave polarization states: (a) vertical polarization, (b) right-hand circular polarization, (c) representing linear polarization as the superposition of two circular polarized states, (d) right-handed elliptical polarization.

Circular polarization is shown in Fig. 13.4(b); here the electric vector stays constant in amplitude but rotates at an angular frequency ω . If the wave is approaching the observer, then the rotation direction shown in Fig. 13.4(b) is termed right handed.

A linear polarized wave can be decomposed into two oppositely rotating circular polarized waves having equal magnitudes as shown in Fig. 13.4(c). A circular polarized wave can be generated from two linear polarized waves using two orthogonal dipoles with equal amplitude excitation but 90° electrical phase shift between the excitations. The sense of rotation is controlled by selection of either a leading or lagging 90° phase shift. In general, the polarization of the wave can be elliptical as shown in Fig. 13.4(d). Elliptical polarized waves can be decomposed into two oppositely rotating circular waves of unequal magnitudes and specific electrical phase shift between the circular components.

In a communication system, there can be a polarization mismatch between the transmitting and receiving polarizations. If the transmitted wave is linear polarized, say in the vertical direction, and the receiving antenna is linear polarized in the horizontal direction then, theoretically, there is no far-field received signal at the receiver. If the transmitted wave is linear polarized and the receiving antenna is circular polarized then there is a 3-dB loss in received signal since the linear wave decomposes into two equal amplitude waves as shown in Fig. 13.4(c). This might not be an undesirable situation since the direction of the linear polarized signal could change with time due to propagation environment changes or due to motion of the source (a satellite mounted antenna). In this case, the received signal will be constant in amplitude if received on a circular polarized antenna with a 3-dB signal loss. Polarization mismatch requirements will dictate the type of receiving and transmitting polarizations required in the design of the system.

Fields

The regions around an electrically small radiator contain three types of field terms, that is, electrostatic field terms (fields that decrease as $1/r^3$ where r is the distance from the center of the radiator), induction field terms (fields that decrease as $1/r^2$), and the radiation field or **Fraunhofer region** term (fields that decrease as $1/r$). The electrostatic and induction field terms do not contribute to the radiated power and are responsible for the reactive component to the input impedance of the radiator. The complete electric field expression of a very short ideal dipole is given by

$$E = j\omega\mu \frac{I_0 l}{4\pi} \left[1 + \frac{1}{j\beta r} + \frac{1}{(j\beta r)^2} \right] \frac{e^{-j\beta r}}{r} \sin\theta \theta + j\omega\mu \frac{I_0 l}{2\pi} \left[\frac{1}{j\beta r} + \frac{1}{(j\beta r)^2} \right] \frac{e^{-j\beta r}}{r} \cos\theta \mathbf{r} \quad (13.6)$$

where

- l = length of the electrically short radiator
- I_0 = current in the ideal dipole
- μ = magnetic permeability of the medium
- θ, \mathbf{r} = unit vectors in the theta and radial directions

For larger radiators the **Fresnel** and Fraunhofer regions are important. The boundary between the two regions has been arbitrarily taken to be

$$\frac{2L^2}{\lambda} \quad (13.7)$$

where L is the largest dimension of the antenna and λ is the wavelength. For accurate radiation patterns the measurements should be in the Fraunhofer region or farther where the shape of the pattern is essentially independent of the distance r from the antenna. In the Fresnel region, however, the pattern is dependent upon distance r .

Radiation Patterns

The radiation pattern of an antenna is a curve plotted in either Cartesian or polar coordinates from which the electric field intensity or a quantity proportional to the electric field can be depicted in various polar directions. The radiation pattern is a three-dimensional plot, but for simplicity it is usually plotted as a two dimensional cut along the three-dimensional display. Conventionally, two important cuts are the E -plane and H -plane plots. In the case of a dipole such as that shown in Fig. 13.2, the electric field is in the theta direction, such that it is parallel to any plane that contains the dipole. A plot of the intensity in that plane is called the E -plane radiation pattern. The magnetic field intensity is phi directed and encircles the dipole. The plane that has the dipole element perpendicular to it and also has the magnetic field intensity parallel to it yields the H -plane radiation pattern.

Figure 13.5(a) illustrates both the E - and H -plane patterns for a one-half wavelength dipole oriented along the z coordinate axis. The ELNEC program was used to compute both the current distribution and the radiation pattern. The current distribution, which is graphed using the wire as the axis, is close to what the transmission line approximation would give. The E -plane is shown for the observer in the xz plane. Radiation patterns presume that the observer moves around the antenna while in the far-field region, keeping a constant distance from the antenna. This is a free space pattern with no ground system included. It clearly shows the direction of maximum radiation and that this antenna has a rather broad pattern. Also displayed are null directions where the fields ideally go to zero. Plotted is a quantity proportional to the field intensity, or one could also choose an option to use the decibel scale where usually the maximum is normalized to 0 dB. The H -plane plot for the half-wave dipole is shown in Fig. 13.5(b). Because of symmetry, the dipole is expected to have uniform field intensity as the observer moves around the antenna in the H -plane or specifically the xy plane. For a longer dipole of one full wavelength, Fig. 13.5(c) displays the E -plane radiation pattern. Clearly the main beam of field intensity is narrower than the previous example, and the current distribution takes on a different form having a minimum of current at the center feed point. This case, which has already been considered in Fig. 13.3(b), is one in which the transmission

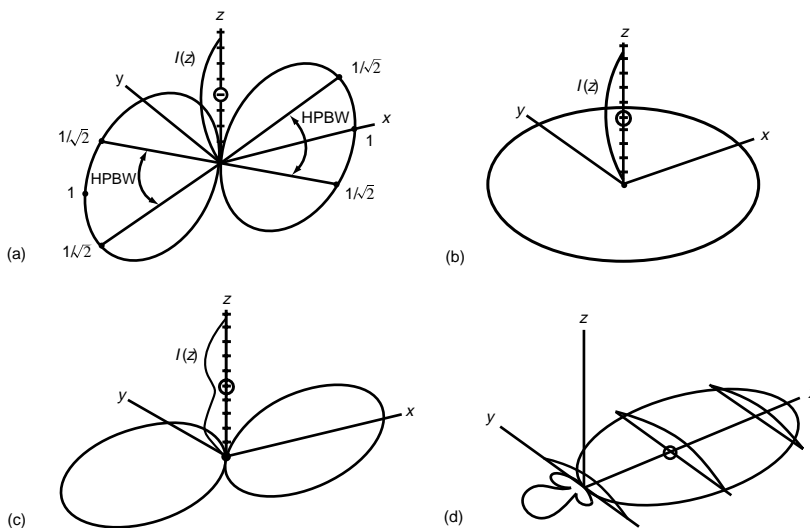

FIGURE 13.5 (a) E -plane plot of the radiation pattern of a half-wave dipole with half power beamwidth shown, (b) H -plane plot of the radiation pattern of a half-wave dipole, (c) E -plane plot of the radiation pattern of a one-wavelength dipole, (d) E -plane plot of the radiation pattern of a three element Yagi.

line approximation would incorrectly predict a null at the feed point. However, using the transmission line current distribution would not show any significant difference in radiation pattern, but would create a sizeable error in the computation of impedance at the center point. A more complex pattern is shown in Fig. 13.5(d), which results from a three element Yagi array. In this type of antenna a central element is fed from a source and two other elements are unfed (parasitic), but due to the mutual coupling with the fed element there is a current induced in the other two. The fed element is close to a half-wavelength long, whereas the element on the right is slightly longer and the one on the left is slightly shorter. Proper pruning of the lengths and spacings results in an *E*-plane pattern that shows the signal is now predominantly directed to the right and that there is a smaller back lobe in the opposite direction. The front-to-back ratio defines the ratio of the field to the right referenced to that directed to the left. The front-to-back ratio is usually measured in decibels. Also evident in Fig. 13.5(d) are smaller sidelobes in the back direction.

A radiation pattern provides good visualization of the distribution of the field intensity in different compass directions. More accurate values could be tabulated if desired. A measure of the broadness of the main beam of energy is called the half-power-beamwidth (HPBW). In the linear plots this is the point where the field diminishes to $1/\sqrt{2}$ of the maximum as illustrated in Fig. 13.5(a).

For an antenna that is not straight or one that is not aligned along the *z* axis as in the previous example, there can be two components of fields, one that is phi and one that is theta directed. In this case patterns can be found for either component or for the magnitude of the total field. Sometimes a pattern is displayed as the power pattern, in which case the points on the plot are proportional to the square of the field pattern values.

Pattern Multiplication

Pattern multiplication is a procedure that allows the determination of the radiation pattern of an array of identical radiators, spaced equally along a baseline. The method permits the rapid visualization of the effect of changing the spacings, the orientation of the radiators, the type of radiators, and the magnitude and phase shift of excitation to the radiators. Central to the method is to first determine the radiation pattern of an array of **isotropic elements** having the same number, spacings and excitations as the original array. Isotropic elements are fictitious elements that radiate equal intensity in all directions. With information of the isotropic array pattern and knowledge of the element pattern one can construct the resultant pattern of the original array graphically. Use of computers can give the pattern directly, but the multiplication technique does allow better insight into the performance of the array and permits visualization of array parameter changes.

Figure 13.6 illustrates the geometry for an array of *N* isotropic elements arranged along the *z* axis, having spacings *d* with equal excitation magnitudes *I* and electrical phase shift α between pairs of elements. It can be shown that the radiation pattern for this array may be expressed as

FIGURE 13.6 Geometry for an array of *N* isotropic elements having spacing *d*, equal excitation magnitudes *I*, and phase shift α between pairs of elements.

$$AF(\theta) = \frac{1}{N} \frac{\sin\left(\frac{N\psi}{2}\right)}{\sin\left(\frac{\psi}{2}\right)} \tag{13.8}$$

where

$$\psi = \beta d \cos \theta + \alpha \tag{13.9}$$

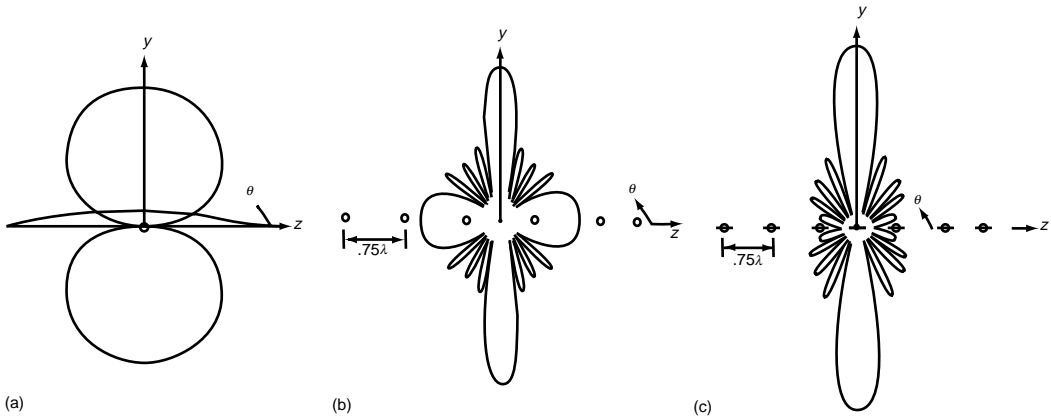

FIGURE 13.7 Example of Pattern multiplication: (a) pattern of a dipole element, (b) pattern of a six-element isotropic array, spacing $d = 0.75\lambda$ and $\alpha = 0^\circ$, (c) result of multiplications of (a) and (b).

If the isotropic elements are replaced by elements having radiation pattern function $f(\theta)$, then it can be shown that the resultant pattern of the array is given by

$$g(\theta) = f(\theta) \times AF(\theta) \tag{13.10}$$

Modification of the element type or orientation requires the updated $f(\theta)$ in order to graph the resultant pattern $g(\theta)$. On the other hand, changes in the geometry of the isotropic array requires a new function for $AF(\theta)$. Antenna books have numerous graphs of $AF(\theta)$ and $f(\theta)$ for different situations; $g(\theta)$ can be sketched graphically from a knowledge of $f(\theta)$ and $AF(\theta)$. For the case of unequal spacings and nonidentical elements, the pattern multiplication method is not applicable.

An example of pattern multiplication is shown in Fig. 13.7. Here a six element array of half-wave dipoles are collinear and arranged on a baseline with center to center spacings of 0.75 wavelengths. The excitations are equal, and the phasing is set to zero degrees between the individual elements. Figure 13.7(a) is the pattern for the half-wave element observed in the yz -plane, whereas Fig. 13.7(b) is the pattern of the six element isotropic array in the same plane. Figure 13.7(c) shows the resultant from the multiplication of the $AF(\theta)$ and $f(\theta)$. In Fig. 13.8, the excitation between elements is changed to 180° , and this results in the pattern shown in Fig. 13.8(b) with the final result of multiplication shown in Fig. 13.8(c). The location of nulls in either $f(\theta)$ or $AF(\theta)$ are preserved in the final pattern, as these figures confirm.

FIGURE 13.8 A second example of pattern multiplication: (a) same as Fig. 13.7(a), (b) pattern of six-element isotropic array with spacing $d = 0.75\lambda$ but α changed to 180° , (c) result of multiplications of (a) and (b).

TABLE 13.1 Radiation Resistance for Various Elements

Element Type	Element Length, λ	Radiation Resistance, Ω
Short dipole in free space	$L < 0.1$	$R_{\text{rad}} = 20\pi^2(L/\lambda)^2$
Short monopole on a perfectly conducting ground plane	$L < 0.05$	$R_{\text{rad}} = 40\pi^2(L/\lambda)^2$
1/2 wavelength dipole in free space	$L = 0.5$	$R_{\text{rad}} = 73$
3/2 wavelength dipole in free space	$L = 1.5$	$R_{\text{rad}} = 105.5$

Impedance

The input impedance of an antenna plays an important role in the matching of the source to the antenna. Knowledge of the impedance over the operating bandwidth is of concern. The *real* part of the impedance is primarily due to the radiation resistance, and in part due to the ohmic loss of the conductors. The radiation resistance is the equivalent resistance, which if connected to the source in place of the antenna absorbs the same power as radiated by the antenna. Impedance can be determined a number of ways. Use of the method of moments gives the most definitive results subject to modeling limitations. Method of moments software was discussed in the first part of [Sec. 13.1.3](#).

From the transmission line approximation for the current distribution, the far electric fields can be computed. From this the Poynting vector, (watts per square meter), can be integrated over a large spherical surface to find the total radiated power. The radiation resistance at the feed point is then found from this radiated power and the known current at the feed point. The near fields dictate the *imaginary* part of the impedance. Some typical values of radiation resistance for various elements, which have small diameter, are given in Table 13.1. The section on dipole characteristics gives the input impedance of dipoles of various lengths computed from the latest moment method formulation described in [Sec. 13.1.4](#).

Mutual Impedance

Several elements collected in an array have interactions among themselves. Since in an array environment the elements could be closely spaced in units of wavelengths, the interaction between them can result in significant mutual coupling measured in terms of the mutual impedance. It is convenient to treat the antenna array as an N -port network in order to determine mutual impedances. Hence, for an antenna array the mutual impedances can be computed from knowledge of the total fields acting upon an element.

The port equations for an N -element array with element excitation V_i and element current I_j can be written as

$$\begin{aligned}
 V_1 &= I_1 Z_{11} + I_2 Z_{12} + \dots + I_N Z_{1N} \\
 V_2 &= I_1 Z_{21} + I_2 Z_{22} + \dots + I_N Z_{2N} \\
 &\vdots \\
 V_N &= I_1 Z_{N1} + I_2 Z_{N2} + \dots + I_N Z_{NN}
 \end{aligned}
 \tag{13.11}$$

Where Z_{ii} is the self-impedance of the i th element and Z_{ij} is the mutual impedance between the i th and j th elements. These lead to expressions for the driving point or input impedance viewed by each source connected to the elements. Thus, from these port equations one obtains

$$\begin{aligned}
 Z_{D1} &= \frac{V_1}{I_1} = Z_{11} + \left(\frac{I_2}{I_1}\right) Z_{12} + \dots + \left(\frac{I_N}{I_1}\right) Z_{1N} \\
 Z_{D2} &= \frac{V_2}{I_2} = \left(\frac{I_1}{I_2}\right) Z_{21} + Z_{22} + \dots + \left(\frac{I_N}{I_2}\right) Z_{2N} \\
 &\vdots \\
 Z_{DN} &= \frac{V_N}{I_N} = \left(\frac{I_1}{I_N}\right) Z_{N1} + \left(\frac{I_2}{I_N}\right) Z_{N2} + \dots + Z_{NN}
 \end{aligned}
 \tag{13.12}$$

Consider the simple case of a two-element array of half-wave dipoles separated by a half-wavelength with elements parallel and side by side. The driving point impedances for each element reduces to

$$\begin{aligned} Z_{D1} &= Z_{11} + \left(\frac{I_2}{I_1}\right)Z_{12} \\ Z_{D2} &= Z_{22} + \left(\frac{I_1}{I_2}\right)Z_{21} \end{aligned} \quad (13.13)$$

The known impedance for a thin half-wave dipole is $73 + j42.5$ and available tables (Hickman and Tillman, 1961) for the mutual impedance give a value of $-12.5 - j30$. At this point knowledge of the complex current ratios is required to complete the analysis. Several interesting cases are $I_1/I_2 = 1$ and $I_1/I_2 = -1$. The mutual impedance tables referred to assumed that the array elements had sinusoidal current distributions. Each case gives the following results:

- If $I_1/I_2 = 1$, then $Z_{D1} = Z_{D2} = 60.5 + j12.5 \Omega$.
- If $I_1/I_2 = -1$, then $Z_{D1} = Z_{D2} = 85.5 + j72.5 \Omega$.

The moment method gives the driving point impedance directly without any need for separate calculations for the self- and mutual terms. The same problem repeated with the ELNEC code yields for a wire radius of 1.0 mm the following results:

- If $I_1/I_2 = 1$, then $Z_{D1} = Z_{D2} = 60.08 + j9.38 \Omega$.
- If $I_1/I_2 = -1$, then $Z_{D1} = Z_{D2} = 97.43 + j70.66 \Omega$.

For the case of a two-element Yagi where only one element is fed and the other obtains excitation from only the mutual coupling, the driving point impedance is derived as

$$Z_{D1} = Z_{11} - Z_{12}^2/Z_{22}$$

since V_2 and, hence, Z_{D2} are zero. The expression shows that the subtraction of the two terms can result in a low input impedance, which can restrict bandwidth and lower efficiency. Numerical results from ELNEC for the Yagi with two parallel and side-by-side half-wavelength dipoles spaced 0.1 and 0.05 wavelengths are as follows:

- If spacing is 0.1λ , then $Z_{D1} = 22.29 + j59.27 \Omega$.
- If spacing is 0.05λ , then $Z_{D1} = 5.50 + j31.15 \Omega$.

Generally, if the dipoles in an array are not parallel or collinear, the computation for self- and mutual impedances is more difficult, and using the method of moments code is a more suitable approach.

Directivity, Directive Gain, and Power Gain

The **directivity** of an antenna provides a measure of performance compared to a reference antenna. The reference is either the hypothetical isotropic element or the practical half-wave dipole. Specifically, if the antenna under test and the reference are supplied with the same input power, then the directivity would simply compare the ratio of the power densities of the former with the latter. The directivity is used to express the performance in the direction of maximum power density from the antenna under test. It is presumed that all of the power supplied to the antenna is radiated, that is, it is 100% efficient. The *directive gain* is similar to directivity except it can be used for any direction and not necessarily the direction of maximum radiation. The power gain takes into account the efficiency of the antenna system since all of the power supplied is not radiated. This can include the losses in the transmission line feed configuration.

Figure 13.9 shows the concept for defining the directive gain and directivity. The antenna under test and the isotropic radiator are supplied with the same power W_R , which is 100% radiated. The power density P is measured from both antennas at the same distance R . The directive gain $D(\theta, \phi)$ is the ratio

FIGURE 13.9 Comparison of power densities between an antenna and an isotropic reference. W_R is the power radiated, $P(\theta, \phi)$ is the power density, P_{\max} is the maximum power density and R is the range at which measurements are made.

$P(\theta, \phi)/P_{\text{iso}}$. The quantity P_{iso} is the power density from the isotropic antenna that is radiating W_R watts. If P is measured in the direction of maximum, P_{\max} , then the ratio is called the directivity, otherwise it is known as directive gain. From the three-dimensional radiation pattern $f(\theta, \phi)$, the directive gain and directivity can be computed from the following:

$$D(\theta, \phi) = \frac{4\pi f^2(\theta, \phi)}{\int_0^{2\pi} \int_0^\pi f^2(\theta, \phi) \sin \theta d\theta d\phi} \tag{13.14}$$

when $f^2(\theta, \phi) = 1$, that is, in the direction of P_{\max}

$$D = \frac{4\pi}{\int_0^{2\pi} \int_0^\pi f^2(\theta, \phi) \sin \theta d\theta d\phi} \tag{13.15}$$

where $f^2(\theta, \phi)$ is the power pattern, which is the square of the field pattern.

Table 13.2 gives the values of directivity for some common antenna types. The results are referenced to both the isotropic and half-wave dipole.

The *power gain* G is derived in a similar manner, except the total power input to the antenna is used in place of the radiated power; thus, the relationship between G and D is

$$G = (\text{eff}) \times D \tag{13.16}$$

where *eff* is the antenna efficiency.

TABLE 13.2 Directivity for Various Antenna Types

Antenna Type	Directivity, dB, Isotropic Reference	Directivity, dB, Half-Wave Dipole Reference
Isotropic	0	-2.15
Free space half-wave dipole	2.15	0
Short dipole	1.76	-0.39
Free space full-wave dipole (from ELNEC)	3.92	1.77
Three element Yagi of Fig. 13.5(d) (from ELNEC)	9.52	7.37

Efficiency

The efficiency of an antenna element depends on the radiation resistance R_{rad} and the ohmic resistance R_{Ω} . If a dipole, for instance, has peak current I_{in} at the feed point, then the radiated power is $I_{in}^2/2R_{rad}$, whereas the ohmic power loss is dependent on the current values at the various positions along the antenna wire. The ohmic power loss per unit length of the wire is the given by

$$dW_{\Omega} = \frac{I^2(z)}{2} R_{\Omega} \tag{13.17}$$

The total ohmic power lost over the entire wire is found from

$$W_{\Omega} = \int \frac{I^2(z)}{2} R_{\Omega} dz \tag{13.18}$$

The calculation of radiation resistance has been discussed in an earlier subsection. Here an approximate value of R_{Ω} will be found. This information may be used to find the efficiency from the expression

$$eff = \frac{W_{rad}}{W_{rad} + W_{\Omega}} \tag{13.19}$$

Figure 13.10(a) depicts the geometry used for calculating the surface impedance of a flat conductor 1×1 m but very deep. The **surface impedance** (Stutzman and Thiele, 1981) for this case is shown for a good conductor to be

$$Z_s = \sqrt{\frac{j\omega\mu_0}{\sigma}} \tag{13.20}$$

where

- σ = conductivity of the wire
- μ_0 = permeability of free space
- ω = angular frequency of the antenna source

The real part of Z_s gives the surface resistance R_s to be

$$R_s = \sqrt{\frac{\omega\mu_0}{2\sigma}} \tag{13.21}$$

In the case of a cylindrical wire, as shown in Fig. 13.10(b), the small section with dimensions Δz and Δs can approximate the flat conductor of Fig. 13.10(a). At high frequencies, due to skin effect, the current will be confined to the surface and so a deep section of conductor is not required. Under these circumstances,

FIGURE 13.10 (a) Surface impedance for a flat thick conductor, (b) application of the surface impedance for finding the ohmic resistance of a cylindrical conductor at high frequencies.

unfolding the cylindrical surface will approximate a flat conductor of dimensions $2\pi a$ and Δz . This results in an approximate ohmic resistance of

$$R_{\Omega} = R_s \frac{\Delta z}{2\pi a} \tag{13.22}$$

From a knowledge of the current distribution discussed earlier, the total ohmic power loss can be computed. A less strenuous method of computing the efficiency is with a method of moments code. Since wire conductivity can be inputted into the code, it is possible to evaluate the directivity (assuming perfectly conducting wires) and then repeat with wire conductivity included. From a knowledge of D and G , efficiency can be inferred.

13.1.4 Antenna Characteristics

Antennas over ground can be modeled by several methods. The simplest is to assume a perfectly conducting Earth. This would be an excellent approximation for some situations, such as an antenna above sea water. For this case the method of images can be used. If Earth parameters do not warrant the perfectly conducting approximation, then the Fresnel reflection coefficients can be used to compute the ground reflected wave, which is superimposed with the direct wave. For antennas very close to Earth the **Sommerfeld/Norton solution** is used. This method uses the exact solution for fields in the presence of Earth. The NEC code discussed earlier uses this method as an option, although computations require more time to complete.

Effect of the Earth

Perfectly Conducting Ground Plane

If the Earth can be approximated as perfectly conducting, then the method of images can be applied and the solution is straightforward. Figure 13.11 shows a horizontal and vertical dipole elevated above a perfectly conducting and infinitely large ground plane. For the horizontal case, it can be shown that there is an image that can account for the correct amplitude and phase of the reflected wave. The image has the same current distribution as the antenna above ground but is 180° out of phase. The image is the same distance below the ground plane interface as the antenna is above the ground plane interface. The image and original antenna acting together in free space properly accounts for the reflected wave from the ground plane. The combination of the direct and ground reflected waves can be done by using the dipole field equation given earlier. For the vertical dipole, the image has the same current distribution as the original antenna and is in phase. The distance requirements of the image are indicated in Fig. 13.11.

FIGURE 13.11 (a) Horizontal dipole above perfectly conducting ground plane and the image equivalent, (b) vertical dipole above perfectly conducting ground plane and the image equivalent.

The driving point impedance of the dipole above Earth is easily calculated from the self- and mutual impedances already discussed. This gives for the case of a single dipole above a perfectly conducting Earth

$$Z_{D1} = \frac{V_1}{I_1} = Z_{11} + \left(\frac{I_2}{I_1} \right) Z_{12} \tag{13.23}$$

for the horizontal dipole

$$I_1/I_2 = -1$$

therefore

$$Z_{D1} = Z_{11} - Z_{12}$$

for the vertical dipole

$$I_1/I_2 = 1 \tag{13.24}$$

therefore

$$Z_{D1} = Z_{11} + Z_{12} \tag{13.25}$$

Imperfectly Conducting Ground Plane

For the case of a ground defined by the electrical permittivity and conductivity, the reflection coefficient can be computed (Kraus and Carver, 1973). The reflection coefficient defines the amplitude of the reflected wave relative to the direct wave so that the two fields can be added to determine the far-field radiation pattern. The reflection coefficients for horizontal and vertical polarizations are given respectively by

$$\rho_H = \frac{\sin \alpha - \sqrt{\epsilon_r - \cos^2 \alpha}}{\sin \alpha + \sqrt{\epsilon_r - \cos^2 \alpha}} \tag{13.26}$$

$$\rho_V = \frac{\epsilon_r \sin \alpha - \sqrt{\epsilon_r - \cos^2 \alpha}}{\epsilon_r \sin \alpha + \sqrt{\epsilon_r - \cos^2 \alpha}} \tag{13.27}$$

where

- α = elevation angle for the reflected ray (see Fig. 13.12)
- ϵ_r = complex permittivity, $\epsilon'_r - j\sigma/\omega\epsilon_0$
- ϵ'_r, σ = actual ground permittivity and conductivity parameters of the Earth, respectively.

The terminology *horizontal* and *vertical* polarizations refers to the electric field and magnetic field being parallel to the Earth interface, respectively. For example, if the source shown in Fig. 13.12 is the end view of a dipole, then the far electric field is perpendicular to the figure and, consequently, parallel to the interface. The value of the reflected electric field is computed from the quantity ρ_H . If the source in Fig. 13.12 is a vertical dipole in the plane of the figure, then the far magnetic field is parallel to the interface or the far electric field has a component perpendicular to the interface; hence, the ρ_V is used to determine the reflected field.

The resultant far field from a short horizontal dipole of length ds perpendicular to the page would be expressed by

$$E = j30\beta I_0 ds \left(\frac{e^{-j\beta R_1}}{R_1} + \rho_H \frac{e^{-j\beta R_2}}{R_2} \right) \tag{13.28}$$

For a short vertical dipole of length ds parallel to the page, the resultant far field would be expressed by

$$E = j30\beta I_0 ds \cos \alpha \left(\frac{e^{-j\beta R_1}}{R_1} - \rho_V \frac{e^{-j\beta R_2}}{R_2} \right) \tag{13.29}$$

FIGURE 13.12 Direct and reflected waves for an antenna above an imperfect Earth.

Several examples (Jordan and Balmain, 1968) of the influence of an imperfect ground on an antenna are available in the literature.

The Sommerfeld/Norton Method

The NEC codes provide for several options of modeling a structure over ground. For the perfectly conducting ground the code generates an image as discussed earlier. For a finitely conducting ground plane the code generates an image modified by the Fresnel reflection coefficients as discussed previously. The alternate method uses the Sommerfeld/Norton exact solution for the fields in the presence of Earth and is claimed to be accurate for wire antennas close to the ground. However, computational times are considerably longer. NEC also includes the option to model a radial-wire ground screen as an approximation and a two medium ground approximation, such as a cliff overlooking a different medium.

Irregular Terrain

The assumption of a flat ground plane is not always realistic because terrain can be very irregular. Some recent work (Young, 1994) has developed a practical computer code for the simulation of antenna patterns over three-dimensional terrain using the **uniform geometrical theory of diffraction (UTD)**. The software is capable of generating a three-dimensional terrain model from existing terrain databases. Using existing diffraction programs, patterns can be obtained. This code is useful for siting antennas and determining optimum locations for high frequency (HF) communications. Various two- and three-dimensional generic shape profiles were analyzed and tabulated as a quick reference guide in selecting an antenna site.

Dipole Characteristics

Consider a center-fed dipole antenna of length $2L$ and diameter $2a$ oriented along the z axis, as illustrated in Fig. 13.13. If it is assumed that the current on the surface of the wire dipole is circumferentially invariant, then it has been shown that the exact form of the current distribution $I(z')$ on the dipole may be determined by solving the following integral equation (Pocklington, 1897):

$$\int_{-L/2}^{L/2} \left[\frac{\partial^2}{\partial z'^2} + \beta^2 \right] K(z - z') I(z') dz' = -j4\pi\omega\epsilon E_z^i(z) \tag{13.30}$$

where E_z^i represents the field incident or impressed on the surface of the wire by a source and

$$K(z - z') = \frac{1}{2\pi} \int_0^{2\pi} \frac{e^{-j\beta R'}}{R'} d\phi' \tag{13.31}$$

FIGURE 13.13 Dipole antenna geometry.

is the cylindrical wire kernel, in which

$$R' = \sqrt{(z - z')^2 + \rho^2 + a^2 - 2\rho a \cos(\phi - \phi')} \quad (13.32)$$

This is known as Pocklington's integral equation in which the unknown $I(z')$ appears under the integral.

For modeling of thin-wire antennas, that is, wires with radii $a \lesssim 0.01\lambda$, the reduced kernel approximation of Eq. (13.31) is often used. This approximation is

$$K(z - z') \approx K_0(z - z') = \frac{e^{-j\beta r_0}}{r_0} \quad \text{for} \quad \rho \geq a \quad (13.33)$$

where

$$r_0 = \sqrt{(z - z')^2 + \rho^2} \quad (13.34)$$

It should be noted that Eq. (13.33) is exact for a vanishingly thin wire ($a = 0$) and becomes approximate as soon as the wire radius begins to increase ($a > 0$). On the other hand, for moderately thick wires with radii in the range $0.01\lambda \lesssim a \lesssim 0.1\lambda$, the complete kernel expression of Eq. (13.31) must be considered in order to achieve an accurate solution. Several techniques for evaluating Eq. (13.31) have been discussed in Werner (1995). These techniques include numerical integration schemes, as well as analytical methods. Among the more useful techniques is a recently found exact representation of Eq. (13.31) given by (Werner, 1993, 1995)

$$K(z - z') = -\frac{e^{-j\beta R}}{R} \sum_{n=0}^{\infty} \sum_{k=0}^{2n} A_{nk} \frac{(\beta^2 \rho a)^{2n}}{(\beta R)^{2n+k}} \quad (13.35)$$

where

$$R = \sqrt{(z - z')^2 + \rho^2 + a^2} \quad (13.36)$$

and the coefficients A_{nk} may be determined through the following set of recursions:

$$A_{nk} = \frac{(2n + 1 - k)(2n + k)}{j(2k)} A_{nk-1}, \quad n > 0 \quad \text{and} \quad k > 0 \quad (13.37)$$

$$A_{n0} = \begin{cases} -1, & n = 0 \\ -\frac{1}{(2n)^2} A_{n-10}, & n > 0 \end{cases} \quad (13.38)$$

A common technique for obtaining solutions to Eq. (13.30) is the method of moments (Harrington, 1968). The beauty of this technique is that it converts the integral equation to an associated matrix equation, which can then be readily solved using digital computers. In other words, suppose we express Eq. (13.30) in the form

$$\int_{-L/2}^{L/2} I(z') G(z, z') dz' = -E_z^i(z) \quad (13.39)$$

where

$$G(z, z') = \frac{1}{j4\pi\omega\epsilon} \left[\frac{\partial^2}{\partial z^2} + \beta^2 \right] K(z - z') \quad (13.40)$$

Then the MoM may be used to reduced Eq. (13.39) to a system of simultaneous linear algebraic equations of the form

$$\sum_{n=1}^N Z_{mn} I_n = V_m \quad \text{for} \quad m = 1, 2, \dots, N \quad (13.41)$$

which may be written in compact matrix notation as

$$[Z_{mn}][I_n] = [V_m] \tag{13.42}$$

where $[Z_{mn}]$, $[I_n]$, and $[V_m]$ are known as the impedance, the current and voltage matrices, respectively. Hence, the problem has been reduced from solving for the unknown current distribution $I(z')$ in Eq. (13.30) to solving for the I_n in Eq. (13.42).

There are several powerful antenna analysis codes available that are based on a MoM formulation. These codes are used by antenna engineers to aid in the design of complex antenna systems where it is important to be able to predict the interaction of antennas with each other and their environment. Some of the more popular antenna modeling codes, which have already been briefly discussed include NEC, ELNEC, and MININEC.

The MoM formulations used in these codes are essentially valid for the analysis of electrically thin wires since they are based on the reduced kernel approximation of Eq. (13.33). A thin-wire antenna analysis capability is sufficient for many practical applications. However, there are some situations that may require the analysis of moderately thick-wire antennas, especially at higher frequencies ($100 \text{ MHz} \leq f \leq 1 \text{ GHz}$). For these cases, a MoM code has been developed at the Pennsylvania State University, Applied Research Laboratory, which is capable of accurately analyzing moderately thick- as well as thin-wire antennas. This code uses a robust treatment of the cylindrical wire kernel Eq. (13.31) in its analysis of thicker wires. Figure 13.14 graphically illustrates the improvements in input impedance predictions for moderately thick wires when using a robust treatment of the kernel as compared to a strictly reduced kernel thin-wire treatment. The code predictions as well as measured values of input resistance and reactance for various moderately thick monopoles are plotted in Fig. 13.14(a) and Fig.13.14(b), respectively.

Figure 13.15 contains design curves of impedance as a function of length for a center fed dipole in free space. The data for these curves was generated using the Pennsylvania State University, MoM code. The MoM may also be used to determine radiation patterns and directivity of a particular antenna. The radiation patterns for several popular dipole antennas, including the half-wave and full-wave dipole, have already been discussed in Sec. 13.1.3 with their corresponding directivities listed in Table 13.2.

Loop Antennas

A thin wire bent into a closed contour is called a loop antenna. The terminals of a loop antenna are formed by a small discontinuity or gap in the conducting wire. Loops have been used in such diverse applications as radio receiving antennas, direction finding, magnetic field-strength probes, as well as array elements.

FIGURE 13.14 Code predictions for the input impedance of a 0.4λ monopole compared to measurements: (a) input resistance, (b) input reactance.

FIGURE 13.15 Design curves of input impedance vs. dipole length for a fixed radius of $a = 1 \times 10^{-6}\lambda$.

There are various types of loop antennas including rectangular, triangular, rhombic, and circular. In this section we will focus on the thin circular loop antenna, which is one of the most popular and commonly used configurations.

Radiated Fields

Figure 13.16 illustrates the coordinate system that will be adopted for the circular loop antenna of radius a . The source point and field point are designated by the spherical coordinates $(r' = a, \theta' = 90^\circ, \phi')$ and (r, θ, ϕ) , respectively. Hence, using the geometry depicted in Fig. 13.16 it may be shown that the distance from the source point on the loop to the field point at some arbitrary location in space is

$$R' = \sqrt{R^2 - 2ar \sin \theta \cos(\phi - \phi')} \tag{13.43}$$

where

$$R = \sqrt{r^2 + a^2} \tag{13.44}$$

FIGURE 13.16 Circular loop antenna geometry.

The vector potential for the circular loop with a ϕ -directed current $I(\phi)$ may be expressed in the general form (Balanis, 1982)

$$\mathbf{A}(r, \theta, \phi) = A_r(r, \theta, \phi)\mathbf{r} + A_\theta(r, \theta, \phi)\boldsymbol{\theta} + A_\phi(r, \theta, \phi)\boldsymbol{\phi} \tag{13.45}$$

where

$$A_r(r, \theta, \phi) = \frac{\mu a \sin \theta}{4\pi} \int_0^{2\pi} I(\phi') \sin(\phi - \phi') \frac{e^{-j\beta R'}}{R'} d\phi' \tag{13.46}$$

$$A_\theta(r, \theta, \phi) = \frac{\mu a \cos \theta}{4\pi} \int_0^{2\pi} I(\phi') \sin(\phi - \phi') \frac{e^{-j\beta R'}}{R'} d\phi' \tag{13.47}$$

$$A_\phi(r, \theta, \phi) = \frac{\mu a}{4\pi} \int_0^{2\pi} I(\phi') \cos(\phi - \phi') \frac{e^{-j\beta R'}}{R'} d\phi' \tag{13.48}$$

A general method for evaluating the vector potential integrals defined in Eqs. (13.46–13.48) has been developed in (Werner, 1996). This exact integration technique is based on the fact that Eqs. (13.46–13.48) may be expressed in the following way:

$$A_r(r, \theta, \phi) = -\frac{\mu}{j2\beta r} \frac{d}{d\phi} \mathfrak{S}(r, \theta, \phi) \tag{13.49}$$

$$A_\theta(r, \theta, \phi) = -\frac{\mu}{j2\beta r \tan \theta} \frac{d}{d\phi} \mathfrak{S}(r, \theta, \phi) \tag{13.50}$$

$$A_\phi(r, \theta, \phi) = \frac{\mu}{j2\beta r \cos \theta} \frac{d}{d\phi} \mathfrak{S}(r, \theta, \phi) \tag{13.51}$$

where the integral

$$\mathfrak{S}(r, \theta, \phi) = \frac{1}{2\pi} \int_0^{2\pi} I(\phi') e^{-j\beta R'} d\phi' \tag{13.52}$$

is common to all three components of the vector potential. This integral may be expressed in the form of an infinite series given by

$$\mathfrak{S}(r, \theta, \phi) = G_0 e^{-j\beta R} + \sum_{m=1}^{\infty} G_m(\phi) \frac{(\beta^2 a r \sin \theta)^m}{m!} \frac{h_{m-1}^2(\beta R)}{(\beta R)^{m-1}} \tag{13.53}$$

where

$$G_0 = \frac{1}{2\pi} \int_0^{2\pi} I(\phi') d\phi' \quad (13.54)$$

$$G_m(\phi) = \frac{1}{2\pi} \int_0^{2\pi} I(\phi + \phi') \cos^m \phi' d\phi' \quad (13.55)$$

and $h_{m-1}^{(2)}$ are spherical Hankel functions of the second kind of order $m - 1$. An exact representation for \mathfrak{N} may be obtained from Eq. (13.53), provided closed-form solutions to the integrals Eq. (13.54) and Eq. (13.55) exist for a particular current distribution. Fortunately, it is possible to evaluate these integrals analytically for the majority of commonly assumed current distributions. Once an exact representation for a specific \mathfrak{N} has been found, then it is a straightforward procedure to determine exact expressions for the vector potential components A_r , A_θ , and A_ϕ by substituting the series expansion for \mathfrak{N} into Eq. (13.46), Eq. (13.47), and Eq. (13.48), respectively, and performing the necessary differentiation. Finally, expressions for the electric and magnetic fields of the circular loop may be derived from its vector potential by making use of the relationships

$$\mathbf{H} = \frac{1}{\mu} (\nabla \times \mathbf{A}) \quad (13.56)$$

$$\mathbf{E} = \frac{1}{j\omega\epsilon} \nabla \times \mathbf{H} = \frac{1}{j\omega\mu\epsilon} [\nabla(\nabla \cdot \mathbf{A}) + \beta^2 \mathbf{A}] \quad (13.57)$$

Scalar equations for the three components of the magnetic field, which are in terms of the vector potential components, follow directly from Eq. (13.56). These equations are given by

$$H_r(r, \theta, \phi) = \frac{1}{\mu r \sin \theta} \left[\frac{\partial}{\partial \theta} (\sin \theta A_\phi) - \frac{\partial}{\partial \phi} A_\theta \right] \quad (13.58)$$

$$H_\theta(r, \theta, \phi) = \frac{1}{\mu r} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \phi} A_r - \frac{\partial}{\partial r} (r A_\phi) \right] \quad (13.59)$$

$$H_\phi(r, \theta, \phi) = \frac{1}{\mu r} \left[\frac{\partial}{\partial r} (r A_\theta) - \frac{\partial}{\partial \theta} A_r \right] \quad (13.60)$$

Likewise, the vector form of the electric field Eq. (13.57) may be separated into three scalar components, which results in

$$E_r(r, \theta, \phi) = \frac{\eta}{j\beta r \sin \theta} \left[\frac{\partial}{\partial \theta} (\sin \theta H_\phi) - \frac{\partial}{\partial \phi} H_\theta \right] \quad (13.61)$$

$$E_\theta(r, \theta, \phi) = \frac{\eta}{j\beta r} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \phi} H_r - \frac{\partial}{\partial r} (r H_\phi) \right] \quad (13.62)$$

$$E_\phi(r, \theta, \phi) = \frac{\eta}{j\beta r} \left[\frac{\partial}{\partial r} (r H_\theta) - \frac{\partial}{\partial \theta} H_r \right] \quad (13.63)$$

where

$$\eta = \sqrt{\frac{\mu}{\epsilon}} \quad (13.64)$$

is the characteristic impedance of the medium.

Electrically Small Circular Loop

Circular loop antennas in which the radius of the loop is less than about 0.04λ may be considered electrically small. Electrically small-loop antennas are not usually used in transmitting applications because of their very low-radiation resistance, making them inefficient radiators. On the other hand, small circular loops

are frequently employed in receiving applications. The standard approximation for the current distribution on an electrically small circular loop is uniform, that is, $I(\phi) = I_0$ where I_0 is a constant (Balanis, 1982).

The integral form of the vector potential for a uniform current loop is well known and may be expressed as

$$\mathbf{A} = A_\phi(r, \theta)\phi \tag{13.65}$$

where

$$A_\phi(r, \theta) = \frac{a\mu I_0}{2} \frac{1}{\pi} \int_0^\pi \cos \phi' \frac{e^{-j\beta R'}}{R'} d\phi' \tag{13.66}$$

and R' of Eq. (13.43) reduces to

$$R' = \sqrt{R^2 - 2ar \sin \theta \cos \phi'} \tag{13.67}$$

The procedure outlined in the Radiated Fields subsection may be followed to find an analytical expression for the uniform current vector potential integral of Eq. (13.66). This results in the following exact series representation for the near-zone of the loop:

$$A_\phi(r, \theta) = \frac{\beta a \mu I_0}{2j} \sum_{m=1}^\infty \frac{[(\beta^2 ar \sin \theta)/2]^{2m-1} h_{2m-1}^{(2)}(\beta R)}{m!(m-1)! (\beta R)^{2m-1}} \tag{13.68}$$

The corresponding exact representations of the magnetic and electric field components may be obtained from Eqs. (13.58–13.60) and (13.61–13.63), respectively, by making use of Eq. (13.68). These field expressions are given by

$$H_r(r, \theta) = \frac{\beta(\beta a)^2 I_0 \cos \theta}{2j} \sum_{m=1}^\infty \frac{[(\beta^2 ar \sin \theta)/2]^{2m-2} h_{2m-1}^{(2)}(\beta R)}{[(m-1)!]^2 (\beta R)^{2m-1}} \tag{13.69}$$

$$H_\theta(r, \theta) = \frac{\beta(\beta a)^2 I_0 \sin \theta}{2j} \left[\frac{(\beta r)^2}{2} \sum_{m=1}^\infty \frac{[(\beta^2 ar \sin \theta)/2]^{2m-2} h_{2m}^{(2)}(\beta R)}{m!(m-1)! (\beta R)^{2m}} - \sum_{m=1}^\infty \frac{[(\beta^2 ar \sin \theta)/2]^{2m-2} h_{2m-1}^{(2)}(\beta R)}{[(m-1)!]^2 (\beta R)^{2m-1}} \right] \tag{13.70}$$

$$H_\phi = 0 \tag{13.71}$$

$$E_r = E_\theta = 0 \tag{13.72}$$

$$E_\phi(r, \theta) = -\frac{\eta\beta(\beta a) I_0}{2} \sum_{m=1}^\infty \frac{[(\beta^2 ar \sin \theta)/2]^{2m-1} h_{2m-1}^{(2)}(\beta R)}{m!(m-1)! (\beta R)^{2m-1}} \tag{13.73}$$

Small-loop approximations to the fields may be obtained from Eq. (13.69), Eq. (13.70), and Eq. (13.73) by retaining only the first term ($m = 1$) in each series and recognizing that $R \rightarrow r$ as $a \rightarrow 0$. Under these conditions, we find that

$$H_r(r, \theta) \approx \frac{j\beta a^2 I_0 \cos \theta}{2r^2} \left[1 + \frac{1}{j\beta r} \right] e^{-j\beta r} \tag{13.74}$$

$$H_\theta(r, \theta) \approx -\frac{(\beta a)^2 I_0 \sin \theta}{4r} \left[1 + \frac{1}{j\beta r} - \frac{1}{(\beta r)^2} \right] e^{-j\beta r} \tag{13.75}$$

$$E_\phi(r, \theta) \approx \frac{(\beta a)^2 \eta I_0 \sin \theta}{4r} \left[1 + \frac{1}{j\beta r} \right] e^{-j\beta r} \tag{13.76}$$

FIGURE 13.17 Three-dimensional radiation pattern produced by an electrically small-loop antenna with a uniform current distribution.

In the far zone of the loop, that is, when $\beta r \gg 1$, expressions (13.74)–(13.76) may be used to show that the fields reduce to the simple form given by

$$H_r \approx H_\phi = E_r = E_\theta = 0 \quad (13.77)$$

$$H_\theta \approx -\frac{(\beta a)^2 I_0 e^{-j\beta r}}{4r} \sin \theta \quad (13.78)$$

$$E_\phi \approx \eta \frac{(\beta a)^2 I_0 e^{-j\beta r}}{4r} \sin \theta \quad (13.79)$$

Hence, the far-field radiation pattern of an electrically small-loop antenna has a $\sin \theta$ variation as demonstrated by Eq. (13.78) and Eq. (13.79). Figure 13.17 illustrates the three-dimensional radiation pattern that would be produced by a small loop. Finally, by using Eq. (13.15) with $f(\theta, \phi) = \sin \theta$, it follows that the directivity of a small loop is

$$D = \frac{3}{2} \quad \text{or} \quad 1.76 \text{ dB} \quad (13.80)$$

which is the same as that of an infinitesimal or short dipole (see Table 13.2). The corresponding radiation resistance of a small circular loop with circumference $C = 2\pi a$ is given by the formula (Balanis, 1982)

$$R_{\text{rad}} = 20\pi^2 \left(\frac{C}{\lambda} \right)^4 \Omega \quad (13.81)$$

Circular Loops with Nonuniformly Distributed Current

The uniform current analysis that was presented earlier in this section is valid for electrically small loops. However, as the radius of the loop increases, the current is no longer uniform as it begins to vary along the circumference of the loop. One common assumption for the variation of the loop current under these conditions is a cosinusoidal distribution of the form (Balanis, 1982; Lindsey, 1960)

$$I(\phi) = I_n \cos(n\phi); \quad n = 0, 1, 2, \dots \quad (13.82)$$

This assumption may be generalized to include loops having an arbitrary current distribution represented by the following Fourier cosine series (Werner, 1996; Storer, 1956):

$$I(\phi) = \sum_{n=0}^{\infty} I_n \cos(n\phi) \quad (13.83)$$

This form of the current distribution is very general and may be applied to the analysis of the radiation characteristics of loop antennas for a wide variety of circumstances (King and Smith, 1981; King, 1969).

Exact expressions for the vector potential and electromagnetic fields may be derived from the current distributions Eq. (13.82) and Eq. (13.83) by following the procedure outlined earlier in this section (Werner, 1996). The resulting field expressions, although useful, are complicated and beyond the scope of this chapter.

The actual form of the current distribution on a particular loop antenna may be determined by performing a method of moments analysis, as discussed in two earlier sections. It is a straightforward procedure to find the input impedance, radiation pattern, and gain of a loop once the current distribution is known. Method of moments generated plots of the input impedance vs. loop radius may be found in Fig. 13.6 of Harrington (1968).

Yagi-Uda Arrays

A **Yagi-Uda** (or Yagi) antenna is a parasitic linear array that contains one driven element and one or more parasitic elements. A parasitic element is called a *reflector* when the radiation pattern enhancement is from the parasitic to the driver, or it is referred to as a *director* when the radiation enhancement is from the driver to the parasitic. A reflector and director can be obtained by properly adjusting the length of the parasitic. Usually, a reflector is cut longer than the driver and a director is cut shorter than the driver, so that the main beam is enhanced in the same direction by both reflector and director. Numerous curves (Hall, 1992) are available to show the effect of element spacings and lengths on input resistance, input reactance, front-to-back ratio, gain, and radiation patterns. These features are for two, three, and four element Yagis. Generally a Yagi having closely spaced elements has a low-radiation resistance and suffers from having a narrow bandwidth of 3–5% of the center frequency.

The numerical electromagnetic codes described in the first subsection of Sec. 13.1.3 are suitable for analyzing Yagi arrays. However, these codes can only be used for thin-wire analysis (wire radius less than 0.01λ). They do have limitations on the radius of the elements and are considered to be thin-wire codes. There are many applications where thick wires are used to construct antennas. The same wire radius for relatively lower frequencies are no longer a thin wire at a much higher frequency. Also, thick wires, such as large diameter aluminum or copper tubing, are often used to increase antenna radiation resistance, lower power loss, as well as to increase mechanical stability. In any of these cases, the thin wire codes in the first subsection of Sec. 13.1.3 can no longer provide accurate results. The electromagnetic code developed at the Pennsylvania State University, discussed in the second subsection of Sec. 13.1.4, has improved the moment method to allow very thick conductors to be modeled (wire radius from 0.01 to 0.1λ) and, consequently, can give improved accuracy in the design of a Yagi. Figure 13.18 shows the geometry for a six-element Yagi array where a thicker wire was used for the driven element.

The maximum gain of a Yagi can be improved by increasing the number of directors. However, there is no significant improvement by having more than one reflector (Stutzman and Thiele, 1981). The gain or the front-to-back ratio (front-to-back ratio was discussed in an earlier section) can be controlled by adjusting the spacing between elements and the length of the elements.

Input impedance, which is measured at the feeding point of the driver, is affected by the reflector and directors due to the mutual coupling effect. The amount of effect on resistance and reactance on the driven element by the parasitic depends on the spacing and the length of the elements. A good front-to-back ratio gives maximum forward signal and minimum rearward signal. Normally, the best front-to-back ratio can not be obtained without sacrificing the maximum gain. An optimum design, which gives a maximum front-to-back ratio with a small sacrifice in gain, is obtainable by proper adjustment of the spacing and length of Yagi elements.

Tables 13.3 and 13.4 give design data for thin-wire and thick-wire antennas, respectively. Yagis having 3–7 elements provide the designer with the various options for gain and input impedance. (All calculations were made with the Pennsylvania State University method of moments code discussed earlier). Note the dramatic increase in input impedance for the case of a six-element Yagi array that was achieved by using a thicker driven element.

13.1.5 Apertures

Equivalence Theorem

The calculation of the characteristics of a wire antenna started from the knowledge of the current distribution. In the case of an aperture antenna, shown in Fig. 13.1(e), there is no easy solution to finding the distribution of current. In this case the currents that flow on the inner surfaces of the waveguide and the horn are the primary currents responsible for radiation. Problems of this type are more easily solved using the *equivalence theorem*. The theorem states that if the electric and magnetic fields are known over a closed surface, then this surface can be replaced by a distribution of magnetic and electric surface currents. Maintaining the inner volume of the closed surface as source free, then the two surface currents can reproduce the fields exterior to the closed surface. This equivalence leads to powerful methods for analyzing apertures. The electric and magnetic surface currents are given by

$$\begin{aligned} \mathbf{J}_s &= \mathbf{n} \times \mathbf{H}_A \\ \mathbf{M}_s &= -\mathbf{n} \times \mathbf{E}_A \end{aligned} \quad (13.84)$$

where

- $\mathbf{J}_s, \mathbf{M}_s$ = electric and magnetic surface currents
- \mathbf{n} = unit outward normal to the closed surface
- $\mathbf{H}_A, \mathbf{E}_A$ = magnetic and electric fields over the closed surface

In the case of an aperture, the closed surface would include the open aperture, such as the mouth of the horn. Even in this case, knowledge of the distribution of the electric and magnetic fields over the aperture is not known exactly. One can use, for instance, waveguide theory to estimate the field distribution over

TABLE 13.4 Characteristics of Equally Spaced Yagi–Uda Antennas (driven element radius = .015λ, all other conductor radii = .0015λ)

No. of Elements	Spacing, λ	Reflector, λ	Driver, λ	Directors, λ	Gain, dB	Z _{in} , Ω
3	0.25	0.479	0.453	0.451	9.54	35.71 + j65.16
4	0.25	0.486	0.463	0.456	11.08	35.70 + j65.16
5	0.25	0.477	0.451	0.442	11.04	17.92 + j59.84
6	0.25	0.484	0.459	0.446	12.20	70.34 + j56.04
7	0.25	0.477	0.454	0.434	12.07	34.84 + j59.43

the aperture. Or in some instances a good engineering guess can be made. With these approximations in mind, the equivalence theorem still remains a good technique for calculating the radiation characteristics of aperture structures.

Huygens' Sources

Figure 13.19 gives the geometry for an elementary aperture of dimensions $dx \times dy$ having a uniform electric field E_{XA} distribution across it. Visualizing this distribution as part of a wavefront, then the magnetic field distribution H_{YA} is computed based on the electric field and the intrinsic impedance, η_0 , of free space; that is, $H_{YA} = E_{XA}/\eta_0$. Applying the equivalence theorem, it can be shown that the far field from this elementary aperture is

FIGURE 13.19 Geometry of an elementary aperture: a Huygen's source.

$$E_\theta = \frac{jE_{XA}dx dy e^{-j\beta r}}{2\lambda r} \cos\phi(1 + \cos\theta) \tag{13.85}$$

$$E_\phi = \frac{-jE_{XA}dx dy e^{-j\beta r}}{2\lambda r} \sin\phi(1 + \cos\theta) \tag{13.86}$$

The application of these results to a larger aperture is found from Huygens' principle. This states that each point on a wavefront sends out secondary waves that can be combined to form a new wavefront. Thus by knowing the distribution of amplitude and phase of the fields across the aperture under examination, the superposition of the Huygens' source fields across the aperture can determine the remote field on a wavefront elsewhere.

Practical Apertures

Figure 13.20 shows several practical aperture antennas. Figure 13.20(a) to Figure 13.20(d) pertain to horn types, whereas Fig. 13.20(e) is the paraboloidal antenna, which is popular with satellite television receiving systems for home use. Shown in Fig. 13.20(a) to Fig. 13.20(c) is a TE_{10} electric field distribution. The terminology TE_{10} implies a transverse electric field, as shown, with one-half of a cosine variation in one direction and no variation in the other direction, hence the subscript 10. In Fig. 13.20(a), it is called a

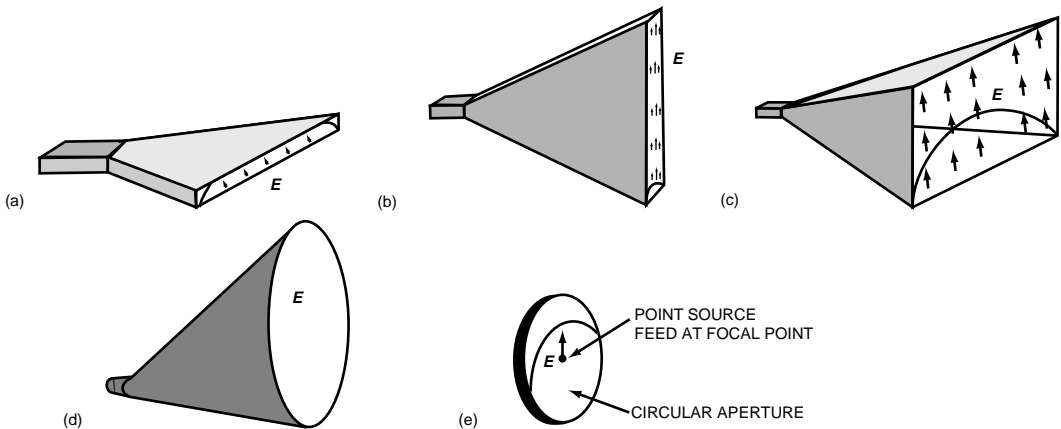

FIGURE 13.20 Some practical aperture antennas: (a) sectoral H -plane, (b) sectoral E -plane, (c) pyramidal, (d) conical, (e) paraboloid.

TABLE 13.5 Characteristics of a Circular Aperture of Radius a with Uniform Excitation

Parameter	Result
Radiation pattern	$\frac{2J_1(\beta a \sin \theta)}{\beta a \sin \theta}$

Directivity	$\frac{4\pi}{\lambda^2} (\pi a^2)$
Side lobe level, dB	-17.6

sectorial H -plane because the horn is flared out in the H -field direction; whereas in Fig. 13.20(b), the horn is a sectorial E -plane because the horn is flared out in the E -field direction. Flaring out in both directions gives the pyramidal horn shown in Fig. 13.20(c). Universal radiation patterns and directivity curves (Stutzman and Thiele, 1981) provide design data.

The paraboloidal antenna derives its name from the paraboloidal shape of the reflecting metallic surface. A source is placed at the feed point, like a horn, and the reflected wave illuminates the circular aperture. For the simplistic case of a uniform field distribution over the circular aperture, the useful parameters for this case are given in Table 13.5.

The quantity J_1 is the Bessel function of the first kind of order unity. Although a uniform distribution is not realistic, it shows the general characteristics of a paraboloidal reflector antenna. For more accuracy, it is usually assumed that there is a parabolic taper (Stutzman and Thiele, 1981) to the field distribution with the maximum being at the center and tapering to smaller values at the edge of the circular aperture. The value of the field at the edges is a function of the beamwidth of the feed antenna.

13.1.6 Wideband Antennas

Antennas can be designed to work over several octaves in frequency. Dipoles or arrays of dipoles as discussed in earlier sections are very frequency dependent. This section discusses some of the principles that in the ideal sense lead to frequency-independent characteristics. Generally, the ideal structure is infinite in extent; hence, it is not practical. However, truncating these ideal structures to finite dimensions can lead to wide-band operation.

Frequency-Independent Principles

There are two basic concepts that are inherent in the conception of a frequency-independent antenna. The first is to arrive at a geometry of conductors that can be defined independent of a dimension. For it is the lengths, spacings, and diameters of wires that appear in the electromagnetic formulas as a ratio to wavelength, thus changing frequency results in nonconstant antenna characteristics. If a structure can be defined only by angles, then one eliminates the characteristic dimensions that are responsible for the frequency dependence of an antenna. Figure 13.21 shows the infinite bow tie and infinite biconical antenna. These structures when truncated in length are no longer frequency independent. They do find usefulness for increasing the bandwidth over a cylindrical wire dipole. This concept of defining a structure entirely by angles is due to Rumsey (1966).

A second concept is centered around a self-complementary planar structure. If the metallic part of the antenna is replaced by free space and the free space is replaced by metal, then this forms the complement of the structure. If the complementing results in the same original structure except for a rotation, then this is a self-complementary structure. In Fig. 13.21, if the infinite bow tie has α equal to 90° for instance, then this can create a self-complementary structure. It has been shown (Stutzman and Thiele, 1981) that the input impedance relationship between an antenna and its complement is

$$Z_A(f) \times Z_{AC}(f) = \frac{Z_0^2}{4} \quad (13.87)$$

FIGURE 13.21 Two antenna shapes defined by an angle α : (a) bow tie, (b) biconical.

where $Z_A(f)$ and $Z_{AC}(f)$ are the input impedances for the antenna and its complement and $Z_0 = 120\pi$ is the characteristic impedance of free space. For a self-complementary structure $Z_A = Z_{AC}$, since it is exactly the original structure, so that

$$Z_A(f) = Z_{AC}(f) = 60\pi \ \Omega \tag{13.88}$$

From this one infers that the input impedance is independent of frequency and equals $60\pi \ \Omega$.

The spiral shape has been used to develop a series of wide-band antennas. Figure 13.22 shows two arms of an antenna constructed from conductors with edges forming a spiral shape. The equation of a single spiral as shown in Fig. 13.23 is

$$\rho = \rho_0 e^{a\phi} \tag{13.89}$$

where

ρ_0 = radius when $\phi = 0$

a = constant that controls the rate of expansion of the spiral

This is an infinite spiral, it continues into the origin as well as out to infinity. It is completely described by an angle and not by any characteristic dimensions. The parameters ρ_0 and a control the specific characteristics of the spiral. The shape in Fig. 13.22 is shown with truncation near the origin. In practice, the feed is connected to the two conductors near the origin. The antenna in Fig. 13.22 can be made self-complementary and, if infinite in extent, will be frequency independent as already discussed. Truncation at the feed point leads to an upper useful frequency limit, whereas truncation of the outer region leads to a lower frequency limit. Wide-band operation is achieved by controlling the dimensions of the truncated regions.

FIGURE 13.22 Spirals for forming the two arms of a self-complementary antenna.

Log-Periodic Antennas

The most practical form of a wide-band antenna originates from the log-periodic dipole array (LPDA) (Stutzman and Thiele, 1981). The property of a spiral like that shown in Fig. 13.23 is that the ratio of distances from the origin of adjacent arms is a fixed quantity τ . This idea is carried over into the design of the

LPDA shown in Fig. 13.24. The dimensions that are scaled by the factor τ are the lengths of the elements L , the diameters of the wire conductors $2a$, and the positions R of the elements measured from the apex

$$\tau = \frac{R_{n+1}}{R_n} = \frac{L_{n+1}}{L_n} = \frac{a_{n+1}}{a_n} \tag{13.90}$$

At frequency f_n , the element of length L_n has a certain length in fractional wavelengths. If the frequency is increased to f_n/τ , then the next smallest element of length L_{n+1} has the same fractional length in wavelengths as the previous element. Therefore, the array in total is scaled as the frequency is increased to $f_n/\tau, f_n/\tau^2, f_n/\tau^3$, etc. This relationship allows the array to be scaled to each of these frequencies so that it is expected that the performance of the array at these frequencies should be identical. This would be absolutely true if the LPDA were infinite in both directions toward and away from the origin. Because the relationship of the frequencies is τ , the performance is repeatable in $\log f$, hence the name log periodic. A useful design curve for finding the gain of a LPDA is given in Figs. 6–30 of Stutzman and Thiele (1981). Note the optimum gain is defined at the point where the parameter τ is the smallest, thus leading to a smaller number of required elements. In practice, the lowest frequency of operation is where the longest element is approximately a half-wave long and the upper frequency of operation is where the shortest element is approximately a half-wave long,

$$L_1 \simeq \frac{\lambda_{\text{lower}}}{2} \tag{13.91}$$

and

$$L_N \simeq \frac{\lambda_{\text{upper}}}{2} \tag{13.92}$$

The mainbeam of the LPDA is away from the apex, that is, toward the shortest elements. A few extra elements are added onto each end for approximately complying with the idea that the structure should be infinite in the direction of the traveling wave.

FIGURE 13.23 Basic spiral shape.

FIGURE 13.24 LPDA geometry.

Frequency Independent Phased Arrays

If the LPDA is part of an array, for example, of equally spaced elements, such as those discussed in [Sec. 13.1.3](#) (Pattern Multiplication subsection), then a characteristic dimension is introduced (the spacings between the LPDAs) and the wide-band operation can be seriously affected. A concept for maintaining log-periodic behavior and still arraying the elements is found in the three-dimensional frequency-independent phased array (FIPA) (Breakall, 1992). In this array, elements in the log periodic, which make up this array, are positioned such that each wire's height above a ground plane is some constant (i.e., 0.25λ) in wavelengths at each wire's resonant frequency. At the prescribed height in wavelengths above the ground plane, each wire's center is also at a constant spacing distance in wavelengths (i.e., 0.60λ) from adjacent wire centers. Scaling of the antenna elements in a log-periodic sense causes the physical wire lengths, heights, and interwire spacings to get progressively smaller as one moves toward the feed end of the element. The scaling factor is the same τ factor as used in the classical log-periodic design.

Figure 13.25 shows an overhead view of a 4×4 circularly polarized model of the three-dimensional FIPA. The dark highlighted wires depict the planar nature of the array with the excitation frequency creating large currents at the resonant element frequency. The figure is shown for operation at a midfrequency. The 4×4 planar array maintains fixed lengths, spacings, and heights in wavelengths as the frequency is changed. Therefore the gain, impedance and radiation pattern remain fairly constant making this a respectable wide-band array. The feed wires shown in this figure are a single wire for simplicity.

The three-dimensional FIPA antenna described overcomes traditional phased-array limitations by using arrays of log-periodic elements.

FIGURE 13.25 A 4×4 3D-FIPA (top view) shown excited at the midfrequency.

Self-Similar Fractal Antennas

It has been recognized that one of the fundamental properties of frequency-independent antennas is their ability to retain the same shape under certain scaling transformations. It has been demonstrated that this property of self-similarity is also shared by many fractals (Mandelbrot, 1983). This commonality has led to the notion that fractal geometric principles be used to provide a natural extension to the traditional approaches for classification, analysis, and design of frequency-independent antennas (D.H. Werner and P.L.Werner). This theory allows the classical interpretation of frequency-independent antennas to be generalized to include the radiation from structures that are not only self-similar in the smooth or discrete sense but also in the rough sense.

The standard approach of categorizing frequency-independent antennas is to consider them as being constructed from a multiplicity of adjoining cells. Each cell is identical to the previous cell except for a scaling factor. This periodicity may be characterized in terms of the constant tau (Lo and Lee, 1988)

$$\tau = D_n/D_{n+1} \tag{13.93}$$

where D_n represents the dimension of the n th cell and D_{n+1} represents the dimension of the next adjoining cell. In view of the recent introduction of fractal geometry, however, a natural extension to this classical definition of broadband antennas is to consider them as being composed of a sequence of self-similar cells with a similarity factor of τ . For instance, scaling the logarithmic spiral defined in Eq. (13.89) by a factor of τ yields the same spiral rotated by a constant angle $\ell n(\tau)/a$. This suggests that the logarithmic spiral is self-similar, with a similarity factor $\tau = e^{2\pi|a|}$. If rotations are disregarded, however, then the logarithmic spiral can be considered self-similar for any real scaling factor τ . The self-similarity arguments developed for the log spiral are easily generalized to apply to the conical log spiral as well.

Another example of a broadband antenna in common use is the log-periodic dipole antenna discussed earlier in this section. Log-periodic dipole antennas exhibit self-similarity in their geometrical structure at discrete frequencies, as illustrated by Fig. 13.26. The lengths and spacings of adjacent dipole elements are scaled by the same similarity factor τ . Figure 13.26 also demonstrates how the log-periodic dipole antenna may be constructed through the use of an initiator and an associated generator.

The scaling properties of log-periodic dipole antennas have also been exploited in the design of a three-dimensional frequency-independent phased array (3D-FIPA) presented earlier in this section. The 3D-FIPA concept can be thought of as having many separate $N \times N$ vertically stacked self-similar planar dipole subarrays. The lengths, heights, and horizontal spacings of the dipoles in each consecutive subarray are physically scaled by a similarity factor of τ . This has the desired effect of ensuring that the dimensions of each dipole subarray remain electrically invariant. Other concepts for broadband arrays of log periods

FIGURE 13.26 Fractal geometric description of a log-periodic dipole antenna with initiator and generator.

are discussed in Duhammel and Berry (1958), Mei and Moberg (1965), and Johnson and Jasik (1984), which also take advantage of self-similarity in their designs.

A special class of nonuniformly but symmetrically spaced linear arrays, known as Weierstrass arrays, which possess a self-similar geometrical structure, have been investigated in D.H. Werner and P.L. Werner (1996, 1995) and Werner (1994). It can be shown that the array factor of a Weierstrass array satisfies the self-similarity relation

$$f(\gamma v) = \gamma^{(2-D)} f(v) \tag{13.94}$$

when

$$v = \cos \theta - \cos \theta_0 \tag{13.95}$$

and

$$\gamma = \tau^k \quad \text{for } k = 0, 1, 2, \dots \tag{13.96}$$

provided $0 < \tau < 1$ and $1 < D < 2$. The parameters τ and D represent the similarity factor and fractal dimension, respectively. The box-counting definition of fractal dimension for a given fractal F was adopted in this case. In other words

$$D = \lim_{\delta \rightarrow 0} \frac{\ell n N_\delta(F)}{\ell n(1/\delta)} \tag{13.97}$$

where N_δ represents the smallest number of sets of diameter at most δ required to cover the fractal F (Falconer, 1988). The connection between the box-counting definition of fractal dimension and the intuitive Euclidean concept of dimension is discussed in Voss (1988) and Jaggard (1990).

The self-similarity in the geometrical structure and radiation pattern of infinite Weierstrass arrays suggest that they may be used as multiband arrays that maintain the same radiation characteristics at an infinite number of frequencies. For example, this multiband performance may be achieved by selecting a sequence of discrete frequencies that satisfy the relationship

$$\frac{f_{k+1}}{f_k} = \tau \quad \text{for } k = 0, 1, \dots \tag{13.98}$$

By making use of the multiband properties of Eqs. (13.94), (13.96) and (13.98), it may easily be demonstrated that the directive gain obeys the relationship

$$G(\gamma v) = \frac{|f(\gamma v)|^2}{\frac{1}{2} \int_{-1-u_0}^{1-u_0} |f(\gamma v)|^2 dv} = \frac{|f(v)|^2}{\frac{1}{2} \int_{-1-u_0}^{1-u_0} |f(v)|^2 dv} = G(v) \tag{13.99}$$

where $u_0 = \cos \theta_0$. This suggests that the directive gain of an infinite Weierstrass array is a log periodic function of frequency with a log period of τ , that is

$$G(w) = G(w + kT) \quad \text{for } k = 0, 1, \dots \tag{13.100}$$

where

$$w = \log v \tag{13.101}$$

$$T = \log \tau \tag{13.102}$$

Defining Terms

Dipole antenna: A straight length of wire excited by a signal source at its center.

Directivity: Provides a measure of performance compared to a reference antenna, such as the isotropic element.

- Fraunhofer region:** The region that the field from an antenna is a good representation of the far-field expected values. The pattern is essentially independent of the distance from the antenna.
- Frequency independent:** The term used to define an antenna that has some parameter, such as impedance, independent of frequency. This is an idealization but the concepts can lead to broadband operation.
- Fresnel region:** In this region the pattern is dependent on the distance from the antenna and does not represent the far-field expected values.
- Isotropic source:** A fictitious antenna element that radiates equal intensity in all directions. This source is usually the reference antenna element to which gain or directivity of an actual antenna is compared to.
- Log periodic:** A particular type of broadband antenna in which an antenna parameter, such as impedance, is essentially constant at multiple frequencies that are related logarithmically.
- Loop antenna:** A type of antenna that is constructed by bending a thin wire into a closed contour.
- Method of moments:** A numerical method for transforming an integral equation to an associated matrix equation, which can then be readily solved using a computer.
- Numerical electromagnetic code:** Various antenna software that compute the parameters of an antenna method of moments formulation. NEC, MININEC, and ELNEC are names of some of the popular codes for modeling antennas.
- Sommerfeld/Norton solution:** A technique that provides the exact solution for fields of wires in the presence of a ground. It is used in antenna modeling software such as NEC for greater accuracy when wires are close to ground.
- Surface impedance:** The ratio of the tangential electric field on a conductor divided by the resulting linear current density that flows in the conductor.
- Uniform theory of diffraction (UTD):** Concept allows diffracted fields to be computed for various types of incident waves, such as spherical, plane, and cylindrical.
- Yagi-Uda:** A Form of antenna array in which there is only one driven element. The other elements derive the current excitations from the mutual coupling between elements. Element spacing must be a small fraction of a wavelength in order to have sufficient current excitation.

Further Information

Additional information on Antenna Technology is available from the following sources:

The IEEE Antennas and Propagation Society (AP-S) publishes a monthly journal, *IEEE Transactions on Antennas and Propagation*, and holds an annual conference. IEEE Headquarters is located in Piscataway, NJ.

International Unions of Radio Science (URSI) holds an annual meeting in conjunction with AP-S in the summer and publishes abstracts of conference papers. URSI is headquartered in Brussels, Belgium.

Radio Science is a bimonthly journal, which is published by the American Geophysical Union and cosponsored by International Union of Radio Science (URSI). The American Geophysical Union is headquartered in Washington, D.C.

13.2 Radio Wave Propagation

Gerhard J. Straub

13.2.1 Introduction

From the sparks of the beginning of radio to the present day congested radio frequency environment, the understanding of radio wave propagation plays a vital role in any communications system. With the ever increasing demand to communicate farther with less power and with less interference comes the demand to know how to design a reliable radio frequency propagation path and how to evaluate the potential for system outages and interference. Without a firm grasp of radio wave propagation principles, the system engineer may be forced to specify equipment with performance in excess of that necessary so as to feel secure that the planned communications system will perform as expected. Use of higher than necessary power to establish the desired communications link may result in better path reliability; however, there is the increased risk of interference to others and, in many instances, a violation of applicable rules and regulations. The basics of radio wave propagation are the same whether one is designing a system for operation at 100 kHz or 1000 MHz, but each frequency range has its own advantages, disadvantages, and peculiarities that must be understood if optimum use of the electromagnetic spectrum is to be achieved.

13.2.2 Radio Wave Basics

To visualize a radio wave, consider the image of a sine wave being traced across the screen of an oscilloscope. As the image is traced, it sweeps across the screen at a specified rate, constantly changing amplitude and phase with relation to its starting point at the left side of the screen. Consider the left side of the screen to be the antenna, the horizontal axis to be distance instead of time, and the sweep speed to be the speed of light, or at least very close to the speed of light, and the propagation of the radio wave is visualized. To be correct, the traveling, or propagating, radio wave is really a wavefront, as it comprises an electric field component and an orthogonal magnetic field component as shown in Fig. 13.27. The distance between wave crests is defined as the **wavelength** and is calculated by

FIGURE 13.27 Propagation of wavefront.

$$\lambda = \frac{c}{f}$$

where

λ = wavelength, m

c = the speed of light, approximately 2.998×10^8 m/s

f = frequency, Hz

At any point in space far away from the antenna, on the order of 10 wavelengths or 10 times the aperture of the antenna to avoid near-field effects, the electric and magnetic fields will be orthogonal and remain constant in amplitude and phase in relation to any other point in space. The polarization of the radio wave is defined by the polarization of the electric field, horizontal if parallel to the Earth's surface and vertical if perpendicular to it. Typically, polarization can be determined by the orientation of the antenna radiating elements.

An **isotropic antenna** is one that radiates equally in all directions. To state this another way, it has a gain of unity. If this isotropic antenna is located in an absolute vacuum and excited with a given amount of power at some frequency, as time progresses the radiated power must be equally distributed along the

surface of an ever expanding sphere surrounding the isotropic antenna as in Fig. 13.28. The power density at any point on the surface of this imaginary sphere is simply the radiated power divided by the surface area of the sphere, or,

$$P_d = \frac{P_t}{4\pi D^2}$$

where

- P_d = power density, W/m²
- D = distance from antenna, m
- P_t = radiated power, W

FIGURE 13.28 Power density distribution for an isotropic radiator.

Since power and voltage, in this case power density and electric field strength, are related by impedance, it is possible to determine the electric field strength as a function of distance given that the impedance of free space is taken to be approximately 377 Ω

$$E = \sqrt{ZP_d} = 5.48 \frac{\sqrt{P_t}}{D}$$

where E is the electric field strength in volts per meter. Converting to units of kilowatts for power, the equation becomes

$$E = 173 \frac{\sqrt{P_t(kW)}}{D} \text{ V/m}$$

which is the form in which the equation is usually seen. Since a half-wave dipole has a gain of 2.15 dB over that of an isotropic radiator (dBi), the equation for the electric field strength from a half-wave dipole is

$$E = 222 \frac{\sqrt{P_t(kW)}}{D} \text{ V/m}$$

From these equations it is evident that, for a given radiated power, the electric field strength decreases linearly with the distance from the antenna and power density decreases as the square of the distance from the antenna.

13.2.3 Free Space Path Loss

A typical problem in the design of a radio frequency communications system requires the calculation of the power available at the output terminals of the receive antenna. Although the gain or loss characteristics of the equipment at the receiver and transmitter sites can be ascertained from manufacturer’s data, the effective loss between the two antennas must be stated in a way that allows for the characterization of the transmission path between the antennas. The ratio of the power radiated by the transmit antenna to the power available at the receive antenna is known as the *path loss* and is usually expressed in decibels. The minimum loss on any given path occurs between two antennas when there are no intervening obstructions and no ground losses. In such a case when the receive and transmit antennas are isotropic, the path loss is known as **free space path loss**.

If the transmission path is between isotropic antennas, then the power received by the receive antenna is the power density at the receive antenna multiplied by the effective area of the antenna and is expressed as

$$P_r = \frac{P_t A}{4\pi D^2}$$

where A is the effective area of the receive antenna in square meters.

FIGURE 13.29 Path loss variables.

The effective area of an isotropic antenna is defined as $\lambda^2/4\pi$. Note that an isotropic antenna is not a point source, but has a defined area; this is often a misunderstood concept. As a result, the received power is

$$P_r = \frac{P_t}{4\pi D^2} \cdot \frac{\lambda^2}{4\pi} = P_t \left(\frac{\lambda}{4\pi D} \right)^2$$

The term $(\lambda/4\pi D)^2$ is the free space path loss. Expressed in decibels with appropriate constants included for consistency of units, the resulting equation for free space path loss, written in terms of frequency, becomes

$$L_{fs} = 32.5 + 20 \log D + 20 \log f$$

where

D = distance, km

f = frequency, MHz

The equation for the received power along a path with no obstacles and long enough to be free from any near-field antenna effects, such as that in Fig. 13.29, then becomes

$$P_r = P_t - L_t + G_t - L_{fs} + G_r - L_r$$

where

P_r = received power, dB

P_t = transmitted power, dB

L_t = transmission line loss, dB

G_t = gain of transmit antenna referenced to an isotropic antenna, dBi

L_{fs} = free space path loss, dB

G_r = gain of receive antenna, dBi

L_r = line loss of receiver downlead, dB

It should be pointed out that the only frequency-dependent term in the equation for free space path loss occurs in the expression for the power received by an isotropic antenna. This is a function of the antenna area and, as stated previously, the area of an isotropic radiator is defined in terms of wavelength. As a result, the calculated field strength at a given distance from sources with equal radiated powers but on frequencies separated by one octave will be identical, but the free space path loss equation will show 6-dB additional loss for the higher frequency path. To view this another way, for the two paths to have the same calculated loss, the antennas for both paths must have equal effective areas. An antenna with a constant area has higher gain at higher frequencies. As a result, to achieve the same total path loss over these two paths, the higher frequency path requires a higher gain antenna, but the required effective areas of the antennas for the two paths are equal. The most important concept to remember is that the resultant field strength and power density at a given distance for a given radiated power are the same regardless of frequency, as long as the path approximates a free space path, but that the free space path loss increases by 6 dB for a doubling of frequency or distance.

The representation of the radio wave path in Fig. 13.29 and the previous discussion have only considered a direct path between the receiver and transmitter. In reality, there are two major modes of propagation: the **skywave** and the **groundwave**. The skywave refers to propagation via the ionosphere, which consists of several layers of ionized particles in the Earth's atmosphere from approximately 50 to several hundred kilometers in altitude. Some frequencies will be reflected by the ionosphere resulting in potentially long-distance propagation. This propagation mode is discussed in detail in a later section.

The other major mode of propagation is known as groundwave propagation. Groundwave propagation itself consists of two components, the space wave and the surface wave. The space wave also has two components known as the direct path and the reflected path. The direct path is the commonly depicted line-of-sight path that has been previously discussed and is represented in Fig. 13.29. The reflected path is that path that ends at the receiver by way of reflection from the ground or some other object. Note that there may be multiple reflected paths. The surface wave is that portion of the wavefront that interacts with and travels along the surface of the Earth. The surface wave, which will be discussed in more detail in the next section, is commonly incorrectly called the groundwave.

13.2.4 Reflection, Refraction, and Diffraction

As with light, the direction of propagation of a radio wave may be changed by reflection, **refraction**, or **diffraction**. Like light from a mirror, the propagation of a radio wave may be abruptly changed by reflection from a smooth surface. Smooth in this case is a relative term since the surface must be smooth in terms of wavelength. As a result, although a surface may not appear smooth to the eye of an observer, that is at optical frequencies, the surface may be very smooth and serve as an excellent reflector at the frequencies of interest. Reflection from a perfectly conducting surface results in no energy loss and a complete phase reversal at the reflecting surface. In reality some energy will be lost in the process, as there is no such perfectly conducting surface to be found, but large metal objects or bodies of water may come very close. Perfect reflection results in equal angles of arrival and departure of the direct and reflected wavefronts relative to the reflecting surface.

Assume for a moment that an RF propagation path has been established parallel to and at some height above a perfectly conducting surface. The receive antenna will intercept the transmitted energy by two separate paths: the direct path and the reflected path from the conducting surface. There will be a path height such that the total reflected path length will be 180° longer than the direct path. At this height, the direct and reflected fields will add to result in a 6-dB increase in field strength, since there is a 180° change in phase at the point of reflection. The path height at the point of reflection under these conditions is known as the radius of the first **Fresnel zone** (Fig. 13.30). As the path height at the point of reflection is increased farther, a point will be reached where the direct and reflected paths will be equal in terms of phase. At this point, due to the phase reversal at the reflection point, the fields from the direct and reflected paths will cancel. The height of the path above the reflection point under these conditions is known as the radius of the second Fresnel zone. These conditions repeat themselves as the path height is increased with every odd Fresnel zone radius resulting in a field strength increase and every even Fresnel zone radius resulting in field strength cancellation, or at least a very significant reduction. The Fresnel zone radius increases with increasing distance from the transmitter reaching a maximum at the path midpoint and then decreases with decreasing distance to the receiver. This is a three-dimensional phenomenon, since reflections may occur from a surface on any side of the path. To be more precise, the first Fresnel zone is defined as the locus of all points from which a reflected path will have a pathlength one-half wavelength greater in length. These points form an ellipsoid with the transmitter and receiver antennas as focal points.

FIGURE 13.30 First Fresnel zone: Reflected path length equals direct path length plus 180° .

Although it is not necessarily incorrect, and many times in fact useful, to visualize the path of the radio frequency energy as a ray between the transmitting and receiving antennas, the path actually has dimensions that are important to the path designer. It is generally accepted that an RF path must have at least 0.6 Fresnel zone radius clearance to any obstruction to be considered an unobstructed or free space path for which the free space path loss equation is directly applicable. A formula for calculating the approximate first Fresnel zone radius at any point along the path is

$$F_1 = \frac{\sqrt{(D - d_1)d_1\lambda}}{D}$$

where

F_1 = radius of the first Fresnel zone

d_1 = distance from the transmitter to the point of interest

Assuming a 50-km path the radius of the first Fresnel zone at the path midpoint is approximately 61 m at 1 GHz, 194 m at 100 MHz, and 612 m at 10 MHz. From these examples, it is apparent that free space path loss conditions do not often exist for lower frequency systems. If there is less than 0.6 Fresnel zone radius clearance on a given path, then it is presumed that diffraction effects must be considered.

Diffraction may occur on any path that does not meet the requirements for free space propagation. When an obstacle is placed in the path of an electromagnetic wavefront, some energy may be bent around the obstacle such that areas expected to be completely shadowed from the source of the energy may actually receive a signal. This diffraction is really an interference effect between the radiated energy from the source and currents induced in the surface of the obstruction. Any time a path is subject to diffraction effects, losses greater than those predicted by free space path equations will occur. The minimum additional loss occurs when the path is partially obstructed by a sharp edge. This is known as *knife-edge diffraction* and paths may actually be designed to rely on this propagation mode. Where a path is at grazing or near grazing incidence over a gently rolling surface, such as a smooth hill or the surface of the Earth, losses can be very high and may render the path unusable. Several methods for calculating diffraction losses have been developed, including those of the National Institute of Standards and Technology compiled in a long standing reference for non-line-of-sight propagation loss calculation methods (Rice et al., 1967). It should be understood that although propagation paths using a mode such as knife-edge diffraction are sometimes said to have obstacle gain, the total path loss will never be less than that of a free space path of the same length.

Refraction is a change of direction of the wavefront due to a change of the refractive index of the medium of propagation. As a wavefront, either at light or radio frequencies, passes through the interface between two media with different refractive indices, as shown in Fig. 13.31, the velocity of propagation of the portion of the wavefront entering the medium with the smaller refractive index will be increased relative to that in the denser medium. As the entire wavefront enters the new medium, the resulting effect will be to change the direction of propagation of the wavefront. The medium through which terrestrial communications travel is the Earth's atmosphere, which decreases in density, as well as refractive index, as the altitude increases. As a result, as the wavefront increases in altitude, it undergoes a constant bending back toward the Earth.

An interesting effect of this atmospheric refraction is that, depending on the actual conditions at the time, the radio horizon may be closer or farther away than the true horizon. For an antenna aimed at the horizon, with no intervening terrain or other obstructions, the radiated energy, using a ray analogy, travels toward the horizon. At the horizon, as the Earth's surface curves away, the path of propagation begins to increase in altitude. As the altitude increases, the density of the atmosphere decreases and the propagation

FIGURE 13.31 Effect of refraction: The wavefront is bent toward the denser medium.

path is gradually bent back toward the surface of the Earth, effectively traveling beyond the horizon and somewhat following the curvature of the Earth. As a result, the effective communications range, even for line-of-sight type links, is somewhat beyond the horizon due to the refraction. Stated another way, the distance to the radio horizon, or the **effective Earth radius**, has been increased.

Under typical atmospheric conditions, the effective Earth radius used in propagation planning is 4/3 of the actual Earth radius. Assuming 4/3 Earth radius, the distance to the radio horizon derived from equations in White (1975) can be calculated by

$$d = 3.56\sqrt{Kh}$$

where

- d = distance to the radio horizon, km
- h = height of the antenna above ground, m
- K = effective Earth radius multiplier, usually 4/3

By rearranging this equation, the amount of Earth bulge at any point along a path can be calculated by

$$h = \frac{(D - d_1)d_1}{12.69K}$$

where h is the height of the Earth bulge in meters and D and d_1 are expressed in kilometers.

To aid in planning line-of-sight propagation paths without performing calculations, many times the desired path is plotted on what is known as 4/3 Earth paper as shown in Fig. 13.32. This graph paper is curved with height on the vertical axis and distance on the horizontal axis. The curve of the coordinate system represents the effective curvature of the Earth's surface. The height of the path endpoints as well as the height of significant intervening terrain or manmade obstructions are plotted at the appropriate distances to determine whether or not the path is obstructed. As stated previously, however, clearance of the direct path of transmission based on ray theory is not sufficient, as the radius of the first Fresnel zone must also be considered.

FIGURE 13.32 4/3 Earth paper for path design.

Although the preceding discussion applies generally to all frequencies, each portion of the electromagnetic spectrum has unique qualities that make it suitable for specific tasks. Line-of-sight type links are normally established on VHF and higher frequencies, whereas the lower frequencies are normally suitable for longer distance communications. A brief discussion of the propagation characteristics of various frequency ranges follows.

13.2.5 Very Low Frequency (VLF), Low Frequency (LF), and Medium Frequency (MF) Propagation

This portion of the frequency spectrum includes frequencies below 3 MHz and has been the mainstay of communications systems since the beginning of wireless communications. Use of higher frequencies has only been a relatively recent occurrence. This portion of the spectrum today is primarily used for relatively low data rate, long distance communications and long range navigation. The Omega and LORAN navigation systems operate in this frequency range. Also found in this portion of the spectrum is the familiar AM or medium wave broadcast band. Frequencies in this range are characterized by very stable communications over a relatively large distance. A major disadvantage to this portion of the spectrum is that due to the very long wavelength, greater than 100 m at the high frequency end of this range and measured in terms of kilometers in the lower portion of this range, efficient antennas or antennas with considerable directional characteristics are very difficult to construct. As a result, communications systems operating in this frequency range typically require acres of antennas and transmitters with very high power. Atmospheric and man-made noise can also cause significant disruption to communications on these frequencies.

At these frequencies, propagation is primarily by surface wave and waveguide modes. The direct and reflected waves of the space wave essentially cancel leaving only the surface wave component. Again, due to the proximity of the ground, at least in typical installations, horizontally polarized antennas experience very high losses and so most antennas in this frequency range are vertically polarized. At the very low end of the frequency range, significant surface penetration is possible so that communications with subsurface facilities, submarines for instance, are possible.

When the distance from the surface of the Earth to the lower boundary of the ionosphere is on the order of one wavelength, long distance propagation by waveguide modes is possible. The surface of the Earth forms one boundary of the waveguide and the ionosphere the other. The energy is essentially continually reflected between these two boundaries. At frequencies supporting this mode of propagation, the surface of the Earth can be thought of as a smooth reflecting plane. Propagation via this mode results in characteristics that are quite stable in terms of phase and amplitude, and is influenced by typical waveguide propagation characteristics, including frequency cutoff and reflections due to changes in properties of the waveguide along the path (Aarons et al., 1984).

As the frequency of operation increases into the MF region, propagation by groundwave, or more correctly surface wave, becomes the dominant mode during daytime hours. Skywave propagation is rare during daylight hours due to almost complete absorption by the lower portion of the ionosphere. In this propagation mode, the wavefront travels along the surface of the Earth. As it does so, currents are generated on the surface of the Earth. If the conductivity of the surface is poor, these currents cause energy to be dissipated as heat and attenuation is increased. As a result, propagation range is heavily dependent on the ground conductivity of the desired path with transmission over high conductivity surfaces, such as sea water, providing the greatest range. In spite of this, since ground conductivity along a particular path remains fairly constant, the characteristics of a given path generally remain quite stable. The exception to this is in areas with a significant change in ground moisture content between various seasons. For example, a large change in a particular path could be expected if the soil is generally dry and has a poor conductivity and then is subject to unusual amounts of rainfall.

Another effect of the ground losses is known as *wave tilt*. The wavefront is not confined to the immediate surface of the Earth but extends significantly upward. The ground losses tend to reduce the velocity of travel of the portion of the wavefront nearest the ground. As a result, the electric field vector, instead of remaining

FIGURE 13.33 Ground wave field strength; electric field strength vs. distance for various soil conductivities for the band edges of the AM broadcast band. Conductivities are in millisiemens per meter.

vertical, begins to lean in the direction of travel. This wave tilt becomes more pronounced with increasing frequency, and attenuation increases with increasing wave tilt, as the wavefront alters its polarization from vertical with no horizontal component to having a significant horizontally polarized component, because of the effect of the Earth's short circuiting condition on the horizontally polarized component. This effect and the effect of ground conductivity can be seen in Fig. 13.33 showing FCC propagation curves for the high- and low-frequency limits of the AM broadcasting band for various soil conductivities.

After sunset, when the D layer of the ionosphere (the source of MF skywave attenuation) disappears (see next section), skywave propagation is possible. With this propagation mode, coverage beyond normal surface wave range is possible as the energy directed upward is reflected back to Earth at great distances. This particular mode of propagation is treated in more detail in the next section on HF propagation. It should be noted that not all skywave propagation is beneficial. Energy radiated at high angles can return to Earth within the groundwave coverage area of a station. If the groundwave and skywave field strengths are approximately equal, then severe fading can occur, effectively reducing the groundwave range of that station during daytime hours. Also, skywave interference inside the normal groundwave service area can be experienced from other stations removed by such a distance that groundwave interference is not a concern.

13.2.6 HF Propagation

The HF portion of the radio spectrum, from about 3 to 30 MHz, has recently experienced renewed interest. Systems operating in this frequency range are capable of worldwide communications without the use of satellites or other types of relay stations. This capability can be enjoyed with relatively low-power levels and unsophisticated antennas with consequently relatively low cost.

Beyond horizon propagation on HF circuits is made possible by reflection from the ionosphere. Actually, there are several specific layers that form this region of ionized particles created primarily by solar radiation and occurring from approximately 50 to 350 km above the surface of the Earth. Because of the dependency on solar radiation, the ionization density of these layers, and the resulting propagation characteristics, are highly dependent on not only solar activity variations, but seasonal and diurnal variations as well. As a result, any communications system operating in this region must vary frequency and times of operation for the expected conditions.

HF radio waves interacting with a layer of the ionosphere undergo refraction in the direction of the Earth. If the wave is sufficiently refracted, its path will return to the Earth at some distance from the transmitter, normally well beyond the theoretical radio horizon. This is known as the skywave. It is common to visualize this phenomenon with ray concepts with a reflection from the ionosphere at some virtual height. This virtual height is the height at which a reflection would result in the same downward path as traversed by the refracted wave. Multiple hops are possible as the wave is reflected from the Earth back up to the ionosphere for another pass. The area beyond the usable range of the groundwave and the point of return to Earth of the skywave is known as the skip zone as no usable signal is present in this area. Knowledge of the extent of this zone can be used to establish communications with a low probability of intercept by unwanted receivers. Conversely, inadvertently designing a system with the desired receiver located in the skip zone will yield disappointing results.

The range of single hop propagation and extent of the skip zone are directly related to the virtual height of the ionosphere layer in use and the takeoff angle of the radiated energy from the antenna, the angle between the radiated energy and horizontal, with the longest propagation range and skip zone occurring with the smallest takeoff angle. For some frequency and takeoff angle, there will be insufficient refraction for the wave to be bent far enough to actually return to Earth and the wave penetrates the ionosphere and is lost into space. In areas where the skywave and groundwave are both present at relatively equivalent field strength, severe distortion and fading can occur as the two waves alternatively cancel and reinforce each other. This is a rather annoying problem for some AM broadcasters, who depend primarily on groundwave coverage, and some work has been done on antiskywave antennas to eliminate, or at least significantly reduce, radiation upward toward the ionosphere at high enough angles to return to Earth within the groundwave coverage area. Figure 13.34 demonstrates the interaction of the virtual height, takeoff angle, and communications range.

The virtual height of an ionospheric layer can be measured with a device known as an ionosonde. This device radiates a swept frequency signal directly toward the zenith and times the return echo much like a conventional radar system. Half the round-trip travel time multiplied by the speed of light yields the virtual height of the ionosphere layer. The frequency at which no echo is returned is known as the critical frequency for that layer.

A very useful HF propagation mode is known as *near vertical incidence skywave* (NVIS) propagation. As the name implies, this mode utilizes high-angle radiation to provide relatively short range propagation, perhaps on the order of 0 to several hundred kilometers. Energy radiated toward the zenith, below the

FIGURE 13.34 The mechanism of skywave propagation.

critical frequency of the pertinent ionospheric layer, is reflected down around the transmitter. As a result, frequencies used for NVIS propagation are usually in the lower-half of the HF spectrum. Note that directional characteristics of the transmitting antenna are not important, or necessarily desirable, as the returned energy from the ionosphere forms an essentially omnidirectional radiation pattern around the transmitter.

This form of propagation has found followers in the military and in agencies charged with providing emergency communications. Since the transmitted energy is reaching the receiver from such a high arrival angle, it is essentially unaffected by terrain, foliage, or other terrestrial attenuators, resulting in a relatively uniform field strength throughout the coverage area. Using this propagation mode it is possible to communicate from deep canyons or over local hills and mountains without the use of relays or repeaters that would be required if line-of-sight type propagation modes were being utilized in areas shielded by terrain features. From a security standpoint, this propagation mode is useful as it is extremely difficult to use direction finding techniques to locate the transmitter of a signal that has a very large angle of arrival. For NVIS propagation, it is desirable to have the majority of the radiation aimed at high angles with almost no radiation at the horizon. Specifically, it is important not to have groundwave and skywave propagation paths of similar loss characteristics simultaneously to any given receiver site or signal cancellation or severe fading and distortion could occur. As a result, NVIS antennas are typically horizontally polarized antennas mounted less than one quarter wavelength above ground. Because of the high angle radiation, the resultant antenna pattern and coverage area is essentially omnidirectional.

There are three major layers of the ionosphere that are of importance in HF propagation. The lowest layer of concern is known as the D layer and is only present during daylight hours. Of all of the important ionospheric layers, the D layer is located in the region of highest atmospheric density. Because of this, recombination of ionized particles occurs rather rapidly and constant solar energy is required to sustain ionization in this layer. As the sun sets, this layer recombines and disappears. This layer is primarily responsible for almost complete absorption of frequencies below about 4 MHz. As energy from the electromagnetic wave sets electrons in motion, there is a high probability that the energy will be absorbed in a collision with a neutral particle. More precisely, the electromagnetic energy has been changed to useless, at least for radio wave propagation purposes, kinetic energy. Note that as the angle of incidence of the wave entering the layer is increased, which also means that the takeoff angle from the antenna is increased, the absorption is decreased. This occurs because of the shorter distance traveled in the ionized layer. However, as the angle of incidence is decreased, so is the usable communications range.

The next higher layer of the ionosphere at an altitude of approximately 115 km is the E layer. This is generally considered to be the lowest useful region of the ionosphere. Still low enough so that recombination occurs quickly, this layer is also only present during daylight hours, forming a useful ionized density around midday and disappearing after sunset.

The most useful ionosphere layer for over the horizon propagation is known as the F layer. This layer is located in the least dense portion of the atmosphere at an altitude of approximately 300 km at night. During daylight hours, this layer essentially splits into two separate layers known as the F1 and F2 layers at altitudes of approximately 200 and 300 km, respectively. This layer remains ionized throughout the night with minimum ionization density just before sunrise. [Figure 13.35](#) shows the relative positions of these layers.

In characterizing the propagation characteristics between two geographical locations at a given time of day and time of year with a given level of solar activity, two frequencies are of considerable importance. These are the *maximum usable frequency* (MUF) and the *lowest usable frequency* (LUF). Propagation between the two points must occur on a frequency between these two limits. Lower frequencies require a lower electron density for sufficient refraction for usable service and are consequently reflected from lower ionospheric levels. Also, absorption in the lower levels increases with decreasing frequency. As a result, the LUF is typically determined by the absorption in the lower regions of the ionosphere. The MUF is usually determined by the peak electron density in the ionosphere, which occurs in the F layer, as higher electron density is required for sufficient refraction. The optimum operating frequency, known as the *frequency optimum de travail* (FOT), is typically 75–80% of the MUF where the refracting layer electron density is sufficient for reflection and the absorption in lower ionospheric layers is low. Note that frequencies refracted back to Earth by the F layer experience absorption as they pass through the D and E layers twice,

FIGURE 13.35 The ionosphere.

assuming daytime propagation. As a result, the MUF usually gradually increases to its highest point in the afternoon and then gradually decreases, reaching a minimum during the hours of darkness.

Although HF prediction programs are available that will compute the MUF, LUF, and FOT based on available solar data, HF propagation is subject to some unpredictability, making the choice of frequency and time for a particular propagation path not a precise science. As with line-of-sight-type propagation modes on higher frequencies, HF propagation paths are subject to multipath interference. Ionospheric conditions may support reflection from more than one layer or multiple hop propagation from energy radiated at a higher angle from the transmitter. This type of multipath interference may result in deep fading as the phase of the fields from the two paths alternatively cancel and reinforce each other. Proper system design and choice of frequency can help to reduce this type of interference.

Other HF propagation anomalies are difficult to predict and occur without warning. Many of these anomalies are the result of solar flares. A shortwave fade (SWF) is a sudden and complete absorption of HF radio waves in the D region of the ionosphere. It occurs on the sunlit side of the Earth and is caused by ultraviolet and X-ray emissions from a solar flare. The fade occurs approximately 8 min after the solar event and can last from a few minutes to a few hours. Protons entering the ionosphere near the magnetic poles can cause a complete loss of HF propagation in these regions. This effect may occur several hours after the flare. Ionospheric storms are another potential effect that can drastically alter the expected MUF and may occur one to two days after the solar event. Sporadic ionization in the E layer, known as sporadic E, may occur at any time and is not necessarily solar related. This effect can isolate the F layer, altering the path characteristics such that communication is disrupted or perhaps enhanced. Even VHF frequencies may be affected by sporadic E conditions causing a significant increase in effective range.

13.2.7 VHF and UHF Propagation

VHF and UHF frequencies, considered to be 30–3000 MHz, are used primarily for line-of-sight communications. Aircraft, public service, government, Amateur, and business communications as well as FM and TV broadcasting have allocations in this frequency range. These frequencies are typically used for local area and point-to-point communications. Usable propagation range is usually limited to the radio horizon. At these frequencies, antenna heights that result in sufficient path clearance for free space propagation to be applicable are practical. Ionospheric skywave propagation at these frequencies, at least the higher portion of the band, is essentially nonexistent with the exception of occasional sporadic E propagation.

Transmit antennas are located as high above ground as practical in order to have the greatest range to the radio horizon. Communications paths requiring propagation to areas beyond line of sight from the transmitter, either because the receiver is located over the radio horizon or is obstructed by terrain or manmade obstacles, are routinely constructed using repeaters located on mountain tops or tall buildings.

Since they are essentially line-of-sight paths, propagation at VHF and UHF is relatively consistent, although, there are several potential disturbances to reliable propagation at these frequencies. Wavelengths in this frequency range vary from 0.1 to 10 m. At these wavelengths, many natural and manmade objects appear smooth enough to exhibit good reflective properties. As a result, the potential for radiated energy to arrive at the receiver from the direct path to the transmitter as well as various reflected paths is quite high. If the energy from the reflected path and from the direct path reach the receiver in phase, the strength of the received signal is enhanced. If, on the other hand, the energy from the reflected path arrives out of phase with that from the direct path, then there will be complete signal cancellation. This phenomenon is known as *multipath interference* and can be apparent as picket-fence-type noise on a VHF signal, such as that from an FM broadcast station while in a moving vehicle. The picket fencing occurs with an interval related to the wavelength of the operating frequency as the receiver passes through standing waves of destructive interference between the direct and reflected signal. If stopped at a fixed location, moving only a few inches usually can make a significant difference in the strength of the received signal. For analog video signals, such multipath problems may cause “ghosting” in pictures as the reflected signal arrives slightly time delayed from the direct signal.

Although VHF and UHF frequencies are used primarily for line-of-sight paths, propagation beyond the radio horizon is not only possible, but sometimes depended on. Such propagation can also unexpectedly cause disruption to established communications paths and interference to paths in use far beyond the radio horizon. Tropospheric **ducting** is one such phenomena that occurs mostly in warm marine climates. Tropospheric ducting occurs because of a large and rapid change in the atmospheric index of refraction and can result in propagation distances as large as 4000 km (Hutchinson, 1985). This type of propagation can occur in two different ways, but both are typically caused by temperature inversions where atmospheric temperature increases with altitude. In one type of tropospheric ducting, a well-defined boundary between warm and cool air, and the resulting rapid change in refractive index, bends the traveling wave significantly and essentially traps it between the inversion layer and the surface of the Earth, resulting in greatly enhanced communications range. For this to occur, however, the wave must have a very shallow arrival angle at the inversion layer.

The second type of tropospheric ducting occurs between two layers of air with temperature inversions. In this case the wave is trapped between the two layers and propagates much like a wave in a waveguide as shown in Fig. 13.36. Also, as in a waveguide, the dimensions of the atmospheric duct result in some frequency selectivity for this mode of propagation. For this mode of propagation to be useful, both the transmitter and receiver antennas must be located within the duct. Such ducting can disrupt an existing

FIGURE 13.36 The mechanism of atmospheric ducting; The propagation path is limited by the boundaries of the duct. Communications with lower receive antenna not possible.

FIGURE 13.37 The principle of tropospheric scattering.

communications system, especially if highly directive antennas are used, by trapping the transmitted wave inside a duct with the receive antenna located either above or below the duct. This problem can occur with aircraft flying within a duct trying to communicate with a receiver on the ground well below the duct. At higher frequencies, such ducting can cause radar systems to miss close targets or to detect targets at ranges that are theoretically beyond detection.

Another method of propagation beyond the radio horizon is known as tropospheric scatter or *troposcatter* and is shown in Fig. 13.37. In this mode of propagation, energy is reflected and refracted by small changes in the atmospheric index of refraction and by various particulate matter in the troposphere, such as dust. Communications range is limited by the height of the scattering region as both stations must have a line of sight to it. The amount of energy scattered depends on the density of the scattering particles and the power impinging on that area, and so systems regularly using this mode are typically designed with high transmit power levels.

Another mode of propagation that extends the range of VHF systems is known as meteor scatter or *meteor burst* propagation. In this propagation mode, the traveling wave is reflected from the ionized trail of a meteor passing through the Earth's atmosphere. These ionized trails occur at an altitude of approximately 100 km, resulting in a single-hop communications range of approximately 1500–2000 km. Frequencies in the range of 40–60 MHz are most effective for meteor scatter work, although higher frequencies are sometimes used. While meteor paths are sporadic, they are sufficient in number that digital systems with acceptable throughput can be established. Because of the orbit of most meteors and the Earth around the sun, the number of meteors and, hence, meteor scatter performance is typically highest in the early morning hours (Weitzen and Ralston, 1988). There are seasonal variations as well. Remote sensing systems have been established around this propagation mode. Meteor scatter systems have some distinct advantages besides over the horizon propagation. Meteor scatter systems do not need to change frequency over the course of the day and with changing seasons as HF systems would. Additionally, in order for communication to occur between two stations, both stations must be able to “see” the meteor trail at a proper angle for reflection to occur. This makes meteor scatter systems somewhat secure from unintended reception as well as providing some level of antijam capability. This characteristic also allows simplified frequency sharing or reuse as opposed to other communications systems.

13.2.8 Microwave Propagation

Propagation at microwave frequencies, which for purposes of this discussion will be considered anything above approximately 3 GHz, is quite similar to that at VHF and UHF frequencies with the addition of a few peculiarities. Because of the very small wavelength at these frequencies, obtaining appropriate Fresnel zone clearance is usually relatively easy. However, also because of the very small wavelength, energy in this frequency range may be readily absorbed by atmospheric gases or scattered by particulate matter in

the atmosphere. Vegetation and foliage become obstructions at these frequencies and, if a path is through an area of deciduous trees, the performance between the various seasons can be substantially different. For this reason, propagation paths at microwave frequencies should be completely clear of any type of obstruction, often requiring visual inspection of the path.

Rain attenuation may be significant on paths operating at frequencies above approximately 10 GHz. The actual amount of attenuation is a function of many variables including the size and shape of the drops and the instantaneous intensity of the rainfall as well as the frequency of operation. For a frequency of 13 GHz, rainfall intensity of 1 in/h can result in over 1 dB/km of additional attenuation (White, 1975). The amount of attenuation increases with rainfall intensity and frequency. Significantly less attenuation is caused by snow and fog as the water density is considerably less. Absorption by atmospheric gases, oxygen to be specific, may be an additional consideration for paths operating in the tens of gigahertz range. As a result, if a path is being planned in areas subject to periods of locally intense rainfall, this additional attenuation must be accounted for in the design of the path fade margin. Other causes of atmospheric absorption are usually secondary considerations for most typical paths.

At these frequencies, diversity receiving systems are often used to combat various forms of multipath fading. Although a path may perform flawlessly most of the time, it may be subject to occasional deep fades. These fades can be very brief or can last for minutes or even hours. The fading is primarily caused by multipath effects. The fading conditions are not constant, however, as changes in the refractive index of the atmosphere effectively change the point of reflection. These fades can also be caused by changes on the ground between the receiver and transmitter. Indeed, these multipath effects can occur with no true reflective surface, but rather from atmospheric effects themselves, such as the already discussed temperature inversion. To minimize these effects, either frequency or space diversity are used.

Diversity systems are based on the premise that fades are a function of frequency and distance from the point of reflection, since the direct and reflected signals must have a phase difference of 180° . Using another frequency, preferably far removed from the primary frequency, usually ensures that both paths will not have simultaneous fades. The drawback to this system is that it is an inefficient use of spectrum. Alternatively, space diversity can be used. With a space diversity system, two receive systems are used with antennas spaced many wavelengths apart, usually vertically. The desired distance is a function of path length and wavelength. With such spaced antennas, the point of reflection will not be the same at both heights so that while one antenna is in a deep fade, the other is not. It is important to note that a diversity system will not improve reliability due to obstructions, such as foliage, insufficient path clearance, or other such nonfrequency specific problems.

At microwave frequencies, non-line-of-sight paths can be established with the use of passive repeaters as well as active repeaters. At the millimeter wavelengths involved, passive reflectors can be constructed with sufficient gain to make their use practical. The most common passive repeater is a large, flat, billboard-looking reflector that acts exactly like an optical mirror. As with an active repeater, the passive repeater must have line of sight to both the receiver and transmitter. A single passive reflector can not act as a relay when all three components of the link are in-line or are nearly in-line. In such a case, two closely spaced passive reflectors are required.

Communications between Earth and space are also conducted in this frequency range as well as at lower frequencies. The primary concern with space communications is to choose a frequency high enough that will not be refracted back to Earth by the ionosphere and low enough so that absorption by atmospheric gases is not significant. Because of the lower powers and great distances involved, high-gain antennas are typically required and rain and other causes of atmospheric absorption are important considerations. Further complicating space communications is the RF noise associated with thermal radiation from celestial objects, notably the sun. This interference can completely destroy a path when the sun is directly in line with the space borne transmitter.

Defining Terms

Diffraction: Change in direction of propagating energy around an object caused by interference between the radiated energy and induced currents in the object.

Ducting: A change in typical propagation conditions caused by anomalous atmospheric conditions which result in a waveguide effect.

Effective Earth radius: The assumed Earth radius required to result in a distance to the horizon equivalent to the radio horizon.

Free space path loss: The amount of attenuation of RF energy on an unobstructed path between isotropic antennas.

Frequence optimum de travail (FOT): The optimum working frequency.

Fresnel zone: A locus of points along a path where a reflection results in a change of overall path length by $n \times 180^\circ$.

Groundwave: That portion of radiated radio frequency energy that is not influenced by the ionosphere.

Isotropic antenna: An antenna with a gain of unity.

Refraction: Change in direction of propagating radio energy caused by a change in the refractive index, or density, of a medium.

Skywave: That portion of radiated radio frequency energy that propagates skyward and interacts with the ionosphere.

Wavelength: The distance traveled by a radio frequency wavefront in one cycle.

Further Information

Additional information on the topic of radio wave propagation is available from the following sources:

The American Radio Relay League, Newington, Connecticut, publishes *QST*, a monthly magazine with HF propagation predictions and occasional articles regarding radio wave propagation. The organization also publishes books, aimed primarily at amateur radio operators, that discuss radio wave propagation.

The IEEE Antennas and Propagation Society, New York, NY, publishes *Transactions on Antennas and Propagation* on a monthly basis.

Near real-time information concerning HF propagation is broadcast by National Institute of Standard and Technology radio stations WWV and WWVH.

13.3 Practical Antenna Systems

Jerry C. Whitaker

13.3.1 Introduction

Transmission is accomplished by the emission of coherent electromagnetic waves in free space from one or more radiating elements that are excited by RF currents. Although, by definition, the radiated energy is composed of mutually dependent magnetic and electric vector fields, it is conventional practice to measure and specify radiation characteristics in terms of the electric field only.

The purpose of an antenna is to efficiently radiate the power supplied to it by the transmitter. A simple antenna, consisting of a single vertical element over a ground plane can do this job quite well at low to medium frequencies. Antenna systems may also be required to concentrate the radiated power in a given direction and minimize radiation in the direction of other stations sharing the same or adjacent frequencies. To achieve such directionality may require a complicated antenna system that incorporates a number of individual elements or towers and matching networks.

As the operating frequency increases into VHF and above, the short wavelengths permit the design of specialized antennas that offer high directivity and gain.

Operating Characteristics

Wavelength is the distance traveled by one cycle of a radiated electric signal. The frequency of the signal is the number of cycles per second. It follows that the frequency is inversely proportional to the wavelength. Both wavelength and frequency are related to the speed of light. Conversion between the two parameters can be accomplished with the formula

$$c = f \times \lambda$$

where c is the speed of light, f is the operating frequency, and λ is the wavelength. The velocity of electric signals in air is essentially the same as that of light in free space (2.9983×10^{10} cm/sec).

The *electrical length* of a radiating element is the most basic parameter of an antenna

$$H = \frac{H_t \times F_o}{2733}$$

where H is the length of the radiating element in electrical degrees, H_t is the length of the radiating element in feet, and F_o is frequency of operation in kHz. Where the radiating element is measured in meters

$$H = \frac{H_t \times F_o}{833.23}$$

The *radiation resistance* of an antenna is defined by

$$R = \frac{P}{I^2}$$

where R is the radiation resistance, P is the power delivered to the antenna, and I is the driving current at the antenna base.

Antenna Bandwidth

Bandwidth is a general classification of the frequencies over which an antenna is effective. This parameter requires specification of acceptable tolerances relating to the uniformity of response over the intended operating band.

Strictly speaking, *antenna bandwidth* is the difference in frequency between two points at which the power output of the transmitter drops to one-half the midrange value. The points are called *half-power points*. A half-power point is equal to a VSWR of 5.83:1, or the point at which the voltage response drops

to 0.7071 of the midrange value. In most communications systems, a VSWR of less than 1.2:1 within the occupied bandwidth of the radiated signal is preferable.

Antenna bandwidth depends on the radiating element impedance and the rate at which the reactance of the antenna changes with frequency.

Bandwidth and RF coupling go hand in hand, regardless of the method used to excite the antenna. All elements between the transmitter output circuit and the antenna must be analyzed, first by themselves, and then as part of the overall system bandwidth. In any transmission system, the *composite bandwidth*, not just the bandwidths of individual components, is of primary concern.

Polarization

Polarization is the angle of the radiated electric field vector in the direction of maximum radiation. Antennas may be designed to provide horizontal, vertical, or circular polarization. Horizontal or vertical polarization is determined by the orientation of the radiating element with respect to Earth. If the plane of the radiated field is parallel to the ground, the signal is said to be *horizontally polarized*. If it is at right angles to the ground, it is said to be *vertically polarized*. When the receiving antenna is located in the same plane as the transmitting antenna, the received signal strength will be maximum.

Circular polarization (CP) of the transmitted signal results when equal electrical fields in the vertical and horizontal planes of radiation are out-of-phase by 90° and are rotating a full 360° in one wavelength of the operating frequency. The rotation can be clockwise or counterclockwise, depending on the antenna design. This continuously rotating field gives CP good signal penetration capabilities because it can be received efficiently by an antenna of any random orientation. Figure 13.38 illustrates the principles of circular polarization.

FIGURE 13.38 Polarization of the electric field of a transmitted wave.

Antenna Beamwidth

Beamwidth in the plane of the antenna is the angular width of the directivity pattern where the power level of the received signal is down by 50% (3 dB) from the maximum signal in the desired direction of reception.

Antenna Gain

Directivity and gain are measures of how well energy is concentrated in a given direction. Directivity is the ratio of power density in a given direction to the power density that would be produced if the energy were radiated isotropically. The reference can be linearly or circularly polarized. Directivity is usually given in dBi (decibels above isotropic).

Gain is the field intensity produced in a given direction by a fixed input power to the antenna, referenced to a dipole. It is frequently used as a figure of merit. It is closely related to directivity, which in turn is dependent upon the radiation pattern. High values of gain are usually obtained with a reduction in beamwidth.

An antenna is typically configured to exhibit “gain” by narrowing the beamwidth of the radiated signal to concentrate energy toward the intended coverage area. The actual amount of energy being radiated is the same with a unity-gain antenna or a high-gain antenna, but the useful energy (commonly referred to as the *effective radiated power*, or ERP) can be increased significantly.

Electrical *beam tilt* can also be designed into a high-gain antenna. A conventional antenna typically radiates more than half of its energy above the horizon. This energy is lost for practical purposes in most applications. Electrical beam tilt, caused by delaying the RF current to the lower elements of a multi-element antenna, can be used to provide more useful power to the service area.

Pattern optimization is another method that can be used to maximize radiation to the intended service area. The characteristics of the transmitting antenna are affected, sometimes greatly, by the presence of the supporting tower, if side-mounted, or by nearby tall obstructions (such as another transmitting tower) if top-mounted. Antenna manufacturers use various methods to reduce pattern distortions. These generally involve changing the orientation of the radiators with respect to the tower and adding parasitic elements.

Space Regions

Insofar as the transmitting antenna is concerned, space is divided into three regions:

- *Reactive near-field region*. This region is the area of space immediately surrounding the antenna in which the reactive components predominate. The size of the region varies, depending on the antenna design. For most antennas, the reactive near-field region extends 2 wavelengths or less from the radiating elements.
- *Radiating near-field region*. This region is characterized by the predictable distribution of the radiating field. In the near-field region, the relative angular distribution of the field is dependent on the distance from the antenna.
- *Far-field region*. This region is characterized by the independence of the relative angular distribution of the field with varying distance. The pattern is essentially independent of distance.

Impedance Matching

Most practical antennas require some form of impedance matching between the transmission line and the radiating elements. The implementation of a matching network can take on many forms, depending on the operating frequency and output power.

The *negative sign* convention is generally used in impedance matching analysis. That is, if a network delays or retards a signal by θ° , the phase shift across the network is said to be “minus θ degrees.” For example, a 1/4-wave length of transmission line, if properly terminated, has a phase shift of -90° . Thus, a *lagging* or low-pass network has a negative phase shift, and a *leading* or high-pass network has a positive phase shift. There are three basic network types that can be used for impedance matching: *L*, *pi*, and *tee*.

Equation 1:

$$Q = \sqrt{\frac{R_2}{R_1}} - 1 = \left| \frac{X_1}{R_1} \right| = \left| \frac{R_2}{X_2} \right|$$

Equation 3:

$$X_1 = \frac{-R_1 R_2}{X_2}$$

Equation 2:

$$X_2 = \frac{\pm R_2}{Q}$$

Equation 4:

$$\theta = \text{TAN}^{-1} \left(\frac{R_2}{X_2} \right)$$

Where

 R_1 = L network input resistance (ohms) R_2 = L network output resistance (ohms) X_1 = Series leg reactance (ohms) X_2 = Shunt leg reactance (ohms) Q = Loaded Q of the L network

FIGURE 13.39 L network parameters.

L Network

The L network is shown in Fig. 13.39. The loaded Q of the network is determined from Equation 1. Equation 2 defines the shunt leg reactance, which is negative (capacitive) when θ is negative, and positive (inductive) when θ is positive. The series leg reactance is found using Equation 3, the phase shift via Equation 4, and the currents and voltages via Ohm's law. Note that R_2 (the resistance on the shunt leg side of the L network) must always be greater than R_1 . An L network cannot be used to match equal resistances, or to adjust phase independently of resistance.

Tee Network

The tee network is shown in Fig. 13.40. This configuration can be used to match unequal resistances. The tee network has the added feature that phase shift is independent of the resistance transformation ratio. A tee network can be considered simply as two L networks back-to-back. Note that there are two loaded Q s associated with a tee network: an input Q and an output Q . To gauge the bandwidth of the tee network, the lower value of Q must be ignored. Note that the Q of a tee network increases with increasing phase shift.

Equations 5 through 14 describe the tee network. It is a simple matter to find the input and output currents via Ohm's law, and the shunt leg current can be found via the Cosine law (Equation 12). Note that this current increases with increasing phase shift. Equation 13 describes the mid-point resistance of a tee network, which is always higher than R_1 or R_2 . Equation 14 is useful when designing a *phantom tee network*; that is, where X_2 is made up only of the antenna reactance and there is no physical component in place of X_2 . Keep in mind that a tee network is considered as having a lagging or negative phase shift

Equation 5:

$$X_3 = \frac{\sqrt{R_1 R_2}}{\sin(\theta)}$$

Equation 8:

$$Q_1 = \left| \frac{X_1}{R_1} \right|$$

Equation 11:

$$I_2 = \sqrt{\frac{P}{R_2}}$$

Equation 13:

$$R_3 = (Q_2^2 + 1)R_2$$

Equation 6:

$$X_1 = \frac{R_1}{\tan(\theta)} - X_3$$

Equation 9:

$$Q_2 = \left| \frac{X_2}{R_2} \right|$$

Equation 12:

$$I_3 = \sqrt{I_1^2 + I_2^2} = 2(I_1)(I_2)\cos(\theta)$$

Equation 14:

$$\theta = \tan^{-1}\left(\frac{X_1}{R_1}\right) \pm \tan^{-1}\left(\frac{X_2}{R_2}\right)$$

Equation 7:

$$X_2 = \frac{R_2}{\tan(\theta)} - X_3$$

Equation 10:

$$I_1 = \sqrt{\frac{P}{R_1}}$$

when the shunt leg is capacitive (X_3 negative), and vice versa. The input and output arms can go either negative or positive, depending on the resistance transformation ratio and desired phase shift.

Pi Network

The pi network is shown in Fig. 13.41. It can also be considered as two L networks back-to-back and, therefore, the same comments about overall loaded Q apply. Note that susceptances have been used in Equations 15 through 19 instead of reactances in order to simplify calculations. The same conventions regarding tee network currents apply to pi network voltages (Equations 20, 21, and 22). The mid-point resistance of a pi network is always less than R_1 or R_2 . A pi network is considered as having a negative or lagging phase shift when Y_3 is positive, and vice versa.

Equation 15:

$$Y_3 = \frac{1}{-\text{SIN}(\theta) \sqrt{R_1 R_2}}$$

Line Stretcher

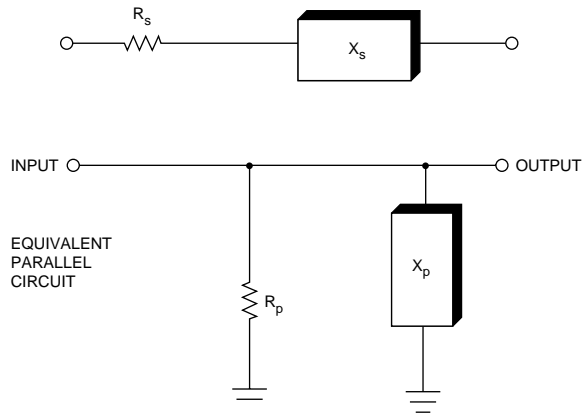

A *line stretcher* makes a transmission line look longer or shorter in order to produce sideband impedance symmetry at the transmitter PA (see Fig. 13.42). This is done to reduce audio distortion in an envelope detector, the kind of detector that most AM receivers employ. Symmetry is defined as equal sideband resistances, and equal—but opposite sign—sideband reactances.

There are two possible points of symmetry, each 90° from the other. One produces sideband resistances greater than the carrier resistance, and the other produces the opposite effect. One side will create a pre-emphasis effect, and the other a de-emphasis effect.

Depending on the Q of the transmitter output network, one point of symmetry may yield lower sideband VSWR at the PA than the other. This results from the Q of the output network opposing the Q of the antenna in one direction, but aiding the antenna Q in the other direction.

13.3.2 Antenna Types

The *dipole antenna* is simplest of all antennas, and the building block of most other designs. The dipole consists of two in-line rods or wires with a total length equal to $1/2$ -wave at the operating frequency. Figure 13.43 shows the typical configuration, with two $1/4$ -wave elements connected to a transmission line.

Equation 25:

$$R_p = \frac{R_s^2 + X_s^2}{R_s}$$

Equation 26:

$$X_p = \frac{R_s^2 - X_s^2}{X_s}$$

Where

- R_s = Series configuration resistance (ohms)
- R_p = Parallel configuration resistance (ohms)
- X_s = Series reactance (ohms)
- X_p = Parallel reactance (ohms)

FIGURE 13.42 Line stretcher configuration.

The radiation resistance of a dipole is on the order of 73 Ω. The bandwidth of the antenna may be increased by increasing the diameter of the elements, or by using cones or cylinders rather than wires or rods, as shown in the figure. Such modifications also increase the impedance of the antenna.

The dipole can be straight (in-line) or bent into a V-shape. The impedance of the V-dipole is a function of the V angle. Changing the angle effectively tunes the antenna. The vertical radiation pattern of the V-dipole antenna is similar to the straight dipole for angles of 120° or less.

FIGURE 13.43 Half-wave dipole antenna: (a) conical dipole, and (b) conventional dipole.

A *folded dipole* can be fashioned as shown in Fig. 13.44. Such a configuration results in increased bandwidth and impedance. Impedance can be further increased by using rods of different diameter and by varying the spacing of the elements. The 1/4-wave dipole elements connected to the closely-coupled 1/2-wave element act as a matching stub between the transmission line and the single-piece 1/2-wave element. This broadbands the folded dipole antenna by a factor of 2.

FIGURE 13.44 Folded dipole antenna.

A *corner-reflector* antenna may be formed as shown in Fig. 13.45. A ground plane or flat reflecting sheet is placed at a distance of 1/16- to 1/4-wavelengths behind the dipole. Gain in the forward direction can be increased by a factor of 2 with this type of design.

Quarter-Wave Monopole

A conductor placed above a ground plane forms an image in the ground plane such that the resulting pattern is a composite of the *real antenna* and the *image antenna* (see Fig. 13.46). The operating impedance is one-half of the impedance of the antenna and its image when fed as a physical antenna in free space. An example will help illustrate this concept. A 1/4-wave monopole mounted on an infinite ground plane has an impedance equal to one-half the free-space impedance of a 1/4-wave dipole. It follows, then, that the theoretical characteristic resistance of a 1/4-wave monopole with an infinite ground plane is 37 Ω.

For a real-world antenna, an infinite ground plane is neither possible nor required. An antenna mounted on a ground plane that is 2 to 3 times the operating wavelength has about the same impedance as a similar antenna mounted on an infinite ground plane.

FIGURE 13.45 Corner-reflector antenna.

FIGURE 13.46 Vertical monopole mounted above a ground plane.

FIGURE 13.47 The Yagi-Uda array.

Log-Periodic Antenna

The log-periodic antenna can take on a number of forms. Typical designs include the *conical log spiral*, *log-periodic V*, and *log-periodic dipole*. The most common of these antennas is the log-periodic dipole. The antenna can be fed either by using alternating connections to a balanced line, or by a coaxial line running through one of the feeders from front to back. In theory, the log-periodic antenna can be designed to operate over many octaves. In practice, however, the upper frequency is limited by the precision required in constructing the small elements, feed lines, and support structure of the antenna.

Yagi-Uda Antenna

The Yagi-Uda is an *end-fire array* consisting typically of a single driven dipole with a *reflector dipole* behind the driven element, and one or more *parasitic director elements* in front (see Fig. 13.47). Common designs use from one to seven director elements. As the number of elements is increased, directivity increases. Bandwidth, however, decreases as the number of elements is increased. Arrays of more than four director elements are typically narrowband.

The radiating element is $1/2$ -wavelength at the center of the band covered. The single reflector element is slightly longer, and the director elements are slightly shorter, all spaced approximately $1/4$ -wavelength from each other.

Table 13.6 demonstrates how the number of elements determines the gain and beamwidth of a Yagi-Uda antenna.

Waveguide Antenna

The waveguide antenna consists of a dominant-mode-fed waveguide opening onto a conducting ground plane. Designs may be based on rectangular, circular, or coaxial waveguide (also called an *annular slot*). The slot antenna is simplicity itself. A number of holes of a given dimension are placed at intervals along a section of waveguide. The radiation characteristics of the antenna are determined by the size, location,

TABLE 13.6 Typical Characteristics of Single-Channel Yagi-Uda Arrays

No. of Elements	Gain (dB)	Beam Width (°)
2	3–4	65
3	6–8	55
4	7–10	50
5	9–11	45
9	12–14	37
15	14–16	30

Source: Benson, B., Ed., *Television Engineering Handbook*, McGraw-Hill, New York, 1986, 388.

and orientation of the slots. The antenna offers optimum reliability because there are no discrete elements, except for the waveguide section itself.

Horn Antenna

The horn antenna may be considered a natural extension of the dominant-mode waveguide feeding the horn in a manner similar to the wire antenna, which is a natural extension of the two-wire transmission line. The most common types of horns are the *E-plane sectoral*, *H-plane sectoral*, *pyramidal horn* (formed by expanding the walls of the TE_{0,1}-mode-fed rectangular waveguide), and the *conical horn* (formed by expanding the walls of the TE_{1,1}-mode-fed circular waveguide). Dielectric-loaded waveguides and horns offer improved pattern performance over unloaded horns. Ridged and tapered horn designs improve the bandwidth characteristics. Horn antennas are available in single and dual polarized configurations.

Reflector Antenna

The reflector antenna is formed by mounting a radiating feed antenna above a reflecting ground plane. The most basic form of reflector is the loop or dipole spaced over a finite ground plane. This concept is the basis for the parabolic or spherical reflector antenna. The *parabolic reflector antenna* may be fed directly or through the use of a subreflector in the focal region of the parabola. In this approach, the subreflector is illuminated from the parabolic surface. The chief disadvantage of this design is the aperture blockage of the subreflector, which restricts its use to large-aperture antennas. The operation of a parabolic or spherical reflector antenna is typically described using physical optics.

Parabolic reflector antennas are usually illuminated by a flared-horn antenna with a flare angle of less than 18°. A rectangular horn with a flare angle less than 18° has approximately the same aperture field as the dominant-mode rectangular waveguide feeding the horn.

Spiral Antenna

The bandwidth limitations of an antenna are based on the natural change in the critical dimensions of the radiating elements caused by differing wavelengths. The spiral antenna overcomes this limitation because the radiating elements are specified only in angles. A two-arm equiangular spiral is shown in Fig. 13.48. This common design gives wideband performance. Circular polarization is inherent in the antenna. Rotation of the pattern corresponds to the direction of the spiral arms. The gain of a spiral antenna is typically slightly higher than a dipole.

The basic spiral antenna radiates on both sides of the arms. Unidirectional radiation is achieved through the addition of a reflector or cavity.

FIGURE 13.48 Two-arm equiangular spiral antenna.

Array Antenna

The term “array antenna” covers a wide variety of physical structures. The most common configuration is the *planar array antenna*, which consists of a number of radiating elements regularly spaced on a rectangular or triangular lattice. The *linear array antenna*, where the radiating elements are placed in a single line, is also common. The pattern of the array is the product of the element pattern and the array configuration. Large array antennas may consist of 20 or more radiating elements.

Correct phasing of the radiating elements is the key to operation of the system. The radiating pattern of the structure, including direction, can be controlled through proper adjustment of the relative phase of the elements.

13.3.3 Antenna Applications

An analysis of the applications of antennas for commercial and industrial use is beyond the scope of this chapter. It is instructive, however, to examine three of the most obvious antenna applications: AM and FM radio, and television. These applications illustrate antenna technology as it applies to frequencies ranging from the lower end of the MF band to the upper reaches of UHF.

AM Broadcast Antenna Systems

Vertical polarization of the transmitted signal is used for AM broadcast stations because of its superior groundwave propagation, and because of the simple antenna designs that it affords. The Federal Communications Commission (FCC) and licensing authorities in other countries have established classifications of AM stations with specified power levels and hours of operation. Protection requirements set forth by the FCC specify that some AM stations (in the U.S.) reduce their transmitter power at sunset, and return to full power at sunrise. This method of operation is based on the propagation characteristics of AM band frequencies. AM signals propagate further at nighttime than during the day.

The different day/night operating powers are designed to provide each AM station with a specified coverage area that is free from interference. Theory rarely translates into practice insofar as coverage is concerned, however, because of the increased interference that all AM stations suffer at nighttime.

The tower visible at any AM radio station transmitter site is only half of the antenna system. The second element is a buried ground system. Current on a tower does not simply disappear; rather, it returns to Earth through the capacitance between the Earth and the tower. Ground losses are greatly reduced if the tower has a radial copper ground system. A typical single-tower ground system is made up of 120 radial ground wires, each 140 electrical degrees long (at the operating frequency), equally spaced out from the tower base. This is often augmented with an additional 120 interspersed radials 50 ft long.

Directional AM Antenna Design

When a nondirectional antenna with a given power does not radiate enough energy to serve the station's primary service area, or radiates too much energy toward other radio stations on the same or adjacent frequencies, it is necessary to employ a directional antenna system. Rules set out by the FCC and regulatory agencies in other countries specify the protection requirements to be provided by various classes of stations, for both daytime and nighttime hours. These limits tend to define the shape and size of the most desirable antenna pattern.

A directional antenna functions by carefully controlling the amplitude and phase of the RF currents fed to each tower in the system. The directional pattern is a function of the number and spacing of the towers (vertical radiators), and the relative phase and magnitude of their currents. The number of towers in a directional AM array can range from two to six, or even more in a complex system. One tower is defined as the *reference tower*. The amplitude and phase of the other towers are measured relative to this reference.

A complex network of power splitting, phasing, and antenna coupling elements is required to make a directional system work. [Figure 13.49](#) shows a block diagram of a basic two-tower array. A power divider

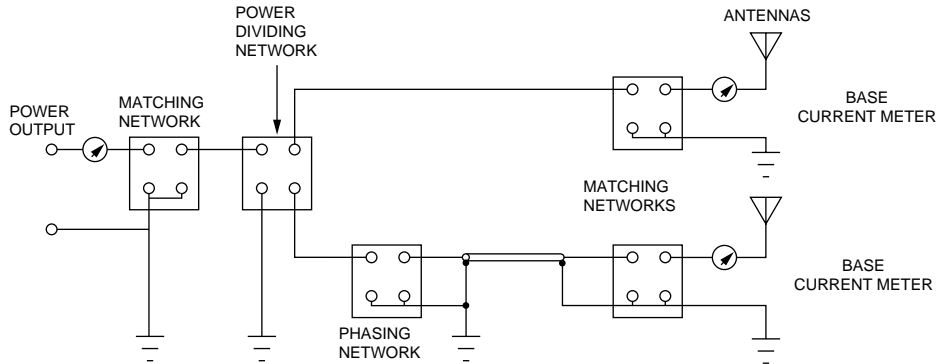

FIGURE 13.49 Block diagram of an AM directional antenna feeder system for a two-tower array.

network controls the relative current amplitude in each tower. A phasing network provides control of the phase of each tower current, relative to the reference tower. Matching networks at the base of each tower couple the transmission line impedance to the base operating impedance of the radiating towers.

In practice, the system shown in the figure would not consist of individual elements. Instead, the matching network, power dividing network, and phasing network would all usually be combined into a single unit, referred to as the *phasor*.

Antenna Pattern Design

The pattern of any AM directional antenna system (array) is determined by a number of factors, including

- Electrical parameters (phase relationship and current ratio for each tower)
- Height of each tower
- Position of each tower with respect to the other towers (particularly with respect to the reference tower)

A *directional array* consists of two or more towers arranged in a specific manner on a plot of land. [Figure 13.50](#) shows a typical three-tower array, as well as the pattern such an array would produce. This is an *in-line array*, meaning that all the elements (towers) are in line with one another. Notice that the *major lobe* is centered on the same line as the line of towers, and that the *pattern nulls (minima)* are positioned symmetrically about the line of towers, protecting co-channel stations A and B at true bearings of 315° and 45° , respectively.

[Figure 13.51](#) shows the same array, except that it has been rotated by 10° . Notice that the pattern shape is not changed, but the position of the major lobe and the nulls follow the line of towers. Also notice that the nulls are no longer pointed at the stations to be protected.

If this directional antenna system were constructed on a gigantic turntable, the pattern could be rotated without affecting the shape. But, to accomplish the required protections and to have the major lobe(s) oriented in the right direction, there is only one correct position. In most cases, the position of the towers will be specified with respect to a single reference tower. The location of the other towers will be given in the form of a distance and bearing from that reference. Occasionally, a reference point, usually the center of the array, will be used for a geographic coordinate point.

Bearing

The bearing or azimuth of the towers from the reference tower or point is specified clockwise in degrees from *true north*. The distinction between true and *magnetic north* is vital. The magnetic North Pole is not at the true or geographic North Pole. (In fact, it is in the vicinity of 74° north, 101° west, in the islands of northern Canada.) The difference between magnetic and true bearings is called variation or *magnetic declination*. Declination, a term generally used by surveyors, varies for different locations. It is

FIGURE 13.50 Radiation pattern generated with a three-tower in-line directional array using the electrical parameters and orientation shown.

FIGURE 13.51 Radiation pattern produced when the array of Fig. 13.50 is rotated to a new orientation.

FIGURE 13.52 A typical three-tower directional antenna monitoring system.

not a constant. The Earth's magnetic field is subject to a number of changes in intensity and direction. These changes take place over daily, yearly, and long-term (or *secular*) periods. The secular changes result in a relatively constant increase or decrease in declination over a period of many years.

Antenna Monitoring System

Monitoring the operation of an AM directional antenna basically involves measuring the power into the system, the relative value of currents into the towers, their phase relationships, and the levels of radiated signal at certain monitoring points some distance from the antenna. Figure 13.52 shows a block diagram of a typical monitoring system for a three-tower array. For systems with additional towers, the basic layout is extended by adding more pickup elements, sample lines, and a monitor with additional inputs.

Phase/Current Sample Loop

Two types of phase/current sample pickup elements are commonly used: the *sample loop* and *torroidal current transformer* (TCT). The sample loop consists of a single turn unshielded loop of rigid construction, with a fixed gap at the open end for connection of the sample line. The device must be mounted on the tower near the point of maximum current. The loop can be used on towers of both uniform and nonuniform cross-section. It must operate at tower potential, except for towers of less than 130 electrical degrees height, where the loop can be operated at ground potential.

When the sample loop is operated at tower potential, the coax from the loop to the base of the tower is also at tower potential. To bring the sample line across the base of the tower, a sample line isolation coil is used.

A shielded torroidal current transformer can also be used as the phase/current pickup element. Such devices offer several advantages over the sample loop, including greater stability and reliability. Because they are located inside the tuning unit cabinet or house, TCTs are protected from wind, rain, ice, and vandalism.

Unlike the rigid, fixed sample loop, torroidal current transformers are available in several sensitivities, ranging from 0.25 to 1.0 V per ampere of tower current. Tower currents of up to 40 A can be handled, providing a more usable range of voltages for the antenna monitor. Figure 13.53 shows the various arrangements that can be used for phase/current sample pickup elements.

Sample Lines

The selection and installation of the sampling lines for a directional monitoring system are important factors in the ultimate accuracy of the overall array.

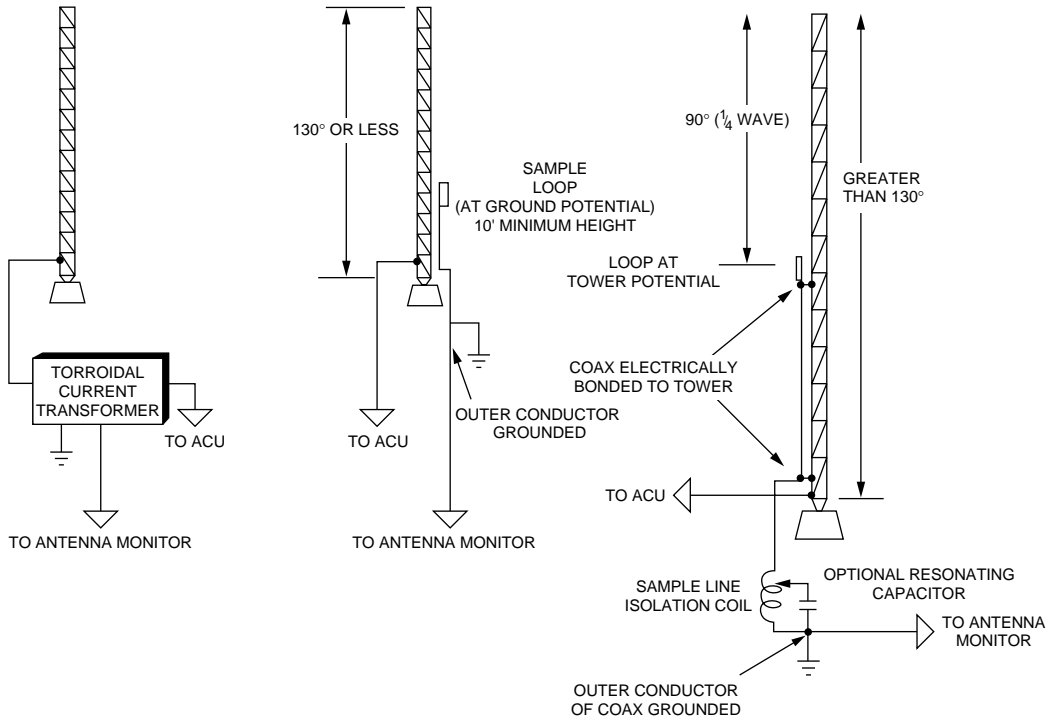

FIGURE 13.53 Three possible circuit configurations for phase sample pickup.

With *critical arrays* (antennas requiring operation within tight limits specified in the station license), all sample lines must be of equal electrical length and installed in such a manner that corresponding lengths of all lines are exposed to equal environmental conditions.

While sample lines may be run above ground on supports (if protected and properly grounded), the most desirable arrangement is direct burial using jacketed cable. Burial of sample line cable is almost a standard practice because proper burial offers good protection against physical damage and a more stable temperature environment.

FIGURE 13.54 The folded unipole antenna can be thought of as a $1/2$ -wave folded dipole antenna perpendicular to the ground and cut in half.

The Common Point

The power input to a directional antenna is measured at the phasor *common point*. Power is determined by the *direct method*

$$P = I^2 R$$

where P is the power in watts (W), I is the common point current in amperes (A), and R is the common point resistance in ohms (Ω).

Monitor Points

Routine monitoring of a directional antenna involves the measurement of field intensity at certain locations away from the antenna, called *monitor points*. These points are selected and established during the initial tune-up of the antenna system. Measurements at the monitor points should confirm that radiation in prescribed directions does not exceed a value that would cause interference to other stations operating on the same or adjacent frequencies. The field intensity limits at these points are normally specified in the station license. Measurements at the monitor points may be required on a weekly or a monthly basis, depending on several factors and conditions relating to the particular station. If the system is not a critical array, quarterly measurements may be sufficient.

Folded Unipole Antenna

The *folded unipole* antenna consists of a grounded vertical structure with one or more conductors folded back parallel to the side of the structure. It can be visualized as a half-wave folded dipole perpendicular to the ground and cut in half (see Fig. 13.54). This design makes it possible to provide a wide range of resonant radiation resistances by varying the ratio of the diameter of the folded-back conductors in relation to the tower. Top loading can also be used to broaden the antenna bandwidth. A side view of the folded unipole is shown in Fig. 13.55.

The folded unipole antenna can be considered a modification of the standard shunt-fed system. Instead of a slant wire that leaves the tower at an approximate 45° angle (as used for shunt-fed systems), the folded unipole antenna has one or more wires attached to the tower at a predetermined height. The wires are supported by standoff insulators and run parallel to the sides of the tower down to the base.

The tower is grounded at the base. The folds, or wires, are joined together at the base and driven through an impedance matching network. Depending on the tuning requirements of the folded unipole, the wires may be connected to the tower at the top and/or at predetermined levels along the tower with shorting stubs.

The folded unipole can be used on tall (130° or greater) towers. However, if the unipole is not

FIGURE 13.55 The folds of the unipole antenna are arranged either near the legs of the tower or near the faces of the tower.

divided into two parts, the overall efficiency (unattenuated field intensity) will be considerably lower than the normally expected field for the electrical height of the tower.

FM Broadcast Antenna Systems

The propagation characteristics of VHF FM radio are much different than for MF AM. There is essentially no difference between day and night FM propagation. FM stations have relatively uniform day and night service areas with the same operating power.

A wide variety of antennas is available for use in the FM broadcast band. Nearly all employ circular polarization. Although antenna designs differ from one manufacturer to another, generalizations can be made that apply to most units.

Antenna Types

There are three basic classes of FM broadcast transmitting antennas in use today: *ring stub* and *twisted ring*, *shunt-* and *series-fed slanted dipole*, and *multi-arm short helix*. While each design is unique, all have the following items in common:

- The antennas are designed for side-mounting to a steel tower or pole.
- Radiating elements are shunted across a common rigid coaxial transmission line.
- Elements are placed along the rigid line every one wavelength.
- Antennas with one to seven bays are fed from the bottom of the coaxial transmission line.
- Antennas with more than seven bays are fed from the center of the array to provide more predictable performance in the field.
- Antennas generally include a means of tuning out reactances after the antenna has been installed through the adjustment of variable capacitive or inductive elements at the feed point.

Figure 13.56 shows a shunt-fed slanted dipole antenna that consists of two half-wave dipoles offset 90° . The two sets of dipoles are rotated 22.5° (from their normal plane) and are *delta-matched* to provide a $50\text{-}\Omega$ impedance at the radiator input flange. The lengths of all four dipole arms can be matched to

FIGURE 13.56 Mechanical configuration of one bay of a circularly polarized FM transmitting antenna.

TABLE 13.7 Various Combinations of Transmitter Power and Antenna Gain that will Produce 100-kW ERP for an FM Station

No. Bays	Antenna Gain	Transmitter Power (kW)

resonance by mechanical adjustment of the end fittings. Shunt-feeding (when properly adjusted) provides equal currents in all four arms.

Wide-band *panel antennas* are a fourth common type of antenna used for FM broadcasting. Panel designs share some of the characteristics listed previously, but are intended primarily for specialized installations in which two or more stations will use the antenna simultaneously. Panel antennas are larger and more complex than other FM antennas, but offer the possibility for shared tower space among several stations and custom coverage patterns that would be difficult or even impossible with more common designs.

The ideal combination of antenna gain and transmitter power for a particular installation involves the analysis of a number of parameters. As shown in Table 13.7, a variety of pairings can be made to achieve the same ERP.

Television Antenna Systems

Television broadcasting uses horizontal polarization for the majority of installations worldwide. More recently, interest in the advantages of circular polarization has resulted in an increase in this form of transmission, particularly for VHF channels.

Both horizontal and circular polarization designs are suitable for tower-top or side-mounted installations. The latter option is dictated primarily by the existence of a previously installed tower-top antenna. On the other hand, in metropolitan areas where several antennas must be located on the same structure, either a stacking or candelabra-type arrangement is feasible. Figure 13.57 shows an example of antenna stacking on the top of the Sears Tower in Chicago, where numerous TV and FM transmitting antennas are located. Figure 13.58 shows a candelabra installation atop the Mt. Sutro tower in San Francisco. The Sutro tower supports eight TV antennas on its uppermost level. A number of FM transmitting antennas and two-way radio antennas are located on lower levels of the structure.

Another approach to TV transmission involves combining the RF outputs of two stations and feeding a single wide-band antenna. This approach is expensive and requires considerable engineering analysis to produce a combiner system that will not degrade the performance of either transmission

FIGURE 13.57 Twin-tower antenna array atop the Sears Tower in Chicago. Note how antennas have been stacked to overcome space restrictions.

FIGURE 13.58 Installation of TV transmitting antennas on the candelabra structure at the top level of the Mt. Sutro tower in San Francisco. This installation makes extensive use of antenna stacking.

system. In the Mt. Sutro example (Fig. 13.58), it can be seen that two stations (channels 4 and 5) are combined into a single transmitting antenna.

Top-Mounted Antenna Types

The typical television broadcast antenna is a broadband radiator operating over a bandwidth of several megahertz with an efficiency of over 95%. Reflections from the antenna and transmission line back to the transmitter must be kept small enough to introduce negligible picture degradation. Furthermore, the gain and pattern characteristics of the antenna must be designed to achieve the desired coverage within acceptable tolerances. Tower-top, pole-type antennas designed to meet these parameters can be classified into two categories: *resonant dipoles* and *multi-wavelength traveling-wave elements*.

The primary considerations in the design of a top-mounted antenna are the achievement of uniform omnidirectional azimuth fields and minimum windloading. A number of different approaches have been tried successfully. [Figure 13.59](#) illustrates the basic mechanical design of the most common antennas.

Turnstile Antenna

The turnstile is the earliest and most popular resonant antenna for VHF broadcasting. The antenna is made up of four *batwing*-shaped elements mounted on a vertical pole in a manner resembling a turnstile. The four batwings are, in effect, two dipoles fed in quadrature phase. The azimuth-field pattern is a function of the diameter of the support mast. The pattern is usually within 10 to 15% of a true circle.

The turnstile antenna is made up of several layers, usually six layers for channels 2 through 6 and twelve layers for channels 7 through 13. The turnstile is not suitable for side-mounting, except for standby applications in which coverage degradation can be tolerated.

FIGURE 13.59 Various antennas used for VHF and UHF broadcasting. All designs provide linear (horizontal) polarization. Illustrated are (a) turnstile antenna, (b) coax slot antenna, (c) waveguide slot antenna, (d) zigzag antenna, (e) helix antenna, and (f) multi-slot traveling-wave antenna.

Coax Slot Antenna

Commonly referred as the *pylon antenna*, the coax slot (Fig. 13.59b) is the most popular top-mounted unit for UHF applications. Horizontally polarized radiation is achieved using axial resonant slots on a cylinder to generate RF current around the outer surface of the cylinder. A good omnidirectional pattern is achieved by exciting four columns of slots around the circumference, which is basically just a section of rigid coaxial transmission line.

The slots along the pole are spaced approximately one wavelength per layer, and a suitable number of layers are used to achieve the desired gain. Typical gains range from 20 to 40. By varying the number of slots around the periphery of the cylinder, directional azimuth patterns can be achieved.

Waveguide Slot Antenna

The UHF waveguide slot (Fig. 13.59c) is a variation on the coax slot antenna. The antenna is simply a section of waveguide with slots cut into the sides. The physics behind the design is long and complicated. However, the end result is the simplest of all antennas. This is a desirable feature in field applications because simple designs translate into long-term reliability.

Zigzag Antenna

The zigzag is a panel array design that utilizes a conductor routed up the sides of a three- or four-sided panel antenna in a “zigzag” manner (see Fig. 13.59d). With this design, the vertical current component along the zigzag conductor is mostly canceled out, and the antenna can effectively be considered an array of dipoles. With several such panels mounted around a polygonal periphery, the required azimuth pattern can be shaped by proper selection of feed currents to the various elements.

Helix Antenna

A variation on the zigzag, the helix antenna (Fig. 13.59e) accomplishes basically the same goal using a different mechanical approach. Note the center feed point shown in the figure.

VHF Multi-slot Antenna

Mechanically similar to the coax slot antenna, the VHF multi-slot antenna (Fig. 13.59f) consists of an array of axial slots on the outer surface of a coaxial transmission line. The slots are excited by a traveling wave inside the slotted line. The azimuth pattern is typically within 5% of omnidirectional. The antenna is generally about 15 wavelengths long.

Circularly Polarized Antennas

Circular polarization holds the promise of improved penetration into difficult coverage areas. There are a number of points to weigh in the decision to use a circularly polarized (CP) antenna, not the least of which is that a station must double its transmitter power in order to maintain the same ERP if it installs a CP antenna. This assumes equal vertical and horizontal components.

It is possible, and sometimes desirable, to operate with *elliptical polarization*, in which the horizontal and vertical components are not equal. Furthermore, the azimuth patterns for each polarization can be customized to provide the most efficient service area coverage.

Three major antenna types have been developed for CP television applications: the *normal mode helix*, *various panel antenna designs*, and the *interlaced traveling wave array*.

Normal Mode Helix

The normal mode helix consists of a supporting tube with helical radiators mounted around the tube on insulators. The antenna is broken into sub-arrays, each powered by a divider network. The antenna is called the “normal mode helix” because radiation occurs normal to the axis of the helix, or perpendicular to the support tube. The antenna provides an omnidirectional pattern.

Panel Antennas

The basic horizontally polarized panel antenna can be modified to produce circular polarization through the addition of vertically polarized radiators. Panel designs offer broad bandwidth and a wide choice of radiation patterns. By selecting the appropriate number of panels located around the tower, and the proper phase and amplitude distribution to the panels, a number of azimuth patterns can be realized. The primary drawback to the panel is the power distribution network required to feed the individual radiating elements.

Interlaced Traveling Wave Array

As the name implies, the radiating elements of this antenna are interlaced along an array, into which power is supplied. The energy input at the bottom of the antenna is extracted by the radiating elements as it moves toward the top. The antenna consists of a cylindrical tube that supports the radiating elements. The elements are slots for the horizontally polarized component and dipoles for the vertically polarized component. The radiating elements couple RF directly off the main input line; thus, a power dividing network is not required.

Side-Mounted Antenna Types

Television antennas designed for mounting on the faces of a tower must meet the same basic requirements as a top-mounted antenna—wide bandwidth, high efficiency, predictable coverage pattern, high gain, and low windloading—plus the additional challenge that the antenna must work in a less-than-ideal environment. Given the choice, no broadcaster would elect to place its transmitting antenna on the side of a tower instead of at the top. There are, however, a number of ways to solve the problems presented by side-mounting.

Butterfly Antenna

The butterfly is essentially a batwing panel developed from the turnstile radiator. The butterfly is one of the most popular panel antennas used for tower-face applications. It is suitable for the entire range of VHF applications. A number of variations on the basic batwing theme have been produced, including modifying the shape of the turnstile-type wings to rhombus or diamond shapes. Another version utilizes multiple dipoles in front of a reflecting panel.

For CP applications, two crossed dipoles or a pair of horizontal and vertical dipoles are used. A variety of cavity-backed crossed-dipole radiators are also utilized for CP transmission.

The azimuth pattern of each panel antenna is unidirectional, and three or four such panels are mounted on the sides of a triangular or square tower to achieve an omnidirectional pattern. The panels can be fed in-phase, with each one centered on the face of the tower, or fed in rotating phase with the proper mechanical offset. In the latter case, the input impedance match is considerably better.

Directionalization of the azimuth pattern is realized by proper distribution of the feed currents to individual panels in the same layer. Stacking layers provides gains comparable with top-mounted antennas.

The main drawbacks of panel antennas include (1) high windload, (2) complex feed system inside the antenna, and (3) restrictions on the size of the tower face, which determine to a large extent the omnidirectional pattern of the antenna.

UHF Side-Mounted Antennas

Utilization of panel antennas in a manner similar to those for VHF applications is not always possible at UHF installations. The high gains required for UHF broadcasting (in the range of 20 to 40, compared with gains of 6 to 12 for VHF) require far more panels with an associated complex feed system.

The zigzag panel antenna has been used for special omnidirectional and directional applications. For custom directional patterns, such as a cardioid shape, the pylon antenna can be side-mounted on one of the tower legs. Many stations, in fact, simply side-mount a pylon-type antenna on the leg of the tower that faces the greatest concentration of viewers. It is understood that viewers located behind the tower will receive a poorer signal; however, given the location of most TV transmitting towers—usually on the outskirts of their licensed city or on a mountaintop—this practice is often acceptable.

Broadband Antennas

Radiation of multiple channels from a single antenna requires the antenna to be broadband in both pattern and impedance (VSWR) characteristics. As a result, a broadband TV antenna represents a significant departure from the narrowband, single-channel pole antennas commonly used for VHF and UHF. The typical single-channel UHF antenna uses a series feed to the individual radiating elements, while a broadband antenna has a branch feed arrangement. The two feed configurations are shown in [Fig. 13.60](#).

- At the design frequency, the series feed provides co-phased currents to its radiating elements. As the frequency varies, the electrical length of the series line feed changes such that the radiating elements are no longer in-phase outside of the designed channel. This electrical length change causes significant beam tilt out of band, and an input VSWR that varies widely with frequency.
- In contrast, the branch feed configuration employs feed lines that are nominally of equal length. Therefore the phase relationships of the radiating elements are maintained over a wide span of frequencies. This provides vertical patterns with stable beam tilt, a requirement for multi-channel applications.
- The basic building block of the multi-channel antenna is the broadband panel radiator. The individual radiating elements within a panel are fed by a branch feeder system that provides the panel with a single input cable connection. These panels are then stacked vertically and arranged around a supporting spine or existing tower to produce the desired vertical and horizontal radiation patterns.

Bandwidth

The ability to combine multiple channels in a single transmission system depends on the bandwidth capabilities of the antenna and waveguide or coax. The antenna must have the necessary bandwidth in both pattern and impedance (VSWR). It is possible to design an antenna system for low-power applications using coaxial transmission line that provides whole-band capability. For high-power systems, waveguide bandwidth sets the limits of channel separation.

Antenna pattern performance is not a significant limiting factor. As frequency increases, the horizontal pattern circularity deteriorates, but this effect is generally acceptable. Also, the electrical aperture increases with frequency, which narrows the vertical pattern beamwidth. If a high-gain antenna were used over a wide bandwidth, the increase in electrical aperture might make the vertical pattern beamwidth unacceptably narrow. This, however, is usually not a problem because of the channel limits set by the waveguide.

Horizontal Pattern

Because of the physical design of a broadband panel antenna, the cross-section is larger than the typical narrowband pole antenna. Therefore, as the operating frequencies approach the high end of the UHF band, the *circularity* (average circle to minimum or maximum ratio) of an omnidirectional broadband antenna generally deteriorates.

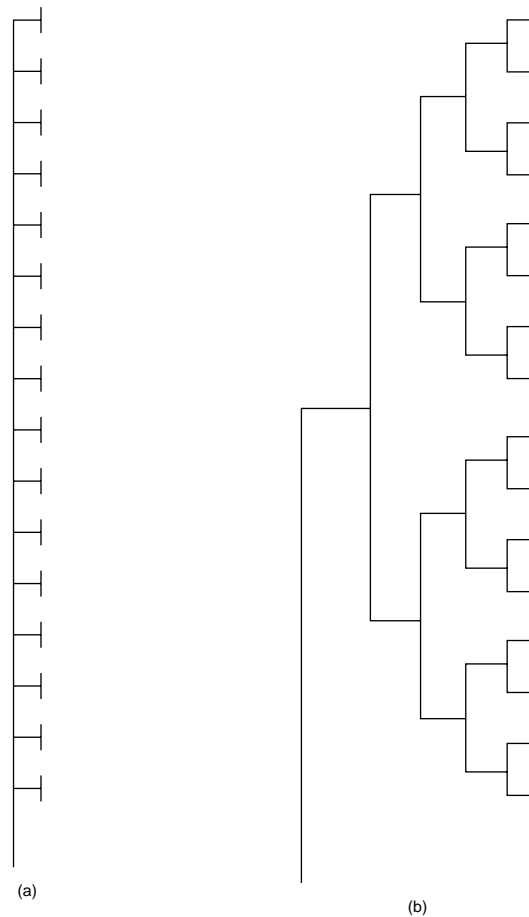

FIGURE 13.60 Antenna feed configurations: (a) series feed, and (b) branch feed.

Improved circularity is possible by arranging additional panels around the supporting structure. Typical installations have used five, six, and eight panels per bay. These are illustrated in Fig. 13.61 along with measured patterns at different operating channels. These approaches are often required for power handling considerations, especially when three or four transmitting channels are involved.

The flexibility of the panel antenna allows directional patterns of unlimited variety. Two of the more common applications are shown in Fig. 13.62. The peanut and cardioid types are often constructed on square support spines (as indicated). A cardioid pattern may also be produced by side-mounting on a triangular tower. Different horizontal radiation patterns for each channel may also be provided, as indicated in Fig. 13.63. This is accomplished by changing the power and/or phase to some of the panels in the antenna with frequency.

Most of these antenna configurations are also possible using a circularly polarized panel. If desired, the panel can be adjusted for elliptical polarization with the vertical elements receiving less than 50% of the power. Using a circularly polarized panel will reduce the horizontally polarized ERP by half (assuming the same transmitter power).

13.3.4 Phased-Array Antenna Systems

Phased-array antennas are steered by tilting the phase front independently in two orthogonal directions called the array coordinates. Scanning in either *array coordinate* causes the beam to move along a cone

FIGURE 13.61 Measured antenna patterns for three types of panel configurations at various operating frequencies: (a) five panels per bay, (b) six panels per bay, and (c) eight panels per bay.

FIGURE 13.62 Common directional antenna patterns: (a) peanut, and (b) cardioid.

FIGURE 13.63 Use of a single antenna to produce two different radiation patterns, omnidirectional (trace “A”) and peanut (trace “B”).

FIGURE 13.64 Optical antenna feed systems: (a) lens, and (b) reflector.

the center of which is at the center of the array. As the beam is steered away from the array normal, the projected aperture in the beam's direction varies, causing the beamwidth to vary proportionately.

Arrays can be classified as either *active* or *passive*. Active arrays contain duplexers and amplifiers behind every element or group of elements of the array. Passive arrays are driven from a single feed point. Active arrays are capable of high-power operation. Both passive and active arrays must divide the signal from a single transmission line among all the elements of the system. This can be accomplished through one of the following methods:

- *Optical feed*: a single feed, usually a monopulse horn, is used to illuminate the array with a spherical phase front (illustrated in Fig. 13.64). Power collected by the rear elements of the array is transmitted through the phase shifters to produce a planar front and steer the array. The energy can then be radiated from the other side of the array, or reflected and reradiated through the collecting elements. In the latter case, the array acts as a steerable reflector.
- *Corporate feed*: a system utilizing a series-feed network (Fig. 13.65) or parallel-feed network (Fig. 13.66). Both designs use transmission-line components to divide the signal among the elements. Phase shifters can be located at the elements or within the dividing network. Both the series- and parallel-feed systems have several variations, as shown in the figures.
- *Multiple-beam network*: a system capable of forming simultaneous beams with a given array. The Butler matrix, shown in Fig. 13.67, is one such technique. It connects the N elements of a linear array to N feed points corresponding to N beam outputs. The phase shifter is one of the most critical components of the system. It produces controllable phase shift over the operating band of the array. Digital and analog phase shifters have been developed using both ferrites and pin diodes.

FIGURE 13.65 Series-feed networks: (a) end feed, (b) center feed, (c) separate optimization, (d) equal path length, and (e) series phase shifters.

Frequency scan is another type of multiple-beam network, but one that does not require phase shifters, dividers, or beam-steering computers. Element signals are coupled from points along a transmission line. The electrical path length between elements is longer than the physical separation, so a small frequency change will cause a phase change between elements that is large enough to steer the beam. This technique can be applied only to one array coordinate. If a two-dimensional array is required, phase shifters are normally used to scan the other coordinate.

FIGURE 13.66 Types of parallel-feed networks: (a) matched corporate feed, (b) reactive corporate feed, (c) reactive stripline, and (d) multiple reactive divider.

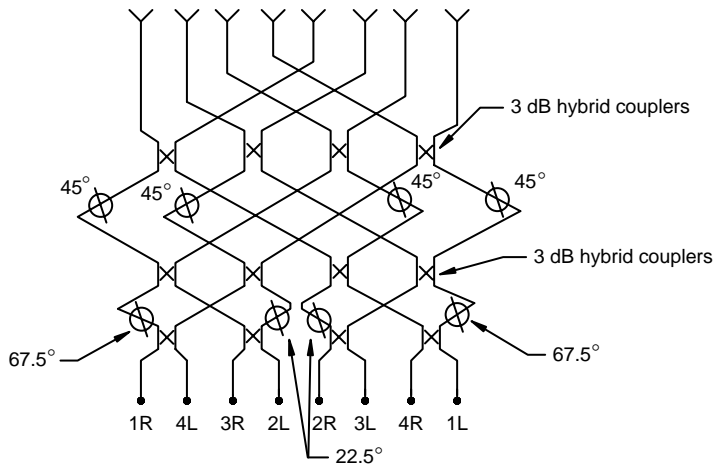

FIGURE 13.67 The Butler beam-forming network.

Phase-Shift Devices

The design of a phase shifter must meet two primary criteria

- Low transmission loss
- High power-handling capability

The Reggia-Spencer phase shifter meets both requirements. The device, illustrated in Fig. 13.68, consists of a ferrite rod mounted inside a waveguide that delays the RF signal passing through the waveguide, permitting the array to be steered. The amount of phase shift can be controlled by the current in the solenoid, because of the effect a magnetic field has on the permeability of the ferrite. This design is a

FIGURE 13.68 Basic concept of a Reggia-Spencer phase shifter.

FIGURE 13.69 Switched-line phase shifter using pin diodes.

reciprocal phase shifter, meaning that the device exhibits the same phase shift for signals passing in either direction (forward or reverse). Nonreciprocal phase shifters are also available, where phase-shift polarity reverses with the direction of propagation.

Phase shifters may also be developed using pin diodes in transmission line networks. One configuration, shown in Fig. 13.69, uses diodes as switches to change the signal path length of the network. A second type uses pin diodes as switches to connect reactive loads across a transmission line. When equal loads are connected with $1/4$ -wave separation, a pure phase shift results.

Radar System Duplexer

The duplexer is an essential component of any radar system. The switching elements used in a duplexer include gas tubes, ferrite circulators, and pin diodes. Gas tubes are the simplest. A typical gas-filled TR tube is shown in Fig. 13.70. Low-power RF signals pass through the tube with little attenuation. Higher-power signals, however, cause the gas to ionize and present a short-circuit to the RF energy.

Figure 13.71 illustrates a balanced duplexer using hybrid junctions and TR tubes. When the transmitter is on, the TR tubes fire and reflect the RF power to the antenna port of the input hybrid. During the receive portion of the radar function, signals picked up by the antenna are passed through the TR tubes and on to the receiver port of the output hybrid.

Newer radar systems often use a ferrite circulator as the duplexer. A TR tube is required in the receiver line to protect input circuits from transmitter power reflected by the antenna because of an imperfect match.

FIGURE 13.70 Typical construction of a TR tube.

FIGURE 13.71 Balanced duplexer circuit using dual TR tubes and two short-slot hybrid junctions: (a) transmit mode, and (b) receive mode.

A four-port circulator generally is used with a load between the transmitter and receiver ports so that power reflected by the TR tube is properly terminated.

Pin diode switches have also been used in duplexers to perform the protective switching function of TR tubes. Pin diodes are more easily applied in coaxial circuitry, and at lower microwave frequencies. Multiple diodes are used when a single diode cannot withstand the expected power.

Microwave filters are sometimes used in the transmit path of a radar system to suppress spurious radiation, or in the receive signal path to suppress spurious interference.

Harmonic filters commonly are used in the transmission chain to absorb harmonic energy output by the system, preventing it from being radiated or reflected back from the antenna. Figure 13.72 shows a filter in which harmonic energy is coupled out through holes in the walls of the waveguide to matched loads.

FIGURE 13.72 Construction of a dissipative waveguide filter.

Narrow-band filters in the receive path, often called *preselectors*, are built using mechanically tuned cavity resonators or electrically tuned TIG resonators. Preselectors can provide up to 80 dB suppression of signals from other radar transmitters in the same RF band, but at a different operating frequency.

13.4 Combiners and Combining Networks

Robert A. Surette

13.4.1 Introduction

Transmitting several frequencies from a single broadband antenna system requires the use of combining networks. In general, a combiner can be categorized as one of three types: runout, branched (star point), and balanced (constant impedance). Any of these types may employ band-reject (notch) or bandpass filters. Finally, components such as isolators can be added to a combiner network tailor the basic system to a specific application. This section discusses the use of filters, isolators, and other components in FM, UHF-TV, VHF-TV, and land mobile communication combiner networks.

13.4.2 Why Combiners Are Used

As populations migrate from rural areas to the suburbs, it has become more desirable to construct large transmission facilities that can reach these heavily populated areas from central locations. Of course, these prime locations have become more valuable, and so it makes sense to use each to its fullest potential. This can best be done by sharing a transmitter site and a common antenna among several users. To accomplish this, the industry uses combiners of various types and sizes.

For example, in San Francisco, Toronto, and Montreal, huge towers have been built to consolidate as many broadcasting facilities as possible, including VHF-TV, UHF-TV, FM, and land mobile communications services. This approach has proven very effective, not only using real estate economically, but spreading the tower costs over many users. In fact, the CN tower carries virtually all of the services in the Toronto area. These installations, of course, employ combiner networks to prevent interference among services.

Federal Communications Commission (FCC) Isolation Requirements

Why not just merge two or more signals together in a tee and send them to a common antenna? Because unless they are stopped by some means, the signals will backfeed up each other's input lines and into the transmitters where spurious intermodulation products (*spurs*) will be generated within the final cavities of the transmitters. These spurs will then be transmitted up to the antenna and broadcast. FCC rules specify that spurs must be 80 dB below the carrier frequency, so care must be taken to prevent them.

To keep a transmitter from generating spurs, it must be isolated from unwanted signals by approximately 40 dB. Therefore, the basic design criterion for a combiner is to provide 40 dB of isolation, plus a 6–10 dB safety margin. The closer the spacing of the frequencies between transmitters, the more filtering that is required to attain the 46–50 dB of isolation. The farther the spacing, the less filtering that is required. Modern FM combiners provide isolation of 75–80 dB, and along with transmitter losses of 13 dB, ensure that the 80-dB FCC spur rule is met.

Group Delay Equalization

The complex signals that make up today's broadcasts require extensive use of the full channel bandwidth. Any filter system has a tendency to throw the edges of the channel out of phase with the fundamental frequency, inducing crosstalk among the subcarriers. This is called *group delay* or *group delay difference*. Modern transmitter/combiner systems include group delay equalization devices, which compensate for this phase distortion. In FM, this is normally done at the combiner input, using high-power components. A television channel, with its many subcarriers, requires similar equalization, but here this is commonly achieved using low-level equipment within the transmitter. In contrast, a land mobile channel uses such a narrow bandwidth that group delay typically is not an issue. With these principles in mind, the type of combiner and the components used will depend on the number of channels to be combined and their frequency spacing.

13.4.3 History of FM Combiners in the U.S.

Dr. Andrew Alford designed several of the early combiner systems in the U.S. A major installation was the multichannel system on the Empire State Building in New York in the mid-1950s. This system used pairs of hybrids with a phase-delaying cavity in one leg of each hybrid pair. In the mid-1960s, for the John Hancock Building in Chicago, he designed a runout combiner system, again using quadrature hybrids, but the phase matching was accomplished with coaxial *runout* lines instead of cavities, to combine 10 stations into one broadband antenna. Both of these early combiners have since been replaced by balanced bandpass systems.

Many manufacturers now design and build combining systems. Just outside Houston, Texas, the Senior Road project is a 10 channel system. This early 1980s installation was the last of the large notch-filter balanced combiners in the U.S. In Miami, Florida, the first high-powered, expandable balanced combiner system using bandpass filtering and group delay equalization was installed in the mid 1980s.

13.4.4 Components of Combiners

Tee and Star Junctions

A tee junction, shown in Fig. 13.73, is a coaxial component that provides for two RF signals to flow into a common path; a star junction is a tee with more than two input paths. This basic coaxial component is one of the building blocks of a *branched combiner*.

FIGURE 13.73 Tee junction schematic diagram.

Filters

Filters sort RF frequencies, attenuating some while allowing others to pass readily. Depending on the filter design, a narrow bandwidth may be attenuated (*band-reject type*), or only a narrow bandwidth may be passed (*bandpass type*).

Bandpass Filters

Figure 13.74 shows the basic configuration of a bandpass filter cavity. The cavity is tuned to a resonant frequency by adjusting the length of the tuning probe. When RF energy is applied to the input coupling loop, the loop inductively couples the energy into the cavity. Energy is transferred through the cavity and is inductively coupled to the output coupling loop. As Fig. 13.76, curve A indicates, the transfer of energy is maximized at the resonant frequency of the cavity. A cavity that is larger overall is more efficient in that it will provide a lower insertion loss at the desired frequency at comparable isolation of other frequencies.

The placement, size, and rotation of the coupling loops are chosen to give a range of coupling that corresponds with a range of attenuation required for a given application. Figure 13.75 is an impedance diagram for a single bandpass cavity, and Fig. 13.76 shows its frequency response. As the loops are adjusted away from full coupling (curves A) to less coupling (curves B) and still less coupling (curves C), the impedance curve (Fig. 13.75) moves farther from the center of the chart for a given frequency change, and the isolation increases (Fig. 13.76). The increase in insertion loss is represented by the movement away from the center of the chart at f_0 for both the impedance curve (Fig. 13.75) and the response curve (Fig. 13.76).

In most cases, a single bandpass cavity will not yield enough isolation or impedance band width for modern transmitters. To increase the isolation and improve impedance bandwidth, a second cavity may be added to the first, as shown in Fig. 13.77.

FIGURE 13.74 Typical bandpass filter cavity design.

When two identical cavities are coupled 1/2-wave apart, the impedances superimpose themselves as shown in Fig. 13.78, and when the results are added together mathematically, their much-improved combined impedance bandwidth is as shown in Fig. 13.79. Curve A of Fig. 13.80 shows the frequency response of the two-cavity filter.

When still more isolation is required, more cavities can be added. Figure 13.81 is an impedance diagram for a three-cavity system; Fig. 13.82 for a four-cavity system. Curves B and C of Fig. 13.80 show the frequency responses of a three-cavity system and a four-cavity system, respectively. A four cavity bandpass filter is about as large a filter system as is needed for most high-isolation applications.

It is important to realize that the optimum spacing of the cavities is 1/2-wave, and that as the frequency increases the electrical wavelength decreases. Therefore, the length of the intercavity coax must be shortened. At the top end of the FM band, the 24-in-diam cavities used for high-power applications are difficult to link together, because the large cavities themselves approach 1/4 electrical wavelength in radius. As a result, when the intercavity coax is added the mechanical spacing is longer than 1/2-wavelength. In this case, the coupling loops can be manipulated to compensate for the extra length, so that the impedance bandwidth of the cavities is maintained.

This problem can also be prevented by building the cavities contiguous to each other and coupling them through an iris in the wall between them, as shown in Fig. 13.83. The electrical 1/2-wave spacing is maintained by the coupled fields between the cavities.

FIGURE 13.75 Impedance diagram for a single cavity, showing the effects of loop adjustment.

FIGURE 13.76 Frequency response for a single cavity, showing the effects of loop adjustment.

FIGURE 13.77 Loop-coupled cavities.

Band-Reject or Notch Filters

There are several ways to design a notch filter, but they all accomplish the same purpose. In one form, a notch filter is a bandpass cavity with only an input coupling loop, mounted off the transmission line by means of a matched tee. Other designs employ some form of capacitive coupling of the tuned frequency into a cavity and away from the main transmission line.

A notch filter provides a path, which removes the tuned frequency from the system, allowing other frequencies to pass with minimum loss, instead of passing the RF energy through the cavity as described in the last section. The response curve of a single-cavity notch filter is shown in Fig. 13.84; its impedance plot is basically the same as that of a bandpass cavity (Fig. 13.74). When a single notch cavity is used, an impedance matching network is added to the filter to improve the impedance bandwidth. When more isolation is needed two notch cavities are coupled in sequence, and if 1/2-wave spacing is used, the impedance bandwidth is basically the same as for a two-cavity bandpass system (shown in Fig. 13.79).

When two notch filters are used in sequence, the resonant frequencies of the cavities can be identical, yielding a response curve with a deep narrow-band notch, as shown in Fig. 13.85, or they can be staggered to give a broader notch response, as shown in Fig. 13.86.

Hybrids

A *quadrature hybrid* (usually just called *hybrid*) is a broadband device that has the ability to operate in various modes either singly or simultaneously. Figures 13.87 and 13.88 show a typical hybrid. In Fig. 13.87, the hybrid is acting as a power and phase splitter. When an RF signal is applied to port 1 the hybrid splits the signal in half and the phase of the port-4 output is delayed with respect to port 3 by 90°. Port 2 is called the *isolated port* and is usually terminated with a 50-Ω resistive load.

Use of a hybrid for combining is shown in Fig. 13.88. If two equal RF signals, with the proper phase, are introduced at ports 1 and 2, the combined signal exits the hybrid through port 4. If the phase of the two input signals is reversed, the signal will exit the hybrid through port 3. Again the isolated port is usually terminated with a resistive load.

The hybrid's third mode of operation is called the *reflected mode* and is shown in Fig. 13.89. When

FIGURE 13.78 Impedance diagram showing the superposition of two identical cavities $\lambda/2$ apart.

FIGURE 13.79 Combined impedance diagram for a two-cavity system.

FIGURE 13.80 Typical frequency response diagrams: (a) Two-, (b) three-, (c) four-cavity bandpass filters.

two identical devices with high impedance to the signal frequency, such as bandpass or band-reject cavities, are attached to ports 3 and 4 of the hybrid, the signal entering at port 1 is reflected and exits the hybrid through port 2.

Two hybrids can be connected together to form what some engineers call a *hybrid ring*. As shown in Fig. 13.90, when an RF signal is applied to port 1, the energy flows diagonally across and exits port 4 with little loss; ports 2 and 3 are isolated by a factor of 35 dB. If the two hybrids are tuned for a specific frequency this isolation can be optimized to 40 dB.

The multiple operational modes of the quadrature hybrid make it the backbone of the *balanced* and *runout* combiners, which will be described later in this chapter.

Resistive Loads

Resistive loads, often called *dummy* loads, are used in many applications and can be manufactured in many sizes and impedances depending on the requirements. In a dummy load, incoming power is absorbed and converted to heat. The heat must then be dissipated to the surrounding air, so that the power rating of a dummy load is determined by the size of the resistor and the amount of heat that can be dissipated before the resistor overheats and fails. If enough resistors can be chained together with enough cooling, they can dissipate a substantial amount of RF energy. Most coaxial systems use either 50- or 75-Ω dummy loads, depending on the base impedance of the system.

Isolators and Circulators

An isolator provides nonreciprocal transmission of a desired RF signal. The working component of an isolator is a *circulator*, a three-port device that will conduct a signal between its ports in a circular mode, as shown in Fig. 13.91(a). Power from the transmitter, introduced at leg 1, will flow with low loss to leg 2,

FIGURE 13.81 Impedance diagram for a three-cavity bandpass filter.

FIGURE 13.82 Impedance diagram for a four-cavity bandpass filter.

FIGURE 13.83 Iris-coupled cavities.

but will encounter high impedance in leg 3. Reflected power entering at leg 2 will likewise be diverted to leg 3. When leg 3 is terminated with a matched load, it effectively isolates the transmitter from its own reflected power and from externally generated signals from antennas, transmitters, and other sources on leg 2. Modern circulators provide as little as 0.1-dB insertion loss, while providing isolation of 30–35 dB per junction.

The two basic types of circulators, shown in Fig. 13.91(b) and Fig. 13.91(c), consist of Y-shaped conductors sandwiched between magnetized ferrite discs. The final shape, dimensions, and type of material varies according to frequency of operation, power handling requirements, and the method of coupling. The distributed constant circulator is the older design; it is a broadband device, not quite as efficient in terms of insertion loss and leg-to-leg isolation, and considerably more expensive to produce, but useful in applications where broadband isolation is needed. More common is the *lump constant circulator*, a less expensive and more efficient but narrow-band design.

At least one filter is always installed directly after an isolator, since the ferrite material of the isolator generates harmonic signals. If an ordinary bandpass or band-reject filter is not to be used, a harmonic filter will be needed.

13.4.5 Types of Combiners

Runout Combiners

In the early days of FM combining systems, the easiest way known to combine two frequencies was to use a hybrid ring where one leg contained an extended path equaling an even multiple of both electrical lengths. This was accomplished by adding a long length of coaxial transmission line (the runout) between the two hybrids to connect two of the internal ports, as shown in Fig. 13.92, while the other two internal ports were directly connected. The transmitter-to-transmitter isolation for this combining system depends on the accuracy of the runout line length and the tuning of the hybrid ring.

For a two-station system, this is fairly straightforward. But for each additional station, an additional combining stage and another long length of line are necessary. The line length for each stage is calculated from the new frequency and the center frequency of the preceding stage. The major disadvantage of this method is that the runout lines tend to be hundreds

FIGURE 13.84 Typical frequency response for a single cavity band-reject filter.

FIGURE 13.85 Frequency response for a two-cavity band-reject filter with identical resonant frequencies.

FIGURE 13.86 Frequency response for a two-cavity band-reject filter with staggered resonant frequencies.

of feet long and are difficult to store and protect. Also, this type of combiner is narrow band, because it is line-length dependent. Finally, the isolation is not high enough for modern transmitters. Therefore, notch filters have had to be added to retrofit existing systems.

A variation of the FM runout combiner used a filter in place of the long runout line to provide the same electrical delay. However, this modification did not substantially improve the electrical performance of the system, and notch filtering has also been added to retrofit these systems.

Runout combiners are no longer used for high-powered FM broadcast systems, but they are commonly used for low-powered UHF TV combiners, where shorter wavelengths and lower power allow the unit and its runout line to fit in a standard rack mount.

Branched or Star Point Combiners

A branched combiner is a simple combination of a tee junction and the required number of filters to ensure a sufficient amount of isolation. For example, an FM branched combiner containing a three-cavity bandpass filter in series with a two-cavity band-reject filter may be used to combine two close-spaced (0.8 MHz) frequencies. This close spacing requires maximum filtration.

Refer again to Fig. 13.80, curve B (response curve for a three-cavity bandpass filter) and Fig. 13.86 (response curve for a two-cavity band-reject filter). When these filters are added in series, the resulting

response curve is shown in Fig. 13.93. Note that the insertion loss for the pass frequency f_1 is only about 0.25 dB and the isolation at the reject frequency f_2 is greater than 50 dB across the channel. The impedance plot, Fig. 13.94, is the combination of impedance plots, Fig. 13.81 and Fig. 13.79, for the same filter combination. The filter system is tuned for one of the channels in a two-station branched combiner, and forms one leg of the combiner. The second leg is a similar combination of filters tuned for the other frequency, and its response plot resembles a mirror-image of Fig. 13.93. The basic schematic, Fig. 13.95, shows the combiner configuration. TX1 and TX2 are the signals from transmitters 1 and 2 as they enter the combiner. The length of the coaxial line between each set of filters and the tee junction is tuned to

FIGURE 13.87 A hybrid used as a signal splitter.

FIGURE 13.92 Runout combiner schematic diagram.

provide a high impedance to the other frequency, so that the power flow of each signal is through its own filter, out of the tee junction, and up to the antenna.

A branched combiner is efficient for a two-station installation, but as more stations are tied into the common tee junction, not only does the tee junction become impractically large, but the mechanics of tuning the interconnecting coax become more complex. Above about four or five stations, a balanced combiner becomes more practical and cost effective.

Balanced Combiners

The balanced combiner, like the runout combiner, uses a hybrid ring as the basis for its operation. Each leg of the ring contains an identical set of either bandpass or band-reject filters, hence the term balanced.

Notch Filter Balanced Combiners

In the notch-filter balanced combiner (Fig. 13.96), both notch filters within the hybrid ring are tuned to reflect TX1’s frequency, which enters the combiner (black arrows) at the narrow-band input port, port 1. That signal is reflected by the filters, and exits at the broadband output port, port 2. TX2 (gray arrows) enters the broadband input port of the module, port 3, passing through in the diagonal mode shown in Fig. 13.90, with minimal loss in the reject cavities. The isolation of TX1 through the module to TX2 is a function of both the hybrid ring isolation of 35 dB and the depth of the notch cavities, which can approach 35 dB, as shown in Fig. 13.86. The isolation of TX2 to TX1 is only that of the hybrid ring, about 35 dB. Therefore, additional filtering

FIGURE 13.96 A typical notch-filter balanced combiner.

FIGURE 13.97 A typical notch filter balanced combiner with an added notch filter at the TX1 input.

tuned to TX2 is required to ensure that no spurs are generated within the transmitters. This added filter is shown in Fig. 13.97.

More modules must be added as the number of stations entering the system is increased. Figure 13.98 shows a three-station, two-module combiner. Note the filter in the TX1 input line, as described previously. The module 1 output becomes the input at module 2 port 1. Since both TX1 and TX2 are entering module 2 at port 1, the filter at the TX3 input at module 2s port 3 must now reject both frequencies, TX1 and TX2. This can be done with two reject filters or a bandpass filter tuned to TX3.

A further extension of this pattern is shown in Fig. 13.99, showing a five-station, four-module combiner. Note that in this example, each input filter is a bandpass tuned to the frequency of that input. If reject filters were to be used at the various inputs, each input would have to filter all of the frequencies previously introduced. Therefore, port 3 of module 2 would have to contain two filters; port 1 of module 3, three filters; and port 3 of module 4, four filters. This complicates the system. This situation is avoided by the use of a combination of internal band-reject and external bandpass filters, as shown.

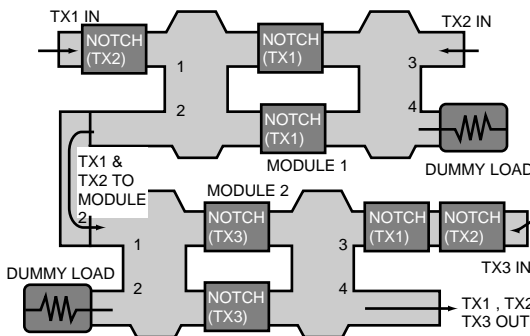

FIGURE 13.98 A typical three-station two-module notch-filter combiner.

FIGURE 13.99 A five-station, four-module balanced combiner system.

In some cases, instead of having a station located at port 3 of module 1, that port is terminated in a 50- Ω load and can be used as an emergency input for any station in the system. By providing an extra port in this way, a damaged module can be bypassed. Because of the particular configuration of that port, as long as the external filter at port 1 of module 1 is a bandpass filter, no input filtering is necessary.

A disadvantage of using internal notch filters is that if the two filters in a module are not identically tuned, an imbalance occurs within the hybrid ring, reducing the isolation to a point where a spur can be generated within a transmitter. Once a spur has been generated, there are no filters within the system to reject that spur, since the filters are tuned only to the expected frequencies. Therefore, the spur is broadcast.

A second disadvantage of using internal notch filters is that since each module in turn has to conduct the accumulated power of all of the previous modules, for a high-powered system each module must be larger than the previous one, and the power rating of the system can handle is limited by the size of the final module. Third, because of their electrical characteristics, notch-filter combiners tend to be narrow-band in nature, especially when the frequencies combined are close together. Because of these and other limitations of notch-filter systems, they are seldom used. Modern FM combiners use bandpass filters.

Bandpass Filter Balanced Combiners

In a bandpass filter balanced combiner system, the filters used within the hybrid ring are bandpass instead of notch filters. The basic layout is the same as that of a notch combiner. The difference in the power flow is shown in Fig. 13.100, as compared to Fig. 13.96. In the notch system, the filters are used to reflect signal TX1 entering the combiner's narrow-band input port (port 1). In the bandpass system the narrow-band signal TX1 also enters port 1, but passes through the hybrid ring bandpass filters and out the broadband output port (port 4), while the broadband input signal TX2, entering at port 3, is reflected by the filters and exits at port 4.

FIGURE 13.100 A bandpass-filter balanced combiner.

The isolation of TX1 to TX2 is only the hybrid ring isolation of about 35 dB, and the isolation of TX2 to TX 1 is the combination of the hybrid ring isolation (35 dB) and the isolation of the bandpass filter, which depends on the slope of the filter’s response curve.

For a single-module two-station installation, since the isolation of the TX1 to TX2 path is only 35 dB, a filter must be added between transmitter 2 and its input port (Fig. 13.101). Alternatively, a second module may be added, and port 3 of module 1 terminated in 50 Ω (and available as an emergency input port). Signal TX2 is then introduced at port 1 of module 2. A multiple-station installation (Fig. 13.102) is an extension of the latter configuration, where each frequency has its own module.

Unlike notch systems, in a bandpass system the accumulated power entering each module flows only through the output hybrid, so the power-handling capacity of the system is limited only by the size of the output hybrids and interconnecting transmission line, not the entire module.

When two FM broadcast stations are 1.2 MHz apart or closer, the bandpass filter’s response curve will not provide quite enough isolation, allowing a small amount of signal interaction. This interaction narrows the group delay curve of the module which is farthest from the antenna, as shown in Fig. 13.103. This phase distortion can be compensated for by adding a *group delay equalizer*, as shown in Fig. 13.104. This is a hybrid containing two dead-ended bandpass filters, which selectively delay the carrier frequency relative to the sidebands, yielding a net group delay curve, which approaches a square wave, as shown in Fig. 13.105. Group delay equalization can be achieved with high-power components at the input to the module or with low-power components at the output of the exciter of the transmitter.

Television Combiners

The first VHF-TV combiners were balanced combiners (Fig. 13.106), which used one notch cavity per leg of the hybrid ring. The aural or audio portion of the TV channel used the narrow-band port of the combiner

FIGURE 13.101 A typical bandpass-filter balanced combiner with an added filter at the TX2 input.

FIGURE 13.103 Asymmetrical phase distortion in the module farthest from the antenna.

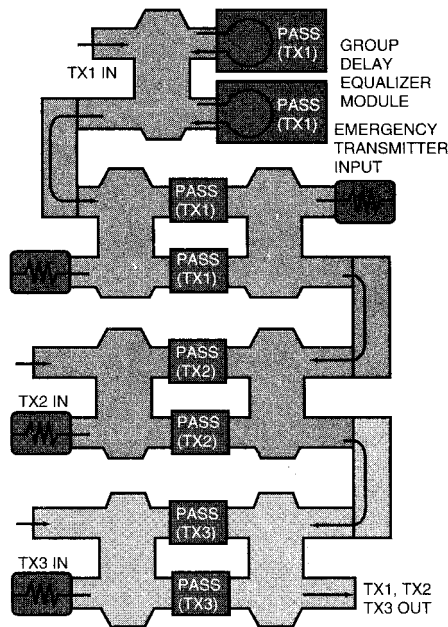

FIGURE 13.104 A bandpass-filter balanced combiner with a group delay equalizer.

FIGURE 13.105 Group delay for a bandpass filter module with a group delay equalizer.

FIGURE 13.106 A notch-filter television combiner.

module, while the broadband visual signal was introduced at the broadband port of the module.

With the advent of color TV a second set of notch cavities was added to the hybrid ring, and when TV stereo sound was introduced, a second set of aural notch cavities was added to the hybrid ring to increase the bandwidth on the narrow-band input port for the stereo aural channel. A modification to the basic TV combiner was later made by removing the color notch cavities from the hybrid ring and placing a single notch cavity in the transmission line between the visual transmitter and the combiner.

FIGURE 13.107 A bandpass-filter combiner for an inductive output tube signal.

For years UHF-TV combiners were basically the same as VHF-TV combiners, because the transmitters were the same design at different frequencies. Modern UHF-TV transmitters use a new type of amplifying device called an *inductive output tube* (IOT). Thus we call the UHF-TV combiner an IOT combiner. The IOT combiner is still a balanced system (Fig. 13.107), but instead of a number of specifically tuned notch cavities, a series of bandpass cavities allow the broadband UHF signal (black arrows) to pass through the combiner with little distortion while keeping spurs (gray arrows) to a minimum.

Combiners Using Isolators

Combiners using isolators and a single-bandpass cavity in place of multiple-bandpass cavities in each input line have been in use in land mobile applications for more than 30 years. Isolators lend themselves readily where the power requirements are limited and the channel bandwidth is relatively narrow. Figure 13.108

FIGURE 13.108 A branched combiner with isolators.

shows the schematic of a two-station branched combiner using an isolator and a single-filter cavity in each leg instead of a multiple-cavity filter as shown in Fig. 13.109.

Figure shows a *star-junction combiner*, earlier referred to as a star point. This is an extension of the branched combiner concept to multiple-channel combining, made possible because of the relatively small size of the components and the low-power requirements. Combiners up to 20 inputs have been built successfully using this method, provided that sufficient channel-to-channel spacing is available.

Figure 13.110 shows a line-segmented or line-insertion combiner, where the various transmitter inputs are introduced sequentially. The line lengths between the cavities and the tee junctions are critical, each about 1/2-wavelength long, adjusted for effects of cavity loop effective length, effective length of the tee connections, and velocity factor of the cable type employed.

The branched (or star-junction) type and the line-segmented type combiner are comparable in electrical performance. The choice of configuration is generally dictated by mechanical layouts, frequencies of transmitters to be combined, and cable characteristics. Occasionally, combinations of the two types are found, in which groups of star-junction combined transmitters are coupled to other groups by branches or line segments. In all cases, however, cable lengths and cavity loop adjustments are critical.

Figure 13.111 shows a two-station hybrid combiner, where two transmitters are merged in a single hybrid. Since there are no filters between the isolators and the hybrid, harmonic filters are added to remove the harmonics generated by the isolators. More stations may be added by adding additional combiner stages, in effect pyramiding the combiners. This configuration is used where channel-to-channel frequency spacing is very small (≈ 25 kHz), and since half the transmitter power is always lost in the load, this design is not for applications where high losses would be a problem.

Isolator combiners work well in land mobile applications because the RF power requirements are only a few hundred watts, compared to the broadcast industry, where many kilowatts of power are the standard.

Other caveats in the use of isolators include the following:

- It is critical that the impedance at all ports of the circulator, including the dummy load, be matched precisely. Poor matches result in poor isolation.
- Characteristics of transmission line and antennas influence isolator performance. The power rating of the load termination at the last isolator stage before feeding the antenna must be sized to handle the maximum, worst-case reflected power level.

FIGURE 13.109 A branched combiner with isolators.

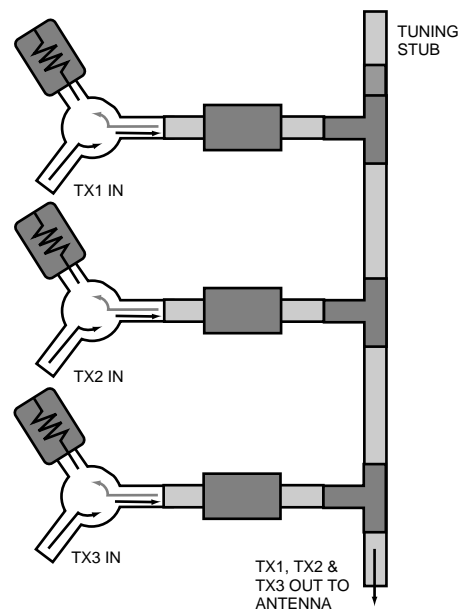

FIGURE 13.110 A line-segmented style combiner.

FIGURE 13.111 A hybrid isolator combiner.

- An isolator is not an impedance matching device. Proper cable lengths and the possible use of line matchers are means to match other devices to the characteristic design impedance of an isolator.
- Single isolators may be cascaded to secure added isolation. Better overall performance, less insertion loss, and lower overall costs are achieved through using multiple junction isolators.
- Benefits other than system isolation are provided by isolators. These include the firm source impedance of the isolator to amplifiers, filters, duplexers, and other devices.

Acknowledgments

The material in this chapter is the original contribution of the authors.

Robert A. Surette of Shively Labs, a producer of combiners, antennas, and other passive products for the FM broadcast industry, was primary contributor and oversaw the compilation of the chapter.

William F. Lieske, Sr. of EMR Corporation, which specializes in intermodulation control devices and antenna site consulting services, contributed the material on isolators and land mobile combiners.

Albert G. Friend of Shively Labs edited the text and created the illustrations.

14.1 Magnetic Tape

David Stafford

14.1.1 Introduction

Since its earliest use magnetic tape has been constantly evolving: paper backing has given way to polyester **base films**, chemical technology has advanced allowing higher performing particles to be used. It is true to say that many of the advances in recording formats would not have been possible if the associated advances in magnetic tape technologies had not also taken place.

This evolution has resulted in tape being a great deal more than just, as some people say, rust on plastic. Magnetic tape is an integral part of the recording process, as important a part as the recorder on which it is running. Many users tend to forget that, although tape is a relatively inexpensive item, its value, after the recording is finished, can be immense.

14.1.2 Trends in Magnetic Media

Although magnetic media, and their uses, have changed across many market segments since their inception, there is, perhaps, no segment that more typifies the changes that have taken place than the experience of the professional videotape market. Consequently, while acknowledging the significant changes that have been experienced in other segments of the magnetic tape market, the author chooses to concentrate mainly on the professional videotape market.

Applications

Just as videotape formats, and the magnetic tape used with them, have become more complex and demanding, so have the end user applications. In the early days of magnetic tape usage, simple recording and reproduction were the basic uses of the technology. Although this is still true, today's applications demand much more from magnetic tape than did their predecessors. Still framing, slow motion control, stop frame animation, high end graphics compiling, multiple pass performance (particularly in commercial and program insertion systems), and a host of other innovative applications demand a great deal from magnetic tape. In fact, magnetic media is now such an integral part of the production process many users tend to forget its fragile nature. The developments in videotape format technology have demanded that today's magnetic media must be stronger, more **durable**, of much higher quality and surface integrity, and utilize highly sophisticated chemicals and formulations compared with their predecessors. These factors present the magnetic media manufacturers with a complex set of design criteria. Many times one particular design criteria may contradict another, and the design of a particular product becomes a situation of balancing all requirements and producing the best possible product.

14.1.3 Manufacture of Magnetic Tape

The manufacture of magnetic tape, or *recording media* as it has more recently been named, is a complex process involving a wide variety of sciences and manufacturing disciplines. The process itself is essentially linear in concept, that is, one portion of the process follows its predecessor and cannot be started until its predecessor is complete. Clearly, the manufacturing process varies somewhat from manufacturer to manufacturer, and the intricacies of the process are closely guarded secrets. Consequently, the description of the process that follows is a generic one, and it is intended to give an overview of the process rather than an in-depth discussion of any one portion of the entire process. The flow chart shown in Fig. 14.1 graphically represents the entire manufacturing process.

FIGURE 14.1 Process flow diagram for the manufacture of magnetic tape.

Research and Development

The first step in the manufacture of a recording media product actually occurs well before the coating commences: research and development. The various chemists involved in the development effort determine the appropriate master formulation for a tape product of given performance parameters. Once this has been achieved, the formulation is then passed onto the manufacturing side for full-scale production.

This research and development phase may take several months, or even years, before a suitable formulation is developed. During this time, many trials, or experiments are conducted. Each of these trials examines a different chemical component and how its performance will affect the performance of the final product.

Typically, these trials are performed on coating lines especially developed for this purpose. They are usually 5–10 in wide (i.e., considerably narrower than their production counterparts) and capable of much shorter roll lengths. The use of these research and development lines enables the development effort to proceed in an environment conducive to rapid feedback and test data.

Mix Constituents

The formulation contains several components, each performing a specific function. Although the types of constituents may differ from one formulation to another, essentially all recording media coatings contain some or all of the following.

Magnetic Particles

As discussed earlier, the type of magnetic particles used has changed dramatically over the history of magnetic recording. Early audio tape products used ferric oxide (FeO_2) with coercivities in the 300–350 Oersted range. Trending toward higher energy particles, manufacturers then moved to gamma-ferric oxide, cobalt doped gamma-ferric oxide, metal particles, and barium-ferrite particles.

The trend is clearly toward metal particle products exhibiting high coercivities (1500–2200 Oe) and high retentivity performance. Generally, magnetic particles can be described as acicular in shape (somewhat like a sewing needle). The smaller size of metal particles enables more particles to be packed into a given surface area on the tape and allows much higher data packing densities.

Binders

In a very crude analogy, binders can be likened to glue. In this sense they provide the cross linking necessary to glue all of the mix ingredients together (*cohesion*) and to ensure the coating does not shed or flake off the base film (**adhesion**). Binders also add considerably to the stiffness of the finished tape product. Stiffness is required so that the tape wraps the **helical scanner** and transport assemblies properly and head-to-tape intimacy is maintained. Stiffness is often measured as coating modulus.

The term binder is a generic term covering a wide range of polymeric material such as polyurethane and vinyl chloride. A trend is toward the use of functionalized binder systems. These binders more effectively provide the cross linking necessary compared with their nonfunctionalized counterparts. Moreover, functionalized binder systems allow the formulating chemist to use fewer solvents and dispersants, thus simplifying the formulation chemistry. An added advantage is that as formulations become less complex in terms of the number of ingredients, the effect of random variations in raw chemicals is minimized. This helps to ensure a more consistent product.

Plasticizers

Many of the guides in tape transport require wrap angles of greater than 90° . This is particularly true in videotape transports. In some formats the tape must be moved around the scanner at the helix angle; consequently, some of these guides force tape in an other than vertical plane. This type of physical requirement places great demands on a tape product. There is a clear need for the tape to be flexible yet have relatively high **coating modulus**. Plasticizers perform this function. Without plasticizers, tape would be somewhat brittle and unable to survive the torture test of a transport. To be fair, however, equipment manufacturers design their transports so as to place the minimum possible physical requirements on the tape.

Head Cleaning Agents

Typically, head cleaning agents are added to formulations. Usually, this is in the form of alumina particles of a specific size. The purpose of these particles is to ensure the heads of the machine remain clean. In addition, these cleaning agents also keep the remaining portions of the tape path free from dirt and contamination.

There are a number of questions that are raised when discussing the amount of head cleaning agent. These pertain to head life and transport maintenance. Regarding head life, it is frequently stated that the alumina added to a tape formulation is responsible for premature head deterioration. This is not necessarily the case. The amount of head cleaning agent added is extremely important. If too much alumina is added certainly the abrasivity of the tape is higher and head life deterioration becomes an issue. If too little alumina is added the tape may not be able to keep the transport clean enough to ensure good head-to-tape intimacy and a poor quality recording results. Either way, there are many other factors that influence the abrasivity of a given tape. The type of particles, binder systems, and other formulation ingredients all play a role in determining a particular tape's abrasivity.

Regarding transport maintenance, the head cleaning agents added to a tape's formulation are no substitute for good engineering practices in the form of routine cleaning and transport maintenance. Routine cleaning and alignment checking are part of any good preventative maintenance regime and will help to reduce the incidence of dropouts and machine-induced physical damage.

Solvents

All of the mix ingredients are added together to form a *slurry*. Part of the formulation will include some solvents. These are used to dissolve other mix chemicals such as binders during the milling process. In addition, these solvents add to the formulation's rheological properties and effect the manner in which the finished mix flows. This directly impacts the manner in which the particular formulation performs on the coating line.

These solvents are not required in the final tape product. Accordingly, they are typically evaporated off the tape during the drying process. Many companies collect the solvent laden air and route it to some form of solvent recovery. Here the solvents are recovered using a distillation process. This is an environmental friendly process and typically yields solvents of better quality than those originally purchased from suppliers.

Dispersants

Because of their magnetic nature, particles tend to clump together in their raw form. This situation is not desirable as it would tend to result in some areas on the tape surface highly saturated with particles, whereas other areas may be entirely void of magnetic material. Dispersants are added to the formulation to aid in dispersing the particles evenly throughout the mix. The **dispersion** process is completed in mix preparation and can be achieved through a variety of methods. These methods are discussed in the subsequent section on mix preparations.

Fungicides

Surprisingly, fungus growth on the surface of tape is not uncommon. However, this situation is almost entirely confined to storage or operating environments with very high humidity. Fungicides are added to help prevent this phenomenon. Despite manufacturers' best efforts, however, poor storage environments are commonplace. Any reputable manufacturer will be able to provide information on the proper storage and handling procedures for their magnetic tape products.

Antistatic Agents

One of the causes of dropouts (i.e., the momentary loss of head-to-tape intimacy) is static electricity buildup. The buildup causes dust and dirt particles to attach themselves to the tape surface and cause a lack of head-to-tape intimacy. Antistatic agents are, therefore, added to tape formulations, particularly backcoat formulations. In most cases, carbon black is used for this purpose.

Mix Preparation

Once all of the formulation ingredients have been combined, it is necessary to *mill* the slurry so that two conditions are met. First, the magnetic particles, and other mix ingredients, must be thoroughly dispersed throughout the slurry. Second, all ingredients must be dissolved so that no particles larger than a given size remain. This process is achieved in a milling process, which can be performed in a variety of ways. Regardless of the method chosen, however, it is normal to filter the mix after milling to ensure no foreign particles were introduced during that process.

At the end of the milling process, the slurry is ready for coating and is a relatively thick, viscous liquid with a consistency somewhat like house paint.

Ball or Pebble Mills

Ball mills are the oldest of the milling technologies. Simply put, the ball mill is a horizontally oriented cylindrical rotating vessel into which the formulation is poured. The vessel is then rotated for a predetermined amount of time. The time is determined during the formulation development process. Inside the vessel is the milling media. In this case the media can either be steel balls or smooth pebbles. The media in the mill act on the formulation ingredients causing them to be fully dispersed throughout the slurry.

Sand Mills

Sand mills are a more recent technology and operate on a flow system rather than the static batch system of the ball mills. Sand mills are actually banks of milling vessels vertically oriented. The sand mills themselves do not rotate; rather, the mix is pumped through each vessel from bottom to top. As the mix is pumped through the vessel it must pass through a series of rotating disks and milling media. The media in this case is typically zirconium silicate. The number of vessels through which the mix must pass is determined during the formulation development process.

High Solids Mixers

The most recent advances in milling technology are high solids mixers, the most common of which, double planetary mixers, can be likened to an industrial dough mixer in a bakery. High solids mixers can operate in either a batch mode, like ball mills, or a continuous flow mode, like sand mills. As the name implies, this type of technology requires a much more viscous mix than do ball or sand mills. Consequently, this technology provides an efficient and effective milling procedure.

Base Film

As mentioned earlier, many of the base films in common use are *polyethylene terephthalate* films, usually known simply as polyester or PET films. Base films are made by a handful of manufacturers around the world. Films come in a variety of widths, lengths, thicknesses, and tensile properties. Different magnetic tape products call for different tensile properties.

Base films are becoming thinner with newer tape formats. This presents a unique challenge to the tape manufacturer. It is essential that tensile properties are maintained despite the move toward thinner films. Base film derives a lot of its stiffness from its thickness. Obviously, the thinner the film, the less stiff it may be.

Base film suppliers are constantly developing newer products to meet the changing needs of the tape manufacturer. *Polyethylene naphthalate* (PEN) and *polyaramide* base films are the next generation of films. As a general rule of thumb, both PEN and polyaramide films provide greater tensile strength than the same thickness PET film. This fact makes both PEN and polyaramide films attractive candidates for large-scale use in the future.

Coating

Coating can be achieved by a variety of methods with each method being desirable for certain types of coatings.

Knife Coating

Knife coating is probably the oldest type of coating method employed in the manufacture of magnetic tape. As Fig. 14.2 indicates, the wet mix is fed onto the base film and then past the knife blade. The blade height (with respect to the film) determines how much mix is left on the film. Knife coating is particularly good for relatively thick coatings such as those found on analog professional audio mastering tapes.

FIGURE 14.2 The knife coating process.

Reverse Roll

Reverse roll coating is somewhat newer and more complex than knife coating and, consequently, is capable of coating much thinner coatings. As indicated in Fig. 14.3, in this method, the mix is picked up from a holding vessel by the pick up roller and transferred to the applicator roll. A metering roll then meters the amount of mix on the applicator roll. The amount of mix remaining on the pick up roll is determined by the distance between the two rolls. The mix is then transferred to the base film.

Reverse roll coating was the mainstay of the tape industry for many years and is still in common use. Reverse roll coating is better suited to thinner coatings (compared to knife coating) such as those found on some older professional videotape formats.

Gravure Coating

Gravure coating comes to the tape industry from the printing industry. As Fig. 14.4 shows, the mix is picked up from a mix vessel and applied to the gravure roll. The gravure roll is pitted with cells, small holes of given diameter and depth. The diameter and depth of the cell, as well as the viscosity of the mix, together determine how much mix is coated onto the base film. Gravure coating is an ideal method for very thin coatings such as consumer VHS and the backcoats found on many professional video tapes.

More Recent Methods

Two other methods, multiple layer and evaporation, are in production use today. Multiple layer coating is a proprietary method capable of coating, as the name implies, multiple layers on a single base film. The layers can be coated at the same time and be of different formulations. The different layers, then, can serve different purposes in the recording process. Nonmagnetic layers are also possible.

Metal Evaporation (ME)

Metal evaporation tape (MET) is a relative newcomer to the tape industry and is generally restricted to newer videotape formats. As Fig. 14.5 indicates, the base film is passed over a cooled drum in a vacuum

FIGURE 14.3 Reverse roll coating.

FIGURE 14.4 The gravure coating process.

chamber. A pure metal rod is bombarded with electrons, and a metal vapor is produced. The vapor rises in the chamber and, by virtue of the cooler film surface, adheres to the base film. The metal evaporation technique can coat extremely thin magnetic layers. In fact, ME is capable of coatings that are measured in terms of angstroms rather than micrometers or microinches.

Orientation

After leaving the coating area, the web, as it is now called, passes through the **orientation process**. This process physically moves the individual particles into a specific direction. The direction desired is always identical to the direction of head travel across the tape, or as near to this direction as possible. In the case of the original videotape format quadruplex, develop by Ampex Corporation in 1956, the head traveled in a lateral or transverse direction. The particles in quad tape were therefore **oriented** in the lateral, or transverse, direction. Orienting particles increases electrical output and decreases noise introduced into the recorded or replayed signal by the tape itself. Since the introduction of helical scan technology, particles must be oriented in roughly a longitudinal direction.

Drying, Solvent Evaporation, and Recovery

As noted earlier, the mix formulation contains a number of different solvents. These solvents are, of course, undesirable in a finished product and, therefore, must be removed. The solvents are removed during the drying process.

FIGURE 14.5 The metal evaporation process.

After leaving the orientation stage, the coated web passes through a series of ovens. Each oven is a different temperature (matched to the evaporation temperature of one of the solvents in use). Within the ovens, the web typically travels over a series of *plenums*, which carry the tape on a cushion of hot air. This prevents the tape from touching any of the surfaces inside the oven, which would damage the coated surface.

The solvent laden air gathered in the process is then sent to solvent recovery. This is a relatively simple process whereby the air is passed through a vessel containing activated charcoal. The charcoal absorbs the evaporated solvent and the air is passed into the atmosphere. The charcoal is then flushed with steam and the solvents recovered in a *cracking tower* as part of a distillation process.

Calendering

After passing through the ovens, the coated web then passes through a series of calenders. Calendering may either be performed in-line, that is, in a continuous process, or off-line, which involves a separate set of calender stacks to those found on the coating line itself.

A calender stack consists of two rolls located side by side. The meeting point of the two rolls is called a *nip*. One of the rolls provides pressure and the other heat. The calendering process can be roughly likened to ironing. During the process, which may be multiple numbers of nips, the tape surface is smoothed. Smoother surfaces tend to give higher electrical outputs than rougher ones.

Take Up

If the calendering process is performed in-line, the last task in the coating line is to wind the coated and calendered web onto a hub ready for the slitting process. This station acts in the very same manner as the take up reel on a reel-to-reel audio recorder.

Slitting

Of course, a jumbo roll of tape is useless to the end user. It must be slit and packaged into a usable form. Slitting takes the jumbo roll and cuts it into strands of the appropriate width for the given format. Each strand is then wound onto a hub and is then known as a *pancake*. All slitters operate in a similar manner. The web passes through a series of blades, known as *arbors*. There are two major parts to the arbor. The first is the male cutting blade, which is typically positioned above the web surface. The second is the female guides, which are typically positioned below the surface.

The male and female portions of the arbor operate together to form the slitting process. Edge weave, so-called *country laning*, and edge quality are all critical factors that are controllable during this process. As noted earlier tape formats are becoming more demanding on the integrity of the magnetic surface. As well as the tape surface itself, edge quality becomes a major issue. Defects in edges are greatly magnified in smaller formats, which depend on every mechanical component of the recording process being within a very small tolerance range.

Assembly

Having now mixed, coated, calendered, and slit the tape into the appropriate lengths and widths, the final task is to load and assemble the cassettes or to add flanges to reels.

In cassette formats manufacturers now have a choice between spool loading and *in-cassette* loading. Spool loading is a process where the spools are wound with the correct amount of tape prior to being placed into the unfinished cassettes. The cassette is then assembled around the spools. In-cassette loading assembles the cassette first, and then winds the footage into the cassette by cutting and splicing the leader material from outside of the cassette. Each method has both advantages and disadvantages and depends, to a great extent, on production considerations, most notably that of automation.

Large-scale assembly of cassettes and their component parts is largely achieved through the use of relatively simple robotics and industrial controls. Typically, assembly lines have several stations where a certain task is performed: placing a guide, placing a break, inserting and driving screws into final position, etc. The use of robotics helps to improve consistency of product and lower the overall cost of manufacture.

Having now assembled the cassette or flanged the reel, the finished product is then placed in the appropriate packaging, labeled, and boxed ready for use.

Defining Terms

Adhesion: A condition that describes the degree to which a formulation is affixed to the associated base film.

Base film: A generic name for different types of polyester films that are used to support the formulation(s).

Binder: Material used to “bind” all the formulation ingredients together in a cohesive manner. Also used to ensure good adhesion to the base film.

Cobalt doped oxide: Typically gamma ferric oxide particles that have been doped, or treated, with cobalt in order to achieve a higher coercivity.

Coercivity: A measurement of the magnetic characteristics of a given particle. Technically, coercivity refers to the amount of magnetic energy required to bring a saturated magnetic particle to a zero, or demagnetized, state.

Component: A system whereby the components of a video signal remain in their component form, i.e., one luminance signal and two color difference signals. This method is used in order to maximize the luminance and chrominance bandwidth.

Composite: A system whereby the components of a video signal are combined into one signal.

Dispersion: Typically the degree to which a magnetic particle has been distributed through a formulation.

Durability: The ability of a piece of magnetic recording tape, or media, to perform under multiple shuttle, play or still frame conditions.

Helical scan: A method of video recorder and format design where the recording, replay, and flying erase heads are mounted on a rotating cylinder that lies at the helix angle.

High-energy tape: A generic term for magnetic recording media of higher than approximately 500 Oe. This family of products could use a variety of magnetic particles including cobalt dope gamma ferric oxide, BaFe, or metal particles.

Orientation: A process during which the magnetic particles are physically moved and aligned in a certain direction. This process is performed before the coated surface becomes dry and hard.

Orientation direction: The direction in which the magnetic particles are oriented during the manufacturing process, usually described with reference to the linear motion of the tape on the transport. For example in the Quadruplex format, the tape motion is linear but the orientation direction is traverse, or lateral. This is because the orientation direction matches the direction of head travel across the tape surface.

Packing density: A method of describing the amount of information that can be recorded on a given piece of magnetic tape of given size.

Quadruplex: The first practical videotape recording format. The format uses a series of four heads (hence quad.) mounted on the head drum. The head drum rotates transversely with respect to the direction of tape travel.

Retentivity: The amount of magnetic energy retained by a given particle when that particle has been raised to a saturated level.

14.2 Data Storage Systems

Jerry C. Whitaker

14.2.1 Introduction

The astounding volume of data being transmitted between systems today has created an obvious need for data management. As a result, more servers—whether they are PCs, UNIX workstations, minicomputers, or supercomputers—have assumed the role of information providers and managers. The number of networked or connectable systems is increasing by leaps and bounds as well, thanks to the widespread adoption of the client-server computing model. Hard disk storage plays an important role in enabling improvements to networked systems, because the vast and growing ocean of data needs to reside somewhere. It also has to be readily accessible, placing a demand upon storage system manufacturers to not only provide high-capacity products, but products that can access data as fast as possible and to as many people at the same time as possible. Such storage also needs to be secure, placing an importance on reliability features that best ensure data will never be lost or otherwise rendered inaccessible to network system users.

14.2.2 Redundant Arrays of Independent Disks (RAID) Systems

The common solution to providing access to many gigabytes of data to users fast and reliably has been to assemble a number of drives together in a gang or array of disks, known as **redundant arrays of independent disks (RAID)** subsystems. Simple RAID subsystems are basically a cluster of up to five or six disk drives assembled in a cabinet that are all connected to a single controller board. The RAID controller orchestrates read and write activities in the same way a controller for a single disk drive does, and treats the array as if it were in fact a single or **virtual drive**. RAID management software that resides in the host system provides the means to manage data to be stored on the RAID subsystem. A typical RAID configuration is illustrated in Fig. 14.6.

RAID Elements

Despite its multidrive configuration, the individual disk drives of a RAID subsystem remain hidden from users; the subsystem itself is the virtual drive, though it can be infinitely large. The phantom virtual drive is created at a lower level within the host operating system through the RAID management software. Not only does the software set up the system to address the RAID unit as if it were a single drive, it allows the subsystem to be configured in ways that best suit the general needs of the host system.

RAID subsystems can be optimized for performance, highest capacity, fault tolerance, or a combination of these attributes. Different **RAID levels** have been defined and standardized in accordance with these

FIGURE 14.6 A typical RAID configuration. (Source: Adapted from Heyn, T. 1995. The RAID Advantage. Seagate Technology Paper, Seagate, Scotts Valley, CA.)

general optimization parameters. There are six such standardized levels RAID, called RAID 0, 1, 2, 3, 4, and 5, depending on performance, redundancy and other attributes required by the host system.

The RAID controller board is the hardware element that serves as the backbone for the array of disks; it not only relays the input/output (I/O) commands to specific drives in the array, but provides the physical link to each of the independent drives so that they may easily be removed or replaced. The controller also serves to monitor the integrity of each drive in the array to anticipate the need to move data should it be placed in jeopardy by a faulty or failing disk drive (a feature known as *fault tolerance*).

RAID Levels

The RAID 0–5 standards offer users and system administrators a host of configuration options. These options permit the arrays to be tailored to their application environments. Each of the various configurations focus on maximizing the abilities of an array in one or more of the following areas:

- Capacity
- Data availability
- Performance
- Fault tolerance

RAID Level 0

An array configured to RAID level 0 is an array optimized for performance, but at the expense of fault tolerance or data integrity. RAID level 0 is achieved through a method known as **striping**. The collection of drives (*virtual drive*) in a RAID level 0 array has data laid down in such a way that it is organized in stripes across the multiple drives. A typical array can contain any number of stripes, usually in multiples of the number of drives present in the array. Take, as an example, a four-drive array configured with 12 stripes (four stripes of designated space per drive). Stripes 0, 1, 2, and 3 would be located on corresponding hard drives 0, 1, 2, and 3. Stripe 4, however, appears on a segment of drive 0 in a different location than stripe 0; stripes 5–7 appear accordingly on drives 1, 2, and 3. The remaining four stripes are allocated in the same even fashion across the same drives such that data would be organized in the manner depicted in Fig. 14.7. Practically any number of stripes can be created on a given RAID subsystem for any number of drives: 200 stripes on two disk drives is just as feasible as 50 stripes across 50 hard drives. Most RAID subsystems, however, tend to have between 3 and 10 stripes.

The reason RAID 0 is a performance-enhancing configuration is that striping enables the array to access data from multiple drives at the same time. In other words, because the data is spread out across a number of drives in the array, it can be accessed faster because it is not bottled up on a single drive. This is especially

FIGURE 14.7 In a RAID level 0 configuration, a virtual drive comprises several stripes of information. Each consecutive stripe is located on the next drive in the chain, evenly distributed over the number of drives in the array. (Source: Adapted from Heyn, T. 1995. *The RAID Advantage*. Seagate Technology Paper, Seagate, Scotts Valley, CA.)

beneficial for retrieving a very large file, because it can be spread out effectively across multiple drives and accessed as if it were the size of any of the fragments it is organized into on the data stripes.

The downside to RAID level 0 configurations is that it sacrifices fault tolerance, raising the risk of data loss because no room is made available to store redundant data. If one of the drives in the RAID 0 fails for any reason, there is no way of retrieving the lost data, as can be done in other RAID implementations.

RAID Level 1

The RAID level 1 configuration employs what is known as *disk mirroring*, which is done to ensure data reliability or a high degree of fault tolerance. RAID 1 also enhances read performance, but the improved performance and fault tolerance come at the expense of available capacity in the drives used. In a RAID level 1 configuration, the RAID management software instructs the subsystem's controller to store data redundantly across a number of the drives (mirrored set) in the array. In other words, the same data is copied and stored on different disks to ensure that, should a drive fail, the data is available somewhere else within the array. In fact, all but one of the drives in a mirrored set could fail and the data stored to the RAID 1 subsystem would remain intact. A RAID level 1 configuration can consist of multiple mirrored sets, whereby each mirrored set can be a different capacity. Usually the drives making up a mirrored set are of the same capacity. If drives within a mirrored set are of different capacities, the capacity of a mirrored set within the RAID 1 subsystem is limited to the capacity of the smallest capacity drive in the set, hence the sacrifice of available capacity across multiple drives.

The read performance gain can be realized if the redundant data is distributed evenly on all of the drives of a mirrored set within the subsystem. The number of read requests and total wait state times both drop significantly, inversely proportional to the number of hard drives in the RAID, in fact. To illustrate, suppose three read requests are made to the RAID level 1 subsystem (see Fig. 14.8). The first request looks for data in the first block of the virtual drive; the second request goes to block 0, and the third seeks from block 2. The host-resident RAID management software can assign each read request to an individual drive. Each request is then sent to the various drives, and now—rather than having to handle the flow of each data stream one at a time—the controller can send three data streams almost simultaneously, which in turn reduces system overhead.

RAID Level 2

RAID level 2 is rarely used in commercial applications, but is another means of ensuring data is protected in the event drives in the subsystem incur problems or otherwise fail. This level builds fault tolerance around Hamming error correction code (ECC), which is often used in modems and solid-state memory devices as a means of maintaining data integrity. ECC tabulates the numerical values of data stored on specific blocks in the virtual drive using a formula that yields a checksum. The checksum is then appended to the end of the data block for verification of data integrity when needed.

FIGURE 14.8 A RAID level 1 subsystem provides high data reliability by replicating (*mirroring*) data between physical hard drives. In addition, I/O performance is boosted as the RAID management software allocates simultaneous read requests between several drives. (Source: Adapted from Heyn, T. 1995. The RAID Advantage. Seagate Technology Paper, Seagate, Scotts Valley, CA.)

TABLE 14.1 Example of Error Correction Coding

Assume the phrase being stored is HELLO THERE . The checksum is computed for every 10 bytes of data.										
Data being stored:	H	E	L	L	O	T	H	E	R	E
Numerical representation:	72	69	76	76	79	84	72	69	82	69
Checksum formula:	x1	x2	x3	x4	x5	x6	x7	x8	x9	x10
Multiplied out:	72	138	228	304	395	504	504	414	738	690
[Check]sum of all values:	72	+138	+228	+304	+395	+504	+504	+414	+738	+690
										=3987

Thus, the data is stored on the drive as: 72 69 76 76 79 84 72 69 82 69 3987
 As the data is read back from the drive, the same calculations with the data segment are made. The newly computed checksum is compared against the previously stored checksum, thus verifying data integrity.

Source: Adapted from Heyn, T. 1995. The RAID Advantage. Seagate Technology Paper, Seagate, Scotts Valley, CA.

As data is read back from the drive, ECC tabulations are again computed, and specific data block checksums are read and compared against the most recent tabulations. If the numbers match, the data is intact; if there is a discrepancy, the lost data can be recalculated using the first or earlier checksum as a reference point, as illustrated in Table 14.1.

This form of ECC is actually different from the ECC technologies employed within the drives themselves. The topological formats for storing data in a RAID level 2 array is somewhat limited, however, compared to the capabilities of other RAID implementations, which is why it is not commonly used in commercial applications.

RAID Level 3

This RAID level is essentially an adaptation of RAID level 0 that sacrifices some capacity, for the same number of drives, but achieves a high level of data integrity or fault tolerance. It takes advantage of RAID level 0 data striping methods, except that data is striped across all but one of the drives in the array. This drive is used to store parity information for maintenance of data integrity across all drives in the subsystem. The parity drive itself is divided into stripes, and each parity drive stripe is used to store parity information for the corresponding data stripes dispersed throughout the array. This method achieves high data transfer performance by reading from or writing to all of the drives in parallel or simultaneously but retains the means to reconstruct data if a given drive fails, maintaining data integrity for the system. This concept is illustrated in Fig. 14.9. RAID level 3 is an excellent configuration for moving very large sequential files in a timely manner.

The stripes of parity information stored on the dedicated drive are calculated using the Exclusive OR function. By using Exclusive OR with a series of data stripes in the RAID, any lost data can easily be recovered. Should a drive in the array fail, the missing information can be determined in a manner similar to solving for a single variable in an equation.

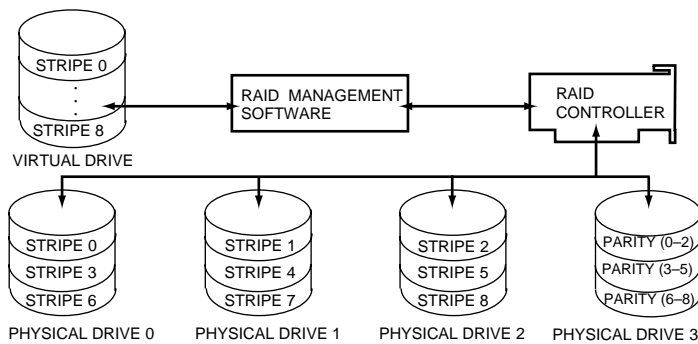

FIGURE 14.9 A RAID level 3 configuration is similar to a RAID level 0 in its utilization of data stripes dispersed over a series of hard drives to store data. In addition to these data stripes, a specific drive is configured to hold parity information for the purpose of maintaining data integrity throughout the RAID subsystem. (Source: Adapted from Heyn, T. 1995. The RAID Advantage. Seagate Technology Paper, Seagate, Scotts Valley, CA.)

FIGURE 14.10 RAID level 4 builds on RAID level 3 technology by configuring parity stripes to store data stripes in a nonconsecutive fashion. This enables independent disk management, ideal for multiple-read-intensive environments. (Source: Adapted from Heyn, T. 1995. *The RAID Advantage*. Seagate Technology Paper, Seagate, Scotts Valley, CA.)

RAID Level 4

This level of RAID is similar in concept to RAID level 3, but emphasizes performance for different applications, e.g., database files vs large sequential files. Another difference between the two is that RAID level 4 has a larger stripe depth, usually of two blocks, which allows the RAID management software to operate the disks more independently than RAID level 3 (which controls the disks in unison). This essentially replaces the high data throughput capability of RAID level 3 with faster data access in read-intensive applications. (See Fig. 14.10.)

A shortcoming of RAID level 4 is rooted in an inherent bottleneck on the parity drive. As data is written to the array, the parity encoding scheme tends to be more tedious in write activities than with other RAID topologies. This more or less relegates RAID level 4 to read-intensive applications with little need for similar write performance. As a consequence, like level 3, level 4 does not see much common use in commercial applications.

RAID Level 5

This is the last of the most common RAID levels in use, and is probably the most frequently implemented. RAID level 5 minimizes the write bottlenecks of RAID level 4 by distributing parity stripes over a series of hard drives. In so doing it provides relief to the concentration of write activity on a single drive, which in turn enhances overall system performance. (See Fig. 14.11.)

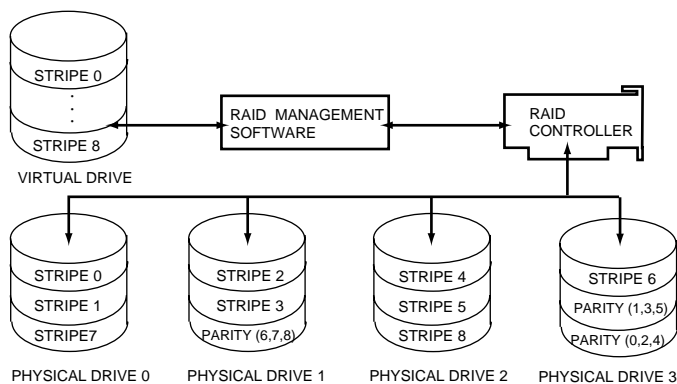

FIGURE 14.11 RAID level 5 overcomes the RAID level 4 write bottleneck by distributing parity stripes over two or more drives within the system. This better allocates write activity over the RAID drive members, thus enhancing system performance. (Source: Adapted from Heyn, T. 1995. *The RAID Advantage*. Seagate Technology Paper, Seagate, Scotts Valley, CA.)

TABLE 14.2 Summary of RAID Level Properties

RAID Level	Capacity	Data Availability	Data Throughput	Data Integrity
0	High	Read/write high	High I/O transfer rate	
1		Read/write high		Mirrored
2	High		High I/O transfer rate	ECC
3	High		High I/O transfer rate	Parity
4	High	Read high		Parity
5	High	Read/write high		Parity
6		Read/write high		Double parity
10		Read/write high	High I/O transfer rate	Mirrored
53			High I/O transfer rate	Parity

Source: Adapted from Heyn, T. 1995. The RAID Advantage. Seagate Technology Paper, Seagate, Scotts Valley, CA.

The way RAID level 5 reduces parity write bottlenecks is relatively simple. Instead of allowing any one drive in the array to assume the risk of a bottleneck, all of the drives in the array assume write activity responsibilities. This distribution frees up the concentration on a single drive, improving overall subsystem throughput. The RAID level 5 parity encoding scheme is the same as levels 3 and 4, and maintains the system's ability to recover lost data should a single drive fail. This can happen as long as no parity stripe on an individual drive stores the information of a data stripe on the same drive. In other words, the parity information for any data stripe must always be located on a drive other than the one on which the data resides.

Other RAID Levels

Other, less common RAID levels have been developed as custom solutions by independent vendors. Those levels include

- RAID level 6, which emphasizes ultrahigh data integrity
- RAID level 10, which focuses on high I/O performance and very high data integrity
- RAID level 53, which combines RAID levels 0 and 3 for uniform read and write performance

Custom RAID Systems

Perhaps the greatest advantage of RAID technology is the sheer number of possible adaptations available to users and systems designers. RAID offers the ability to customize an array subsystem to the requirements of its environment and the applications demanded of it. The inherent variety of configuration options provides several ways in which to satisfy specific application requirements, as detailed in Table 14.2. Customization, however, does not stop with a RAID level. Drive models, capacities, and performance levels have to be factored in as well as what connectivity options are available.

Defining Terms

Fiber channel-arbitrated loop (FC-AL): A high-speed interface protocol permitting high data transfer rates, large numbers of attached devices, and long-distance runs to remote devices using a combination of fiber optic and copper components.

Redundant arrays of independent disks (RAID): A configuration of hard disk drives and supporting software for mass storage whose primary properties are high capacity, high speed, and reliability.

RAID level: A standardized configuration of RAID elements, the purpose of which is to achieve a given objective, such as highest reliability or greatest speed.

Single connector attachment (SCA): A cabling convention for certain interface standards that simplifies the interconnection of devices by combining data and power signals as a common, standardized port.

Small computer systems interface (SCSI): A cabling and software protocol used to interface multiple devices to a computer system. These devices may be internal and/or external to the computer itself. Several variations of SCSI exist.

Striping: A hard disk storage organization technique whereby data is stored on multiple physical devices so as to increase write and read speed.

Thermal calibration: A housekeeping function of a hard disk drive used to maintain proper alignment of the head with the disk surface.

Virtual drive: An operational state for a computing device whereby memory is organized to achieve a specific objective that usually does not exist as an actual physical entity. For example, RAM in the computer may be made to appear as a physical drive, or two or more hard disks can be made to appear as a single physical drive.

Further Information

The technology behind designing and manufacturing hard disk drives is beyond the scope of this chapter, and because most of the applied use of disks involves treating the drive as an operational component (black box, if you will), the best source of current information is usually drive manufacturers. Technical application notes and detailed product specifications are typically available at little or no cost.

14.3 Optical Storage Systems

Praveen Asthana

14.3.1 Introduction

Recordable optical disk drive technology provides a well-matched solution to the increasing demands for removable storage. An optical disk drive provides, in a sense, infinite storage capabilities: Extra storage space is easily acquired by using additional media cartridges (which are relatively inexpensive). Such cost effective storage capabilities are welcome in storage-intensive modern computer applications such as desktop publishing, computer aided design/computer aided manufacturing (CAD/CAM), or multimedia authoring.

14.3.2 The Optical Head

The purposes of the optical head are to transmit the laser beam to the optical disk, focus the laser beam to a diffraction limited spot, and to transmit readout signal information from the optical disk to the data and servo-detectors.

The laser diode is a key component in optical storage, whether the recording technology is magneto-optic, ablative WORM, or phase change. Early generations of optical drives used infrared lasers emitting in the 780 nm or 830 nm wavelengths. Later generation of drives use red laser wavelengths emitting at around 690 nm. The lasers are typically rated to have a maximum continuous output power in the 40-mW range and are index guided to ensure good wavefront quality.

In a laser diode, light is emitted from the *facets*, which are the cleaved ends of the waveguide region of an index guided laser. The facet dimensions are small enough (order of a few micrometers) for diffraction to take place as light is emitted from the facet. As a result the output beam has a significant divergence angle. In many commercial laser diodes, the width of the facet (i.e., the dimensions parallel to the pn-junction plane) is much larger than the height (or the direction perpendicular to the junction plane), which causes the divergence angles to be unequal in the directions parallel and perpendicular to the laser junction. The spatial profile of the laser beam some distance from the laser is thus elliptical.

FIGURE 14.12 Drawing of the optical head in a typical magneto-optic disk drive. Shown is a split-optics design, which consists of a fixed set of components (the laser, detectors, and polarizing optics) and a movable system consisting of a beam bender and an objective lens that focuses the light on the disk. (Source: Asthana, P. 1994. *Laser Focus World*, Jan., p. 75. Penwell Publishing Co., Nashua, N.H. Used by permission.)

The basic layout of the optical head of a magneto-optic drive is shown in Fig. 14.12. The laser is mounted in a heat sink designed to achieve an athermal response. The output from the laser diode is collimated by lens 1. A prismlike optical element called a circularizer is then used to reduce the ellipticity of the laser beam. The beam then passes through a polarizing beamsplitter, which reflects part (30%) of the beam toward a detector and transmits the rest toward the disk.

The output of the laser is linearly polarized in the direction parallel to the junction (which will be referred to as P-polarization). The ratio of the intensity of the P-polarization component of the emitted light to the ratio of the intensity in the S-polarization component is $> 25:1$. This polarizing beam splitter is designed to transmit 70% of the P-polarized light and 100% of the S-polarized light. The light that is reflected is incident on a light detector, which is part of a power servoloop designed to keep the laser at a constant power. Without a power servoloop, the laser power will fluctuate with time as the laser junction heats up, which can adversely affect the read performance.

The beam transmitted by the beam splitter travels to a turning (90°) mirror, called a *beam bender*, which is mounted on a movable actuator. During track seeking operations, this actuator can move radially across the disk. The beam reflected by the turning mirror is incident on an objective lens (also mounted on the actuator), which focuses the light on the disk. This type of optical head design in which the laser, the detectors, and most of the optical components are stationary while the objective lens and beambender are movable is called a *split optics design*. In early optical drive designs, the entire optical head was mounted on an actuator and moved during seeking operations. This led to slow **seek times** (~ 200 ms) because of the mass on the actuator. A split optics design, which is possible because coherent light can be made highly collimated, lowers the mass on the actuator and thus allows much faster seek times.

The size of the focal spot formed by the objective lens on the disk depends on the *numerical aperture* (NA) of the lens and the amount of *overflow* of the lens (i.e., the amount with which the diameter of the incident collimated beam exceeds the aperture of the objective lens). The numerical aperture is given by $NA = n \sin \theta_{\max}$, in which n is the refractive index of the lens and θ_{\max} is the incidence angle of a light ray focused through the margin of the lens. The beam of light incident on the objective lens usually has a

Gaussian electric field (or intensity) profile. The profile of the focused spot is a convolution of the incident intensity profile and the aperture of the objective lens (Goodman, 1968). Overfilling the lens aperture reduces the size of the focused spot at the cost of losing optical energy outside the aperture and increasing the size of the side lobes. Optimization of the amount of overfill (Marchant, 1990) yields an approximate spot diameter of

$$D = 1.18\lambda/NA \quad (14.1)$$

in which λ is the wavelength of light and NA is the numerical aperture of the objective lens. The depth of focus z of the focal spot is given by $z = 0.8\lambda/(NA)^2$.

The depth of focus defines the accuracy with which the objective lens position must be held with respect to the disk surface. The smaller the depth of focus, the less tolerance the system has for media tilt and the more difficult the job of the focus servosystem. Thus trying to reduce the spot size (always a goal as a smaller spot allows a higher storage density) by increasing the NA of the lens becomes impractical beyond an NA of about 0.6. The objective lens also acts as a collector lens for the light that is reflected from the disk. This reflected light, used for the servosystems and during reading, contains the readout information. The reflected light follows the incident path up to the fixed optical element. Beamsplitter 1 reflects all of the S polarized light and 30% of the P polarized light in the direction of the servo and data detectors.

The portion of the light that is transmitted by the beamsplitter is, unfortunately, focused by the collimating lens back into the facet of the laser. This feedback light causes a number of problems in the laser, even though the net amount of feedback does not exceed about 7% of the output light for most magneto-optic media. Optical feedback affects the laser by causing the laser to mode hop randomly, which results in a random amplitude fluctuation in the output. This amplitude noise can be a serious problem and so techniques must be used to control the laser noise (such as injection of high-frequency current) or HFM (Arimoto, 1986). Increasing the HFM current in general can decrease the amount of noise, but as a practical matter, the injection current cannot be made arbitrarily large as it may then violate limits on allowable radiation from computer accessories. Optical feedback also decreases the threshold and increases the slope of the power-current (or PI) curve of the laser, but these effects are not really a problem.

The light reflected by beamsplitter 1 is further split by beamsplitter 2 into servo and data components. The light reflected by the beamsplitter is incident on the data detectors. For magneto-optic read back, two detectors are used in a technique known as *differential detection* (i.e., the difference in the signals incident on the two detectors is taken). The light transmitted through beamsplitter 2 is incident onto a special multielement servodetector and is used to generate the servosignals. The mechanism by which these signals are generated are the subject of the following discussion on the **servosystem**.

The Servosystem

The servosystem is what enables the focused laser spot to be positioned with accuracy onto any of the tracks on the disk and ensure that it can be moved to any track on the disk as required. The high track densities (18,000 tracks/in) on optical disks require that the laser spot position be controlled to within a fraction of a micrometer. To be able to move across the entire disk surface requires a large actuator, but such an actuator will be too massive to quickly respond to the rapid changes in the track position (due to run-out in the disk) as the disk spins. Therefore, a compound actuator consisting of a coarse actuator and a fine actuator is used to control the radial position of the laser beam on the disk. The fine actuator, which has a very low mass, can change the spot position rapidly over a limited range. The coarse actuator has a slower response, but has a much wider range of motion and is used for long seek operations. Optical disks have a continuous spiral groove (as in a phonograph record) to provide information on the relative track location.

In addition to **tracking** and seeking, the laser spot in an optical drive must be kept in perfect focus on the disk regardless of the motion of the disk (there can be quite a lot of vertical motion if the disk has tilt or is slightly warped). To do this, the objective lens must be constantly adjusted to correct for the axial motion of the disk surface as the media spins. The lens position is controlled by a focus servomechanism.

Figure 14.13 shows a block diagram of an optical drive servocontrol system (combined tracking and focusing). The return beam contains information on the focus and position of the spot, which is processed

FIGURE 14.13 Block diagram of the servocontrol system for an optical disk drive.

by the servo detectors. The feedback signals derived from the detectors allow the system to maintain control of the beam.

The focus control system requires a feedback signal that accurately indicates the degree and direction of focus error (Braat and Bouwhuis, 1978; Earman, 1982). To generate a focus error signal, an astigmatic lens is used to focus onto a quadrant detector, a portion of the light reflected from the disk. In perfect focus, the focal spot is equally distributed on the four elements of the quad detector (as shown in Fig. 14.14). However, if the lens is not in focus, the focal spot on the detector is elliptical because of the optical properties of the astigmatic lens. The unequal distribution of light on the detector quadrants generates a *focus error signal* (FES). This signal is normalized with respect to light level to make it independent of laser power and disk reflectivity. The focus actuator typically consists of an objective lens positioned by a small linear voice coil motor. The coils are preferably mounted with the lens to reduce moving mass, while the permanent magnets are stationary. The lens can be supported by either a bobbin on a sliding pin or elastic flexures. The critical factors in the design are range of motion, acceleration, freedom from resonances, and thermal considerations.

Once the spot is focused on the active surface, it must find and maintain position along the desired track. This is the role of the tracking servo. The same quadrant detector that is used to generate the focus signal can be used to generate the *tracking error signal* (TES). The beam returning from the disk contains first-order diffraction components; their intensity depends on the position of the spot on the tracks and varies the light falling along one axis of the quadrant detector. The TES is the normalized difference of the current from the two halves of the detector, and it peaks when the spot passes over the cliff between a land and groove (Mansuripur, 1987; Braat and Bouwhuis, 1978).

As a matter of terminology, the **seek time** usually refers to the actual move time of the actuator. The time to get to data, however, is called the **access time** which includes the latency of the spinning disk in addition to the seek time. For example, a drive spinning a disk at 3600 rpm has a latency of $(0.5 \times (60/3600))$ s or 8 ms. Thus, a 3600-rpm drive with a seek time of 30 ms will have an access time of 38 ms. The standard way to measure seek time is 1/3 of the full stroke of the actuator (i.e., the time it takes to cover 1/3 of the disk). This is a historical artifact from the times of early hard disk drives.

FIGURE 14.14 Focus control system: (a) the quad detector, (b) the spot of light focused on the quad by the astigmatic lens (circular implies objective lens is in focus), and (c) the spot of light on the quad when the objective lens is out of focus.

The ability to accurately follow the radial and axial motions of the spinning disk results directly from the quality of the focus and tracking actuators. To reject the errors due to shock, vibration, and media runout, the servosystem must have high bandwidth. The limitation to achieving high bandwidth is usually the resonance modes of the actuator. As the actuators are reduced in size, the frequencies of the resonances become higher and the achievable bandwidth of the system rises. Servosystems in optical drives face additional challenges because they have to handle removable media, which has variations between different disks (such as media tilt).

Optical Recording and Read Channel

A schematic block diagram of the functions in an optical drive is shown in Fig. 14.15. The SCSI controller handles the flow of information to and from the host (including commands). The optical disk controller

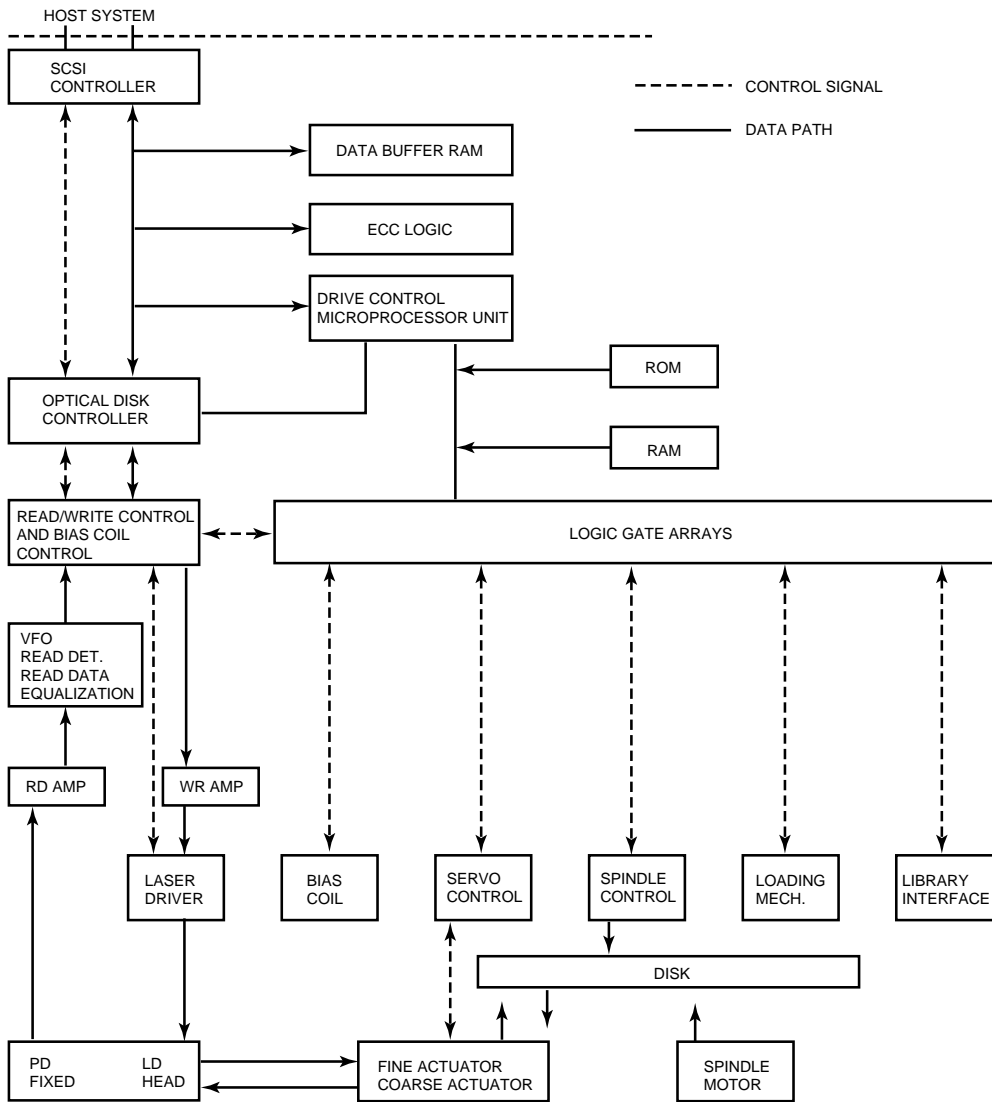

FIGURE 14.15 A functional block diagram of an optical disk drive describing the key electrical functions and interfaces. Some of the abbreviations are: VFO is the variable field oscillator, which is used to synchronize the data, RD amp is the read signal amplifier, WR amp is the write signal amplifier, PD fixed is the photodetector assembly, and LD head is the laser diode.

is a key controller of the data path. It interprets the commands from the SCSI controller and channels data appropriately through the buffer random access memory (RAM) to the write channel, or from the read channel to the output. The drive control microprocessor unit controls, through the logic gate arrays, all the functions of the optical drive including the servo control, spindle motor, actuators, laser driver, etc.

Data that are input to the drive over the SCSI for recording are first broken up into fixed **block sizes** (of, for example, 512 kilobyte or 1024 kilobytes length) and then stored in the data buffer RAM. Magneto-optic, phase-change, and WORM drives can be classified as *fixed block architecture* technologies in which data blocks are recorded much like in hard drives (Marchant, 1990). Blocks of data can be placed anywhere on the disk in any sequence. The current CD recordable drive is, on the other hand, an example of a non-fixed block architecture (because its roots are in CD audio). In common CD-R drives, input data are recorded sequentially (like a tape player) and can be of any continuous length.

Error correction and control (ECC) bytes are added to each block of data. Optical drives use Reed–Solomon codes, which are able to reduce the error rate from 1E-5 to about 1E-13 (Golomb, 1986). After the addition of ECC information, the data are encoded with run length limited (RLL) modulation codes (Tarzaiki, 1983; Treves and Bloomberg, 1986) in order to increase efficiency and improve detection. Special characters are inserted in the bit stream such as a synchronization character to tell where the data begins. All in all, the overhead required to store customer data is about 20%.

In most current optical drives, recording is based on **pulse position modulation (PPM)** techniques. In basic PPM recording, the presence of a mark signifies a one and the absence signifies a zero bit. Thus, a 1001 bit sequence would be recorded as mark-space-space-mark. In **pulse width modulation (PWM)** recording, the edges of the mark represent the one bits (Sukeda et al., 1987). Thus a 1001 bit sequence would be recorded as a single mark of a certain size. A longer bit sequence such as 10001 would be represented by a longer mark, hence the term pulse *width* modulation. The use of pulse width modulation allows a higher linear density of recording than pulse position modulation.

A comparison of PWM recording with the current technique of PPM is shown in Fig. 14.16. It is more difficult to implement PWM technology (a more complicated channel is required), and PWM writing has greater sensitivity to thermal effects. Thus implementing PWM is a challenging task for drive vendors.

FIGURE 14.16 Schematic showing the mark spacing for PPM and PWM recording. The PPM recording is used in most current optical drives. The PWM recording increases capacity by as much as 50% and will be used in almost all forthcoming writable optical drives. PWM recording, however, requires much tighter tolerances than PPM recording.

On readback, the light reflects from the disk and travels to a photodetector (or two detectors in the case of magneto-optic drives). For WORM, phase-change, and CD-R disks, the signal is intensity modulated and thus can be converted to current from the detectors and amplified prior to processing. The WORM, phase-change, and CD-R disks have a high contrast ratio between mark and no-mark on the disk and thus provide a good signal-to-noise ratio. In magneto-optic drives, the read signal reflected off the disk is not intensity modulated but *polarization* modulated. Thus polarization optics and the technique of differential detection must be used to convert the *polarization* modulation to intensity modulation (as is discussed later in the section on magneto-optic recording).

To extract the 1s and 0s from the noisy analog signal derived from the photodetectors, optical drives use a number of techniques, such as equalization, which boosts the high frequencies and thus provides greater discrimination between spots. Using an analog-to-digital converter, the analog data signal is converted into channel bits. The channel bits are converted back into customer data bytes using basically the reverse of the encoding process. The data is clocked into the decoder, which removes the modulation code. The remaining special characters are removed from the data, which is then fed into the ECC alignment buffer to correct any errors (up to 40 bytes long). Once data has been read from the disk, it is stored in a RAM buffer and then output to whatever readout device is hooked by SCSI to the drive. With this basic understanding of how data is recorded on a spinning disk, we can turn to the specific items such as recording physics that delineate the various recording technologies.

Phase-Change Recording

Phase-change recording takes advantage of the fact that certain materials can exist in multiple *metastable* (i.e. normally stable) crystalline phases, each of which have differing optical properties (such as reflectivity). Thermal energy (as supplied by the focused beam of a high-power laser) above some threshold can be used to switch from one metastable state to another (Ovshinsky, 1970; Takenaga et al., 1983). Energy below the switching threshold should have no effect. In this way a low-power focused spot can be used to read out the recorded information without affecting it.

To achieve this kind of multiple metastable states, phase-change materials typically are a mixture of several elements such as germanium, tellurium, and antimony ($\text{Ge}_2\text{Sb}_2\text{Te}_5$). Phase-change materials are available that are suited for either rewritable or write-once recordings. In an erasable material, recording is affected by melting the material under the focused spot and then cooling it quickly enough to freeze it in an amorphous phase. Rapid cooling is critical and, thus, the design of the heat sinking capability of the material is important.

Erasure of the phase-change material is achieved by an annealing process, that is, heating the material to just below the melting point for a long enough period to recrystallise the material and erase any amorphous marks.

The fact that phase-change materials are a mixture of several materials makes recyclability difficult to achieve. The melting/annealing processes increase phase segregation and thus reduce the number of cycles that can be achieved. Early phase-change materials could only achieve a few thousand cycles, which is one of the primary reasons they were passed over by many companies in favor of magneto-optical products when rewritable drives were being introduced. However, the cyclability of phase-change materials has increased substantially.

The advantage of phase-change recording over magneto-optic recording is that a simpler head design is possible (since no bias magnet and fewer polarizing optics are needed). The disadvantages include the fact that there is less standardization support for the phase-change format, and fewer companies produce the drives. For the consumer this means there is less interchange with phase-change than with magneto-optic.

14.3.3 Worm Technology

The earliest writable optical drives were, in fact, WORM drives, and although the rewritable drive is more popular for daily storage needs, the WORM technology has a clear place in data storage because it allows permanent archiving capability.

FIGURE 14.17 Permanent WORM recording provides the highest level of data security available in a removable storage device. In ablative WORM recording, marks are physically burned into the material. In phase-change worm, the recording process is a physical change in the material, which results in a change in reflectivity.

There are a number of different types of write-once technologies that are found in commercial products. Ablative WORM disks consist of tellurium-based alloys. Writing of data is accomplished by using a high-powered laser to burn a hole in the material (Kivits et al., 1982). A second type of WORM material is what is known as textured material, such as in a moth's eye pattern. The actual material is usually a platinum film. Writing is accomplished by melting the textured film to a smooth film and thus changing the reflectivity. Phase-change technology provides a third type of WORM technology using materials such as tellurium oxide. In the writing process, amorphous (dark) material is converted to crystalline (light) material by application of the heat from a focused laser beam (Wrobel et al., 1982). The change cannot be reversed. A comparison of phase-change and ablative WORM recording is shown schematically in Fig. 14.17.

14.3.4 Magneto-Optic Technology

In a magneto-optic drive, data recording is achieved through a thermomagnetic process (Mayer, 1958), also known as *Curie point writing* as it relies on the threshold properties of the Curie temperature of magnetic materials. In this process, the energy within the focused optical spot heats the recording material past its Curie point (about 200°C), a threshold above which the magnetic domains of the material are susceptible to moderate (about 300 G) external magnetic fields. Application of an external magnetic field is used to set the state of the magnetization vector (which represents the polarization of the magnetic domains) in the heated region to either up (a one bit) or down (a zero bit). When the material is cooled to below the Curie point this orientation of the magnetic domains is fixed. An illustration of the magneto-optic recording process is given in Fig. 14.18. This recording cycle has been shown to be highly repeatable (>1 million cycles) in any given region without degradation of the material. This is an important aspect if the material is to be claimed as fully rewritable.

In any practical recording process, it is necessary to have a sharp threshold for recording. This ensures the stability of the recorded information both to environmental conditions as well as during readout. Thermo-magnetic recording is an extremely stable process. Unless heated to high temperatures (>100°C), the magnetic domains in magneto-optic recording films are not affected by fields under several kilogauss in strength (in comparison, the information stored on a magnetic floppy is affected by magnetic fields as low as a 100 G). The coercivity of a magneto-optic material remains high until very close to the Curie temperature. Near the Curie temperature (about 200°C), the coercivity rapidly drops by two or three orders of magnitude as the magnetic domain structure becomes disordered.

Readout of the recorded information can safely be achieved with a laser beam of about 2-mW power at the disk, a power level which is high enough to provide good signal strength at the detectors, but low enough not to affect the recorded information because any media heating from it is far below the Curie threshold. During readout, the magnetic state of the recorded bits of information is sensed through the *polar-Kerr effect* by a low-power linearly polarized readout beam. In this effect the plane of polarization of the light beam is rotated slightly (0.5°) by the magnetic vector. The direction of rotation, which defines

FIGURE 14.18 Schematic showing the recording, readout, and erasure processes of a magneto-optic material.

whether the bit is a one or a zero, is detected by the readout detectors and channel. Although the tiny amount of Kerr rotation results in a very small amount of signal modulation riding on a large DC bias, the technique of differential detection permits acceptable signal-to-noise ratio (SNR) to be achieved.

The output signal in an MO recording system is the signal from the light falling on one detector minus the signal from the light falling on the other detector. By placing a polarizing beamsplitter at 45° to the incident polarization, the two data detectors get the signals (Mansuripur, 1982)

$$d_1 = \frac{I_0}{2} (\cos \theta_k/2 - \sin(\theta_k/2))^2 \approx \frac{I_0}{2} (1 - \theta_k) \quad (14.2)$$

$$d_2 = \frac{I_0}{2} (\cos \theta_k/2 + \sin(\theta_k/2))^2 \approx \frac{I_0}{2} (1 + \theta_k)$$

in which d_1 and d_2 refer to the detector signals, I_0 is the incident intensity, and $\theta_k/2$, the rotation angle, is assumed to be small. The readout signal is taken as

$$s = (d_1 - d_2)/(d_1 + d_2) \quad (14.3)$$

As can be seen, this signal does not contain intensity noise from either the laser or from reflectivity variations of the disk. But the signal is very sensitive to polarization noise, which may be introduced by polarization sensitive diffraction, by substrate birefringence effects, by inhomogeneities in the magneto-optic films, or by other polarization sensitive components.

Early MO recording media, such as manganese bismuth (MnBi) thin films (Chen et al., 1968), were generally crystalline in nature. The magnetic domains followed the crystalline boundaries and thus were irregular in shape (Marchant, 1990). The crystalline nature of the films caused optical scattering of the readout signal, and the irregular domains led to noise in the recorded signal. The combination degraded the SNR sufficiently to make polycrystalline magneto-optic media impractical.

The discovery in 1976 of magneto-optic materials based on the rare earth/transition metal (RE/TM) alloys (Choudhari et al., 1976) provided a practical material system for rewritable magneto-optic recording. These materials were amorphous and thus allowed acceptable signal-to-noise ratio to be obtained. Most commercial magneto-optic films today are based on terbium iron cobalt (TbFeCO).

14.3.5 Compact Disk-Recordable (CD-R)

The writable version of the popular CD-R disk looks very much like a stamped CD-ROM disk, and can be played in most CD-ROM players.

One of the reasons why CD-audio and CD-ROM have become so successful is the strict, uniform standards that all of the manufacturers of these products have adhered to. The standards were drawn up by Philips and Sony and are described by the colors of the books that they were first printed in. The standards describing CD-audio are found in the Red Book, those describing CD-ROM are found in the Yellow book, and those describing CD-R are found in the Orange Book. These books describe the physical attributes that the disks must meet (such as reflectivity, track pitch, etc.), as well as they layout of recorded data (Bouwhuis et al., 1985).

In prerecorded CD-ROM disks, the information is stamped as low reflectivity pits on a high reflectivity background. The disk has a reflectivity of 70% (achieved by using an aluminum layer), whereas the pits have a reflectivity of 30% (these reflectivity specifications have been defined in the Red Book). The CD-ROM drive uses this difference in reflectivity to sense the information stamped on the disk. To be compatible with CD-ROM readers, a CD-R disk must also use this reflectivity difference when recording data. To accomplish this, a CD-R disk is coated with an organic polymer that can change its local reflectivity permanently upon sufficient heating by a laser spot. The structure of a CD-R disk is shown in Fig. 14.19.

When the organic dye polymer is locally heated by the focused spot of a laser beam, polymeric bonds are broken or altered resulting in a change in the complex refractive index within the region. This refractive index change results in a change in the material reflectivity. There are a half-dozen organic dye polymers that are commercially being used. Two examples are phthalocyanine and poly-methane cyanine.

Like the CD-ROM drives, the CD-R drives have relatively low performance (when compared with optical or hard drives). The seek times are on the order of a few hundred milliseconds, whereas the maximum data rate for a 4X speed drive is about 600 kilobytes/s. The seek time is slow because the CD-R drives spin the disks in *constant linear velocity* (CLV) mode as defined in the Red Book standards. Constant linear velocity means that the disk rotation speed varies with the radius at which the read head is positioned in such a way as to ensure that the linear velocity is constant with radius.

Pure data devices such as hard disks and optical WORM drives, however, can handle constant angular velocity (CAV) operation in which the linear velocity and data rate increase with radial position. The disadvantage of CLV operation is that it results in a very slow access time. When a seek of the optical head is performed, the motor speed has to be adjusted according to the radial position of the head. This takes time and thus lengthens the seek operation to 250–300 ms. In contrast, constant angular velocity devices like optical WORM disks have seek times on the order of 40 ms.

The roots of CD-R are found in audio CD, and thus some of the parameters, recording formats, and performance features are based on the Red Book standard (which has tended to be a handicap). The CD format (Bouwhuis et al., 1985) is not well suited for random access block oriented recording. The CD format leads to a sequential recording system, much like a tape recorder.

FIGURE 14.19 The basic structure of a CD-R disk.

Recording Modes of CD-R

To understand the attributes and limitations of CD-R, it is important to understand the various recording modes that it can operate in. For fixed block architecture devices, the question of recording modes never comes up as there is only one mode, but in CD-R, there are four modes (Erlanger, 1994).

The four recording methods in CD-R drives are

- Disk-at-once (or single session)
- track-at-once
- Multisession
- Incremental packet recording

In disk-at-once recording, one recording session is allowed on the disk, whether it fills up the whole disk or just a fraction of the disk. The data area in a single session disk consists of a lead-in track, the data field, and a lead out track. The lead-in track contains information such as the table of contents (TOC). The lead-in and lead-out are particularly important for interchange with CD-ROM drives. In single session writing, once the lead-in and lead-out areas are written, the disk is considered finalized and further recording (even if there are blank areas on the disk) cannot take place. After the disk is finalized, it can be played back on a CD-ROM player (which needs the lead-in and lead-out tracks present just to read the disk).

Having just the capability of recording a single session can be a quite a limitation for obvious reasons, and so the concept of *multisession* recording was introduced. An early proponent of multisession recording was Kodak, which wanted multisession capability for its photo-CD products. In multisession recording, each session is recorded with its own lead-in and lead-out areas. Multisession recorded disks can be played back in CD-ROM drives that are marked multisession compatible (assuming that each session on the disk has been finalized with lead-in and lead-out areas). Unfortunately, the lead-in and lead-out areas for each session take up lots of overhead (about 15 megabytes). With this kind of overhead, the ultimate maximum number of sessions that can be recorded on a 650 megabyte disk is 45 sessions.

Rather than do multisession recording, the user may choose track-at-once recording. In this type of recording, a number of tracks (which could represent distinct instances of writing) could be written within each session. The maximum number of tracks that can be written on the whole disk is 99. However, the disk or session must be finalized before it can be read on a CD-ROM drive.

Because of the way input data are encoded and spread out, it is imperative to maintain a constant stream of information when recording. If there is an interruption in the data stream, it affects the whole file being recorded (not just a sector as in MO or WORM drives). If the interruption is long enough, it will cause a blank region on the disk and will usually lead to the disk being rendered useless.

Many of these problems or inconveniences can be alleviated through a recording method called *packet recording*. In packet recording, the input data are broken up into packets of specified size (for example 128 kilo-bytes or 1 megabyte). Each packet consists of a link block, four run-in blocks, the data area, and two run-out blocks. The run-in and run-out blocks help delineate packets and allow some room for stitching, that is, provide some space for overlap if perfect synching is not achieved when recording an adjacent packet in a different CD-R drive.

Packet recording has several advantages. To begin with, there is no limit to the number of packets that can be recorded (up to the space available on the disk, of course), and so limitations imposed by track-at-once, multisession, or disk-at-once can be avoided. Also, if the packet size is smaller than the drive buffer size (as is likely to be the case), a dedicated hard drive is not needed while recording. Once the packet of information has been transferred to the drive buffer, the computer can disengage and do other tasks while the CD-R drive performs the recording operation.

With the advent of packet recording, CD-R technology becomes much more flexible than in the past and thus more attractive as a general purpose removable data storage device. It can be used for backup purposes as well the storage of smaller files. However, there is a problem of interchange with CD-ROM players. Some CD-ROM players cannot read a CD-R disk that has been packet written because they post a hard error when they encounter the link block at the beginning of each packet. Packet written CD-R disks can be read on CD-R drives and on CD-ROM drives that are packet enabled.

FIGURE 14.20 Schematic showing a 5.25-in disk cartridge. The various slots in the cartridge can be sensed by the drive and thus provide information about the disk to the drive.

14.3.6 Optical Disk Systems

Disks

An important component of the optical storage system is, of course, the media cartridges. In fact, the greatest attraction of optical storage is that the storage media is removable and easily transported, much like a floppy disk. Most of the writable media that is available comes in cartridges of either 3.5- or 5.25-in. form factors. An example of the 5.25-in. cartridge is shown in Fig. 14.20. The cartridge has some sensory holes to allow its media type to be easily recognized by the drive. The tracks on the media are arranged in a spiral fashion. The first block of data is recorded on the innermost track (i.e., near the center). Recordable CD media is cartridgeless and is played in CD-R/CD-ROM drives either using a caddy or through tray loading (like audio CD players).

Cartridged media has been designed to have a long shelf and archival life (without special and expensive environmental control) and to be robust enough to survive the rigors of robotic jukeboxes and customer handling. Magneto-optic and WORM media is extremely stable and so data can be left on the media with great confidence (Okino, 1987). A chart showing projected lifetimes (after accelerated aging) of IBM WORM media is given in Fig. 14.21, which indicates that the lifetimes for 97.5% of the media surfaces for shelf and archival use are projected to exceed 36 and 510 years, respectively, for storage at 30°C/80%

FIGURE 14.21 Estimated lifetime of an IBM WORM disk. Lognormal plot of lifetimes for shelf and archival use. (Source: Wong, J.S. et al., 1993. Life expectancy of IBM write-once media. IBM White Paper, IBM Publications.)

relative humidity. Shelf life is the length of time that data can be effectively written, whereas archival life is the length of time that data can be effectively read.

Optical media is perhaps the most stable digital storage technology: magnetic drives are prone to head crashes, tape deteriorates or suffers from print through (in which information on one layer is transferred to another layer in the tightly wound tape coil), and paper or microfiche also deteriorate with time (Rothenberg, 1995).

Automated Optical Storage Systems

Optical drives can be extended to automated storage systems, which are essentially jukeboxes consisting of one or more optical drives and a large number of optical disk cartridges. Optical libraries can provide on-line, direct-access, high-capacity storage.

Applications of Optical Library Systems

Optical library systems fit well into a large computer-based environment, such as client-server systems, peer-to-peer local area networks, or mainframe-based systems. In such environments, there is a distinct storage hierarchy based on cost/access trade-off of various types of data. This hierarchy is shown schematically in Fig. 14.22 as a pyramid. The highest section of the pyramid contains the highest performance and highest cost type of memory. The most inexpensive (on a cost/megabyte) basis and lowest performance is that of tape. Optical libraries are an important part of this segment because they provide storage with performance capabilities approaching that of magnetic, but at a cost approaching that of tape.

An optical library contains a cartridge transport mechanism called an autochanger. The autochanger moves optical cartridges between an input/output slot (through which cartridges can be inserted into the library), the drives (where the cartridges are read or written), and the cartridge storage cells.

Sophisticated storage systems provide a hierarchical storage management capability in which data are automatically migrated between the various layers of the pyramid depending on the access needs of the data. For example, a telephone company can keep current billing information on magnetic storage, whereas billing information older than a month can be stored in optical libraries, and information older than six months can be stored on tape. It does not make sense to keep data that the system does not frequently access on expensive storage systems such as semiconductor memory or high-performance magnetic drives.

One of the applications for which automated optical storage is ideally suited is document imaging. Document imaging directly addresses the substantial paper management problem in society today. The way we store and manage paper documents has not changed significantly in over a century, and largely does not take advantage of the widespread availability of computers in the workplace. Trying to retrieve old paper documents is one of the most inefficient of business activities today (some businesses have stockrooms full of filing cabinets or document boxes). The way information is currently stored can be represented by a pyramid (as shown in Fig. 14.23), in which paper accounts for almost all of the document storage.

An application aimed squarely at re-engineering the way we handle and store documents is

FIGURE 14.22 The storage hierarchy.

document imaging. In document imaging, documents are scanned onto the computer and stored as computer readable documents. Storing documents in computer format has many advantages, including rapid access to the information. Recall of the stored documents is as easy as typing in a few key search words. Document imaging, however, is very storage intensive and, thus, a high-capacity, low-cost storage technology is required, ideally with fast random access. Optical storage is now recognized as the optimal storage technology in document imaging. Optical libraries can accommodate the huge capacities required to store large numbers of document images (text and/or photos), and optical drives can provide random access to any of the stored images. Figure 14.24 illustrates the equivalent storage capacity of a single 1.3 gigabyte optical disk.

Future Technology and Improvements in Optical Storage

Optical drives and libraries, like any high-technology products, will see two types of improvement processes. The first is an incremental improvement process in which quality and functionality will continuously improve. The second is a more dramatic improvement process in which disk capacity and drive performance will improve in distinct steps every few years.

For the library, the improvements will be in the speed of the automated picker mechanism as well as the implementation of more sophisticated algorithms for data and cartridge management. Most of the improvements in the library systems will arise out of improvements in the drives themselves.

For the optical drive, the incremental improvement process will concentrate on the four core technology elements: the laser, the media, the recording channel, and the optomechanics. The laser will see continual improvements in its beam quality (reduction of wavefront aberrations and astigmatism), lifetime (which will allow drive makers to offer longer warranty periods), and power (which will allow disks to spin faster). The media will see improvements in substrates (reduction of tilt and birefringence), active layers (improved sensitivity), and passivation (increased lifetimes). The optics and actuator system will see improvements in the servosystem to allow finer positioning, reductions in noise, smaller optical components, and lighter actuators for faster seek operations. The recording channel and electronics will see an increase in the level of electronics integration, a reduction in electronic noise, the use of lower power electronics, and better signal processing and ECC to improve data reliability. One of the paramount directions for improvement will be in the continuous reduction of cost of the drives and media. This step is necessary to increase the penetration of optical drives in the marketplace.

FIGURE 14.25 Technological directions to achieve performance and capacity improvements in optical drives.

In terms of radical improvements, there is a considerable amount of technical growth that is possible for optical drives. The two primary directions for future work on optical drives are (1) increasing capacity and (2) improving performance specifications (such as data rate and seek time). The techniques to achieve these are shown schematically in Fig. 14.25.

The performance improvements will include spinning the disk at much higher revolutions per minute to get higher data rates, radically improving the seek times for faster access to data, and implementing direct overwrite and immediate verify techniques to reduce the number of passes required when recording. Finally, the use of parallel recording (simultaneous recording or readback of more than one track), either through the use of multielement lasers or through special optics, will improve the data rates significantly.

In optical disk products, higher capacities can only be achieved by higher areal densities since the size of the disk cannot increase from presently established standard sizes. There are a number of techniques that are being considered for improving the storage capacity of optical drives. These include

- Use of shorter wavelength lasers or *superresolution* techniques to achieve smaller spot sizes
- Putting the data tracks closer together for greater areal density
- Reducing the sensitivity to *focus misregistration* (FMR) (i.e., misfocus) and *tracking misregistration* (TMR) (i.e., when the focused spot is not centered on the track)
- Reducing the sensitivity to media tilt

Finally, improvements in the read channel such as the use of partial-response-maximum-likelihood (PRML) will enable marks in high-density recording to be detected in the presence of noise.

Acknowledgments

The author is grateful to two IBM Tucson colleagues: Blair Finkelstein for discussions and suggestions on the read channel section and Alan Fennema for writing some of the paragraphs in the servo section.

Defining Terms

Compact disk erasable/compact disk recordable (CD-E/CD-R): These define the writable versions of the compact disk. CD-E is a rewritable media and CD-R is a write-once media.

Data block size: The data that is to be recorded on an optical disk is formatted into minimum block sizes. The standard block size, which defines a single sector of information, is 512 byte. Many DOS/windows programs expect this block size. If the block size can be made larger, storage usage becomes more efficient. The next jump in block size is 1024 byte, often used in Unix applications.

Device driver: This is a piece of software that enables the host computer to talk to the optical drive. Without this piece of software, you cannot attach an optical drive to a PC and expect it to work. As optical

drives grow in popularity, the device driver will be incorporated in the operating system itself. For example, the device driver for CD-ROM drives is already embodied in current operating systems.

Error correction and control (ECC): These are codes (patterns of data bits) that are added to raw data bits to enable detection and correction of errors. There are many types of error correcting codes. Compact disk drives, for example, use cross interleaved Reed–Solomon codes.

Magneto-optical media: An optical recording material in which marks are recorded using a thermomagnetic process. That is, the material is heated until the magnetic domains can be changed by the application of a modes magnetic field. This material is rewritable.

Optical jukebox: This is very similar to a traditional jukebox in concept. A large number of disks are contained in a jukebox and can be accessed at random for reading or writing.

Phase-change media: An optical recording material consisting of an alloy that has two metastable phases with different optical properties. Phase-change media can be rewritable or write-once.

Pulse-position modulation (PPM): A recording technique in which a mark on the disk signifies a binary 1 and its absence signifies a binary 0. A 1001 bit sequence is mark-space-space-mark.

Pulse-width modulation (PWM): A recording technique in which the edges of the mark represent the ones and the length of the mark represents the number of zeros. Thus, a 1001 sequence is represented by one mark.

Seek time/access time: The two terms are often used interchangeably, which is incorrect. The seek time is, by convention, defined as the length of time taken to seek across one-third of the full stroke of the actuator (which is from the inner data band to the outer data band on the disk). The access time is the seek time plus some latency for settling of the actuator and for the disk to spin around appropriately. The access time really states how quickly you can get to data.

Servosystem: The mechanism, which through feedback and control, keeps the laser beam on track and in focus on the disk—no easy task on a disk spinning at 4000 rpm.

Tracking: The means by which the optical stylus (focused laser beam) is kept in the center of the data tracks on an optical disk.

Further Information

There are a number of excellent books that provide an overview of optical disk systems. A classic is *Optical Recording* by Alan Marchant (Addison-Wesley, Reading, MA, 1990), which provides an overview of the various types of recording as well as the basic functioning of an optical drive. A more detailed study of optical disk drives and their opto-mechanical aspects is provided in *Principles of Optical Disc Systems* by G. Bouwhuis, J. Braat, A. Huijser, J. Pasman, G. van Rosmalen, and K. Schouhamer Immink (Adam Hilger Ltd., Bristol, England, 1985). An extensive study of magneto-optical recording is presented in *The Physical Properties of Magneto-Optical Recording* by Masud Mansuripur (Cambridge University Press, London, 1994).

For recent developments in the field of optical storage, the reader is advised to attend the meetings of the International Symposium on Optical Memory (ISOM) or the Optical Data Storage (ODS) Conferences (held under the auspices of the IEEE or the Optical Society of America).

For information on optical storage systems and their applications, a good trade journal is the *Computer Technology Review*. *Imaging Magazine* usually has a number of good articles on the applications of optical libraries to document imaging, as well as periodic reviews of commercial optical products.

14.4 Error Correction

Fabrizio Pollara

14.4.1 Background

Digital data transmitted over channels with impairments such as noise, distortions, and fading is inevitably delivered to the user with some errors. A similar situation occurs when digital data is stored on devices such as magnetic or other media that contain imperfections. The rate at which errors occur is a very important design criterion for digital communication links and for data storage. Usually, it must be kept smaller than a given preassigned value, which depends on the application. Error correction techniques based on the addition of **redundancy** to the original message can be used to control the error rate. The most obvious, albeit not efficient, example is the repetition of the same message. In this chapter we illustrate several efficient error correction techniques.

In 1948 Claude Shannon revolutionized communication technology with the publication of his classic paper in which he showed that the most efficient solution for reliable communications necessarily involved *coding* (i.e., introducing a controlled amount of redundancy) the selected message, before transmission over the channel. Shannon did not say exactly how this coding should be done; he only proved mathematically that efficient coding schemes must exist. Since 1948, a whole generation of later researchers has validated Shannon's work by devising explicit and practical coding schemes, which are now part of nearly every modern digital communication system. Satellite communication systems, high-performance military systems, computer communication networks, high-speed modems, and compact-disk and magnetic recording and playback systems, all rely heavily on sophisticated coding schemes to enhance their performance.

FIGURE 14.26 Coded communication system.

Shannon showed that to every communication channel we can associate a **channel capacity** C , and that there exist error correcting codes such that information can be transmitted across a noisy channel at rates less than C , with arbitrarily low bit error rate. In fact, an important implication of Shannon's theory is that it is wasteful to build a channel that is too good; it is more economical to use an appropriate code. Until Shannon's discovery, it was believed that the only way to overcome channel noise was to use more powerful transmitters or build larger antennas.

A communication system connects a data source to a data user through a channel. Microwave links, coaxial cables, telephone circuits, and even magnetic tapes are examples of channels. Coded digital communication systems (or data storage systems) include a device that creates appropriate redundant bits (the encoder) and a corresponding device (the decoder) that uses this redundancy to correct some of the errors introduced by the channel, as shown in Fig. 14.26. The encoder takes a block of information bits and produces a larger block of channel symbols, which is called a **codeword**. The channel in Fig. 14.26 contains all of the devices necessary to transmit digital information on a physical medium, including: a modulator to convert each symbol of the codeword into a corresponding analog symbol from a finite set of possible analog symbols (waveforms), and a demodulator to convert each received channel output signal into one of the codeword symbols. Each demodulated symbol is a best estimate of the transmitted symbol, but the demodulator makes some errors because of channel noise.

14.4.2 Introduction

The basic ideas of efficient error correction are illustrated in the following example of a *Hamming code*, a single-error-correcting code belonging to the first class of practical codes invented by Richard Hamming in 1948.

Example of single-error-correcting code: Hamming code. The data to be transmitted consists of blocks of four bits denoted by $\{d_1, d_2, d_3, d_4\}$. Three redundant bits $\{p_1, p_2, p_3\}$, the parity-check bits, are computed from the bits in the data block and are appended to this block by the *encoder*. The parity-check p_1 is set to the value 0 if the number of 1s among the bits d_2, d_3 , and d_4 is even and is set to 1 otherwise. Similarly, p_2 is set to 0 or 1 by the parity, that is, the even- or oddness, of the number of 1s among d_1, d_3 , and d_4 . Finally, p_3 is determined by the parity of d_1, d_2 , and d_4 . For example, if the data bits are $\{1011\}$, then the parity bits will be $\{010\}$. The combination of the data bits and the parity bits (seven bits, in this example) is sent over the channel or stored in a memory device and is called the codeword.

When the codeword is recovered, possibly with some bit errors, the decoder checks to see if the three parity-check rules are still satisfied. The decoder computes a 0 for legitimate parity checks and a 1 for incorrect parity checks, thus generating three bits that are called the **syndrome**. For example, if $\{1001010\}$ is received, the first syndrome bit is set to 1, because the received data bits $d_2 = 0, d_3 = 0$ and $d_4 = 1$ have odd parity but the first parity-check bit is 0. Similarly, the second and third syndrome bits are set to 1 and 0, to produce the syndrome $\{110\}$. This syndrome is then used to find the location of the error using the one-to-one correspondence between syndromes and error locations illustrated in Fig. 14.27, for this example. In our example, the syndrome is $\{110\}$ which indicates that an error occurred at location d_3 , the third data bit. The decoder will then change $\{1001010\}$ into $\{1011010\}$ and deliver to the user the corrected data $\{1011\}$. This strategy will successfully locate any single error in a block of four data bits encoded with three additional parity bits. If more than one error occurs this method will fail.

More sophisticated coding strategies are available for applications where it is necessary to correct more errors. From a practical standpoint, the essential limitation of all coding and decoding schemes proposed to date has not been a lack of good codes but the complexity (and cost) of the decoder. For this reason, efforts have been directed toward the design of coding and decoding schemes that could be easily implemented.

SYNDROME	000	001	010	011	100	101	110	111
ERROR LOCATION	-	p_3	p_2	d_1	p_1	d_2	d_3	d_4

FIGURE 14.27 Syndrome table.

The amount of redundancy inserted by the code is usually expressed in terms of the **code rate** R . This rate is the ratio of the number of information bits k in a block to the total number of transmitted symbols n in a codeword ($n = k +$ number of redundant symbols, i.e., $n > k$, or, equivalently, $R = k/n < 1$).

The Benefits of Error Correction Coding

Let us assume that we want to transmit data at a rate of R_b information bits per second. The redundancy of the code forces us to increase the transmitted symbol rate R_s to $R_s = R_b/R > R_b$. If the transmitted energy per information bit E_b is fixed, then the received energy per transmitted symbol is reduced from E_b to $E_s = R \times E_b$. If we did not perform any special decoding operations, the bit error rate (BER) would actually be worse than its original value obtained by using no coding at all! However, if we use the redundancy to correct some of the errors and the code was well selected, the BER at the output of the decoder is better than that at the output of the demodulator of the original uncoded system. This improvement in BER is obtained with the same E_b and R_b of the uncoded system. This explains how coding can improve BER at given E_b and R_b . Alternatively, the effect of coding can be seen as a reduction of required E_b at given BER and R_b , or as an increase in R_b (throughput) at given BER and E_b . The ratio by which the throughput is increased, or the transmitter power can be decreased, is called the *coding gain* of a given coding system.

This improvement in BER is obtained with the same E_b and R_b of the uncoded system. This explains how coding can improve BER at given E_b and R_b . Alternatively, the effect of coding can be seen as a reduction of required E_b at given BER and R_b , or as an increase in R_b (throughput) at given BER and E_b . The ratio by which the throughput is increased, or the transmitter power can be decreased, is called the *coding gain* of a given coding system.

14.4.3 The Development of Error Correction Codes

The Hamming codes were disappointingly weak compared with the far stronger codes promised by Shannon's theoretical results. The major advance came when Bose and Ray-Chaudhuri (1960) and Hocquenghem (1959) found a large class of multiple-error-correcting codes (the BCH codes), and Reed and Solomon (1960) found a related class of codes for nonbinary channels. All of these codes were based on algebraic properties of finite fields (**Galois fields**).

A completely different attack to the construction of efficient codes, more probabilistic in flavor, was the discovery in the late 1950s of **convolutional codes**, based on the properties of binary sequences generated by shift registers. These codes gained widespread popularity when an efficient decoding algorithm was discovered in 1967. The use of an algebraic **block code** cascaded with a convolutional code (**concatenated codes**) provided the most powerful codes available until the early 1990s.

The major progress in the 1970s was the discovery of family of codes that are good asymptotically, that is, when the block size of the encoded message becomes arbitrarily large. More efficient and asymptotically good codes, based on algebraic-geometric properties, were discovered in the late 1980s.

Codes that are very efficient for transmission on channels with limited bandwidth were discovered in the early 1980s, by combining the coding operation with an appropriate choice of the modulation scheme, that is, the set of waveforms that are actually used to transmit the encoded symbols. These codes have a major practical significance in the design of virtually any commercial data communication system.

More recently, the development of a new class of codes (**turbo codes**) promises to fill the last gap toward achieving the ultimate limits set by Shannon's theory.

14.4.4 Code Families

Error correction codes can be divided into two different classes: block codes and convolutional codes. The encoder for a block code breaks the continuous sequence of information bits into k -bit sections or blocks,

and then operates on these blocks independently according to the particular code used. With each possible information block is associated an n -tuple of channel symbols, where $n > k$. The quantity n is referred to as the *code length* or *block length*. Codes can be defined on larger than binary alphabets, where each information sample is not just a bit but a symbol taken from an alphabet with q entries.

The other type of codes, called convolutional codes, operate on the information sequence without breaking it up into independent blocks. Rather, the encoder for a convolutional code processes the information continuously and associates each long (perhaps semi-infinite) information sequence with a code sequence containing more symbols.

Block codes and convolutional codes have similar error-correcting capabilities and the same fundamental limitations. In particular, Shannon's fundamental theorems hold for both types of codes.

Which Codes Are Good Codes?

Block codes are judged by three parameters: the block length n , the information length k , and the minimum distance d . The minimum distance is a measure of the amount of difference between the two most similar codewords.

The **Hamming distance** $d(x, y)$ between two q -ary sequences x and y of length n is the number of places in which they differ. The *minimum distance* of a code is the Hamming distance of the pair of codewords with smallest Hamming distance. More refined comparisons among codes make use of the **weight distribution** of a code, which is the list of the Hamming distances of each codeword from a given reference codeword. We will see that for **linear codes** the choice of the reference is irrelevant.

Suppose that a codeword is transmitted, and a single error is made by the channel. Then the received word is at a Hamming distance of 1 from the transmitted codeword. If the distance to every other codeword is larger than 1, then the decoder will properly correct the error if it assumes that the closest codeword to the received word was actually transmitted. In general, if t errors occur and if the distance from the received word to every other codeword is larger than d , then the decoder will properly correct the errors if it assumes that the closest codeword to the received word was actually transmitted. This always occurs if $d \geq 2t + 1$, as illustrated geometrically in Fig. 14.28, where each sphere of radius t consist of all n -tuples within distance t of codeword C , which we think as being the center of the sphere. Nonintersecting spheres of radius t can be drawn about each of the codewords. A received word in a sphere is decoded as the codeword at the center of that sphere. If t or fewer errors occur, then the received word is always in the proper sphere, and the decoding is correct. Some received words that have more than t errors will be in a decoding sphere about another codeword and, hence, will be decoded incorrectly. Other received words that have more than t errors will lie in the interstitial space between decoding spheres. This case can be handled in one of the two following methods: (1) An *incomplete decoder* decodes only those received words lying in a decoding sphere about a codeword. Other received words have more than the allowable number of errors and are declared by the decoder to be unrecognizable (uncorrectable error patterns). (2) A *complete decoder* decodes every received word (whether inside or outside a sphere) by selecting the closest codeword. When more than t errors occur, a complete decoder will often decode incorrectly but occasionally will find the correct codeword. A complete decoder is used when it is preferable to have a best guess of the message than to have no estimate at all.

FIGURE 14.28 Geometric representation of a t -error correcting code ($t = 2$).

14.4.5 Linear Block Codes

Block encoding can be regarded as a table-lookup operation, where each of the $M = q^k$ (q is the alphabet size of information symbols) codewords $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m, \dots, \mathbf{x}_M$ is stored in an n -stage register of a memory bank, and whenever message $\mathbf{u}_m = (u_{m1}, \dots, u_{mk})$ is to be transmitted, the corresponding signal vector $\mathbf{x}_m = (x_{m1}, \dots, x_{mn})$ is read from memory and used as the output of the encoder. We are primarily concerned with binary alphabets, that is, $q = 2$; thus, initially, we take the entries u_{mi} from $\{0, 1\}$ for all m, i .

The linear coding operation for binary data can be represented by

$$\begin{aligned} x_{m1} &= u_{m1}g_{11} \oplus u_{m2}g_{21} \oplus \dots \oplus u_{mk}g_{k1} \\ x_{m2} &= u_{m1}g_{12} \oplus u_{m2}g_{22} \oplus \dots \oplus u_{mk}g_{k2} \\ &\vdots \\ x_{mn} &= u_{m1}g_{1n} \oplus u_{m2}g_{2n} \oplus \dots \oplus u_{mk}g_{kn} \end{aligned} \quad (14.4)$$

where \oplus denotes modulo-2 addition, and $g_{ij} \in \{0, 1\}$ for all i, j . The term $u_{mi}g_{ij}$ is an ordinary multiplication, so that u_{mi} enters into the particular combination for x_{mj} if and only if $g_{in} = 1$. The matrix

$$G = \begin{bmatrix} g_{11}g_{12} \cdots g_{1n} \\ g_{21}g_{22} \cdots g_{2n} \\ \vdots \\ g_{k1}g_{k2} \cdots g_{kn} \end{bmatrix} = \begin{bmatrix} g_1 \\ g_2 \\ \vdots \\ g_k \end{bmatrix} \quad (14.5)$$

is called the **generator matrix** of the linear code and g_i are its row vectors. Thus Eq. (14.4) can be expressed in vector form as $\mathbf{x}_m = \mathbf{u}_m G = \sum_{i=1}^k u_{mi} g_i$, where \sum means modulo-2 addition and both \mathbf{u}_m and \mathbf{x}_m are binary row vectors.

An important property of linear codes is that the modulo-2 termwise sum of two codewords \mathbf{x}_m and \mathbf{x}_l is also a codeword. An interesting consequence of this property is that the set of Hamming distances from a given codeword to the $(M - 1)$ other codewords is the same for all codewords.

It can be shown that the generator matrix G can always be rearranged so that the first k entries of each codeword \mathbf{x}_m are identical to the k entries of the message \mathbf{u}_m and the remaining $n - k$ entries are the parity check symbols, as illustrated in our example of a Hamming code. In this case the code is called **systematic**.

Decoding Linear Block Codes

Suppose the message $\mathbf{u} = u_1, \dots, u_k$ is encoded into the codeword $\mathbf{x} = x_1, \dots, x_n$, which is then sent through the channel. Because of channel noise, the received vector $\mathbf{y} = y_1, \dots, y_n$, may be different from \mathbf{x} . Let us define the error vector $\mathbf{e} = \mathbf{y} \oplus \mathbf{x} = (e_1, \dots, e_n)$.

The decoder must decide from \mathbf{y} which message \mathbf{u} or which codeword \mathbf{x} was transmitted. Since $\mathbf{x} = \mathbf{y} \oplus \mathbf{e}$, it is enough if the decoder finds \mathbf{e} . The decoder can never be certain of what the true \mathbf{e} was. Its strategy, therefore, will be to choose the most likely error vector \mathbf{e} , given that \mathbf{y} was received. Provided the codewords are all equally likely, this strategy is optimum in the sense that it minimizes the probability of the decoder making a mistake and is called **maximum likelihood decoding**.

We now illustrate a table lookup technique for decoding systematic linear codes, which is a generalization of our example on the Hamming code. Define the $n \times (n - k)$ matrix H^T by

$$H^T = \begin{bmatrix} g_{1,k+1} \cdots g_{1n} \\ g_{2,k+1} \cdots g_{2n} \\ \vdots \\ g_{k,k+1} \cdots g_{kn} \\ 1 \ 0 \ 0 \ \cdots \ 0 \\ 0 \ 1 \ 0 \ \cdots \ 0 \\ \vdots \\ 0 \ 0 \ 0 \ \cdots \ 1 \end{bmatrix} \quad (14.6)$$

The matrix H is called the *parity-check matrix*. Any code vector multiplied by H^T yields the null vector $\mathbf{x}H^T = \mathbf{0}$. Now consider postmultiplying any received vector \mathbf{y} by H^T . The resulting $(n - k)$ -dimensional binary vector is called the syndrome of the received vector and is given by $\mathbf{s} = \mathbf{y}H^T$. The decoding procedure is outlined as follows:

- Step 1. Initially, prior to decoding, for each of the 2^{n-k} possible syndromes \mathbf{s} , store the corresponding minimum weight vector \mathbf{e} satisfying $\mathbf{e}H^T = \mathbf{s}$. A table of 2^{n-k} n -bit entries will result.
- Step 2. From the n -dimensional received vector \mathbf{y} , generate one $(n - k)$ -dimensional syndrome \mathbf{s} by the linear operations $\mathbf{s} = \mathbf{y}H^T$; this requires an n -stage register and $n - k$ modulo-2 adders.
- Step 3. Do a table lookup in the table of step 1 to obtain $\hat{\mathbf{e}} = \mathbf{e}$ corresponding to the syndrome \mathbf{s} found from step 2.
- Step 4. Obtain the most likely code vector by the operation $\mathbf{x}_m = \mathbf{y} \oplus \hat{\mathbf{e}}$. The first k symbols are the data symbols.

Examples of Linear Codes: Reed–Solomon Codes

After the discovery of Hamming codes, the development of the theory of **cyclic codes** provided the first large family of efficient error correcting codes (BCH codes). The central concept of cyclic codes is based on mathematical abstractions called *ideals* in the theory of finite fields. Cyclic codes are important practically because they can be implemented using high-speed shift-register-based encoders and decoders, at gigabit-per-second data rates. Within the family of cyclic codes there are specific classes of codes that are extremely powerful: Golay codes, BCH, and Reed–Solomon codes. Cyclic codes are defined in terms of a generator polynomial, which is multiplied by the data polynomial to obtain the codeword polynomial. These polynomials are defined in a finite field, and shift register circuits are used to perform the required polynomial multiplications and divisions. A popular family of codes called *cyclic redundancy check codes* (CRC) was derived from cyclic codes by *shortening* (reducing the block length) of some cyclic codes. CRC codes are primarily used for **error detection**, that is, to signal the presence of errors in the received message. Error detection, which is generally easier to obtain than error correction, is used in applications where it is extremely important to get the correct message or otherwise flag it as unreliable and discard it or ask for *retransmission*, according to a prescribed protocol as used in automatic-repeat-request (ARQ) systems. Reed–Muller codes (1954) are not used in practice any longer, but were the first codes to enable correction of multiple errors. They have fast decoding algorithms, but their rates are typically low. Reed–Muller codes are, however, very important ingredients for the construction of modern more complex codes.

Reed–Solomon (RS) codes, which can be viewed as a nonbinary extension of BCH codes, are a particularly interesting and useful class of linear block codes. The block length n of an RS code is $q - 1$, with q being the alphabet size of the symbols. It can be seen that these codes are useful only for large alphabet sizes. RS codes with k information symbols and block length n have a minimum distance $d = n - k + 1$, which is a property shared by all codes belonging to the class of *maximum distance separable* codes. RS codes are particularly effective on channels that produce errors in clusters, which are called *bursty* channels. Using symbols with $q = 2^m$ for some m , the block length is $n = 2^m - 1$. For an arbitrarily chosen odd minimum distance d , the number of information symbols is $k = n - d + 1$ and any combination of $t = (d - 1)/2 = (n - k)/2$ errors can be corrected. If we represent each letter in a codeword by m binary digits, then we can obtain a binary code with km information bits and block length nm bits. Any noise sequence that alters at most t of these n binary m -tuples can be corrected, and thus the code can correct all bursts of length $m(t - 1) + 1$ or less, and many combinations of multiple shorter bursts.

14.4.6 Convolutional Codes

These codes can be generated by a linear shift-register circuit that performs a convolution operation on the information sequence. Convolutional codes were successfully decoded by **sequential decoding** algorithms in the late 1950s. A much simpler decoding algorithm—the **Viterbi algorithm**—was developed in 1967 and made low-complexity convolutional codes very popular. Unfortunately, this algorithm is impractical for stronger convolutional codes.

A rate $R = 1/n$ convolutional encoder is a linear finite-state machine with one input, n outputs, and a K -stage shift register, where $K = m + 1$ is called the constraint length of the code and m is the memory of the finite-state machine. An encoder with $R = 1/2$ and $K = 3$ is shown in Fig. 14.29. Such an encoder has 2^m possible states and is described by the taps of the shift register that are used to form each output by modulo-2 additions. The set of taps of each output is described by a polynomial with binary coefficients, where a coefficient 1 indicates a tap and a coefficient 0 indicates no tap. The example in Fig. 14.29 shows how each input bit produces two output symbols, based on the present input and on two previous inputs that are stored in the shaded register cells after having been shifted in at previous ticks of the clock.

FIGURE 14.29 Example of convolutional encoder ($K = 3$).

A finite-state machine such as that shown in Fig. 14.29 can be described by a *state diagram*, as shown in Fig. 14.30(a). The state transitions are indicated by directed edges labeled by $u_j/x_0x_1x_j$, that is, the input and the two outputs associated with a transition from a state $u_{j-1}u_{j-2}$ to state u_ju_{j-1} . The **trellis diagram** shown in Fig. 14.30(b) gives an equivalent description of the state transition of this finite-state machine stressing the evolution in time. Here a path traversing states from left to right corresponds to the evolution with time of the encoder. As for block codes, the properties of convolutional codes depend on the Hamming distances of possible output symbol stream, which correspond the codewords of the code. Good codes have large minimum distances, where the minimum distance can be determined by finding the minimum output weight (number of ones) of any path that starts in state 00 and end in the same state after some digression. The choice of a reference state is irrelevant due to the linearity of these codes. The trellis diagram shown in Fig. 14.30(b) was a crucial element in the discovery of an efficient method for decoding these codes: the Viterbi algorithm (1967), from the name of its inventor. This algorithm is an efficient method to compare the distance of a received symbol stream to that of all of the possible paths on the trellis and to select that which has the least Hamming distance. The efficiency of the algorithm is given by the fact that at each state (a node in the trellis) the accumulated distances of paths coming into the state can be compared, and only the path of least distance can be preserved. The other paths can be discarded forever without loss of optimality. This considerably reduces the amount of operations necessary to compute distances to all possible paths. Once this pruning of the trellis has been done, the surviving paths are the only candidates to be at minimum distance from the received sequence. If the trellis is terminated at some time, there will be only one survivor into state 00. Otherwise, as in common practice, if the sequence is semi-infinite, the survivor into the state with minimum accumulated distance will be selected. Once a surviving path is selected, the corresponding sequence of decoded bits can be read following the only

FIGURE 14.30 Examples of state and trellis diagrams.

possible backward path along the survivor. It has been shown (Forney, 1973) that the Viterbi algorithm implements, in fact, maximum-likelihood decoding, that is, the optimum decoding strategy.

Sequential decoding is another method used earlier to decode convolutional codes: its complexity does not increase exponentially with the memory m of the code, but its performance can only approximate that of a true maximum-likelihood decoder, as the Viterbi decoder. Sequential decoding is a procedure for systematically searching through a *code tree* and using received information as a guide, with the objective of eventually tracing out the path representing the actually transmitted information sequence. The two best known sequential decoding algorithms are the *stack algorithm* and the *Fano algorithm*. Sequential decoding is an example of incomplete decoding which yields two types of decoding failure. The first, called an *undetected error*, occurs when the decoder accepts a number of wrong hypotheses and moves ahead anyway. The second, called a *buffer overflow*, occurs when the number of computations permitted per block is exceeded. In this case, the frame cannot be decoded, and is considered an erased or *deleted frame*. Convolutional codes, which are sequentially decoded, typically have a large enough constraint length so that the undetected error probability of the decoder is negligible compared to the probability that a block cannot be successfully decoded in the time allowed.

For applications requiring large coding gain and very low bit error probabilities the idea of cascading two codes has been widely used and called concatenated coding. The most powerful combination in use is that of an outer Reed–Solomon code with an inner convolutional code. The decoding is done in two stages, which makes it intrinsically suboptimal, but its performance is a good approximation of the optimum decoder. Since the inner decoder produces errors clustered in bursts it is usually necessary to use a technique called **interleaving** to scatter such errors and ease the job of the outer decoder. Typically, the inner Viterbi decoder corrects enough errors so that a high-rate outer code can reduce the error probability to the desired level.

Turbo Codes

Coding theorists have traditionally attacked the problem of constructing powerful codes by developing codes with a lot of structure, which lends to feasible decoders. However, coding theory suggests that codes chosen at random should be pretty good if their block size is large enough. The challenge to find practical decoders for almost random, large codes had not been seriously considered until recently.

In 1993 a new class of concatenated codes called turbo codes, was introduced. These codes, which can be viewed as convolutional or block codes, can achieve near-Shannon-limit error correction performance with reasonable decoding complexity.

A turbo encoder is a combination of two simple convolutional encoders. For a block of k information bits, each constituent code generates a set of parity bits. The turbo code consists of the information bits and both sets of parity, as shown in Fig. 14.31. The key innovation is an interleaver P , which permutes the original k information bits before encoding the second code. If the interleaver is well chosen, information blocks that correspond to error-prone codewords in one code will correspond to error-resistant codewords in the other code. The resulting code performs much like Shannon’s random codes, which can approach optimum performance at the price of a prohibitively complex decoder. Turbo decoding uses two simple decoders matched to the constituent codes. Each decoder sends likelihood estimates of the decoded bits to the other decoder, and uses the corresponding estimates from the other decoder as *a priori* likelihoods. The turbo decoder iterates between the outputs of the two constituent decoders until reaching satisfactory convergence.

FIGURE 14.31 Example of turbo encoder/decoder.

FIGURE 14.32 Example of trellis-coded modulation.

Turbo codes outperform even the most powerful codes known to date, but more importantly they are simpler to decode. To achieve their phenomenal performance, turbo codes require the use of large interleavers, but not much larger than those used by current concatenated codes.

14.4.7 Trellis Coded Modulation

Various efforts to improve the signal-to-noise ratio in channels with additive noise and *intersymbol interference*, which is characteristic of severely bandlimited channels (e.g., the telephone channel), led to the original development of *set partitioning* techniques that culminated in Ungerboeck's development (1982) of **trelliscoded modulation** (TCM).

Ungerboeck showed how large Hamming distance between differing data sequences does not necessarily imply large Euclidean distance between modulated data sequences, unless the assignment of coded signals to modulated signals is cleverly made. He proposed a new method of set partitioning, which not only provided a method for the assignment of coded signals to channel signals, but also provided a simple formula for the lowerbound of the Euclidean distance between modulated data sequences. Figure 14.32(b) and Figure 14.32(c) illustrate an example of encoder and modulated signal assignment for trellis-coded modulation, which we will compare to the popular uncoded quadrature phase shift keying (QPSK) scheme of Fig. 14.32(a).

The trellis code (Fig. 14.32(b)) replaces the QPSK signal constellation with an 8-ary PSK signal constellation so as to introduce eight points in the complex plane that represents phase modulation. Instead of using the eight points to increase the data rate by modulating three bits at a time into a channel symbol, the trellis code modulates only two bits of data at a time into a three-bit channel symbol. The three code bits define one of eight possibilities that are labeled in the phase diagram in Fig. 14.32(c). Every pair of incoming data bits is mapped into three code bits by the trellis encoder in order to create a waveform. The transmitted trellis-coded waveform has the same data rate as a QPSK waveform and uses the same bandwidth, but the power requirement is reduced by 2.5 times.

TCM can also be used to increase the transmitted data rate at a fixed transmitted power. Much more complicated signal constellations are required for this purpose.

14.4.8 Applications

Error correcting codes have been applied to a variety of communication systems. Digital data are commonly transmitted between computer terminals, between aircraft, and from spacecraft. Codes can be used to achieve reliable communication even when the received signal power is close to the thermal noise power. As the radio waves spectrum becomes ever more crowded, error-correction coding becomes an even more important subject because it allows communication links to function reliably in the presence of interference. This is particularly true in military applications, where it is often essential to employ an error correcting code to protect against intentional enemy interference.

Error correcting codes are an excellent way to reduce power needs in communications systems where power is scarce, as in communication relay satellites because weak received messages can be recovered correctly with the aid of the code.

Data flow within computer systems usually is intolerant of even very low error rates, because a single error can destroy a computer program, and error correcting codes are becoming important in these applications. Bits can be packed more tightly into dense computer memories, by using simple Hamming codes. Codes are also widely used to protect data in digital tapes and disks.

Communication is also important within complex systems, where a large data flow may exist between subsystems, as in digital switching systems, and in digital radar signal-processing systems. These internal data might be transferred either by hardwired lines or by more sophisticated time-shared data bus systems. In either case, error correcting techniques are becoming important to ensure proper performance.

Defining Terms

Block codes: Codes that take an information block of length k and produce a codeword of length $n > k$ (n is the block length or code length).

Burst error correction: An error correction method that is effective against errors occurring in clusters, as opposed to random errors.

Channel capacity: The maximum information rate that can be transmitted across a channel, with arbitrarily low bit error rate.

Code rate: The ratio of the number of information bits k in a block to the total number of transmitted symbols n in a codeword ($n = k + \text{no. of redundant symbols}$).

Codeword: The sequence of symbols obtained by adding redundant symbols to the original message.

Concatenated codes: Codes based on cascading two codes separated by an interleaver.

Convolutional codes: Codes generated by a linear shift-register circuit that performs a convolution operation on the information sequence.

Cyclic codes: Codes defined in terms of a generator polynomial, which is multiplied by the data polynomial to obtain the codeword polynomial. Polynomials are defined in a finite field, and shift register circuits are used to perform the required polynomial multiplications and divisions; examples: Golay codes, BCH, and Reed–Solomon codes.

Error detection: The mechanism by which a code can detect the presence of errors in a codeword. Error patterns that cannot be detected are called undetected errors.

Galois field: A Galois field (or finite field) is a set of objects or elements on which two operations $+$ and \cdot are defined, obeying some specific rules (i.e., operations are commutative and distributive). Example: The integers $\{0, 1, \dots, p - 1\}$ modulo p form a finite field if p is prime.

Generator matrix: The $k \times n$ matrix that produces a codeword (of length n) of a block code, by multiplication by the information block (of length k).

Hamming distance: The number of places in which two sequences of equal length differ. The minimum distance of a code is the smallest Hamming distance between any pair of codewords.

Interleaving: A device that scrambles the symbols from several codewords so that symbols from a given codeword are well separated.

Linear codes: Codes such that the linear combination of any set of codewords is a codeword.

Maximum-likelihood decoding: A decoding procedure that maximizes the probability of a received sequence given any of the possible codewords. If codewords are equally likely, this decoding method yields the minimum possible error probability.

Redundancy: Additional symbols (parity check symbols) appended to the original message to allow for error correction.

Sequential decoding: A procedure for systematically searching through a code tree with the objective of approximating the solution for the path at minimum distance from the received sequence. Examples: Fano algorithm, stack algorithm.

Syndrome: A vector computed by the decoder to find the location of correctable errors.

Systematic codes: Codes whose first k symbols of each codeword are identical to the information block. All codes can be reordered into systematic form.

Trellis coded modulation: A combined method for joint coding and modulation based on the design of convolutional codes matched to the modulation signal set in such a way to maximize the Euclidean distance between modulated sequence.

Trellis diagram: A graph used to represent the evolution in time of a finite-state machine by defining states as vertices and possible state transitions as edges.

Turbo codes: Codes generated by the parallel concatenation of two (or more) simple convolutional encoders, separated by interleavers.

Viterbi algorithm: An efficient method for decoding convolutional codes based on finding the path on a trellis diagram that is at minimum distance from the received sequence.

Weight distribution: The list of the Hamming distances of each codeword from a given reference codeword.

Further Information

Most of the coding systems discussed in this chapter are too complex for a complete and detailed explanation. For in-depth treatment of general concepts in coding theory it is suggested to consult Clark and Cain (1981), Berlekamp (1974), Berlekamp (1968), MacWilliams and Sloane (1977), Blahut (1983), Viterbi and Omura (1979), and Hamming (1980). These references are a representative cross section of the literature on the subject of error correcting codes.

On the subject of coding for magnetic recording more details can be found in Schouhamer Immink (1989). The compact disk coding problem is discussed in Schouhamer Immink (1991). The origins of concatenated codes are treated in Forney (1967). The important mathematical tools of finite fields are treated in Lidl and Niederreiter (1983).

14.5 Data Compression

Jerome R. Breitenbach

14.5.1 Introduction

The field of data compression is concerned with devising practical and widely applicable methods for efficiently representing digital information. The primary reason for compressing information is to cause it to consume less space on the medium on which it is stored. In addition, though, if the information is to be transmitted to another location, then its prior compression will make it less taxing on the transmission medium; in contemporary parlance, data compression conserves “bandwidth.” Moreover, if the amount of compression is significant, and the compression and decompression algorithms are sufficiently fast, then the time required for the overall communication process—compression, transmission, and decompression—can also be less, because the time used for compression and decompression will be more than offset by the speedier transmission of the compressed data.

This section presents an overview of the both theory and practice of data compression. The discussion is quite general, as it applies to any kind of digital information regardless of what the digits represent (text, audio, video, etc.). Thus, although such additional knowledge about a data source can be quite useful toward its compression (for example, some voice compression techniques are based on the physical structure of the human vocal tract), no use will be made here of any special character of the source.

14.5.2 The Data Compression Problem

The diagram in Fig. 14.33 displays the typical setup for *data compression*, also known as *source coding*. First, an *information source* randomly produces a stream of digital information to be stored, which is then later retrieved from storage for presentation to an *information sink*. Being digital, the output of the source is a sequence (u_1, u_2, \dots) of digits; for simplicity, we will focus on *binary* data, where the digits are *bits* taking on the two possible values 0 and 1. The *storage medium* is also assumed to be binary, and noncorrupting as well; that is, any sequence of 0s and 1s stored on the medium can be retrieved exactly. (Binary sources and storage media are by far the most prevalent. Nevertheless, everything in this chapter can be reformulated to apply without the binary assumption.) Thus, for the sake of our analyses, the storage medium is nothing more than a direct line from its input to its output.

If we were to apply the output of the source directly to the storage medium, and then present the output of the medium directly to the sink, then we would obtain the basic desired result—flawless storage and retrieval of the source output. Our objective, however, is also to minimize the number of bits stored on the medium in order to obtain this result; therefore, pre- and postprocessing are placed around it.

FIGURE 14.33 Basic setup for data compression.

Namely, an *encoder* converts the bit stream from the source into another bit stream applied to the medium, with the conversion rule being called a *code*. (In the context of data compression, the use of a code has nothing to do with encryption; it is not the intention of the encoder to *hide* the information (though the codes we shall discuss can be used for that purpose).) Correspondingly, a *decoder* converts the stored bit stream (x_1, x_2, \dots) into that presented to the sink. Ideally, of course, the total processing is such that the sink bit stream (v_1, v_2, \dots) is identical to that of the source. If the encoder is such that, for an appropriate decoder, this is indeed the case for every possible source sequence, then the code is called *lossless* or *noiseless*; otherwise, it is *lossy*.

As shown in the figure, one kind of code is the *block code*. Here, the encoder waits for the source to emit a *block* $\mathbf{u} = (u_1, \dots, u_k)$ of $k \geq 1$; then, according to the rule of the code, it converts this block into a corresponding *codeword* $\mathbf{x} = (x_1, \dots, x_n)$ of $n \geq 1$ bits. At the output of the medium, the decoder converts \mathbf{x} into another k -bit block $\mathbf{v} = (v_1, \dots, v_k)$, hopefully the same as \mathbf{u} , to present to the sink. (Thus, the encoder is essentially a lookup table specifying the \mathbf{x} corresponding to each possible \mathbf{u} , as is the decoder.) If the value of n is the same for all possible blocks \mathbf{u} , then we have a *fixed-length code* of length n ; whereas if n is allowed to vary, then we have a *variable-length code*. The main question to be addressed in the sequel is: For a given performance criterion (e.g., an upper bound on the probability of decoder error), how many bits n , on average, are required to store the k source bits?

The *rate* R of a block code is defined to be the average number of bits stored per source bit; that is

$$R \triangleq E\{n\}/k \quad \text{bits/source bit}$$

In general, the expectation operation $E\{\cdot\}$ is required because, for a variable-length code, the code length n is a function of the random source block \mathbf{u} and, thus, is random too; however, for a fixed-length code, the definition simplifies to

$$R = n/k \quad \text{bits/source bit}$$

Clearly, R provides a measure of how much compression is achieved by the code; the smaller R is, the better. For the case of no encoding/decoding already mentioned, we have $R = 1$; thus our intention is to achieve some $R < 1$. An essentially equivalent question to the one just posed is: For a given performance criterion, how small can we make R ?

14.5.3 Data Compression via Fixed-Length Codes

The compression of a given stream of information is made possible by its source being statistically biased. First, consider the simplest type of nontrivial source, the *discrete memoryless source* (DMS). A DMS is discrete in that its output is digital, as previously described; it is memoryless in that the output digit u_i at any given time i is statistically independent of the output digits u_j ($j \neq i$) at all other times. Also, it is assumed that the u_i ($i = 1, 2, \dots$) are all taken from the same finite set of possible values, as well as each having the same probability distribution over these values. In the binary case, then, a DMS is completely characterized by the single probability

$$p = \Pr(u_i = 1) \quad (\text{all } i)$$

since $1 - p = \Pr(u_i = 0)$ (all i).

For the purposes of data compression, the fundamental quantity associated with an information source is its *entropy*. As the name implies, the entropy of a source is a measure of its randomness; but, as we will see, it also expresses the average rate at which the source produces information. In general, the entropy H of a source is defined as

$$H \triangleq \lim_{k \rightarrow \infty} \frac{1}{k} E \left\{ \log_2 \frac{1}{P(\mathbf{u})} \right\} \quad \text{bits/source bit} \quad (14.7)$$

FIGURE 14.34 The binary entropy function.

(assuming the limit exists), where $P(\mathbf{u})$ is the probability distribution of \mathbf{u} , and thus

$$E \left\{ \log_2 \frac{1}{P(\mathbf{u})} \right\} = \sum_{\mathbf{u}} P(\mathbf{u}) \log_2 \frac{1}{P(\mathbf{u})}$$

(the entropy of k -bit source block \mathbf{u}). For a binary DMS, H depends only on the probability p , and is given by the *binary entropy function*

$$H_2(p) \triangleq -p \log_2 p - (1-p) \log_2(1-p) \quad (0 < p < 1) \tag{14.8}$$

with $H_2(0) \triangleq 0$ and $H_2(1) \triangleq 0$ (thereby making the function continuous). As shown by Fig. 14.34, the binary entropy function is nonnegative and symmetric about $p = \frac{1}{2}$, at which point it takes on its maximum value of 1.

To understand the fundamental significance of a source’s entropy, recall that it follows from the law of large numbers that if k is large, then for a binary DMS it is highly probable that about kp bits of the k -bit source block \mathbf{u} are 1s; that is, defining the set

$$A = \{\mathbf{u} \mid \mathbf{u} \text{ has approximately } kp \text{ 1s}\}$$

we have

$$\Pr(\mathbf{u} \in A) \approx 1 \quad \text{for } k \text{ large} \tag{14.9}$$

Also, each of the blocks in A has about the same probability of occurring

$$P(\mathbf{u}) \approx p^{kp}(1-p)^{k-kp} = 2^{-kH_2(p)} \quad (\mathbf{u} \in A)$$

by Eq. (14.14); thus, since $H = H_2(p)$, we have

$$P(\mathbf{u}) \approx 2^{-kH} \quad (\mathbf{u} \in A) \tag{14.10}$$

Therefore, combining Eq.(14.15) and Eq. (14.16), we obtain

$$1 \approx \Pr(\mathbf{u} \in A) = \sum_{\mathbf{u} \in A} P(\mathbf{u}) \approx |A| \cdot 2^{-kH} \quad (k \text{ large})$$

where $|A|$ is the size of the set A ; hence

$$|A| \approx 2^{kH} \quad (k \text{ large})$$

That is, if k is large, then of the 2^k possible source blocks \mathbf{u} , only about 2^{kH} of them are likely to occur; and, the probability of each of these typical blocks is about 2^{-kH} .

Without much work, the rough argument just given can be made precise and rigorous. In general, for any information source having an entropy H , one can similarly define the precise source-block set

$$A = \{\mathbf{u} \mid 2^{-k(H+\epsilon)} \leq P(\mathbf{u}) \leq 2^{-k(H-\epsilon)}\}$$

for each block length $k \in \{1, 2, \dots\}$ and value $\epsilon > 0$. The source is then said to possess the *asymptotic equipartition property* (AEP) if and only if given any value for ϵ (however small), we have Eq. (14.9); that is

$$\Pr(\mathbf{u} \in A) \rightarrow 1 \quad \text{as } k \rightarrow \infty \quad (\text{all } \epsilon)$$

The AEP is asymptotic in that it is a limiting condition as the length k of the source block becomes infinite; and, by virtue of Eq. (14.9) and Eq. (14.10), the elements of the set A provide a near equipartition of the total probability 1.

Thus, we have seen that every binary DMS possesses the AEP; in fact, so does every DMS. An information source need not be memoryless, though, to possess the AEP; every *stationary ergodic source*—that is, a discrete source for which the output is a **stationary ergodic random process**—possesses the AEP (and, therefore, an entropy too). Even some nonstationary sources possess the AEP. For example, if the source sequence (u_1, u_2, \dots) is a time-invariant **Markov chain**, then its entropy is given by the formula

$$H = \sum_{u_i} \bar{P}(u_i) \sum_{u_{i+1}} P(u_{i+1} \mid u_i) \log \frac{1}{P(u_{i+1} \mid u_i)}$$

(where the choice of $i \in \{1, 2, \dots\}$ is arbitrary), in which $\bar{P}(\cdot)$ is the average distribution given by

$$\bar{P}(u) = \lim_{k \rightarrow \infty} \frac{1}{k} \sum_{i=1}^k \Pr(u_i = u) \quad (\text{all } u)$$

and, if the chain is also indecomposable, then the source possesses the AEP.

The importance of the AEP for data compression is shown by the *source coding theorem for fixed-length codes*. Defining the probability P_e of decoder error as

$$P_e = \Pr(\mathbf{v} \neq \mathbf{u})$$

the theorem states that for any source having an entropy H and possessing the AEP, if we are given values $\delta > 0$ and $\delta' > 0$, then there exists a fixed-length code of rate R and a corresponding decoder such that

$$R \leq H + \delta \quad \text{and} \quad P_e \leq \delta'$$

On the other hand, the *converse* to the theorem states that this result no longer holds if we replace the first condition with $R \leq H - \delta$. Roughly put, the theorem says that using a fixed-length code on a source possessing the AEP, the error probability P_e can be made arbitrarily small for any code rate R that is greater than (perhaps arbitrarily close to) the source entropy H ; whereas the converse says that P_e cannot be made arbitrarily small when R is any less than H . Put even more roughly, the entropy of a source possessing the AEP is the minimum rate at which reliable fixed-length encoding can be attained.

The proof of the theorem is quite simple; one merely allots storage space only to the approximately 2^{kH} source blocks in the typical set A , which requires approximately kH bits. A decoder error then occurs only when the source emits an atypical block \mathbf{u} , the probability P_e of which can be made arbitrarily small by making the code length k sufficiently large. Of course, such a compression scheme is lossy if $H < 1$; however, it is *nearly* lossless if P_e is made vanishingly small (which can be guaranteed by so choosing δ'). As an example, for a binary DMS with $p = 0.1$, we find from Eq. (14.8) that $H \approx 0.469$ bit/source bit;

therefore, if k is allowed to be large, then less than half as many storage bits are required to reliably store the k bits of \mathbf{u} .

14.5.4 Data Compression via Variable-Length Codes

Suppose we do not require the codewords to all have the same length; then, this creates a decoding difficulty not present before. Namely, it is common in Fig. 14.33 that, instead of merely encoding a single source block of length k , this same encoding step is repeated several times; that is, for some fixed value k , the source sequence (u_1, u_2, \dots) is parsed into a succession of k -bit source blocks

$$(u_1, \dots, u_k), \quad (u_{k+1}, \dots, u_{2k}), \quad \dots$$

each of which is encoded according to the rule of the code to produce a corresponding succession of codewords having respective lengths n_1, n_2, \dots ,

$$(x_1, \dots, x_{n_1}), \quad (x_{n_1+1}, \dots, x_{n_1+n_2}), \quad \dots$$

which when concatenated form the resulting code sequence (x_1, x_2, \dots) . In the case of a fixed-length code (where $n_1 = n_2 = \dots = n$), the decoder can easily parse the code sequence back into n -bit blocks, and then decode each block individually; however, when n is allowed to vary, it is not always possible to determine the proper parsing. For example, consider the following simple code with $k = 1$:

\mathbf{u}	\mathbf{x}
0	0
1	00

Here, even though each source block \mathbf{u} is assigned a unique codeword \mathbf{x} , the two source sequences 01 and 10 both produce the same code sequence 000.

In light of this problem, we require all of our variable-length codes to be *uniquely decodable*; that is, no two finite-length source sequences can produce the same code sequence, and thus it is possible to decode any finite-length code sequence that the encoder might emit. A particularly convenient kind of uniquely decodable code is a *prefix-free* code, which is defined as any block code satisfying the *prefix condition* whereby no codeword is a prefix of any other. To decode a code sequence (x_1, x_2, \dots) generated by a prefix-free code, the decoder simply determines the smallest value of n for which (x_1, \dots, x_n) is a codeword, and decodes it; then, this process is applied, repeatedly, to the remainder of the code sequence.

Not every uniquely decodable code, though, is prefix free; for example, the reader might enjoy precisely describing a decoder for the following code:

\mathbf{u}	\mathbf{x}
0	0
1	01

Given any uniquely decodable code, however, there always exists a prefix-free code having the same number of codewords, with the same respective lengths. In fact, it can be shown that given any M positive integers n_1, n_2, \dots, n_M , there exists a uniquely decodable code, or prefix-free code, with M binary codewords of lengths n_1, n_2, \dots, n_M , if and only if these numbers satisfy the *Kraft inequality*:

$$\sum_{i=1}^M 2^{-n_i} \leq 1$$

Using the Kraft inequality, one can prove the *source coding theorem for variable-length codes* (often called the *noiseless coding theorem*): For any source having an entropy H , if we are given a value $\delta > 0$, then there

exists a uniquely decodable variable-length code of rate

$$R \leq H + \delta$$

for which every source block is assigned a unique codeword. The *converse* to this theorem, though, states that this result no longer holds if we replace the previous condition with $R \leq H - \delta$. Thus, once again, the entropy of a source provides the minimum rate at which it can be reliably encoded. Comparing this result with the theorem for fixed-length codes, we see that the AEP is not required here; moreover, uniquely decodable codes are truly lossless, as compared with the only near-lossless performance of fixed-length codes. The amount of compression that will be obtained by a fixed-length code is known from the outset, however, and can be as close as desired to H bits/source bit. Whereas for a variable-length code, such performance can only be obtained *on average*; that is, it is still possible for the source to emit a particular sequence that will not be compressed so well (and might even be expanded!). In addition, if the codewords are transmitted over some noisy medium before they are decoded, then a variable-length code will be more vulnerable to any errors in the transmission, because these can destroy the uniquely decodable property of the code.

14.5.5 Huffman Coding

We now present some well-established encoding methods that achieve what the aforementioned source coding theorems promise. Continuing our focus on binary-input/binary-output coding, the matter is straightforward for fixed-length codes. Here, given a source, source-block length k , and code length $n \leq k$, one merely assigns the 2^n possible codewords \mathbf{x} to the 2^n highest probability source blocks \mathbf{u} one-to-one; then, the remaining $2^k - 2^n$ source blocks are mapped into these same codewords arbitrarily (thus, if $n < k$, some get reused). The best corresponding decoder will then err only when the source emits a block other than one of the 2^n most probable source blocks. Clearly, this encoding/decoding scheme is optimal in that no other scheme meeting the same constraints can yield a smaller probability P_e of decoder error.

For variable-length codes, however, the coding problem is complicated by the need to have a uniquely decodable code. Also, the performance criterion is different; namely, given a source and block length k , a code is considered optimal if and only if it attains the minimum average length $E\{n\}$ over all uniquely decodable codes, thus minimizing the rate R . Obviously, we should assign shorter codewords to higher probability source blocks, and the codeword lengths must satisfy the Kraft inequality. To obtain the actual codewords of an optimal code, one can use the following encoding algorithm due to David A. Huffman, which in addition yields a *prefix-free* code.

We will explain the Huffman algorithm by a simple example. Assuming a binary DMS with $p = 0.1$, and taking $k = 2$, the first two columns of Table 14.3 show the $2^k = 4$ possible source blocks \mathbf{u} and their corresponding probabilities $P(\mathbf{u})$. The algorithm proceeds by first forming a *code tree*, of which the source-block probabilities are the *leaves*. Choosing any smallest two of these probabilities (0.09 and 0.01, the last two probabilities, were chosen, though the second and fourth would have done just as well; whenever the Huffman algorithm allows for more than selection, the choice is immaterial as far as the resulting value of $E\{n\}$ is concerned) we sum them into a new probability (0.10), and indicate this

TABLE 14.3 Huffman Coding Example

\mathbf{u}	$P(\mathbf{u})$	Code Tree	\mathbf{x}
00	0.81		0
01	0.09		10
10	0.09		110
11	0.01		111

action on the tree by drawing *branches* from the first two probabilities to a single point corresponding to the new one. This reduction step is then performed repeatedly on the remaining probabilities (thus, the second step applies to 0.81, 0.09, and 0.10), until eventually leading to the total probability of 1 at the tree's *root*. Having completed the tree, the two bits 0 and 1 are assigned (in any order) to each pair of branches that join together. Finally, the codeword \mathbf{x} assigned to each \mathbf{u} is obtained by tracing the path through the tree *from its root* back to the appropriate leaf, reading off the bits encountered on the way. In our example, the average codeword length turns out to be $E\{n\} = 1.29$ bit, thereby giving a code rate of $R = 0.645$ bit/source bit. Note that by the source entropy $H \approx 0.469$ bit/source bit given earlier, we have

$$H \leq R < H + 1/k$$

This is always the result when the binary Huffman encoding algorithm is applied to a DMS (even if nonbinary); in particular, this fact implies that $R \rightarrow H$ as $k \rightarrow \infty$. (Indeed, applying the algorithm to the same source with $k = 3$ yields a code for which $R \approx 0.533$ bit/source bit—closer to H .) For an arbitrary source, the algorithm yields

$$E \left\{ \log_2 \frac{1}{P(\mathbf{u})} \right\} \leq R < E \left\{ \log_2 \frac{1}{P(\mathbf{u})} \right\} + 1/k$$

where, by Eq. (14.7), the expectations can be made arbitrarily close to H (if it exists) by taking k sufficiently large; so, again, $R \rightarrow H$ as $k \rightarrow \infty$ (which by the source coding theorem and converse for fixed-length codes must be the case, since for each k the code is optimal).

For example, the Huffman encoding algorithm may be incorporated into facsimile (fax) machines to speed up the telephone transmission of printed documents. First, each page of the document is sampled along horizontal lines while converting the scanned black and white pixels into 0s and 1s. Then, since the alternating black and white segments of these lines usually comprise many consecutive pixels each (especially the white segments), a simple lossless encoding method called *run-length coding* is applied. Here, the binary sequence for each line is represented by a sequence of numbers telling how many 1s begin the sequence, followed by how many 0s, and then how many more 1s, etc.; for example, 00001110 would become (0, 4, 3, 1). Finally, each of these number sequences is Huffman encoded (according to the presumed statistics of an average document) and transmitted. Of course, the inverses of these operations are applied, in reverse order, at the receiver. The net improvement in transmission speed is by about a factor of 7.

14.5.6 Arithmetic Coding

Ignoring the fact that codewords must have integer lengths, then for a given source and block length k , the average length $E\{n\}$ of a block code constrained by the Kraft inequality is minimized if and only if each source block \mathbf{u} is assigned a codeword of length $n(\mathbf{u}) = -\log_2 P(\mathbf{u})$. Thus, a reasonable strategy for designing a low-rate uniquely decodable code is to try to obtain $n(\mathbf{u}) \approx -\log_2 P(\mathbf{u})$ for all \mathbf{u} . The technique of *arithmetic coding*, developed by several researchers, provides a clever way doing this. It is so called because it associates codewords with real numbers; therefore, typical data-processing operations can be expressed as equivalent arithmetic operations (e.g., shifting a bit sequence one position to the left is equivalent to multiplying the corresponding binary number by 2).

Recall that given any infinite binary expansion

$$0.x_1x_2 \cdots \quad (x_1, x_2, \dots, \in \{0, 1\}) \tag{14.11}$$

the n -bit truncation

$$0.x_1x_2 \cdots x_n \tag{14.12}$$

approximates the given number to within an amount somewhere from 0 to less than 2^{-n} ; therefore, given any $\delta > 0$, if we take n to be the integer for which

$$-\log_2 \delta \leq n < -\log_2 \delta + 1$$

then the n -bit truncation approximates the given number to within an accuracy of δ . Similarly, one can show that given any subinterval $[a, b]$ of the unit interval $[0, 1]$, there exists an n -bit number (Eq. (14.12)) for which

$$n < -\log_2(b - a) + 2$$

such that the number and *all* of its extensions (Eq. (14.11)) lie within $[a, b]$. (For any real numbers α and β , $[\alpha, \beta]$ is the set of all real numbers r such that $\alpha \leq r < \beta$.) Accordingly, in arithmetic coding each k -bit source block \mathbf{u} is assigned a subinterval $[a_{\mathbf{u}}, b_{\mathbf{u}}]$ of $[0, 1]$, where $b_{\mathbf{u}} - a_{\mathbf{u}} = P(\mathbf{u})$, such that the subintervals for different source blocks do not overlap; this is possible since

$$\sum_{\mathbf{u}} P(\mathbf{u}) = 1$$

Then, the codeword $\mathbf{x} = (x_1, \dots, x_n)$ corresponding to each \mathbf{u} is formed from the bits of the shortest binary number (Eq. (14.12)) lying within $[a_{\mathbf{u}}, b_{\mathbf{u}}]$ for which all of its extensions (Eq. (14.11)) also lie within $[a_{\mathbf{u}}, b_{\mathbf{u}}]$; or, if there is more than one such number (as happens in the example below), then the smallest one (say) is selected. It follows that we obtain a prefix-free code for which the codeword assigned to each source block \mathbf{u} has a length $n(\mathbf{u}) < -\log_2 P(\mathbf{u}) + 2$. Thus, although such a code need not be optimal (as we will see), its rate R approaches the source entropy H as $k \rightarrow \infty$.

A convenient way to uniquely assign subintervals $[a_{\mathbf{u}}, b_{\mathbf{u}}]$ of $[0, 1]$ to source blocks \mathbf{u} as stipulated above is to utilize the cumulative distribution function

$$F(\mathbf{u}') \triangleq \Pr(\mathbf{u} < \mathbf{u}') = \sum_{\mathbf{u} < \mathbf{u}'} P(\mathbf{u}) \quad (\text{all source blocks } \mathbf{u}')$$

where $\mathbf{u} = (u_1, \dots, u_k)$ is considered to be less than $\mathbf{u}' = (u'_1, \dots, u'_k)$ if and only if the corresponding binary number $0.u_1u_2 \dots u_k$ is less than the binary number $0.u'_1u'_2 \dots u'_k$; namely, we let

$$[a_{\mathbf{u}}, b_{\mathbf{u}}] = [F(\mathbf{u}), F(\mathbf{u}) + P(\mathbf{u})] \quad (\text{all } \mathbf{u}) \tag{14.13}$$

Proceeding this way, the arithmetic encoding of a binary DMS with $p = 0.1$ produces the results shown in Table 14.4 when $k = 2$. (Regarding the codeword \mathbf{x} for $\mathbf{u} = 10$, note that the 5-bit number 0.11110 and all of its extensions lie within the subinterval $[a_{\mathbf{u}}, b_{\mathbf{u}}]$, whereas no shorter binary number has this property; however, the smallest 5-bit number having this property is 0.11101.) In Table 14.4 the average code-length $E\{n\} = 1.69$ bit, making the rate $R = 0.845$ bit/source bit. Comparing this with the optimum code obtained earlier via Huffman encoding for this same source and k , we see that an arithmetic code need not be optimal; in particular, it can be wasteful for low-probability source blocks (the last codeword could be shortened by 3 bit without upsetting the prefix condition).

Nevertheless, arithmetic coding has an implementation advantage in that it can be performed *recursively* as bits enter the encoder; because, using Eq. (14.13), the subinterval $[a_{\mathbf{u},i}, b_{\mathbf{u},i}]$ assigned to the i -bit source block (u_1, \dots, u_i) gradually shrinks as i increases, until we finally obtain $[a_{\mathbf{u}}, b_{\mathbf{u}}] = [a_{\mathbf{u},k}, b_{\mathbf{u},k}]$ when $i = k$.

TABLE 14.4 Arithmetic Coding Example

\mathbf{u}	$P(\mathbf{u})$	$\approx -\log_2 P(\mathbf{u})$	$[a_{\mathbf{u}}, b_{\mathbf{u}}]$	\mathbf{x}
00	0.81	0.3	[0, 0.81)	0
01	0.09	3.5	[0.81, 0.9)	1101
10	0.09	3.5	[0.9, 0.99)	11101
11	0.01	6.6	[0.99, 1)	1111111

TABLE 14.5 Arithmetic Coding Done Recursively

i	u_i	$[a_{\mathbf{u},i}, b_{\mathbf{u},i})$
1	0	$[0, 0.9)$
2	1	$[0.81, 0.9)$
3	1	$[0.891, 0.9)$
4	0	$[0.891, 0.8991)$

Specifically, for a binary DMS with probability p , we can define the initial values of $a_{\mathbf{u},0} = 0$ and $b_{\mathbf{u},0} = 1$, and then for each $i = 1, \dots, k$ let

$$a_{\mathbf{u},i} = a_{\mathbf{u},i-1} + u_i(1 - p)(b_{\mathbf{u},i-1} - a_{\mathbf{u},i-1}) \tag{14.14a}$$

and

$$b_{\mathbf{u},i} = b_{\mathbf{u},i-1} - (1 - u_i)p(b_{\mathbf{u},i-1} - a_{\mathbf{u},i-1}) \tag{14.14b}$$

as determined by the bits u_i of the emitted source block $\mathbf{u} = (u_1, \dots, u_k)$. For example, if $p = 0.1$ and $\mathbf{u} = 0110$ ($k = 4$), we obtain the values shown in Table 14.5 (notice the agreement between $[a_{\mathbf{u},2}, b_{\mathbf{u},2})$ in the table and the subinterval $[a_{\mathbf{u}}, b_{\mathbf{u}})$ given in Table 14.4 for $\mathbf{u} = 01$). Therefore, $[a_{\mathbf{u}}, b_{\mathbf{u}}) = [0.891, 0.8991)$, from which the appropriate codeword \mathbf{x} can be obtained. In particular, unlike Huffman encoding, which typically must wait for much (if not all) of the source block \mathbf{u} before it can begin to emit the corresponding codeword, here after just the first two source bits we can determine that the encoder output must begin with 11, since only then can the eventual binary number $0.x_1x_2 \dots x_n$ lie within the intermediate subinterval $[a_{\mathbf{u},2}, b_{\mathbf{u},2})$ and, thus, within the final subinterval $[a_{\mathbf{u}}, b_{\mathbf{u}})$.

Similarly, the corresponding decoder can also be designed to operate recursively as it comes to know the codeword (x_1, \dots, x_n) bit-by-bit; for after the first $j \leq n$ code bits are known, the decoder can emit as many as possible of its output bits v_i ($i = 1, \dots, k$) such that each v_i is that value of u_i in Eq. (14.14) for which the binary number $0.x_1x_2 \dots x_j$ and all of its extensions lie within the subinterval $[a_{\mathbf{u},i}, b_{\mathbf{u},i})$. Hence, arithmetic coding has an implementation advantage over Huffman coding when the block length k is large. Moreover, should one decide to change k , then a new Huffman code would need to be calculated from scratch, whereas the encoder and decoder for arithmetic coding could be easily modified.

14.5.7 Universal Codes

In contrast to the preceding, suppose we have a binary DMS for which the probability distribution of the output is unknown; that is, we do not know the value of p and, thus, are unable to apply either the Huffman or arithmetic encoding algorithms. We now show that one can nevertheless design an *adaptive* lossless encoding/decoding scheme such that, as the block-length $k \rightarrow \infty$, the code rate R approaches the source entropy H (whatever it happens to be). That is, there exists a *universal code* for all sources of this type. The following is but one way to proceed.

First, for the given value of k , the encoder observes the k -bit source block \mathbf{u} emitted by the source, from which it forms an estimate \hat{p} of p

$$\hat{p} = \langle \mathbf{u} \rangle / k \tag{14.15}$$

where $\langle \mathbf{u} \rangle$ is the number of 1s in \mathbf{u} . Then, the encoder performs the arithmetic encoding algorithm under the assumption that \hat{p} is, indeed, the value of p ; let the resulting codeword be $\hat{\mathbf{x}}$. Finally, to enable the decoder to reproduce \mathbf{u} from $\hat{\mathbf{x}}$, the encoder essentially stores *both* \hat{p} and $\hat{\mathbf{x}}$; specifically, its output is the composite codeword

$$\mathbf{x} = \langle \mathbf{u} \rangle_b \circ \hat{\mathbf{x}},$$

where $\langle \mathbf{u} \rangle_b$ is an N -bit binary representation of $\langle \mathbf{u} \rangle$ for some fixed number N and \circ indicates concatenation. Clearly, since both k and N are known to the decoder, it can reverse these steps to determine \mathbf{u} from \mathbf{x} ; moreover, since the arithmetic code for each \hat{p} is prefix free, the code is uniquely decodable.

To show that the performance claimed is indeed obtained, recall from the previous section that for each source block \mathbf{u} , the length $\hat{n}(\mathbf{u})$ of the intermediate codeword $\hat{\mathbf{x}}$ satisfies the bound

$$\hat{n}(\mathbf{u}) < -\log_2 \hat{P}(\mathbf{u}) + 2 \quad (\text{all } \mathbf{u})$$

where $\hat{P}(\mathbf{u})$ is the probability distribution for \mathbf{u} under the assumption that \hat{p} is the value of p ,

$$\hat{P}(\mathbf{u}) = \hat{p}^{(u)}(1 - \hat{p})^{k-(u)} \quad (\text{all } \mathbf{u})$$

Combining these facts, and using Eq. (14.8) and Eq. (14.15), we obtain

$$\hat{n}(\mathbf{u}) < kH_2(\hat{p}) + 2 \quad (\text{all } \mathbf{u})$$

Also note that the estimate \hat{p} in Eq.(14.15) is just the relative frequency of 1s in \mathbf{u} ; thus, by the law of large numbers, we have

$$\Pr(\hat{p} \approx p) \approx 1 \quad \text{for } k \text{ large}$$

Therefore

$$E\{H_2(\hat{p})\} \approx H_2(p) = H \quad (k \text{ large})$$

More precisely, a rigorous version of this argument would show that for some $\delta > 0$, we have

$$|E\{H_2(\hat{p})\} - H| \leq \delta$$

where $\delta \rightarrow 0$ as $k \rightarrow \infty$. Finally, since the possible values of $\langle \mathbf{u} \rangle$ are $0, 1, \dots, k$, it is sufficient for the storage of $\langle \mathbf{u} \rangle_b$ that N be the largest integer for which $N \leq \log_2 k + 1$. Hence, altogether, the average length of the composite codeword \mathbf{x} is

$$E\{n\} = E\{\hat{n}\} + N < E\{kH_2(\hat{p}) + 2\} + (\log_2 k + 1) \leq k(H + \delta) + \log_2 k + 3$$

Therefore, dividing by k , we obtain

$$R < H + \delta + (\log_2 k + 3)/k \rightarrow H \quad \text{as } k \rightarrow \infty$$

and from this it follows that R (which by the converse to the variable-length source coding theorem cannot be less than H) must approach H as $k \rightarrow \infty$.

14.5.8 Lempel–Ziv Coding

Of all of the source codes presently in use, the most important are the following two, commonly abbreviated *LZ77* and *LZ78*, which were published by Abraham Lempel and Jacob Ziv in 1977 and 1978. Though distinct (it is incorrect to speak generally of *the* Lempel–Ziv encoding algorithm), these two lossless codes are structurally similar in that they both perform data compression by storing a sequence of *pointers* that cite *phrases*, which are previous segments of the source-sequence, within a variable *dictionary* maintained at both the encoder and the decoder. The idea behind such a scheme is that any source that is not completely random (e.g., a binary DMS with an entropy of less than 1 bit/source bit) will often duplicate some of its past behavior; when a duplication is sufficiently long, it is more efficient to store a reference (pointer) to a previous occurrence rather than the duplication itself. The widespread use of these codes is due to their speed, as well as their being universal for all stationary ergodic sources (which need not be memoryless, as was assumed in the previous section).

The algorithm LZ77 operates by passing the source block $\mathbf{u} = (u_1, \dots, u_k)$ through a sliding *window* of a fixed width w , initially filled with 0s. Assuming that, for some $i \geq 0$, the first i source bits u_1, \dots, u_i have already been encoded, then the window contains the last w of these bits; that is, defining $u_j = 0$ ($j \leq 0$) in order to conveniently express the initial 0s, the window is the w -bit block (u_{i-w+1}, \dots, u_i) . In a practical implementation, the window would be followed by a finite buffer containing the next several yet to be encoded source bits; the dictionary would be comprised of all of the source blocks that start somewhere within the window and end somewhere before the last bit of the buffer. However, to streamline the explanation that follows, the buffer is omitted; thus, the dictionary consists of every finite source block starting within the window.

The algorithm matches as much of the remainder (u_{i+1}, \dots, u_k) of \mathbf{u} as possible to a phrase in the dictionary. Specifically, using a pointer $p \in \{1, \dots, w\}$ to tell where (in terms of how many bits before u_{i+1}) in the window the phrase begins, along with the length $l \in \{1, \dots, k - i - 1\}$ of the phrase, the encoder chooses the values of p and l to obtain a match

$$(u_{i+1-p}, \dots, u_{i+l-p}) = (u_{i+1}, \dots, u_{i+l})$$

(where the block on the left is from the dictionary). In addition, p and l are chosen to make l as large as possible; or, if no such match can be obtained, then the encoder sets $p = l = 0$. The first source bit u_{i+l+1} not included in the matching block is now annexed onto it to yield the extended match

$$(u_{i+1}, \dots, u_{i+l+1})$$

of length $l + 1$; hence, for the case of no match, the extended match is just the single bit u_{i+1} .

All of the pertinent information about the extended match is contained in the ordered triple

$$(\text{starting point, length, last bit}) = (p, l + 1, u_{i+l+1})$$

because, using just this information and the previously decoded bits u_1, \dots, u_i , a decoder that mirrors the encoding process (i.e., keeps track of the window) can determine the present extended match. Therefore, using an efficient uniquely decodable code, the triple is encoded into a binary codeword that is stored as the next part of the overall codeword $\mathbf{x} = (x_1, \dots, x_n)$. Finally, the encoder slides the window down the source block \mathbf{u} to make the last bit of the extended match the new last bit of the window. Repeating this process, parsing \mathbf{u} into a succession of extended matches and encoding the corresponding triples, the entire source block is eventually encoded.

As an example of applying LZ77, suppose we wish to encode the source block

$$\mathbf{u} = 101010100110 \tag{14.16}$$

with a window width $w = 5$. Using an overbar to indicate the window, an up-arrow to indicate the pointer, and boldface type to indicate the extended match, the algorithm sequentially produces triples as follows:

$$\begin{array}{l} \overline{00000}101010100110 \rightarrow (0, 1, 1) \\ \quad \uparrow \\ \overline{00000}1\mathbf{01010}100110 \rightarrow (2, 8, 0) \\ \quad \uparrow \\ 000001010\overline{10100}110 \rightarrow (3, 2, 1) \\ \quad \quad \quad \uparrow \\ 00000101010\overline{10011}0 \rightarrow (0, 1, 0) \\ \quad \quad \quad \quad \quad \quad \uparrow \end{array}$$

thus, the resulting codeword is

$$\mathbf{x} = (0, 1, 1)_b \circ (2, 8, 0)_b \circ (3, 2, 1)_b \circ (0, 1, 0)_b$$

where the subscript b indicates the binary encoding of the triple. Since the first source bit in this example is 1, no match is possible at the start. The second step shows that a phrase and its match can overlap, and

even be longer than window; nevertheless, the reader (acting as the decoder) should be able to calculate the second extended match from the corresponding triple and window alone. The third step shows that more than one value of the pointer is sometimes possible (viz., we could have taken $p = 5$). Finally, since only one unencoded source bit is left for the last extended match, no match is performed, and the bit becomes the extended match.

In LZ78, the source block \mathbf{u} is again parsed into segments; however, there is no window. Instead, as each segment is identified, it becomes a new phrase in an ever growing dictionary (initially empty) by which the encoder performs the parsing. Namely, after the first $i \geq 0$ source bits u_1, \dots, u_i have been encoded, the encoder determines the largest length $l \in \{1, \dots, k - i - 1\}$ for which the subsequent block $(u_{i+1}, \dots, u_{i+l})$ matches a phrase in dictionary; then, the first source bit u_{i+l+1} not included in the matching block is annexed onto it to form the extended match

$$(u_{i+1}, \dots, u_{i+l+1})$$

which is expressed as the order-pair

$$(\text{phrase number, last bit}) = (p, u_{i+l+1}) \tag{14.17}$$

Here, the pointer p gives the number (in order of occurrence) of the phrase in the dictionary which provided the match; or, if no match is possible, then $p = 0$ and the extended match is just u_{i+1} . (Of course, a practical encoder has a finite memory and, therefore, must place an upper limit on p .) Using an efficient uniquely decodable code, the pair is encoded into a binary codeword that is stored as the next part of the overall codeword $\mathbf{x} = (x_1, \dots, x_n)$; finally, the extended block is added to the dictionary as a new phrase. This process is repeated until \mathbf{u} is exhausted.

Applying LZ78 to the source-block in Eq. (14.16), we obtain the parsing

$$\mathbf{u} = 1 \circ 0 \circ 10 \circ 101 \circ 00 \circ 11 \circ 0$$

Because, for instance, when the fourth match is attempted, the dictionary is $\{1, 0, 10, 101\}$ and the unencoded portion of \mathbf{u} is 00110 ; therefore, the longest possible match is with the second phrase 0 (i.e., $p = 2$), thereby making the extended match 00 (the next phrase). The final codeword is then

$$\mathbf{x} = (0, 1)_b \circ (0, 0)_b \circ (1, 0)_b \circ (3, 1)_b \circ (2, 0)_b \circ (1, 1)_b \circ (0, 0)_b$$

As before, it happened that only one unencoded source bit was left for the last extended match, and so no match was performed.

Because the \mathbf{u} given in Eq. (14.16) is rather short, these runs of LZ77 and LZ78 do not display the compression to be expected with longer source blocks. For another example, then, consider the encoding of the all-0 sequence $\mathbf{u} = 00 \dots$; here, LZ78 gives

$$\begin{aligned} \mathbf{u} &= 0 \circ 00 \circ 000 \circ 0000 \circ 00000 \circ 000000 \circ \dots \Rightarrow \\ \mathbf{x} &= (0, 0)_b \circ (1, 0)_b \circ (2, 0)_b \circ (3, 0)_b \circ (4, 0)_b \circ (5, 0)_b \circ \dots \end{aligned} \tag{14.18}$$

Also, suppose that each pair from Eq.(14.17) is encoded as

$$(p, u_{i+l+1})_b = (N\text{-bit binary representation of } p)_b \circ u_{i+l+1}$$

where N is the largest integer for which

$$N \leq \log_2[(\text{number of phrases currently in dictionary}) + 1] + 1$$

then (as the reader can verify), the general encoding from \mathbf{u} to \mathbf{x} is uniquely decodable, whereas for the present example we have

$$\mathbf{x} = 00 \circ 010 \circ 100 \circ 1100 \circ 1000 \circ 1010 \circ \dots = 00010100110010001010 \dots \tag{14.19}$$

Comparing Eq. (14.19) with Eq. (14.18), we see that \mathbf{x} eventually grows slower than \mathbf{u} ; indeed, for each $j \in \{1, 2, \dots\}$, the j th phrase of \mathbf{u} has length j , whereas for the respective addition to \mathbf{x} we have

$$(\text{length of } j\text{th encoded pair}) \leq \log_2 j + 2$$

It follows that even though the dictionary and bit allocation N grow indefinitely, we obtain $n/k \rightarrow 0$ as $k \rightarrow \infty$; this is as expected, since we are essentially compressing the output of a binary DMS with $p = 0$, for which the entropy is 0 bit/source bit.

14.5.9 Rate-Distortion Theory

All of our discussion thus far has been directed toward coding that achieves lossless or near-lossless performance at rates R that are above, but perhaps arbitrarily close to, the source entropy H . What if we attempt to achieve even greater compression—that is, encode at some $R < H$? Then, according to the coding theorem converses already discussed, such performance is no longer possible. Instead, the best we can hope for is that the sink sequence (v_1, v_2, \dots) will replicate the source-sequence (u_1, u_2, \dots) with a minimal amount of *distortion*. The study of how well this can be done is called *rate-distortion theory*.

To express the fidelity with which a particular k -bit sink block $\mathbf{v} = (v_1, \dots, v_k)$ represents a given k -bit source block $\mathbf{u} = (u_1, \dots, u_k)$, we first introduce a digitwise *distortion measure*; this is any function $d(u, v)$ of $u, v \in \{0, 1\}$ for which

$$d(u, v) \geq 0 \quad (\text{all } u, v)$$

Then, respectively averaging over all bits of the two blocks, we obtain the blockwise distortion

$$d(\mathbf{u}, \mathbf{v}) \triangleq \frac{1}{k} \sum_{i=1}^k d(u_i, v_i) \quad (\text{all } \mathbf{u}, \mathbf{v})$$

Finally, averaging over the statistics of source, we obtain the *average distortion* \bar{d} between \mathbf{u} and \mathbf{v} ,

$$\bar{d} \triangleq E\{d(\mathbf{u}, \mathbf{v})\} = \sum_{\mathbf{u}} P(\mathbf{u})[d(\mathbf{u}, \mathbf{v}(\mathbf{u}))]$$

where we have explicitly indicated on the right the functional dependence of \mathbf{v} on \mathbf{u} , as determined by the encoder and decoder. Just what distortion measure is chosen depends on the application; for example, a common choice is

$$d(u, v) = \begin{cases} 0, & u = v \\ 1, & u \neq v \end{cases} \quad (\text{all } u, v) \tag{14.20}$$

for which

$$d(\mathbf{u}, \mathbf{v}) = \frac{\text{number of bits in which } \mathbf{u} \text{ and } \mathbf{v} \text{ differ}}{k} \quad (\text{all } \mathbf{u}, \mathbf{v})$$

thereby making \bar{d} the bit-error rate (BER) produced by the processing of the encoder/decoder. (Having focused on binary sources, the possible distortion measures $d(\cdot, \cdot)$ are rather limited. If instead, for example, the source emitted a sequence of *bytes*, then one might choose a distortion measure that more heavily weights an error in the most significant bit.)

To proceed further, we define the *mutual information* $I(\mathbf{u}; \mathbf{v})$ between any two random blocks \mathbf{u} and \mathbf{v} , with joint probability-distribution $P(\mathbf{u}, \mathbf{v})$ and individual probability-distributions $P(\mathbf{u})$ and $P(\mathbf{v})$, by

$$I(\mathbf{u}; \mathbf{v}) \triangleq E \left\{ \log_2 \frac{P(\mathbf{u}, \mathbf{v})}{P(\mathbf{u})P(\mathbf{v})} \right\} = \sum_{\mathbf{u}, \mathbf{v}} P(\mathbf{u}, \mathbf{v}) \log_2 \frac{P(\mathbf{u}, \mathbf{v})}{P(\mathbf{u})P(\mathbf{v})}$$

As the name suggests, $I(\mathbf{u}; \mathbf{v})$ provides a measure of the information (entropy, randomness) that \mathbf{u} and \mathbf{v} have in common. Note that once the distribution $P(\mathbf{u})$ and the conditional probability distribution $P(\mathbf{v} | \mathbf{u})$ are specified, then the distributions $P(\mathbf{u}, \mathbf{v})$ and $P(\mathbf{v})$ follow; hence, $I(\mathbf{u}; \mathbf{v})$ can be thought of as a function of $P(\mathbf{u})$ and $P(\mathbf{v} | \mathbf{u})$. In the present situation, $P(\mathbf{u})$ is given by the source, whereas

$$P(\mathbf{v} | \mathbf{u}) = \begin{cases} 1, & \mathbf{v} = \mathbf{v}(\mathbf{u}) \\ 0, & \text{otherwise} \end{cases} \quad (\text{all } \mathbf{u}, \mathbf{v})$$

since \mathbf{v} is a deterministic function of \mathbf{u} . However, fixing $P(\mathbf{u})$, suppose we let $P(\mathbf{v} | \mathbf{u})$ vary over *all* possible conditional probability distributions for \mathbf{v} given \mathbf{u} ; then, the average distortion between \mathbf{u} and \mathbf{v} would be calculated as

$$\bar{d} = \sum_{\mathbf{u}, \mathbf{v}} P(\mathbf{u}) P(\mathbf{v} | \mathbf{u}) d(\mathbf{u}, \mathbf{v})$$

From here, the *rate-distortion function* $R(d)$ for the given source and distortion measure would be defined as

$$R(d) \triangleq \lim_{k \rightarrow \infty} \frac{1}{k} \min_{P(\mathbf{v} | \mathbf{u}): \bar{d} \leq d} I(\mathbf{u}; \mathbf{v}) \quad \text{bits/source bit} \tag{14.21}$$

(for those values $d \geq 0$ for which the limit exists), where the minimum is performed over all conditional distributions $P(\mathbf{v} | \mathbf{u})$ that result in an average distortion $\bar{d} \leq d$.

The significance of the rate-distortion function stems from the *source coding theorem with a fidelity criterion*, which states that for any stationary ergodic source and accompanying distortion measure, if we are given a distortion d for which $R(d)$ is defined, and a value $\delta > 0$, then there exists a fixed-length code of rate

$$R \leq R(d) + \delta$$

and a corresponding decoder, which together yield an average distortion

$$\bar{d} \leq d + \delta$$

However, the *converse* to this theorem states that we must always have $R \geq R(\bar{d})$. Observing that it follows immediately from Eq. (14.21) that $R(d)$ is nonincreasing vs. d (as one would expect, since increasing the allowable distortion should not require a higher encoding rate) the theorem and converse roughly say that $R(d)$ is the minimum rate R at which source coding can attain a given distortion d .

As a simple example, consider a binary DMS with $p = \frac{1}{2}$ (which has an entropy of $H = 1$ bit/source bit), and take the distortion measure given in Eq. (14.20). It can then be shown that the resulting rate-distortion

FIGURE 14.35 Example of a rate-distortion function.

function $R(d)$ is defined for all $d \geq 0$, and

$$R(d) = \begin{cases} 1 - H_2(d), & 0 \leq d < \frac{1}{2} \\ 0, & d \geq \frac{1}{2} \end{cases}$$

As shown in Fig. 14.35, we have $R(d) \leq H$ (all d), as one would expect from the fixed-length source coding theorem. At the lower extreme, the minimum value of $R(d) = 0$ is first obtained at $d = \frac{1}{2}$, which is also what one would expect, because no storage is necessary to achieve $\bar{d} = \text{BER} = \frac{1}{2}$. Also, for instance, since $R(0.12) \approx 0.471$ bit/source bit, it follows that a BER of 12% can be obtained by encoding at a rate $R = \frac{1}{2}$ bit/source bit, which is much better than the best BER (25%) attainable by simply discarding every other bit.

Defining Terms

Ergodic random process: A random process that, with probability 1, never locks into a mode that is unrepresentative of its overall statistics.

Markov chain: A discrete random process having a memory of 1 time unit; that is, if the output of the process is the sequence (u_1, u_2, \dots) , then

$$P(u_{i+1} | u_1, \dots, u_i) = P(u_{i+1} | u_i) \quad (i = 1, 2, \dots)$$

The chain is *time invariant* if and only if these conditional probabilities are the same for all i ; it is then *indecomposable* if and only if there is an output value u such that for all output values u' , we have $\Pr(u_{i+j} = u | u_i = u') > 0$ (where i is arbitrary) for some $j \in \{1, 2, \dots\}$.

Stationary random process: A random process for which the statistics do not vary with time.

Further Information

The theoretical foundation of data compression comprises the source coding portion of *information theory*. The book by Pierce provides an elementary introduction to this field, although a more advanced, yet accessible, introduction can be found in the concise volume by Mansuripur; for a complete treatment, the reader is referred to the works by Cover and Thomas, Gallager, and others. Also worth mentioning is the still interesting book by Shannon and Weaver, in which the original paper on information theory by Claude Shannon appears, preceded by an introduction from the second author. The popular book by Lucky discusses data compression in the context of text, speech, and video compression. As for specific implementation details of the various coding methods, as well as historical perspective, the work by Bell, Cleary, and Witten is recommended.

Current research on data compression can be found in the related journals and conferences of the Institute of Electrical and Electronics Engineers (IEEE) and the Association for Computing Machinery (ACM); in particular, see the *IEEE Transactions on Information Theory* and the *Journal of the ACM*.

15.1 Network Switching Concepts

Tsong-Ho Wu

15.1.1 Introduction

Switching is the control or routing of signals in either physical or virtual circuit form to transmit data between specific points in a network. A switched network is a communication network that has switching facilities or centers to perform the function of message switching, packet switching, or circuit switching. The primary purpose of the network switching function is to maximize the transmission system efficiency by sharing the capacity of the transmission system among communications circuits.

In general, there are two major types of network switching techniques: packet switching and circuit switching. The message switching system may be viewed as a special case of the packet switching system. The traditional circuit switching concept is designed to handle and transport stream-type traffic, such as voice and video. A circuit-switched connection is set up with a fixed bandwidth for the duration of a connection, which provides fixed throughput and constant delay. In other words, network resources are dedicated in circuit-switched systems. In contrast, packet switching is primarily designed to efficiently carry data communications traffic. Its characteristics are access with buffering, statistical multiplexing, and variable throughput and delay, which is a consequence of the dynamic sharing of communication resources

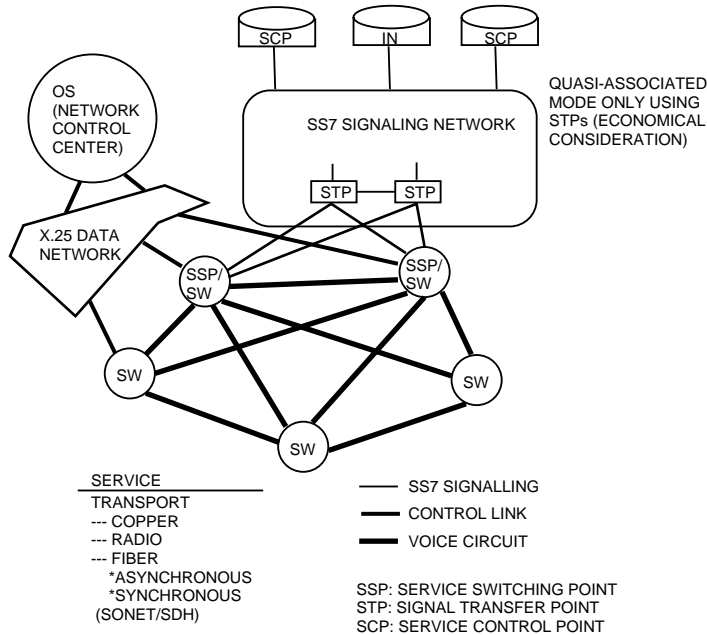

FIGURE 15.1 Today's telecommunications network infrastructure.

to improve utilization. Today, it is used exclusively for data applications. Examples of circuit-switched networks include telephony networks and private line networks. Examples of packet-switched networks include X.25 (with variable packet sizes) and **asynchronous transfer mode (ATM)** networks (with the fixed-cell size).

Telecommunications services are primarily supported by three separate switched networks using two major switching concepts. As depicted in Fig. 15.1, the circuit-switched network supports voice transport, which includes copper, radio, and/or fiber transmission systems using asynchronous or synchronous optical network (SONET) transmission technology. The signaling system needed to support switched voice services is supported by a specialized (delay-sensitive) packet-switched SS7 network. The network supporting the access to the operations systems from the service transport system is a packet-switched X.25 network.

In the future telecommunication network infrastructure, both the narrowband services of today and emerging broadband services will be supported by an integrated B-integrated services digital network (B-ISDN). ATM has been adopted by the International Telecommunications Union (ITU-T) as the core technology to support B-ISDN transport. ATM is a high-speed, integrated multiplexing and switching technology that transmits information using fixed-length cells in a connection-oriented manner. Physical interfaces for the user-network interface (UNI) of 155.52 Mb/s and 622.08 Mb/s provide integrated support for high-speed information transfer and various communication modes, such as circuit and packet modes, and constant/variable/burst bit-rate communications.

In the ATM network, services, control, signaling, and operations and maintenance (OAM) messages are carried by the same physical network, but they are logically separated from each other by using different virtual channels (VCs) or virtual paths (VPs) with different quality of service (QoS) requirements.

ATM is growing and maturing rapidly. It has been implemented today in products by many equipment suppliers and deployed by customers who anticipate such business advantages as:

- Enabling high-bandwidth applications including desktop video, digital libraries, and real-time image transfer

FIGURE 15.2 Relationship between SONET transmission, STM, and ATM switching.

- Coexistence of different types of traffic on a single network platform to reduce both the transport and operations costs
- Long-term network scalability and architectural stability

In addition, ATM has been used in both local and wide area networks. It can support a variety of high layer protocols and will cope with future network speeds of gigabits per second.

In North America standards, as specified by the American National Standards Institute (ANSI) T1S1 committee, ATM cells are transported over the SONET system as the physical layer. (Note that in ITU-T standards, there are two options for the transmission standards: synchronous digital hierarchy (SDH) and cell-based transmission. SDH is functionally equivalent to SONET, although some of the rates are different and the use of some overhead and multiplexing schemes may also be different. For the cell-based transmission, ATM cells will not be accommodated by the SDH frame within the transmission link.) SONET is the North America's standard synchronous transmission network technology for optical signal transmission (Ballart and Ching, 1989). In this multilayer network environment, the switching of the service connection may be implemented at the SONET layer using synchronous transfer mode (STM) or at the ATM layer using ATM. STM is a time division multiplexing and switching technology that uses a similar switching concept as traditional circuit switching systems.

Figure 15.2 depicts the relationship between SONET transmission, STM, and ATM switching. The end-to-end ATM connection is established and transported through a set of transmission links that are terminated at nodes for processing and switching (called transfer mode). The nodal transfer mode may be existing STM or emerging ATM, depending on types of services and QoS being supported. STM switching technology has been widely deployed in today's telecommunications networks, whereas ATM is expected to be widely deployed in the near future. Without loss of generality, we will assume in this section that STM is operated on the SONET system.

To help understand how the broadband SONET/ATM network is used to support high-speed data and video services (discussed subsequently), this section focuses on reviewing switching concepts used in the SONET layer (STM switching) and the ATM layer (ATM switching). The switching concept is based on the characteristics of the signal switching format (e.g., time slot or virtual connection). Thus, this section will first review signal switching formats and their bandwidth relationship in a multilayer SONET/ATM network environment. The operations of STM and ATM switching concepts will then be explained. The protection switching concept for SONET/ATM networks will also be discussed.

15.1.2 Broadband Switching Layer Model and Formats

Multilayer Transport Model

Figure 15.3 shows the B-ISDN signal transport protocol reference model defined in CCITT Rec. I.321. [The International Telegraph and Telephone Consultative Committee (CCITT) has been renamed the International Telecommunication Union (ITU) since 1994.] Three layers are defined in the model: physical,

ATM, and ATM adaptation layer (AAL), where the physical and ATM layers form the ATM transport platform.

In North America, the physical layer uses SONET standards, whereas in ITU-T, it uses the SDH or cell-based transmission system. The AAL layer is a service-dependent layer. Details of this B-ISDN transport reference model can be found in Boudec [1992]. SONET defines a progressive hierarchy of optical signal and line rates. The basic SONET building block is the synchronous transport signal at level 1 (STS-1) signal operating at 51.840 Mb/s. Higher rate signals (STS-N) are multiples (N) of this basic rate. Values of N currently used in standards are 1, 3, 12, 24, and 48, with 192 likely in the near future. Broadband services requiring more than one STS-1 payload capacity are transported by concatenated STS-1s. The function of the SONET layer is to carry ATM cells or non-ATM frames (e.g., STS-1) in a high-speed and transparent manner, as well as to provide very fast protection switching capability to ATM cells or non-ATM frames whenever needed. SONET offers opportunities to implement new network architectures in a cost-effective manner (Wu, 1992) and has been widely deployed by local exchange carriers (LECs) since 1991.

The major function of the ATM layer is to provide fast multiplexing and routing for data transfer based on the header information. The ATM layer is divided into two sublayers: virtual path and virtual channel. A VC is a generic term used to describe a unidirectional communication capability for the transport of ATM cells. The VC identifies an end-to-end connection that can be set via either provisioning (permanent VC) or near real-time call setup (switched VC). Either way the bandwidth capacity of that connection is determined in real-time depending on traffic to be transported over that connection.

The VP accommodates a set of different VCs, all with the same terminations (source and destination). The VPs are managed by network systems, whereas VCs can be managed, end-to-end, by users with ATM terminals. For example, a business user may be provisioned with a VP to another user location to provide the equivalent of leased circuits, and another VP to the serving central office for switched services. Each VP may include several VCs for wide area network (WAN), MAN, private branch exchange (PBX), and video conference traffic.

The VC and VP are identified through virtual channel identifier (VCI) and virtual path identifier (VPI), respectively. For large networks, VCIs and VPIs are assigned on a per link basis (i.e., local significance). Thus, translation of VPI (or VCI) is necessary at intermediate ATM switches for an end-to-end VP (or VC). The switching operation for ATM cells will be discussed in [Sec. 15.1.4](#).

[Figure 15.4](#) shows the relationship among the virtual channel, virtual path, SONET's STS path, and SONET link. The SONET physical link (e.g., an optical carrier level-48 (OC-48) optical system) provides a bit stream to carry digital signals. This bit stream may include one of multiple digital paths, such as SONET STS-3c, STS-12c, or STS-48c. Each digital path may carry ATM cells via multiple VPs, each having multiple VCs. The switching method used for SONET's STS paths is STM using a hierarchical **time slot interchange (TSI)** concept, whereas the switching method for VPs/VCs uses a nonhierarchical ATM switching concept. In addition, STM performs network rerouting through physical network reconfiguration, whereas ATM performs network rerouting using logical network reconfiguration through the update of the routing table.

Physical Path vs. Virtual Path

The switching principles used for SONET's STS Paths (STM) and ATM VPs/VCs (ATM) are completely different due to different characteristics of corresponding path structures. The STS path uses a physical path structure, whereas the VP/VC uses a logical path structure, as depicted in [Fig. 15.5](#). The physical path concept used in the SONET STM system has a hierarchical structure with a fixed capacity for each physical path. For example, the VT1.5 and STS-1 have the capacity of 1.728 and 51.84 Mb/s, respectively. To transport the optical signals over fiber, VT1.5s are multiplexed to a STS-1 and then to STS-12, STS-48

with other multiplexed streams for optical transport. Thus, a SONET transport node may equip a variety of switching equipment needed for each hierarchy of the signals. In contrast, the VP transport system is physically nonhierarchical (see Fig. 15.5(b)) and its capacity can be varied, which ranges from 0 (for protection) up to the line rate or STS-Nc, depending on applications. This nonhierarchical multiplexing structure provides a natural grooming characteristic, which may simplify the nodal system design. Detailed discussions between STM and ATM VP path structures and their implications on network designs can be found in Sato, Ueda, and Yoshikai (1991).

FIGURE 15.5 Physical path vs. virtual path: (a) physical path structure, (b) virtual path structure.

FIGURE 15.6 STM concept and SONET STS-1 example: (a) STM (framing) concept, (b) an example of SONET STS-1 frame.

Channel Formats for STM and ATM

In SONET/STM, data channels are represented by time slots and identified through the relative time slot location within the frame, as depicted in Fig. 15.6(a). Thus, STM switching is performed through time slot interchange. One example of STM equipment is the digital cross-connect system (DCS), which cross connects VT1.5s (1.728 Mb/s) and/or STS-1s (51.84 Mb/s), depending on the type of DCSs (wideband DCS or broadband DCS).

Figure 15.6(b) shows an example of the SONET STS-1 frame that corresponds to a frame in Fig. 15.6(a). In this example, each VT1.5 path carried on the payload of this STS-1 frame represents a channel (time slot) in Fig. 15.6(a). The STS-1 frame is divided into two portions: transport overhead and information payload, where the transport overhead is further divided into line and section overheads. The STS frame is transmitted every 125 μ s. The first three columns of the STS-1 frame contain transport overhead and the remaining 87 columns and 9 rows (a total of 783 bytes) carry the STS-1 synchronous payload envelope (SPE). The SPE contains a 9-byte path overhead that is used for end-to-end service performance monitoring. Optical carrier level-1 (OC-1) is the lowest level optical signal used at equipment and network interfaces. An OC-1 is obtained from a STS-1 after scrambling and electrical-to-optical conversion.

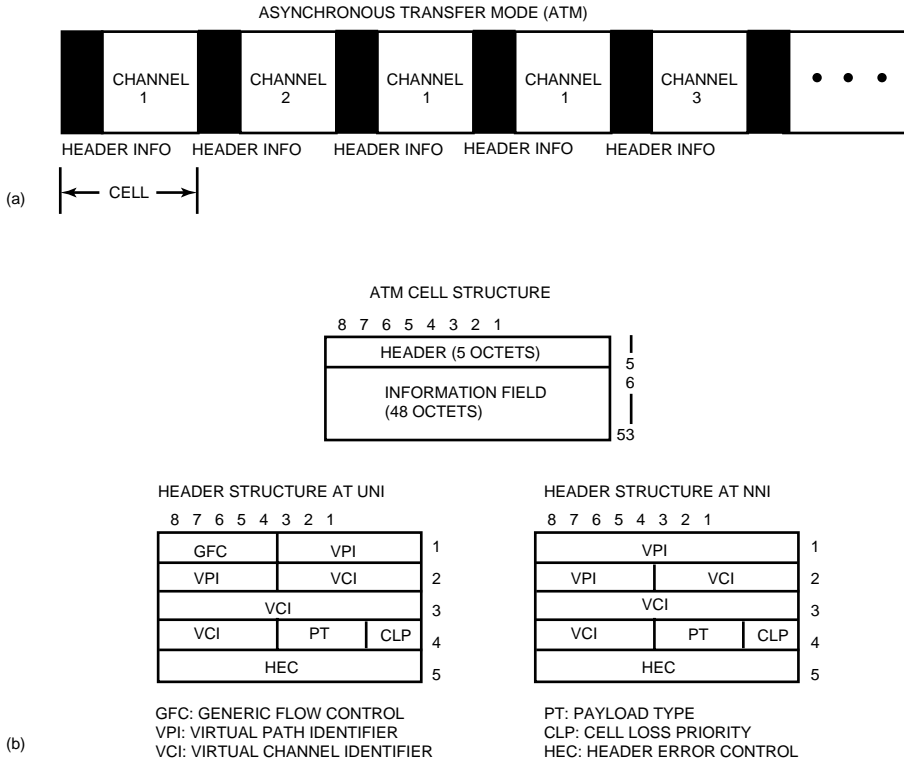

FIGURE 15.7 ATM concept and cell formats: (a) ATM (fixed cell) concept, (b) ATM cell format.

In contrast, ATM channels are represented by a set of fixed-size cells (see Fig. 15.7(a)) and are identified through the channel indicator in the cell header (see Fig. 15.7(b)). Thus, ATM switching is performed on a cell-by-cell basis based on routing information in the cell header.

The ATM cell has two parts: the header and the payload. The header has 5 bytes and the payload has 48 bytes. As mentioned earlier, the major function of the ATM layer is to provide fast multiplexing and routing for data transfer based on information included in the 5-byte header. This 5-byte header includes information not only for routing (i.e., VPI and VCI fields), but also fields used to (1) indicate the type of information contained in the cell payload (e.g., user data or network operations information), (2) assist in controlling the flow of traffic at the UNI, (3) establish priority for the cell, and (4) facilitate header error control and cell delineation functions. One key feature of this ATM layer is that ATM cells can be independently labeled and transmitted on demand. This allows facility bandwidth to be allocated as needed, without fixed hierarchical channel rates required for STM networks. Since ATM cells may be sent either periodically or randomly (i.e., in bursts), both constant and variable bit-rate services are supported at a broad range of bit rates. The connections supported at the VP layer are either permanent or semi-permanent connections that do not require call control, real-time bandwidth management, and processing capabilities. The connections at the VC layer may be permanent, semipermanent, or switched virtual connections (SVCs). SVCs require a signaling system to support its establishment, tear-down, and capacity management.

Figure 15.8 shows an example of ATM cell mapping in SONET payloads for high-speed transport.

FIGURE 15.8 ATM cell mapping on SONET payloads.

In ANSI T1S1, ATM cells are transported through the SONET STS-3c or STS-12c path. Note that ATM Forum has specified other ATM cell mapping formats such as DS1, DS3, and TAXI interfaces.

15.1.3 STM System Configuration and Operations

One example of SONET equipment that performs STS path switching is a SONET DCS. Figure 15.9 depicts a simplified SONET DCS system configuration and an operation for facility grooming. In this figure, an incoming OC-48 optical signal is demultiplexed to 48 STS-1s, which are cross connected to the appropriate output ports destined for appropriate destinations. The STS-1 path cross connection is performed through the TSI switching matrix. The TSI switching matrix within the DCS interfaces STS-1s/STS-Ncs and cross connects STS-1s/STS-Ncs. The SONET DCS is primarily deployed at a hub for facility grooming and test access. For example, in the figure, STS1#7 (carried by an OC-48 fiber system between CO1 and the hub) and STS1#52 (carried by an OC-12 fiber system between CO2 and the hub) are designated for CO3. STS1#7 and STS1#52 terminate at different input ports of the DCS and are cross connected to two output ports that connect to the same fiber system for CO3.

Conceptually, a TSI can be viewed as a buffer, which reads from a single input and writes onto a single output. The input is framed into m fixed-length time slots. The number contained in each input time slot is the output time slot for information delivery. The information in each input time slot is read sequentially into consecutive slots (cyclically) of a buffer of m slots. The output is framed into n time slots, and information from the appropriate slot in the buffer is transmitted on the output slot. Hence, over the duration of an output frame, the content of the buffer is read out in a random manner according to a read-out sequence as shown in Fig. 15.10. This read-out sequence is uniquely determined by the connection pattern. In this manner, the information in each slot of the input frame is rearranged into the appropriate slot in the output frame, achieving the function of time slot interchanging. Since the TSI switching matrix performs physical STS path switching from one input port to one output port, TSI rerouting involves physical switch reconfiguration.

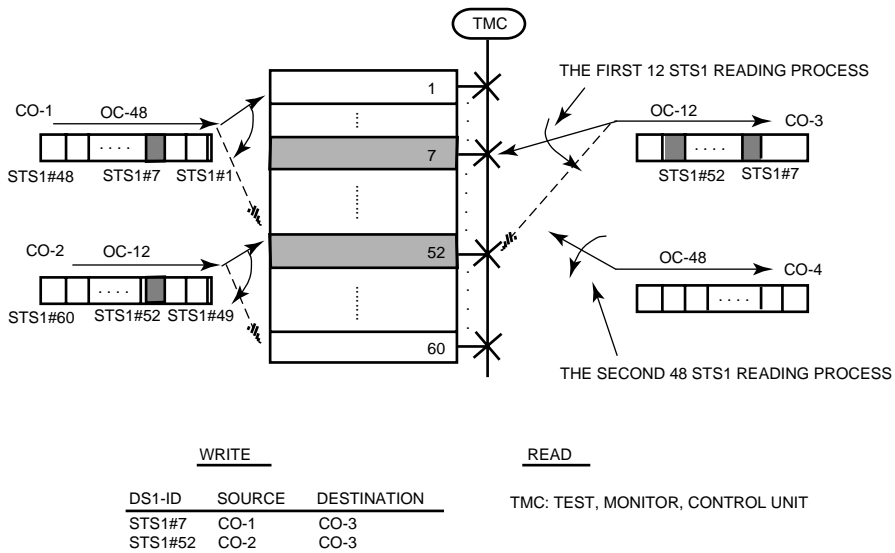

FIGURE 15.10 TSI switching concept.

15.1.4 ATM Cell Switching System Configuration and Operations

Figure 15.11 illustrates a simplified ATM cell switching system configuration and a switching principle. The ATM cell entering input port 3 of the switch arrives with VPI = 9 and VCI = 4 (for example, the first ATM cell in the figure). The call processor has been alerted through the routing table that the cell must leave the ATM switch with VPI = 4 and VCI = 5 on output port 4. The call processor directs the virtual channel identifier converter to remove the 9 VPI and 4 VCI and replaces them with 4 and 5, respectively. If the switch is a large multistage switch, the call processor further directs the virtual channel identifier converter to create a tag that travels with the cell, identifying the internal multistage routing within the

NOTE: THE FIRST AND THE THIRD CELLS ARE IN THE SAME VP.

FIGURE 15.11 An example of ATM cell switching principle.

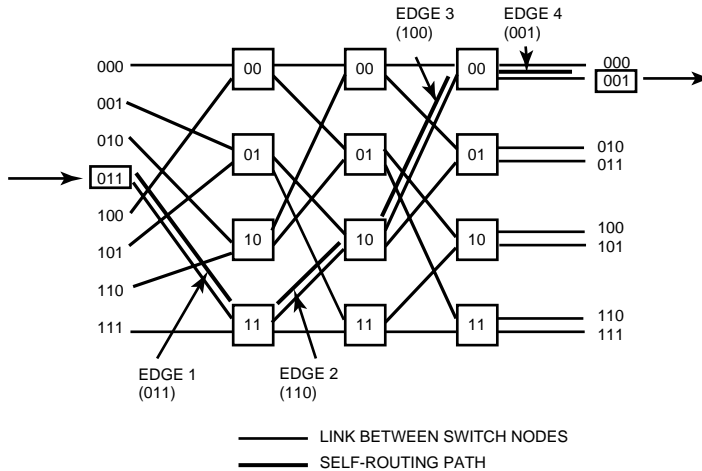

FIGURE 15.12 An example of self-routing concept.

ATM switch matrix. Note that ATM cells belonging to the same VP must have the same VPIs in the input port (e.g., VPI = 9 in input port 3) or the output port (e.g., VPI = 4 in output port 4).

The ATM switch implemented for large telecommunications networks usually uses a **self-routing** switching matrix. (Note: ATM switches designed for enterprise networks may not use the self-routing switching matrix.) An ATM cell is self-routing if the header of the cell contains all of the information needed to route through a switching network. In the following, we use a simple example to explain the self-routing concept, as depicted in Fig. 15.12. The example switching network is a shuffle exchange network, which has $N = 2^n$ inputs and 2^n outputs, interconnected by n stages of 2^{n-1} binary switch nodes. In this example, $n = 3$ and $N = 8$. We assume that the ATM cell is to be routed from input port 4 (i.e., code 011) to output port 2 (i.e., code 001). When the cell arrives input port 4 (011), the call processor will check with VPI/VCI routing table, identifies the destination output 2 (001), and it generates a routing label which combines the source and destination addresses: 011001. Through this code, the system identifies edges in each stage where each edge is represented by three consecutive digits from the left side to the right of the routing label. In this case, 4 edges are identified: edge 1: 011, edge 2: 110, edge 3: 100, and edge 4: 001. Each edge (ijk) connects switch node (ij) in the $M - 1$ stage and switch node (jk) in stage M , if this edge is edge M . For example, edge 2 connects switch node (11) in stage 1 to switch node (10) in stage 2. Thus, a self-routing path is established as follows: Input port (011)-switch node (11) of stage 1-switch node (10) of stage 2-switch node (00) of stage 3-output port (001), as shown in the figure.

15.1.5 Comparison Between STM and ATM

[Table 15.1](#) summarizes differences between STM and ATM switching concepts. In general, the STM system switches signals on a physical and hierarchical basis, whereas ATM switches signals on a logical and nonhierarchical basis, due to their corresponding switching path structures. Thus, ATM may be more flexible than its STM counterpart in terms of bandwidth on demand, bandwidth allocation, and transmission system efficiency, but a relatively more complex control system is needed. Since STM physically switches the signals, its rerouting requires physical switch reconfiguration that may make network rerouting much slower than its ATM counterpart, which only requires an update of the routing table.

15.1.6 Protection Switching Concept

The function of **protection switching** is to reroute new and existing connections around the failure area if a network failure occurs. The basic requirement for network protection switching is to restore services as fast

TABLE 15.1 Comparison Between STM and ATM

System Parameters	STM	ATM
Switching unit	Time slot (STS paths)	Fixed-size cell (VPs/VCs)
Path structure	Physical and hierarchical	Logical and non-hierarchical
Number of allowable path (STS, VP) capacities	Limited	More
Switching system complexity	Simpler	Complex
Network nodal complexity	Complex (hierarchical)	Simpler (non-hierarchical)
Transmission system efficiency (on average)	Lower	Higher
Method of rerouting	Physical network reconfiguration	Logical network reconfiguration
Bandwidth on demand	More difficult	Easier

as possible in a cost-effective manner. ATM technology is more flexible and efficient than STM technology in terms of bandwidth allocation and transmission efficiency. However, these advantages come at an expense of requiring a much more complex control systems, especially when network restoration is an important consideration in system requirements. Unlike STM transport, the service quality in ATM networks is affected by both network component failure and network congestion (because resources are not dedicated).

In addition to fast restoration times, other possible network restoration objectives include the maximal restoration ratio, and the minimal spare capacity and overhead associated with network restoration. A network restoration system may be designed to optimize tradeoffs of these objectives or may be designed for some specific objective (such as minimum protection switching time), depending on the network planning strategy and service requirements being supported.

For SONET/ATM networks, network restoration can be performed at the physical (SONET) or ATM layer. For physical layer protection, service restoration can be performed at the STS-3Nc level (where $N = 1, 4, \text{ or } 16$) or at the physical transmission link level. For ATM layer protection, network restoration can be performed at the VC or VP (or group of VPs) level. Service restoration at the VC level is typically slower and more expensive than that performed at the VP level due to greater VC-based ATM network complexity. The restoration system complexity at the VP level is similar to that at the STS-1/STS-3c level. Determining which layer (SONET, VP, or VC) is an appropriate restoration layer depends on the SONET/ATM network architecture and other factors such as costs and QoS.

The major differences between STM and ATM network restoration technologies are in the restoration unit (e.g., STS-1 or VP) and the network reconfiguration technology. SONET networks restore traffic on physical paths (e.g., STS-3c) and/or links (e.g., SONET links) through the physical network reconfiguration using time slot interchange technology. In contrast, ATM networks restore traffic carried on VPs/VCs through the logical network reconfiguration by modifying the VPI/VCI routing table.

SONET protection switching systems, such as automatic protection switching systems (APSS) and SONET self-healing rings, have been widely deployed in LECs. The impacts of emerging ATM technology on network restoration (compared to SONET network restoration) may be significant due to following factors:

- Separation of capacity allocation and physical route assignment for VPs/VCs that would reduce required spare capacity (e.g., the capacity of protection VPs/VCs can be zero in normal conditions)
- More OAM bandwidth with allocation on demand that would reduce delays for restoration message exchanges, and the detection of system degradation (i.e., soft failure) in the ATM network much more quickly than its SONET counterpart
- Nonhierarchical path multiplexing (for VPs) that would simplify the survivable network design and help reduce intranode processing delays and required spare capacity.

Table 15.2 summarizes the relative comparison between STM and ATM network protection technologies. In general, ATM layer protection may require less spare capacity than SONET layer protection at the

TABLE 15.2 Comparison of SONET and ATM Layer Protection Technologies

Protection Layer	ATM Layer	SONET Layer (STM)
Protection protocol complexity	Moderate	Simple (APS/rings) moderate (DCS mesh)
Restoration time	Moderate	Fast (APS/rings) slow (DCS mesh)
Spare capacity needed	Least	Moderate
Equipment needed	Less	More
Network management systems/OSs	Under development	Already developed
Equipment availability	Available soon	Available now
Protection targets	Node and link	Node and link

expense of a slower restoration time and a more complex control system. How best to use a combination of these two layer protection schemes in the same network is a challenging task for network planners and engineers who are seeking cost-effective solutions for SONET/ATM network protection. More details of network protection schemes and operations for SONET/ATM networks can be found in Wu (1992, 1995); Sato, Ueda, and Yoshikai (1991); and Wu et al. (1994).

15.1.7 Summary and Remarks

We have reviewed the basic switching concepts that are used in emerging SONET/ATM broadband transport networks. Implementations of such switching concepts may be different between enterprise networks and public telecommunications networks due to traditionally different QoS perspectives and operations experiences from computer and telecommunications industries. Such differences may result in two sets of ATM switching network infrastructures that could coexist for a period of time. An open question is how and when they may be merged as an integrated ATM network infrastructure. This challenge may require the change of traditional QoS perspectives, definitions, and requirements from both the computer and telecommunications industries.

Defining Terms

Asynchronous transfer mode (ATM): An international standard high-speed, integrated multiplexing and switching technology that transmits information using fixed length cells in a connection-oriented manner.

Protection switching: A function to reroute new and existing connections around the failure area if a network failure occurs.

Self-routing: An ATM cell is self-routing if the header of the cell contains all of the information needed to route through a switching network.

Switching: Control or routing of signals in either physical or virtual circuit form to transmit data between specific points in a network.

Synchronous optical network (SONET): A North American standard synchronous transmission network technology for optical signal transmission.

Synchronous transfer mode (STM): A time division multiplexing and switching technology that uses a similar switching concept as traditional circuit switching systems.

Time slot interchange (TSI): A technique to exchange the location of time slots within a frame.

15.2 SONET

Brent Allen

15.2.1 Introduction

Synchronous optical network (SONET) refers to an American National Standards Institute (ANSI) standard for fiber optic telecommunications interfaces. It was developed in the late 1980s and telecommunications equipment providing the interface continues to be deployed throughout the North American network. Closely related to SONET is the *synchronous digital hierarchy* (SDH) interface, which is an international fiber optic telecommunications interface standard prepared by the International Telecommunications Union (ITU), an agency of the United Nations. Although SONET and SDH are documented in different standards, the two interfaces are compatible. SONET can be considered a subset of SDH, in the sense that it selects among various options allowed in SDH.

As illustrated in Fig. 15.13, the public telephony network consists of users with telephones, connected to a switching system over an **access** network. To allow connections between users that are not connected to the same switching system, the switching systems are all connected to each other over the **trunk** network. Although access networks can be localized to the area surrounding the switching system, trunk networks span cities, countries, and even the globe.

Today, the majority of connectivity in the trunk network, and much of the connectivity in the access network, is provided using fiber optic transmission. This is referred to as the transport infrastructure. This infrastructure also provides direct digital connections, called private lines, between businesses for private voice, data, and video networks. In fact, the amount of **bandwidth** allocated for private lines rivals that allocated for regular voice.

Although the design and deployment of fiber optic telecommunications systems began in the late 1970s and early 1980s, these systems featured proprietary optical interfaces (Fig. 15.14). The only standard interfaces at that time were the DS1 (1.544-Mb/s interface consisting of 24 digitally encoded voice channels), which was and continues to be the main trunk interface to voice switching systems, and the DS3 (44.736-Mb/s interface consisting of 28 DS1s), which was the primary interface to interoffice transmission systems, including radio and fiber. Both the DS1 and DS3 are electrical interfaces and as such are limited in terms of reach, essentially restricted to connections between equipment within a building.

The creation of a network on the scale of the telecommunications network requires interface standards. Such networks require equipment developed by different manufacturers (and owned by different network providers) to be connected, and this requires an interface specification. A standard results when the equipment manufacturers, as well as network providers and users, come together to negotiate the interface specification.

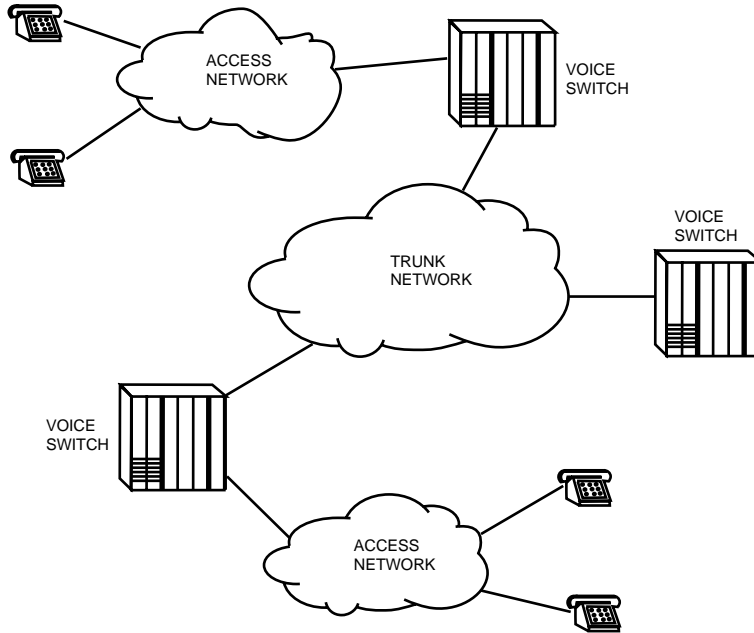

FIGURE 15.13 Telephony network architecture.

Since pre-SONET fiber systems featured proprietary optical interfaces, their application was restricted to the point-to-point transport of DS1s and DS3s. The development of the SONET standard is now resulting in the deployment of all optical networks, the benefits of which include very low noise floors, high reliability and survivability, flexibility, and almost unlimited capacity.

15.2.2 SONET Overview

The structural elements of SONET, and the way they are combined to create a complete SONET signal, are shown in Fig. 15.15. A complete, optically transmitted SONET signal is called an OC- N , where OC is optical carrier and N may be 1, 3, 12, 24, 48, or 192. The OC- N is the optical equivalent of the STS- N where STS is synchronous transport signal. The STS- N or OC- N consists of a **multiplex** of N STS-1s.

Carried within the STS-1 is a *synchronous payload envelope* (SPE). In SONET, all **payloads** are transported within an SPE, and SONET provides a variety of SPEs to accommodate the different bandwidth requirements of various payloads. The STS-1 SPE has a payload capacity of approximately 50 Mb/s and therefore can carry one DS3 (44.736 Mb/s). SONET provides a mechanism, called *concatenation*, whereby the capacity of several STS-1s can be combined to carry a larger SPE and, therefore, a larger payload. For example, M STS-1s can be concatenated to carry an STS- M c SPE, which will have a payload capacity of approximately $M \times 50$ Mb/s.

FIGURE 15.14 Multivendor midspan meet.

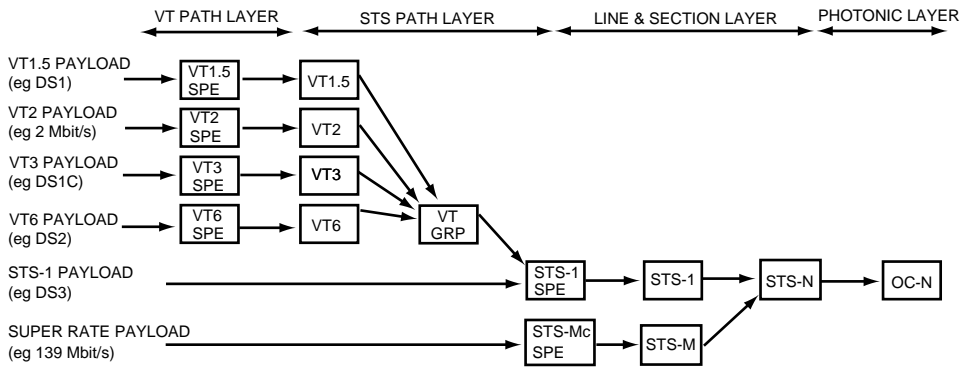

FIGURE 15.15 SONET protocol structure.

The STS-1 SPE can be subdivided into *virtual tributaries* (VTs). These VTs contain VT SPEs in order to carry smaller payloads, such as the DS1 (1.544 Mb/s). There are four VT sizes, which offer different payload capacities ranging from approximately 1.5 to 6 Mb/s. Like-VTs are combined into VT groups, which are then multiplexed into the STS-1 SPE.

Layered Architecture

The SONET protocol is defined in layers to highlight the interface functionality that is required on a particular network element. The layers are illustrated in Fig. 15.16. The interface functionality of a particular network element is closely associated with the overall function of the element, and the functionality associated with all of the layers may not be required.

The *photonic layer* defines the physical parameters of the optical link, such as optical pulse shape, transmit power, wavelength, etc.

The *section layer* provides basic functions that are required before the information contained within the SONET signal can be extracted and processed. Framing is the process of finding the alignment of the constituent bits and bytes within a serial bit stream so that the information contained can be located. Scrambling is the process of pseudorandomizing the outgoing bitstream. A certain density of 0-1 and 1-0

transitions is required by the receiver in order to be able to derive a clock with which to receive the digital signal. **Overhead** is added for the purpose of monitoring the error performance of the interface at the section layer and communicating with a centralized network management system.

The *line layer* provides the *multiplexing* of lower rate SONET structures up to the final line rate. Overhead is added for the purpose of monitoring the error performance of the interface at the line layer, communicating with the network element on the other end of the line to coordinate protection switching, and communicating with a centralized network management system to report situations such as equipment failure or fiber breaks.

The *path layers* provide the mapping of payloads into SONET so that they can be transported across a SONET network. Overhead is added to the payload to allow the integrity of the path layer connection to be verified. There are two granularities of path layer; the STS path layer for payloads on the order of 50 Mb/s or higher, and the VT path layer for payloads on the order of 1.5–6 Mb/s.

The functionality at a given layer works with the corresponding functionality (at the same layer) in another network element, as illustrated in Fig. 15.17. The span between the two **network elements** is named after the layer that connects them.

Only the photonic layer involves a physical connection; all of the others are logical connections that depend on the photonic layer for physical interconnection. A section exists between any two network elements that are physically connected by fiber. A line may span one or more sections and connects two network elements that provide the line layer functionality, such as multiplexing and protection switching. An STS path may span one or more lines and connects two network elements that are providing the entry and exit points for an STS payload such as a DS3. A VT path may span one or more STS paths and connects two network elements that are providing the entry and exit points for a sub-ST3-1 payload such as a DS1.

All SONET network elements have section and photonic layer functionality; however, not all have the higher layers. A network element is classified by the highest layer supported on the interface. Thus a network element with path layer functionality is referred to as *path terminating equipment* (PTE), either VT PTE or STS PTE. Similarly, a network element with line layer functionality but no higher, is *line terminating equipment* (LTE). Finally, a network element with section layer functionality but no higher is *section terminating equipment* (STE).

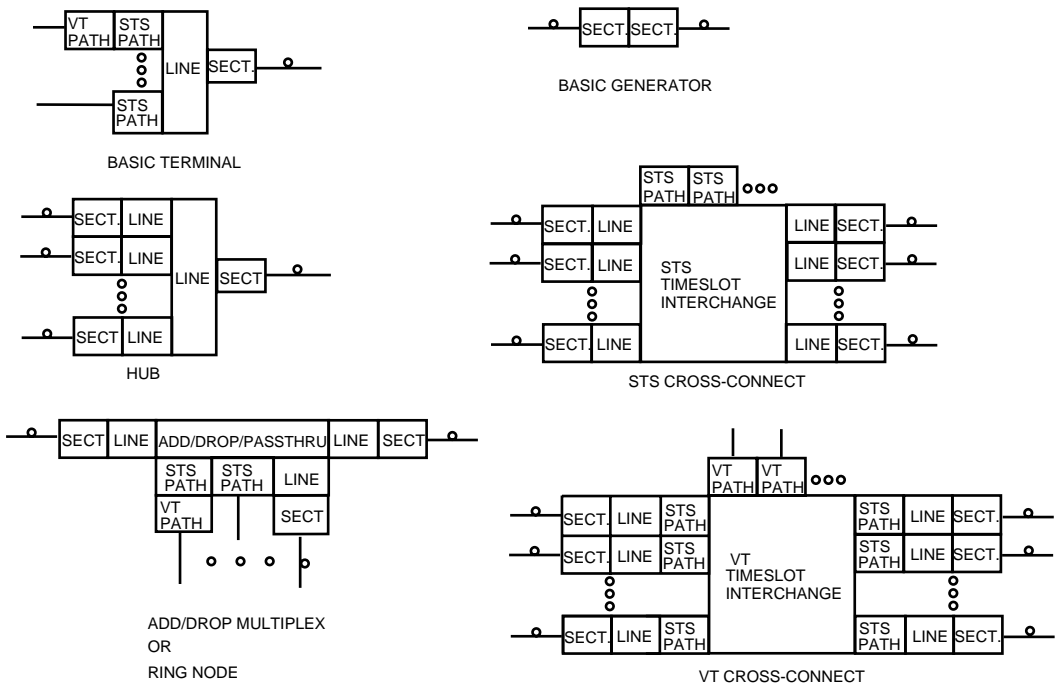

FIGURE 15.18 SONET network elements.

Network Elements

The functionality associated with the various SONET layers can be combined in a variety of ways to create **network elements**. The key network elements (NEs) are illustrated in Fig. 15.18.

The *basic terminal* interfaces a number of non-SONET payloads, maps those signals into the appropriate SONET path layer, and multiplexes them onto a SONET optical signal.

The *regenerator* increases the distance allowed between adjacent line terminals by regenerating the optical signal.

The *hub* is similar to the terminal, except that the tributary interfaces are also SONET signals. For example, a hub might multiplex four OC-3s into an OC-12. It is common for basic terminals to also have hub capabilities.

An *add/drop multiplexer* (ADM) adds and drops signals from a SONET signal. Any traffic that is not added/dropped can pass through directly. The added/dropped signals may be non-SONET signals, in which case the appropriate path terminations are required, or they may be SONET signals.

SONET *cross connects* provide path layer interconnect between a large number of SONET or non-SONET interfaces. The STS cross connect provides STS path layer connections, and the VT cross connect provides VT path layer connections. The connections can be changed via an operations interface.

System Configurations

SONET network elements are combined to create systems that are classified based on the mechanism used to provide **traffic protection** and **survivability**. The two main types of protection provided in SONET are *linear* and *ring* as shown in Fig. 15.19.

Linear systems transport traffic along a single route, which may consist of one or more working fibers. A **standby or protection fiber** exists along route to provide a backup path for 1 or more of the **working fibers**. A one plus one (1 + 1) system has one protection fiber and one working fiber. The traffic is permanently bridged onto both fibers so that the receiving end can autonomously choose the fiber that is operating

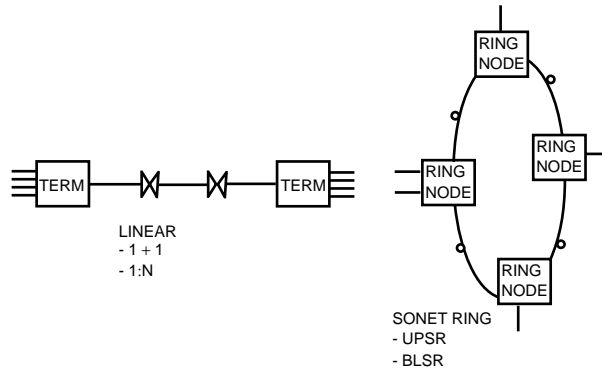

FIGURE 15.19 SONET system types.

better. A one for N (1:N) system has one protection fiber and N working fibers. A protocol operating between the two ends of the system coordinates the bridging of working traffic onto the protection fiber in the event of a failure of one of the working fibers.

Ring systems transport traffic around a ring allowing traffic to be added and dropped anywhere along the ring. Spare capacity is allocated around the ring so that when a failure occurs at any point, the affected traffic can be restored using the spare capacity. In a *unidirectional path switched ring* (UPSR), traffic added to the ring is bridged onto both directions such that the drop node can autonomously select the better path. In a *bidirectional line switched ring* (BLSR), the traffic affected by a failure at any point on the ring is rerouted the other way around the ring. A protocol operating around the ring coordinates this action.

Networks

SONET networks are created by combining network elements and systems. Hubs, ADMs, and cross-connects are used to interconnect linear systems to each other and to rings. The elements and systems used depend on the application and topology of the network and the degree of survivability required.

In the example shown in Fig. 15.20, the ring may be part of an access network collecting voice traffic to be connected to the voice switch and private line traffic to be connected to the interoffice transport network. The VT cross connect consolidates traffic having the same destination from the switch and the

FIGURE 15.20 Example of SONET network.

FIGURE 15.21 Serial transmission over SONET.

access ring to fill up STS-1s before they are put onto the interoffice network. The STS cross connect routes the STS-1 to the appropriate destination. The ADM and hub split traffic off of the main route to the end destinations.

15.2.3 SONET Protocol

A SONET signal is transmitted as a continuous serial bit stream as illustrated in Fig. 15.21. The bit stream is organized into bytes, and the bytes are grouped in 125- μs blocks called *frames*. At the basic STS-1 rate, there are 810 bytes per frame, which results in a basic rate of 51.84 Mb/s. The rate of an OC-*N* is exactly *N* times the basic rate.

The 810 bytes of an STS-1 frame are most conveniently represented as a matrix consisting of 9 rows and 90 columns as shown in Fig. 15.22. The intersection of a row and a column is one byte. The order of transmission is from left to right and from top to bottom.

The first three columns carry transport **overhead**. Transport overhead consists of section overhead and line overhead and is allocated to support section and line layer functionality. It is considered overhead because it is not available to carry payload. The remaining 87 columns of the STS-1 frame carry the STS-1 synchronous payload envelope as illustrated in Fig. 15.23.

The STS-1 SPE has its own frame consisting of 9 rows and 87 columns. The first column of the SPE is path overhead, which is allocated to support path layer functionality. The remainder of the SPE is available for payload. Although the SPE fits within the STS-1 SPE capacity, the first byte of the SPE does not necessarily occupy the first byte position within the SPE capacity. Thus, the SPE is represented as being offset from the STS-1 frame.

The STS *payload pointer* is a line layer function that locates the start of the SPE frame within the SPE capacity. The pointer overhead bytes carry a binary number, which is an offset, in bytes, into the SPE capacity to the beginning of the next SPE frame.

FIGURE 15.22 STS-1 frame structure. (Source: Adapted from ANSI. 1991. *Digital Hierarchy—Optical Interface Rates and Formats Specification (SONET)*, ANSI T1.105-1991, Fig. 7, p. 42. American National Standards Institute, Washington, DC. With permission from the Alliance for Telecommunications Industry Solutions.)

FIGURE 15.23 STS-1 frame with synchronous payload envelope. (Source: Adapted from ANSI. 1991. *Digital Hierarchy—Optical Interface Rates and Formats Specification (SONET)*, ANSI T1.105-1991, Fig. 8, p. 42. American National Standards Institute, Washington, DC. With permission from the Alliance for Telecommunications Industry Solutions.)

It is useful to think of the STS-1 as being a pipe of digital information, as illustrated in Fig. 15.24. The diameter of the pipe represents the bandwidth flowing through the pipe. The length of the pipe represents time which can be marked off in 125- μ s segments representing one frame of transmission. Within the STS-1 pipe is another, slightly smaller pipe, which is the STS-1 SPE. The difference in diameter between the STS-1 pipe and the SPE pipe represents the transport overhead. The pipe diagram helps visualize how the SPE frame alignment can be offset with respect to the STS-1 frame and how the STS-1 pointer indicates the offset to the beginning of the SPE frame.

Multiplexing

An STS-N or OC-N is created by byte-interleaving N frame-aligned STS-1s as shown in Fig. 15.25. Since the STS-1s are frame aligned, the transport overheads from each individual STS-1 will come out as a block occupying the first $3 \times N$ columns of the STS-N, effectively becoming the transport overhead for the STS-N.

Only certain rates (values of N) are defined as standard rates and have physical (photonic) interfaces specified. The currently defined values of N and their corresponding bit rates are shown in Table 15.3. The currently defined SDH rates are also shown.

For SONET, the rates start at the basic 51.84-Mb/s OC-1. SDH has a similar hierarchy but it begins at a basic rate of 155.52 Mb/s, which is called the synchronous transport module—level 1 (STM-1).

FIGURE 15.24 Pipe representation of STS-1 with SPE.

TABLE 15.3 SONET/SDH Bit Rates

SONET	SDH	Rate, Mb/s
OC-1	N/A	51.84
OC-3	STM-1	155.52
OC-12	STM-4	622.08
OC-24	N/A	1244.16
OC-48	STM-16	2488.32
OC-192	STM-64	9953.28

The pipe analogy can be extended to show an STS-N or OC-N carrying N STS-1 SPEs as illustrated in Fig. 15.26. Note that the STS-N becomes a single pipe, although it still contains a separate pointer for each STS-1 SPE.

Concatenation

SONET provides the ability, called *concatenation*, to combine the SPE capacities of N STS-1s to carry a single STS-Nc SPE. This STS-Nc SPE has approximately N times the payload capacity of an STS-1 SPE.

Using the pipe analogy as shown in Fig. 15.27, the STS-Nc SPE looks like a single pipe within the STS-N, however it has N times the diameter (bit rate) of the STS-1 SPE. Note also that there is a single pointer for the STS-Nc SPE.

Payload Pointer Mechanism

The pointer mechanism serves two key purposes: the first is SPE phase identification, and the second is SPE frequency justification. The need for SPE phase identification is illustrated using Fig. 15.28.

Consider a SONET hub that is multiplexing the SPEs from three separate OC-1s into a single OC-3. Although we could assume that the arriving SPEs are aligned within the corresponding STS-1 SPE

FIGURE 15.25 Example of STS-N byte interleaving.

FIGURE 15.26 Pipe diagram for OC-N/STS-N.

FIGURE 15.27 Pipe diagram including concatenated STS-1s.

capacities, we cannot assume that the arriving STS-1 frames are aligned since they have arrived from different places.

SONET requires that the STS-1s within an STS-N be frame aligned so that the transport overhead from each STS-1s can be combined and used as the transport overhead for the STS-N. One way to align the incoming STS-1s would be to use a 125- μ s buffer to delay the early arrivals to align with the latest arrival. However, 125- μ s delay in every transport network element results in an unacceptably high additional propagation delay for delay sensitive services such as voice. Furthermore, if any of the incoming OC-1s is not perfectly synchronous with respect to the hub, then the buffer will periodically overflow or underflow, causing corruption of the payload. The SONET solution is to decouple the phase alignment of the SPE from that of the STS-1 and use a pointer to indicate the offset. Thus buffers are not required and the SPE encounters minimal delay through the hub.

The second purpose of pointers is SPE frequency justification. This is the process of accommodating an offset in the SPE frame rate relative to the frame rate of the STS-1. Of course, in a perfectly synchronous network in which the timing distribution never fails, such a capability would not be required. However, reality is less than perfect.

Timing in the telecommunications network is distributed through a hierarchy of clocks. The position of a clock in the hierarchy is dependent on characteristics of the clock such as accuracy and holdover capabilities. Holdover is the ability of a clock to maintain its frequency after it has lost its frequency reference. At the top of the hierarchy is a primary reference source, or stratum 1 clock. Primary reference sources often lock to a satellite-based source, or they may be a standalone atomic clock. The clock from this source is distributed to other clocks in the network via DS1 or SONET facilities. Typically, there is one clock per network provider office called the *building integrated timing supply* (BITS) and that clock is distributed to each network element in the office. The network element itself will have a built-in clock that locks to the BITS reference. The NE clock is typically stratum 3 or lower.

FIGURE 15.28 Pipe diagram illustrating need for pointer mechanism.

FIGURE 15.29 Pipe diagram illustrating need for frequency justification.

In this architecture, there are a number of reasons why the overall network may not be perfectly synchronous. First, atomic clocks are extremely accurate, but no two atomic clocks will be precisely the same. Second, faults in the timing distribution can cause portions of the network to be temporarily **asynchronous** with respect to the rest. Finally, although the network may be exactly synchronous over the long term, there can be shorter term phase and frequency variations that can be quite large.

The impact of imperfect network synchronization on SONET facilities is illustrated in Fig. 15.29. The hub and the first OC-1 are synchronized to the same reference, f_1 , whereas the second and third OC-1s are each locked to different references. The result is that the incoming OC-1 frames, although containing exactly the same number of bytes, have different lengths when measured in time. The SPEs from these STS-1s must be transferred to STS-1s that are frame aligned and exactly synchronous; a requirement for synchronous multiplexing. As the figure illustrates, the phase relationship between the STS-1 and the SPEs from the second and third OC-1s will be constantly changing because of the difference in frame rates. The rate of change in this phase relationship is highly exaggerated in the figure. Typically, even under worst-case conditions, the offset will remain constant for some time and then change by one byte in one direction or the other. This event is called an increment operation or a decrement operation, depending of whether the pointer offset increases or decreases.

Virtual Tributaries

The STS-1 SPE allows the bandwidth of the fiber transport network to be managed in 50-Mb/s chunks. For example, an STS cross connect can provide the flexible interconnection of STS-1 SPEs between a large number of OC-N interfaces. In many parts of the network, however, the STS-1 granularity is too coarse to allow efficient bandwidth management.

The STS-1 SPE can be subdivided into virtual tributaries (VTs) to allow bandwidth management at finer granularities ranging from approximately 1.5 up to 6 Mb/s. There are four sizes of VT defined, the VT1.5, VT2, VT3, and VT6. These sizes correspond roughly to rates of 1.7, 2, 3, and 6 Mb/s, respectively. The sizes are all multiples of 9 bytes so that they will occupy an integer number of columns in the 9 row structured STS-1 SPE frame.

As illustrated in Fig. 15.30, the VT consists of an overhead part and an SPE capacity part, just as the STS-1 consists of the transport overhead and the STS-1 SPE capacity. The overhead part of the VT only contains one function, the VT payload pointer. The VT SPE capacity carries the VT SPE, which has its own frame structure, the alignment of which may be offset with respect to the VT. The value of the offset is indicated by the VT pointer.

The pipe analogy can be extended to describe the transport of virtual tributaries. In Fig. 15.31, the pipe corresponding to the STS-1 is not shown. The outer pipe is the STS-1 SPE. The VT pointers effectively become part of the STS-1 SPE since they are in a fixed position. The VT pointers identify the alignment of

FIGURE 15.30 Virtual tributary structure.

the VT SPEs within the STS-1 SPE. Note that the VT pointer only occurs once every four 125- μ s frames, effectively creating a VT superframe that spans four consecutive frames of the STS-1 SPE.

15.2.4 SONET Automatic Protection Switching

Automatic protection switching (APS) refers to the ability of SONET network elements to detect a failure and transfer the affected traffic to another line.

Linear Protection

The most basic protection system is a linear 1 + 1 system, illustrated in Fig. 15.32. The term *linear* differentiates from ring systems and the 1 + 1 indicates that there is 1 working fiber and 1 standby fiber and that the traffic in both directions is permanently bridged onto both the working and the standby fiber.

When one end of the system detects that the side from which it is currently selecting the traffic fails, it automatically switches to select the traffic from the other side after first verifying that the switch will restore the traffic and that there are no other reasons why the switch cannot be made. A linear 1 + 1 system can be made survivable by diversely routing the protection channel as is shown in the figure. In this way, a fiber cut on the working channel can still be restored on the protection channel.

FIGURE 15.31 Pipe diagram for VTs within STS-1 SPE.

FIGURE 15.32 1 + 1 linear protection.

A linear 1:N (1 for N) protection system has one protection fiber providing a restoration path for up to N working fibers, as shown in Fig. 15.33. Such a system is not survivable since it is not practical to diversely route all of the fibers. Therefore, a fiber cut, even if it does not affect the protection channel, is likely to affect more than one working channel, and the protection channel can only restore one working channel at a time.

FIGURE 15.33 1:N linear protection.

A 1:N system involves more complicated signaling between the two ends of the system to coordinate the switch. This is because the failed channel must first be bridged onto the protection channel before the receiving end can do the switch, and the end that must do the bridge may not even be directly aware that there is a failure.

Ring-Based Protection

Ring-based APS provides an increased level of survivability for SONET networks by allowing as much traffic as possible to be restored, even in the event of a cable cut or a node failure. In a ring, a number of network elements are connected in a closed loop. In the event of a disruption at any point on the ring, the affected traffic can be restored by rerouting it the other way around the ring.

The two main types of ring are the *unidirectional path switched ring* (UPSR) and the *bidirectional line switched ring* (BLSR).

A 5-node UPSR is illustrated in Fig. 15.34. The ring consists of two fibers on each span, transmitting in opposite directions, between adjacent nodes. Traffic entering the ring at any node is transmitted in both directions around the ring until it reaches its exit point. Each node on the ring is line terminating, such that the connection across the ring is a path layer connection. At the exit point, the path layer integrity information is examined for each of the two paths and a selection made.

FIGURE 15.34 Unidirectional path switch ring.

FIGURE 15.35 UPSR failure example.

All of the selectors will default to a particular direction, such that under nonfailure conditions, all traffic is rotating around the ring in the same direction, hence the name unidirectional. Since the selection is made on a per path basis, using path layer integrity information, the ring is called *path switched*.

Figure 15.35 illustrates a cable cut on the UPSR. The channel traveling from left to right is unaffected by the cut so the selector at the right does not change. However, the channel traveling from right to left is affected. The top node will detect the line failure and send an *path alarm indication signal (AIS)* on downstream to the node on the left. Upon detecting path AIS, the selector at the left will switch to the traffic traveling in the clockwise direction, restoring the bidirectional connection. Note that no signaling is required to coordinate any of the switching.

In a BLSR, as illustrated in Fig. 15.36, the two directions of a single connection occupy the same segment of the ring, that is, both directions of the ring are used even under nonfailure conditions, hence the name bidirectional.

There are two types of BLSR, the two-fiber BLSR and the four-fiber BLSR. In the two-fiber BLSR, there are two fibers, transmitting in opposite directions, between adjacent nodes. In the four-fiber BLSR, there are four fibers between adjacent nodes, two in one direction and two in the other. The four-fiber BLSR supports more traffic on the ring and allows 1 + 1 span switching between adjacent nodes in addition to ring switching.

Note that the BLSR can support more than one connection on the ring using the same channels, as long as the connections do not overlap on any spans. This is not true of the UPSR, which uses an entire channel in both directions all the way around the ring for each and every connection. Therefore, in general, the

FIGURE 15.36 Bidirectional line switched ring.

FIGURE 15.37 BLSR failure example.

BLSR can support many more connections than a UPSR, even if they are both operating at the same line rate.

In the BLSR, half of the capacity in each direction is assigned to working traffic and half is assigned to protection. If it is a two-fiber ring, then half of the STS-1s on each fiber are assigned to working and half to protection. If it is a four-fiber ring, then two fibers, one in each direction, are assigned to working and the other two are assigned to protection.

When a failure occurs and a ring switch is required, the nodes adjacent to the failure and on either side of the failure will reroute (loopback) all of the working traffic that was crossing the failed span onto the protection capacity around the ring. This is illustrated in Fig. 15.37. Since the decision to switch is made by the nodes adjacent to the failure using line layer integrity information, the ring is called *line switched*. Signaling is required to coordinate the switch between the nodes adjacent to the failure. Bytes within the line overhead are used to carry the protocol.

15.2.5 SONET/SDH Relationship

SDH has a similar structure although it uses a different terminology and has some options that are not allowed in SONET. The structure of SDH reflects two main viewpoints: one from North America and one from the European community, as represented by the European Telecommunications Standards Institute (ETSI). The North American (SONET) viewpoint is that the optical network should be managed at the 50-Mb/s granularity (AU-3), whereas the ETSI viewpoint is that the network should be managed at the 150-Mb/s granularity (AU-4).

To address the ETSI view, SDH allows VTs and STS-1 SPEs to be carried in an STS-3c SPE, whereas in SONET they can only be carried within an STS-1. There is also one other difference. SDH allows the VT1.5 SPE to be carried within a VT2. This is not allowed in SONET. However, in SDH it means that a network that can be managed at the VT2 level only will be able to carry both VT1.5 payloads as well as VT2 payloads.

Figure 15.38 shows the structure of SDH and highlights those components that are part of the SONET option, those that are part of the ETSI option, and those that are common. SDH terminology is shown, with the equivalent SONET terminology given in parentheses. Note that there are two boundaries within the common part, which cannot be crossed without choosing either the ETSI option or the SONET option. The first is that one option must be chosen to decide whether to carry the VT1.5 SPE within a VT2 or a VT1.5. The second is that one option must be chosen to decide whether to map the VT group into an STS-3c SPE or an STS-1 SPE. There is complete commonality in systems that map payloads directly into the STS-3c SPE.

FIGURE 15.38 SONET/SDH relationship.

Defining Terms

Access: The portion of the network that connects end user terminals, such as telephones, to the service element, such as a digital switch.

Asynchronous: A network or system is asynchronous if the digital transmission clock rates are not referenced to a common timing source.

Bandwidth: The speed with which digital information is being transported, usually measured in millions of bits per second (Mb/s).

Multiplex: The process of combining a number of lower speed digital signals onto one higher speed digital signal.

Network element: A network element is any device in the telecommunications network that handles end user traffic.

Overhead Bytes within the SONET frame allocated to operations, administration, maintenance, and providing functions. They do not carry payload.

Payload: An end user signal that is transported and switched by the network.

Standby or protection fiber: Fibers that are available to restore traffic that has been affected by a failure elsewhere in the system or network, are considered standby or protection fibers.

Survivable: A network is considered survivable if it can restore traffic connectivity in the event of a complete fiber cable cut, or network element failure.

Synchronous: A network or system is synchronous if all digital transmission clock rates are referenced, directly or indirectly, to a common timing source.

Trunk: A trunk is a connection between service elements, such as digital switches.

Traffic: End user information that is transported and switched by the network.

Working fiber: Fibers that carry live traffic under normal (non-failure) conditions are considered working fibers.

15.3 Facsimile Systems

Rodger E. Ziemer

15.3.1 Introduction

Facsimile combines copying with data transmission to produce an image of a *subject copy* at another location, either nearby or distant. Although the Latin phrase *facsimile* means to make similar, since 1815 the compressed phrase *facsimile* has been taken to mean exact copy of a transmission (Quinn, 1989). The image of the subject copy is referred to as a *facsimile*, or *record*, copy. Often the abbreviated reference “fax” is used in place of the longer term facsimile.

Facsimile was invented by Alexander Bain in 1842; Bain’s system used a synchronized pendulum arrangement to send a facsimile of dot patterns and record them on electrosensitive paper. Over the years, much technological development has taken place to make facsimile a practical and affordable document transmission process. An equally important role in the wide acceptance of facsimile for image transmission has been the adoption of standards by the International Telephone and Telegraph Union (ITU-T), formerly the Consultative Committee on International Telephone and Telegraph (CCITT). The advent of a nationwide dial telephone network in the 1960s provided impetus for the rebirth of facsimile after television put the damper on early facsimile use. Group 2 fax machines, which appeared in the mid-1970s, were capable of transmitting a page within a couple of minutes. These machines, based on analog transmission methods, were developed by Graphic Sciences and 3M. The group 3 fax machines, developed in the mid-1970s by the Japanese, are based on digital transmission technology and are capable of transmitting a page in 20 s or less. They can automatically switch to an analog mode to communicate with the older groups 1 and 2 fax machines. Group 4 fax units offer the highest resolution at the fastest rates, but rely on digital telephone lines (Quinn, 1989). Group 3 facsimile will be featured in the remainder of this article. Group 3 facsimile refers to apparatus that is capable of transmitting an 8.5×11 in page over telephone-type circuits in 1 min or less. Detailed standards for group 3 equipment may be found in Recommendation T.4 of ITU-T, Vol. VII [ITU].

Facsimile transmission involves the separate processes of *scanning*, *encoding*, *modulation*, *transmission*, *demodulation*, *decoding*, and *recording* (Stamps, 1982). Each of these will be described in detail in this section.

FIGURE 15.39 Arrangement for scanning by means of a linear photosensitive array.

15.3.2 Scanning

Before transmission of the facsimile signal, the **subject copy** must be scanned. This involves the sensing of the diffuse reflectance of light from the elemental areas making up the subject copy. For ITU-T group 3 high-resolution facsimile, these elemental areas are rectangles 1/208 in. wide by 1/196 in. high. The signal corresponding to an elemental area is called a **pixel** which stands for *picture element*. For pixels that can assume only one of two possible states (i.e., white on black or vice versa), the term used is a **pel**. Various arrangements of illuminating sources, light sensing transducers, and mechanical **scanning** methods can be employed (Stamps, 1982). For more than six sweeps per second across the subject copy, electronic scanning utilizing a cathode-ray tube or photosensitive arrays, or laser sources with polygon mirrors is utilized. A photosensitive array arrangement for scanning a flood-illuminated subject copy is illustrated in Fig. 15.39. This is the most often encountered scanning mechanism for modern facsimile scanners, and the sensors are typically silicon photosensitive devices. Two photosensor arrays in common use are photodiode arrays and charge-coupled-device linear image sensors. For digital facsimile, the array is typically composed of 1728 sensors in a row 1.02 in long with the optics designed so that an 8.5-in subject copy can be scanned.

15.3.3 Encoding

The output of the photosensor array for one scan or row of the subject copy consists of 1728 pels (1s or 0s) since group 3 facsimile recognizes only black or white. Typically, facsimile subject copy is 85% white. The data from scanning the subject copy is reduced through **run-length encoding**. In the encoding process, it is assumed that a white pel (0) always occurs first. A white run is the number of 0s until the first 1 is encountered (the run length is zero if the first pel is a 1); after a white run, a black run must follow with length equal to the number of 1s until the first 0 is encountered. All possible run lengths of white and black are then encoded into a binary code using a modified Huffman encoding technique (Jayant and Noll, 1984). On an average, fewer binary symbols are needed to encode run lengths of the subject copy than if the binary values of the pels themselves were transmitted. For group 3 facsimile, compression is optionally extended to the vertical dimension through employment of a relative element address designate (READ) code.

Run lengths from 0 to 63 are encoded by *terminating codes*, and run lengths in equal multiples of 64 from 64 to 1728 are encoded by *makeup codes*. Thus any run length up to 1728 can be described by a makeup code plus an appropriate terminating code. Additional makeup codewords are available for equipment that accommodates wider paper while maintaining the same resolution (Stamps, 1982). Tables of modified Huffman run length terminating and makeup codes are given in Stamps (1982).

15.3.4 Modulation and Transmission

Transmission of the encoded facsimile signal makes use of signaling techniques based on ITU-T recommendations V.27 (standard) and V.29 (optional addition). The former utilizes 8-phase modulation at 4800 b/s, and the latter employs 16-QAM quadrature amplitude modulation (QAM) at 9600 b/s with adaptive,

linear equalization (a process that combats effects of intersymbol interference). A facsimile telephone call consists of a five phases, labeled A – E (Stamps, 1982). In phase A, the telephone call is placed, with a training sequence sent consisting of signals to establish carrier detection, automatic gain control, timing synchronization, and adjust equalizer tap settings; phase B consists of the called station responding with a confirmation to receive (CFR) signal. The response is a 300 b/s binary coded frequency-shift keyed signal ($1 = 1650 \pm 6$ Hz and $0 = 1850 \pm 6$ Hz), except for the equalizer training sequence, which is at the fast data rate of the digital modem. In phase C the encoded facsimile image is transmitted. Phase D consists of the end-of-transmission signal consisting of six consecutive end of lines (EOLs), with receipt required from the receiver. If no more images are to be sent or received, phase E (going on-hook) is affected at both terminals.

Demodulation and Decoding

Demodulation consists of the inverse of the modulation process. Standard techniques are used to demodulate the phase modulated or QAM signals. Also included in the demodulation process is equalization. The decoding process converts the run-length-encoded information to a series of 1s and 0s corresponding to the black and white pels of the image. The demodulated and decoded signal is then used to control the recording of the image.

15.3.5 Recording

Recording of the image at the receiver to produce the **record copy** is affected by applying electricity, heat, light, ink jet, or pressure to a recording medium (Stamps, 1982). Xerography or ink jet techniques can be used to record on plain paper. Other recording means using electricity, heat, or pressure require specially coated papers. Marking transducers are used to apply the image to the recording medium. For more description of recording processes, see Stamps (1982).

Whereas character-oriented text is readily transmitted between personal computers by means of **teletex** or computer mail, facsimile transmission in conjunction with personal computers extends this capability to images (Hayashi and Motegi, 1989).

15.3.6 Group 4 Facsimile

As mentioned previously, group 4 facsimile apparatus is used mainly on public data networks of the circuit-switched, packet switched, or integrated services digital network (ISDN) varieties. Group 4 facsimile machines are subdivided into the following three classes (Yasuda et al., 1985):

- Class 1 with the minimum requirement that such equipment can send and receive documents containing facsimile-encoded information.
- Class 2, which in addition to the class 1 capabilities, must be able to receive **mixed-mode documents**.
- Class 3, which in addition to class 1 and class 2 capabilities, must be able to generate and send **mixed-mode documents**.

An additional feature of the specifications for group 4 facsimile is that the resolution is equal in the horizontal and vertical directions. Standard resolution for class 1 is 200 pels per 25.4 mm, and that for classes 2 and 3 is 200 and 300 pels per 25.4 mm. When operating as a mixed-mode terminal, a receiving density of 240 pels per 25.4 mm is required, which is optional for all three classes. Bit rates range from 2.4 to 48 kb/s with 64 kb/s for ISDN.

Defining Terms

Facsimile: The process of making an exact copy of a document through scanning of the subject copy, electronic transmission of the resultant signals modulated by the subject copy, and making a record copy at a remote location.

Mixed-mode documents: Document containing both character and facsimile information within a page. Such documents can be handled by group 4 facsimile very efficiently. Group 3 facsimile treats each document as an image to be transmitted pixel by pixel. Mixed-mode documents are subdivided into increasingly smaller parts, such as pages, frames, and blocks. A block is a rectangular area that can contain only one category (character or facsimile information).

Pel: A picture element which has been encoded as black or white, with no gray scale in between.

Pixel: A picture element of a subject or record copy that is represented in shades of gray.

Record copy: The copy of the document made at the receiving end of a facsimile system.

Run length encoding: The assignment of a codeword to each possible run of 0s (white pel sequence) or run of 1s (black pel sequence in a scan of the subject copy).

Scanning: The process of scanning the subject copy in a facsimile transmission from left to right and from top to bottom.

Subject copy: The document that is scanned and transmitted in a facsimile system.

16.1 Radio Broadcasting

Dennis F. Doelitzsch

16.1.1 Standard Broadcasting (Amplitude Modulation)

Standard broadcasting refers to the transmission of voice and music received by the general public in the 535–1705 kHz frequency band. Amplitude modulation is used to provide service ranging from that needed for small communities to higher powered broadcast stations needed for larger regional areas. The **primary service area** is defined as the area in which the ground or surface-wave signal is not subject to objectionable interference or objectionable fading. The **secondary service area** refers to an area serviced by **skywaves** and not subject to objectionable interference. **Intermittent service area** refers to an area receiving service from either a surface wave or a skywave but beyond the primary service area and subject to some interference and fading.

Frequency Allocations

The carrier frequencies for standard broadcasting in the U.S. (referred to internationally as medium wave broadcasting) are designated in the Federal Communications Commission (FCC) Rules and Regulations (FCC, 1993). A total of 117 carrier frequencies are allocated from 540 to 1700 kHz in 10-kHz intervals. Each carrier frequency is required by the FCC rules to deviate no more than ± 20 Hz from the allocated frequency, to minimize heterodyning from two or more interfering stations.

Modulation Techniques

Double-sideband full-carrier modulation, commonly called amplitude modulation (AM), is used in standard broadcasting for sound transmission. Basically, the amplitude of an analog radio frequency (RF) carrier is controlled by an analog audio frequency (AF) modulating signal. The resulting RF waveform consists of a carrier wave plus two additional signals that are the result of the modulation process: an upper-sideband signal, which is equal in frequency to the carrier plus the audio modulating frequency, and a lower-sideband signal, which equals the carrier frequency minus the audio modulating frequency.

Figure 16.1 shows a fully amplitude modulated signal. When the peak value of the modulated carrier wave (produced by a positive excursion of the audio modulating signal) is twice the value of the unmodulated carrier and the minimum value of the RF carrier reaches zero (produced by a negative excursion of the modulating signal), 100% modulation occurs. If the transmitter is well designed, with sufficient headroom, it is possible to exceed 100% positive modulation with an asymmetrical waveform, but the negative modulation may never exceed 100% (the RF carrier at zero or completely cut off) without causing distortion of the audio signal. The power contained in the audio sidebands created in the process of modulating the carrier 100% is equal to 25% of the carrier power in both the upper and lower sidebands. As a result, the overall power transmitted during periods of 100% modulation is 150% of the unmodulated carrier power.

The overall bandwidth is equal to twice the highest audio modulating frequency. Although full fidelity is possible with amplitude modulation, the FCC requires standard broadcast stations to limit the fidelity, thus restricting occupied bandwidth of the transmitted signal. Typical modulation frequencies for voice and music range from 50 Hz to 10 kHz. Each channel is generally thought of as 10 kHz in width, and thus the frequency band is designated from 535 to 1705 kHz; however, when the modulation frequency exceeds 5 kHz, the radio frequency bandwidth of the channel exceeds 10 kHz and adjacent channel interference may occur. To improve the high-frequency performance of transmission and to compensate for the high-frequency rolloff of many consumer receivers, FCC rules require that stations boost the high-frequency amplitude of transmitted audio using pre-emphasis techniques and to use *brick wall* filters to eliminate any modulation frequencies greater than 10 kHz.

FIGURE 16.1 100% modulation of AM carrier wave.

Channel and Station Classifications

In standard broadcast (AM), stations in the U.S. are classified by the FCC according to their operating power, protection from interference, and hours of operation. A Class A station operates with 10–50 kW of power servicing a large area with primary, secondary, and intermittent coverage and is protected from interference both day and night. These stations are called *clear channel* stations because the channel is cleared of nighttime interference over a major portion of the country. Class B stations operate full time with transmitter powers of 0.25–50 kW and are designed to render primary service only over a principal center of population and contiguous rural area. Whereas nearly all Class A stations operate with 50 kW, most Class B stations must restrict their power to 5 kW or less to avoid interfering with other stations. Class B stations operating in the 1605–1705 kHz band are restricted to a power level of 10 kW daytime and 1 kW nighttime. Class C stations operate on six designated channels (1230, 1240, 1340, 1400, 1450, and 1490) with a maximum power of 1 kW or less full time and render primarily local service to smaller communities. Class D stations operate on Class A or B frequencies with Class B transmitter powers during daytime, but nighttime operation, if permitted at all, must be at low power (less than 0.25 kW) with no protection from interference.

Although Class A stations cover large areas at night (approximately a 1000 km radius), the nighttime coverage of Class B, C, and D stations is limited by interference from other stations, electrical devices, and atmospheric conditions to a relatively small area. Class C stations, for example, have an interference-free nighttime coverage radius of approximately 8–16 km. As a result there may be large differences in the area

TABLE 16.1 Protected Service Signal Intensities for Standard Broadcasting (AM)

0 Class of Station	Power (kW)	Class of Channel Used	Signal Strength Contour of Area Protected from Objectionable Interference ^a ($\mu\text{V}/\text{m}$)		Permissible Interfering Signal	
			Day ^b	Night	Day ^b	Night ^c
A	10–50	Clear	SC 100	SC 500 50% SW	SC 5	SC 25
			AC 500	AC 500 GW	AC 250	AC 250
B	0.25–50	Clear	500	2000 ^b	25	25
		Regional			AC 250	250
C	0.25–1	Local	500	Not precise ^d	SC 25	Not precise

Note: SC = same channel; AC = adjacent channel; SW = skywave; GW = groundwave; RSS = root of sum squares.

^aWhen a station is already limited by interference from other stations to a contour of higher value than that normally protected for its class, this higher-value contour shall be the established protection standard for such station. Changes proposed by Class A and B stations shall be required to comply with the following restrictions. Those interferers that contribute to another station's RSS using the 50% exclusion method are required to reduce their contribution to that RSS by 10%. Those lesser interferers that contribute to a station's RSS using the 25% exclusion method but do not contribute to that station's RSS using the 50% exclusion method may make changes not to exceed their present contribution. Interferers not included in a station's RSS using the 25% exclusion method are permitted to increase radiation as long as the 25% exclusion threshold is not equaled or exceeded. In no case will a reduction be required that would result in a contributing value that is below the pertinent value specified in the table.

^bGroundwave.

^cSkywave field strength for 10% or more of the time. For Alaska, Class SC is limited to 5 $\mu\text{V}/\text{m}$.

^dDuring nighttime hours, Class C stations in the contiguous 48 states may treat all Class B stations assigned to 1230, 1240, 1340, 1400, 1450, and 1490 kHz in Alaska, Hawaii, Puerto Rico and the U.S. Virgin Islands as if they were class C stations.

Source: FCC Rules and Regulations, revised 1991; vol. III, pt. 73.182(a).

that the station covers daytime vs. nighttime. With over 4900 AM stations licensed for operation by the FCC, interference, both day and night, is a factor that significantly limits the service stations may provide. In the absence of interference, a daytime signal strength of 2 mV/m is required for reception in populated towns and cities, whereas a signal of 0.5 mV/m is generally acceptable in rural areas without large amounts of man made interference. Secondary nighttime service is provided in areas receiving a 0.5-mV/m signal 50% or more of the time without objectionable interference. Table 16.1 indicates the interference contour overlap limits. However, it should be noted that these limits apply to new stations and modifications to existing stations. Nearly every station on the air was allocated prior to the implementation of these rules with interference criteria that were less restrictive.

Field Strength

The field strength produced by a standard broadcast station is a key factor in determining the primary and secondary service areas and interference limitations of possible future radio stations. The FCC and others have conducted significant testing to determine what levels of interference are acceptable from adjacent and co-channel stations and have used that data in determining how close stations may be located to one another. If the transmitted power, antenna radiation characteristics, and ground conductivity are known, the extent of coverage (or interference) in a given direction for a particular station can be calculated with a high degree of accuracy. These calculations form the basis of the FCC's station allocation system and are based on field intensities with the unit of measure as volts per meter (the voltage induced in an antenna 1 m in length). The protected service contours and permissible interference contours for standard broadcast stations are shown in Table 16.1. This table, along with a knowledge of the field strength of existing broadcast stations, may be used in determining the potential for establishing new standard broadcast stations.

Propagation

One of the major factors in the determination of field strength is the propagation characteristic, described as the change in electric field intensity with an increase in distance from the broadcast station antenna. This variation depends on a number of factors including frequency, distance, surface dielectric constant, surface loss tangent, polarization, local topography, and time of day. Generally speaking, surface-wave propagation occurs over shorter ranges both during day and night periods. Skywave propagation in the AM broadcast band permits longer ranges and occurs during night periods, and thus some stations must either reduce power or cease to operate at night to avoid causing interference. Propagation curves in the broadcast industry are frequently referred to a reference level of 100 mV/m at 1 km; however a more general expression of surface-wave propagation may be obtained by using the Bremmer series (Bremmer, 1949). A typical surface-wave propagation curve for electric field strength as a function of distance is shown in [Fig. 16.2](#) for an operating frequency of 770–810 kHz. The ground conductivity varies from 0.1 to 5000 mS/m, and the ground relative dielectric constant is 15.

Skywave propagation is much less predictable than surface-wave propagation, because it necessarily involves some fading and less predictable field intensities and is most appropriately described in terms of statistics or the percentage of time a particular field strength level is found. [Figure 16.3](#) shows skywave propagation of a 100 mV/m inverse field strength at a distance of 1 km for midpoint path latitudes of 35–50°.

Transmitters

Standards that cover AM broadcast transmitters are given in the Electronic Industry Association (EIA) Standard (EIA, 1948). Parameters and methods for measurement include the following:

- Carrier output rating
- Carrier power output capability
- Carrier frequency range
- Carrier frequency stability
- Carrier shift
- Carrier noise level
- Magnitude of RF harmonics
- Normal load impedance
- Transmitter output circuit adjustment facilities
- RF and audio interface definitions
- Modulation capability
- Audio input level for 100% modulation
- Audio frequency response
- Audio frequency harmonic distortion
- Rated power supply
- Power supply variation
- Operating temperature characteristics
- AC power input

Standard AM broadcast transmitters range in power output from 5 W up to 50 kW units. Modern transmitters utilize low-voltage, high-current semiconductor devices to generate the RF power. However, in a high-power transmitter, it may take hundreds of transistors to generate the rated power. These transistors are combined into modules, the outputs of which are combined together. This design approach has the added benefit that in the event of a module failure, the transmitter continues to operate, but at slightly reduced power. A block diagram of a 10 KW solid state AM transmitter is shown in [Fig. 16.4](#).

FIGURE 16.2 Typical surface-wave propagation for standard AM broadcasting, 810-kHz surface-wave chart.

FIGURE 16.3 Skywave propagation formula for standard AM broadcasting. (Source: FCC, 1993. FCC Rules and Regulations, revised 1993; vol. III, pt. 73.190(b).)

Antenna Systems

The antenna system for a standard AM broadcast station typically consists of four parts:

1. Vertical radiator. This is a tower, which may be self-supporting or guyed. The tower may be base insulated (a large insulator is installed at the base to electrically isolate the tower) or electrically grounded. An insulated tower is series fed at the base. A grounded tower is shunt or slant wire fed at a point on the tower that presents a usable radiation resistance. If the tower is guyed, the guy wires have insulators inserted in them at intervals of $1/8$ wavelength or less.
2. Ground system. The ground system usually consists of 120 or more quarter-wavelength radials of #10 softdrawn bare copper wire buried a few inches underground. The ground system is very important, even though it is hidden under the ground's surface, since it determines the efficiency and stability of the system. The ground system can be improved further by interspersing more radials or installing an 8-m^2 ground screen under the base of the tower.
3. Antenna tuning unit (ATU). The tower's complex impedance at the feed point must be *matched* to the characteristic impedance of the transmission line so that maximum transfer of power may occur. Elements of inductive and capacitive reactance (coils and capacitors) are combined into a T or L network to accomplish this task. The ATU will also contain provisions for measuring base RF antenna current.
4. Transmission line. The transmission line conducts the RF signal from the transmitter to the ATU. It is generally a coaxial cable of $50\text{-}\Omega$ characteristic impedance, which is buried several feet beneath the ground's surface to protect it from damage.

Typical heights for AM broadcast towers range from 50 to 150 m. The surface-wave radiation efficiency of an antenna (the signal strength at 0° elevation) is determined by the radiation characteristic of the tower. The efficiency increases as the height of the tower increases up to a maximum at approximately $5/8$ wavelength. In addition, when the surface-wave efficiency increases, the radiation at angles above the horizon decreases, thus minimizing nighttime skywave interference to other stations. However, $5/8$ wavelength antennas, especially at the lower standard broadcast band frequencies, are more than 150 m tall and become cost prohibitive and difficult to construct. As a result, $1/4$ wavelength antennas are the generally accepted standard for AM broadcast stations.

When the circular radiated signal pattern must be modified to prevent interference to other stations or to provide better service in a particular direction, additional antenna systems may be combined in a phased array to produce the desired field intensity contours. For example, if a station power increase would cause

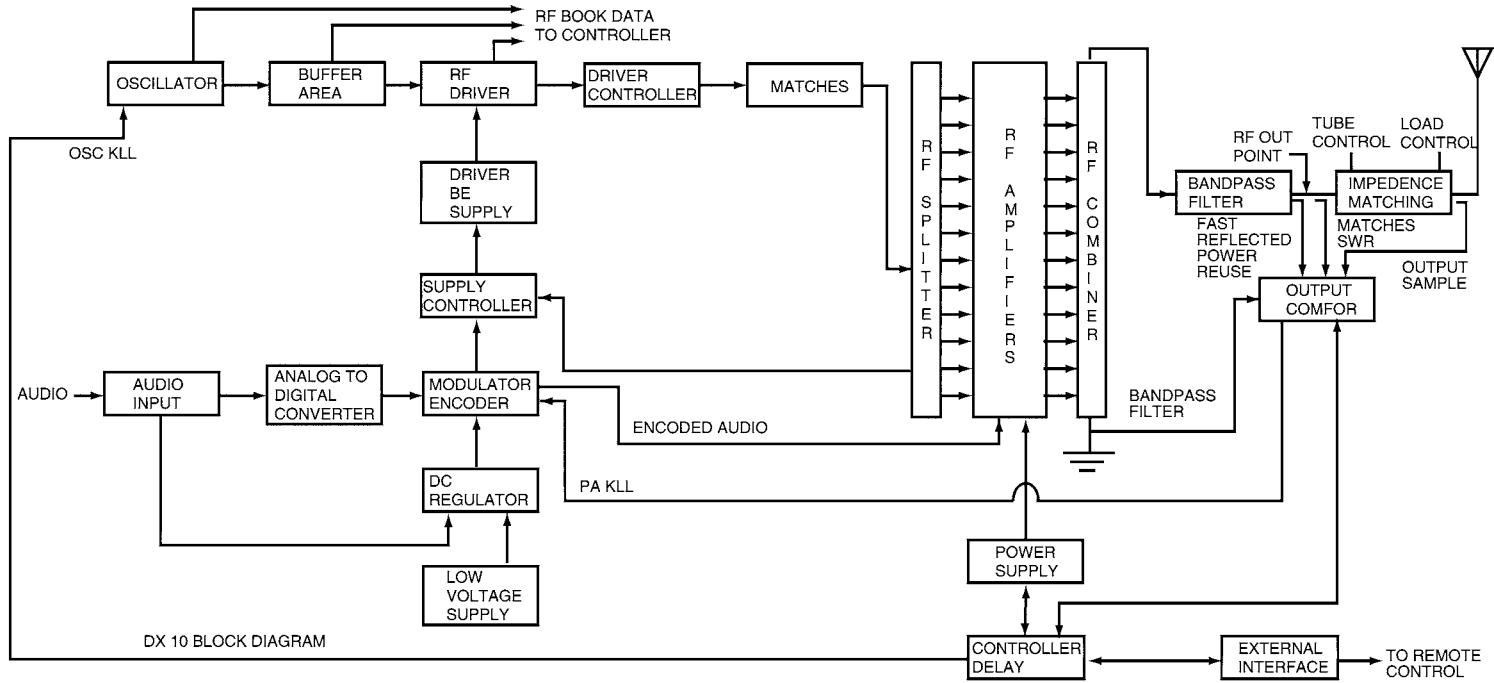

FIGURE 16.4 Block diagram and picture of typical 10-KW Solid State AM transmitter. (Source: Harris Corporation, Broadcast Division, Quincy, Illinois. With permission.)

FIGURE 16.5 Directional AM antenna pattern for three element array. (Source: Independent Broadcast Consultants, Trumansburg, NY. Reprinted with permission of du Treil, Lundin & Rackly, Consulting Engineers.)

interference with existing stations, a directional array could be designed that would tailor the coverage to protect the existing stations while allowing increases in radiation in other directions. The protection requirements can generally be met with arrays consisting of 4 towers or less, but complex arrays have been constructed consisting of 12 or more towers to meet stringent requirements for particular locations. The directional pattern in Fig. 16.5 shows the type of shaping that may be required to meet interference requirements.

16.1.2 Frequency Modulation

Frequency modulation utilizes the audio modulating signal to vary the *frequency* of the RF carrier. The greater the amplitude of the modulating frequency, the greater the frequency deviation from the center carrier frequency. The rate of the frequency variation is a direct function of the frequency of the audio modulating signal. In FM modulation, multiple pairs of sidebands are produced. The actual number of sidebands that make up the modulated wave is determined by the modulation index (MI) of the system. The modulation index is a function of the frequency deviation of the system and the applied modulating signal.

$$\text{MI} = \text{frequency deviation/modulating frequency}$$

As the MI increases there are more sidebands produced. As the modulating frequency increases for a given maximum deviation, there will be a smaller number of sidebands spaced at wider intervals. Unlike amplitude modulation, which has a percentage of modulation directly proportional to the carrier power, the percentage of modulation in FM is generally referenced to the maximum allowable occupied bandwidth set by regulation. For example, FM broadcast stations are required to restrict frequency deviation of ± 75 kHz from the main carrier. This is referred to as 100% modulation for FM broadcast stations.

To determine the frequency spectrum of a transmitted FM waveform, it is necessary to compute a Fourier series or Fourier expansion to show the actual signal components involved. This work is difficult for a waveform of this type, as the integrals that must be performed in the Fourier expansion or Fourier series are difficult to solve. The actual result is that the integral produces a particular class of solution that is identified as the **Bessel function**.

Supporting mathematics will show that an FM signal using the modulation indices that occur in a broadcast system will have a multitude of sidebands. To achieve no distortion, all sidebands would have to be transmitted, received, and demodulated. However, in reality, the ± 75 -kHz maximum deviation, which is used in FM broadcasting, allows the transmission and reception of audio with negligible distortion.

The power transmitted by an FM transmitter is virtually constant, regardless of the modulating signal. Additional noise or distortion of the amplitude of the waveform has virtually no effect on the quality of the received audio. Thus, FM transmitters may utilize Class C type amplifiers, which cause amplitude distortion and allow greater powers to be generated, but are inherently more efficient than the less amplitude distorting Class A or Class B types of amplifiers. In addition, atmospheric and man-made noise has very little effect, since the receiver clips all amplitude variations off the signal prior to demodulation. This is why FM allows high fidelity with very low noise.

Frequency Modulation (FM) Broadcasting

The monophonic system of FM broadcasting was developed to allow sound transmission of voice and music for reception by the general public for audio frequencies from 50 to 15,000 Hz, all to be contained within a ± 75 -kHz RF bandwidth. This technique provided higher fidelity reception than was available with standard broadcast AM along with less received noise and interference. FM broadcasting in the U.S. is allocated the 88–108 MHz frequency band.

Pre-emphasis is employed in an FM broadcast transmitter to improve the received signal-to-noise ratio. The pre-emphasis upper-frequency limit is based on a time constant of $75 \mu\text{s}$ as required by the FCC for FM broadcast transmitters. Audio frequencies from 50 to 2120 Hz are transmitted with normal FM; whereas audio frequencies from 2120 Hz to 15 kHz are emphasized with a larger modulation index. There is significant signal-to-noise improvement at the receiver, which is equipped with a matching **de-emphasis** circuit.

FM Broadcast Modulation Techniques

FM stereo was developed in 1961 to provide transmission capability for a left- and right-stereo audio signal. Stereophonic transmission is accomplished by adding the left- and right-channel stereo information together in the baseband signal. In addition, a left-minus-right channel is added and frequency multiplexed on a subcarrier of 38 kHz using double sideband suppressed carrier modulation. An unmodulated 19-kHz subcarrier is derived from the 38-kHz subcarrier to provide a synchronous demodulation reference for the stereophonic receiver. In the receiver, a synchronous detector at 38 kHz recovers the left-minus-right channel information, which is then combined with the left-plus-right channel information in sum and difference combiners to produce the original left-channel and right-channel signals. The system works well and, because the baseband mono signal is a combination of both left and right audio, provides full compatibility with monophonic FM receivers.

Subsidiary Communications Authorization (SCA)

In addition to its main channel and 38-kHz subcarrier stereo broadcasting, an FM station may utilize additional subcarriers for private commercial use. These SCAs may be used in a variety of ways, such as paging, data transmission, specialized foreign language programs, radio reading services, utility load management, and background music. An FM stereo station may utilize multiplex subcarriers within the range of 53–99 kHz with up to 20% total SCA modulation of the main carrier using any form of modulation, including techniques for the transmission of digital information. The only requirement is that the station does not exceed its occupied bandwidth limitations or cause interference to itself.

TABLE 16.2 FM Station Classifications, Powers, and Antenna Heights

Station Class	Maximum ERP	HATT, m(ft)	Distance, km
A	6 kW (7.8 dBk)	100(328)	28
B1	25 kW (14.0 dBk)	100(328)	39
B	50 kW (17.0 dBk)	150(492)	52
C3	25 kW (14.0 dBk)	100(328)	39
C2	50 kW (17.0 dBk)	150(492)	52
C1	100 kW (20.0 dBk)	299(981)	72
C	100 kW (20.0 dBk)	600(1968)	92

Frequency Allocations

The 100 carrier frequencies for FM broadcast range from 88.1 to 107.9 MHz and are equally spaced every 200 kHz. The channels from 88.1 to 91.9 MHz are reserved for educational and noncommercial broadcasting, and those from 92.1 to 107.9 MHz for commercial broadcasting. Each channel has a 200-kHz bandwidth. The maximum frequency swing under normal conditions is ± 75 kHz. Stations operating with an SCA may, under certain conditions, exceed this level, but in no case may exceed a frequency swing of ± 82.5 kHz. The carrier center frequency is required to be maintained within ± 2000 Hz. The frequencies used for FM broadcasting limit the coverage to essentially line-of-sight distances. As a result, consistent FM coverage is limited to a maximum receivable range of a few hundred kilometers depending on the antenna height above average terrain (HAAT) and **effective radiated power (ERP)**. The actual coverage area for a given station can be reliably predicted after the power and the antenna height are known. Either increasing the power or raising the antenna will increase the coverage area.

Station Classifications

In FM broadcast, stations are classified by the FCC according to their maximum allowable ERP and the transmitting antenna HAAT in their service area. Class A stations provide primary service to a radius of about 28 km with 6000 W of ERP at a maximum HAAT of 100 m. The most powerful class, Class C, operates with maximums of 100,000 W of ERP and heights up to 600 m with a primary coverage radius of over 92 km. The powers and heights above average terrain for all classes are shown in Table 16.2. All classes may operate at antenna heights above those specified but must reduce the ERP accordingly. Stations may not exceed the maximum power specified, even if antenna height is reduced. The classification of the station determines the allowable distance to other cochannel and adjacent channel stations.

Field Strength and Propagation

The field strength produced by an FM broadcast station depends on the ERP, antenna HAAT, local terrain, tropospheric scattering conditions, and other factors. From a statistical point of view, however, an estimate of the field intensity may be obtained from Fig. 16.6. A factor in the determination of new licenses for FM broadcast is the separation between allocated cochannel and adjacent channel stations, the class of station, and the antenna heights. The spacings are given in Table 16.3. The primary coverage of all classes (except B and B1, which are 0.5 and 0.7 mV/m, respectively) is the 1.0-m V/m contour. The distance to the primary contour, as well as to the *city grade* or 3.16-mV/m contour may be estimated using Fig. 16.5. Although FM broadcast propagation is generally thought of as line of sight, larger ERPs along with the effects of diffraction, refraction, and tropospheric scatter allow coverage slightly greater than line of sight.

Transmitters

FM broadcast transmitters typically range in power output from 10 W to 50 kW and have performance standards similar to those specified above for AM broadcast transmitters. Digital technology is used extensively in the processing and exciter stages, allowing for precision modulation control, whereas solid-state devices are predominately used for RF drivers and amplifiers up to several kilowatts. High-power

ESTIMATED FIELD STRENGTH EXCEEDED AT 50 PERCENT

transmitters still rely mainly on tubes in the final stages for the generation of RF power. A block diagram and picture of a typical high-power FM transmitter are shown in Fig. 16.7.

Antenna Systems

FM broadcast antenna systems are required to have a horizontally polarized component. Most antenna systems, however, are circularly polarized, having both horizontal and vertical components. The antenna

TABLE 16.4 Power and Antenna Gain Combinations to Achieve 50- kW ERP

Transmitter Power, kW	No. Bays	Antenna Gain, dB	Feedline Efficiency, %	Effective Radiated Power, kW
30.13	4	3.29	77.8	50.0
13.58	8	6.52	82.0	50.0
10.19	12	8.37	71.3	50.0

system, which usually consists of several individual radiating bays, is fed as a phased array mounted on a tower, has a radiation characteristic that concentrates the transmitted energy in the horizontal plane toward the population to be served, minimizing the radiation out into space and down toward the ground. Thus, the ERP toward the horizon is increased with power gains up to 10 dB. That means that a 5-kW transmitter coupled to an antenna system with a 10-dB gain would have an ERP of 50 kW.

The RF power is transferred to the antenna via a transmission line. At FM broadcast frequencies and powers, coaxial transmission line is used, ranging in size from 7/8 in outside diameter to 3 in. The dielectric (the material between the inner and outer conductors in coaxial transmission lines) is foam or for air types, either dry air or nitrogen. These coax cables are not 100% efficient, and some power is lost as heat in the line. The larger diameter air type cables have the least loss. The combination of transmitter power output (TPO), feedline loss, and antenna gain determine the actual ERP of the station. For a given ERP, a station may install a large, multibay antenna with high gain and relatively low TPO or use a low-gain antenna and a high TPO. The choice is determined by a number of factors, including service area, terrain in the area, and economics.

The radiation pattern of a nondirectional FM broadcast antenna system is designed to radiate equally well in all directions. However, when mounted on a tower as a support structure, the structure itself distorts the uniformity of the pattern, especially on towers with larger cross-sectional dimensions of over 36 in. It is possible to optimize the omnidirectional pattern using additional parasitic elements to offset the effects of the tower and achieve a more circular pattern. The use of such elements also allows an intentional directionalization of the pattern to avoid interference with other stations or to meet spacing requirements. In order to meet FCC requirements, a directional FM antenna system must meet strict standards. Figure 16.8 is a plot of the horizontal and vertical components of a typical nondirectional circularly polarized FM broadcast antenna showing the effect upon the pattern caused by the supporting tower.

16.1.3 Audio Production Systems

Audio production systems are those systems which consist of studios and equipment to capture, generate, or reproduce sounds, convert those sounds into electronic audio signals, and then combine or *mix* the signals together while controlling the individual volume, density, tonal content, and other like characteristics of each of the sounds or signals.

Studios

Audio production includes the generation of audio, combining the audio sources together, and then processing the finished audio to control the characteristics of the audio prior to transmission or recording. Generally, all of the aspects of audio production take place in a broadcast or recording studio. These specially equipped rooms are as acoustically perfect as finances will allow and have elaborate equipment to mix the various sound elements together and produce the audio for broadcast (broadcast studios) or recording (recording studios). However, the manner in which this processing is done is becoming increasingly sophisticated and computer based. A common element in most audio production is the VU meter. The loudness or level of the audio signal is measured on a VU meter, which is simply an AC voltmeter that is calibrated to indicate the number of decibels (dB) above or below a set standard. The broadcast and recording standard is 0 VU, which is 1 mW into 600 Ω , representing a voltage level of 0.775 V.

HORIZONTAL PLANE ELECTRIC FIELD PATTERN
0 dBi = .75

FIGURE 16.8 Typical nondirectional 92.5-MHz FM antenna characteristics showing the effect of the tower structure on the horizontal and vertical radiation patterns. (Source: Electronics Research, Inc. Chandler, IN.)

Audio production systems have rapidly replaced analog with digital as the preferred method for production, storage, and transmission. Analog signals have limited bandwidth and are subject to increasing noise and degradation with multiple generations, unlike digital signals, which are virtually unlimited as to bandwidth and offer signal to noise ratios of over 100 dB.

The basic elements of studio production are

- Audio source equipment such as microphones, musical instruments, CD players, reel-to-reel tape machines, digital tape machines, cassette players, and so forth, virtually any source that can generate or reproduce audio signals
- Audio mixing equipment such as an audio mixing console (either analog or digital)
- Audio processing equipment such as equalizers, limiters, compressors, and digital effects synthesizers and processors
- Audio storage equipment such as digital hard disk storage, reel-to-reel tape equipment, digital tape machines, cassette recorders, minidisk, and CD recorders.

Computer-based systems are becoming common that input a variety of sources, mix, process, and store, all within the computer environment, eliminating much of the equipment found in conventional studios.

The three most common types of audio production studios are: 1) recording studios used for mastering music and movie sound track recordings, 2) on-air studios used for assembling the audio elements of a radio show, and 3) production studios at broadcast stations used to record commercials and other audio elements for later broadcast.

FIGURE 16.9 Block diagram of audio flow through typical FM broadcast station.

Recording Studio

Audio production that is done for movie soundtracks, singers, and musicians requires a large studio, which has been built to a higher standard of acoustical quality. These studios may be large enough to record a symphony orchestra, but most are much smaller. It would not be unusual to find such professional recording studios equipped with dozens of microphones and extremely complex mixing equipment with 64 or more channels. Each channel has controls for the volume, mixing, routing, frequency equalization, and monitoring of the audio source assigned to it. Each channel would be individually recorded and later mixed together to obtain the finished performance.

On-Air Studio

An on-air studio differs from the recording and production studios in that studios of this sort are primarily concerned with controlling the many different audio sources that are used for programming the station. A typical on-air studio may have as many as 30 or more different sources of audio to control, including network audio, other studios, and so forth. Generally, only two or three microphones are available for use and the acoustical properties of the studio are tailored for voice work. Figure 16.9 shows a block diagram of the signal flow and audio source equipment in a typical FM radio station on-air studio.

Production Studio

A production studio in a radio station is used to prepare various audio elements for later broadcast. For example, the production of a typical radio commercial would utilize many production elements. An announcer's voice may be converted into audio signals by a microphone, then equalized, limited, and enhanced by processing equipment, mixed at a preset volume in a mixing console, and finally recorded onto a single track of a multitrack digital editing workstation. Similarly, sound effects (either studio generated or from a sound effects audio library) may be originated, processed, mixed, and recorded onto other tracks. A group of singers and an orchestra may be used, following the same process to be placed on additional tracks. An audio editor would manipulate the multitrack digital editor to produce a perfectly edited, finished commercial for use at one or more radio stations.

Defining Terms

Bessel function: A mathematical integration that produces a set of curves, which in graph form can be used to determine the amplitude of FM sidebands as a result of the modulations process.

Digital audio: Audio signals that have been converted from a continuous range of analog signal levels and frequencies into a digital code.

Effective radiated power: The radiated power output from an antenna in a specified direction, including the effects of transmitter power, transmission line losses, and antenna power gain.

Intermittent service area: The surface-wave service area of a standard broadcast station beyond the primary service area and subject to some interference and fading.

Pre-emphasis–de-emphasis: The process of increasing the relative signal level of some audio frequencies during radio broadcasting (pre-emphasis) and decreasing the level during reception (de-emphasis) to reduce noise and improve quality.

Primary service area: The surface-wave service area of a standard broadcast station that is not subject to objectionable interference or objectionable fading.

Secondary service area: The service area of a standard broadcast station served by a skywave signal only, not subject to objectionable interference and in which the signal is subject to intermittent variations in signal strength.

Skywave: Refers to the ionospheric reflection of a standard broadcast station signal during nighttime hours allowing signals to be received hundreds of miles beyond the radio horizon.

Surface wave: Refers to the propagation of a standard broadcast station signal, which closely follows the surface of the Earth.

16.2 Digital Audio Broadcasting

Stanley Salek and Almon H. Clegg

16.2.1 Introduction

Digital audio broadcasting (DAB) is the term applied to a few independently developed emerging technologies that promise to provide consumers with a new and better aural broadcast system. DAB offers dramatically better reception over existing terrestrial analog AM and FM broadcasts by providing improved audio quality and by integrating technology to provide resistance to interference in stationary and mobile/portable reception environments. Additionally, the availability of a digital data stream direct to consumers opens the prospect of providing extra services to augment basic sound delivery.

As of this writing, DAB transmission and reception systems are available from at least five system developers. Two of the systems, from Sirius Satellite Radio and XM Satellite Radio, transmit via satellite, using ground-based augmentation transmitters as needed, while the system from the Eureka 147/DAB consortium can be deployed as a satellite, terrestrial, or hybrid satellite/terrestrial system. The remaining systems, from iBiquity Digital Corporation and the Digital Radio Mondiale Consortium, are designed for terrestrial signal delivery, operating in established broadcasting frequency bands. This section provides a general overview of the technical aspects of DAB systems, as well as a summary of three example transmission systems.

16.2.2 The Need for DAB

In the years since the early 1980s, the consumer marketplace has undergone a great shift toward digital electronic technology. The explosion of personal computer use has led to greater demands for information, including full multimedia integration. Over the same time period, compact disc (CD) digital audio

technology overtook long-playing records and analog audio cassettes as the consumer audio playback medium of choice. Similar digital transcription methods and effects also have been incorporated into commonly available audio and video equipment, including digital video disc (DVD) and hard disk/flash memory-based recorders and players. Additionally, the presently ongoing transition to high definition television broadcasting systems has included the incorporation of fully digital methods for video and audio transmission. Because of these market pressures, the radio broadcast industry determined that the existing analog methods of broadcasting needed updating to keep pace with the expectations of the advancing audio marketplace.

Along with providing significantly enhanced audio quality, DAB systems have been developed to overcome the technical deficiencies of existing AM and FM analog broadcasting systems. The foremost problem of current broadcast technology, as perceived by the industry, is its susceptibility to interference. AM medium-wave broadcasts, operating in the 530- to 1700-kHz frequency range, are prone to disruption by fluorescent lighting and by power system distribution networks, as well as by numerous other unintentional radiators, including computer and telephone systems. Additionally, natural effects, such as nighttime skywave propagation, interference between stations, and nearby lightning discharges, cause irritating service disruption to AM reception. FM broadcast transmissions in the 88- to 108-MHz band are much more resistant to these types of interference. However, multipath propagation and abrupt signal fading, especially found in urban and mountainous areas containing a large number of signal reflectors and shadowers (e.g., buildings and terrain), can seriously degrade FM reception, particularly to mobile receivers.

16.2.3 DAB System Design Goals

DAB systems are designed with several technical goals in mind. The first goal is to create a service that delivers “compact disc quality” stereo sound for broadcast to consumers. The second is to overcome the interference problems of current AM and FM broadcasts, especially under portable and mobile reception conditions. Third, DAB must be spectrally efficient, in that total bandwidth should be no greater than that currently used for corresponding analog broadcasts. Fourth, the DAB system should provide space in its data stream to allow for the addition of ancillary services, such as textual program information display, software downloading, or subscription data services. Finally, to foster rapid consumer acceptance, DAB receivers must not be overly cumbersome, complex, or expensive.

In addition to these goals, desired features include reduced RF transmission power requirements (when compared to AM and FM broadcast stations having the same signal coverage), a mechanism to seamlessly fill-in coverage areas that are shadowed from the principal transmitted signal, and the ability to easily integrate DAB receivers into personal, home, and automotive sound systems.

16.2.4 Historical Background

DAB development work began in Europe in 1986, with the initial goal to provide high-quality audio services to consumers directly by satellite. Companion terrestrial systems were developed to evaluate the technology being considered, as well as to provide fill-in service in small areas where the satellite signals were shadowed. A consortium of European technical organizations known as Eureka-147/DAB demonstrated the first working terrestrial DAB system in Geneva, Switzerland, in September 1988. Subsequent terrestrial demonstrations of the system followed in Canada in the summer of 1990, and in the U.S. in 1991 (See <http://www.worlddab.org/eureka.aspx>).

VHF and UHF transmission frequencies between 200 and 900 MHz were used for the demonstrations with satisfactory results. Because most VHF and UHF frequency bands suitable for DAB are already in use (or in use by/reserved for digital television and other services), an additional Canadian study in 1991 evaluated frequencies near 1500 MHz (L-band) for use as a potential worldwide DAB allocation. This study concluded that L-band frequencies would support a DAB system such as Eureka-147/DAB, while continuing to meet the overall system design goals.

During the scheduled 1992 World Administrative Radio Conference (WARC-92), frequency allocations for many different radio systems were debated. As a result of WARC-92, a worldwide L-band standard allocation at 1452 to 1492 MHz was designated for both satellite and terrestrial digital radio broadcasting. However, because of existing government and military uses in L-band, the U.S. was excluded from the standard. Instead, an S-band allocation at 2310 to 2360 MHz was substituted. Additionally, nations including Japan, China, and Russia opted for an extra S-band allocation in the 2535- to 2655-MHz frequency range.

During the same time period, most DAB system development work in the U.S. shifted from out-band (i.e., UHF, L-band, and S-band) to in-band, because of uncertainty as to the suitability of using S-band frequencies for terrestrial broadcasting. In-band terrestrial systems would merge DAB services with existing medium wave AM and VHF FM broadcasts, using novel adjacent- and co-channel modulating schemes. Between 1992 and 2000, competing system proponents demonstrated proprietary methods of extracting a compatible digital RF signal from co-channel analog AM and FM broadcast transmissions.

Standardization activities for DAB systems were started in the early 1990s by the Consumer Electronics Group of the Electronic Industries Association (EIA), now known as the Consumer Electronics Association (CEA). In 1996, field testing of some systems was conducted by EIA in the San Francisco, California, Bay Area. Standardization and field testing activities for IBOC AM and FM systems was begun shortly thereafter by the National Radio Systems Committee, a joint committee of the National Association of Broadcasters (NAB) and the CEA. In October 2002, the FCC conditionally approved deployment of proprietary analog/digital in-band on-channel (IBOC) AM and FM technology developed by system proponent iBiquity Digital Corporation (See <http://www.ibiquity.com>). As of mid-2004, IBOC standards activities are ongoing, with a permanent Federal Communications Commission (FCC) authorization for use of the systems by all U.S. broadcasters anticipated in the near future.

In 1998, a worldwide consortium known as Digital Radio Mondiale (DRM) was formed, with the goal of producing “near FM quality” digital broadcasting in AM broadcast bands below 30 MHz (See <http://www.drm.org>). While sharing some technical similarity to the iBiquity AM IBOC system, the non-proprietary DRM system has been primarily demonstrated using all-digital transmission, without a modulated co-channel analog AM component. In 2001, DRM received International Telecommunications Union (ITU) approval, and a technical standard was published. As of mid-2004, a number of international broadcasters have been conducting over-air DRM system testing.

The inception of S-band satellite broadcasting in the U.S. began in 1997, when the FCC auctioned two 12.5 MHz-wide frequency bands to private operators. Commercial Satellite DAB commenced in late 2001 and 2002 when systems licensees XM Satellite Radio and Sirius Satellite Radio began broadcasting to subscribers. Both systems offer numerous commercial-free music channels and other content (See <http://www.xmsatelliteradio.com> and <http://www.sirius.com>).

16.2.5 Technical Overview of DAB

Regardless of the actual signal delivery system used, all DAB systems share a common overall topology. Figure 16.10 presents a block diagram of a typical DAB transmission system.

To maintain the highest possible audio quality, program material must originate from digital sources, such as CD players and digital audio recorders, or digital audio feeds from network sources. Analog sources, such as microphones, are converted to a digital audio data stream using an analog-to-digital (A/D) converter, prior to switching or summation with the other digital sources.

The linear digital audio data stream from the studio is then applied to the input of a source encoder. The purpose of this device is to reduce the required bandwidth of the audio information, helping to produce a spectrally efficient RF broadcast signal. For example, 16-bit linear digital audio sampled at 48 kHz (the standard professional rate) requires a data stream of 1.536 megabits/s to transmit a stereo program in a serial format. This output represents a bandwidth of approximately 1.5 MHz, much greater than that used by an equivalent analog audio modulating signal (Smyth, 1992). Source encoders can reduce the data rate by factors of 8:1 or more, yielding a much more efficient modulating signal.

FIGURE 16.10 An example of DAB transmission system. (Source: Hammett & Edison, Inc., Consulting Engineers.)

Following the source encoder, the resulting serial digital signal is applied to the input of the channel encoder, a device that modulates the transmitted RF wave with the reduced-rate audio information. Auxiliary serial data, such as program information and receiver control functions, also can be input to the channel encoder (or combined within the source encoder) for simultaneous transmission.

The channel encoder uses sophisticated modulating techniques to accomplish the goals of interference cancellation and high spectral efficiency. Methods of interference cancellation include expansion of time and frequency diversity of the transmitted information, as well as the inclusion of error correction codes in the data stream. Time diversity involves transmitting the same information multiple times by using a predetermined time interval. Frequency diversity, such as that produced by spread-spectrum, multiple-carrier, or frequency-hopping systems, provides the means to transmit identical data on several different frequencies within the bandwidth of the system. At the receiver, real-time mathematical processes are used to locate the required data on a known frequency at a known time. If the initial information is found to be unusable because of signal interference, the receiver simply uses the same data found on another frequency or at another time, producing seamless demodulation.

Spectral efficiency is a function of the modulation system used. Among the modulation formats that have been evaluated for DAB transmission are QPSK, M-ary QAM, and MSK (Springer, 1992). Using these and other formats, digital transmission systems that use no more spectrum than their analog counterparts have been designed.

The RF output signal of the channel encoder is amplified to the appropriate power level for transmission. Because the carrier-to-noise (C/N) ratio of the modulated waveform is not generally so critical as that required for analog communications systems, relatively low transmission power often can be used. Depending on the sophistication of the data recovery circuits contained in the DAB receiver, the use of C/N ratios as low as 6 dB are possible without causing a degradation to the received signal.

DAB reception is largely the inverse of the transmission process, with the inclusion of sophisticated error correction circuits. Fig. 16.11 shows a typical DAB receiver.

DAB reception begins in a similar manner as is used in virtually all radio receivers. A receiving antenna feeds an appropriate stage of RF selectivity and amplification, from which a sample of the coded DAB signal is derived. This signal then drives a channel decoder, which reconstructs the audio and auxiliary data streams. To accomplish this task, the channel decoder must demodulate and de-interleave the data contained on the RF carrier and then apply appropriate computational and statistical error correction functions.

The source decoder converts the reduced bit-rate audio stream back to pseudolinear at the original sampling rate. The decoder computationally expands the mathematically reduced data and fills the gaps left from the extraction of irrelevant audio information with averaged code or other masking data. The output of the source decoder feeds audio digital-to-analog (D/A) converters, and the resulting analog stereo audio signal is amplified for the listener.

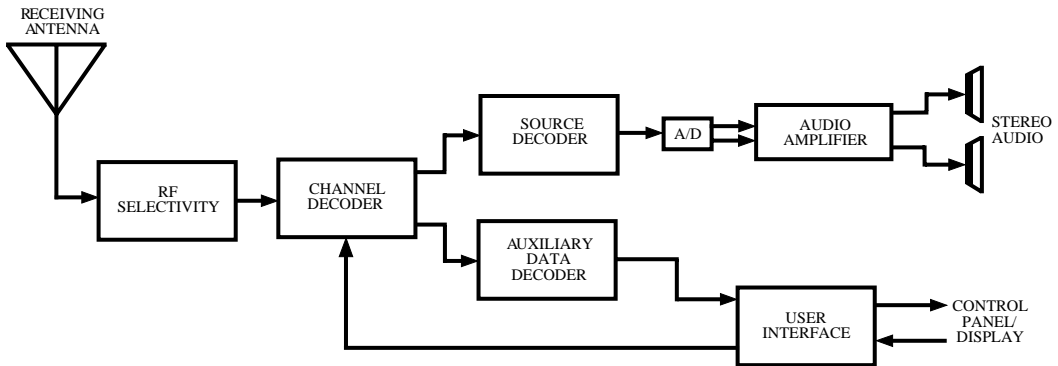

FIGURE 16.11 An example of DAB receiver. (Source: Hammett & Edison, Inc., Consulting Engineers.)

In addition to audio extraction, DAB receivers are generally capable of decoding auxiliary data. These data can be used in conjunction with the user interface to control receiver functions, or for a completely separate purpose. A typical user interface contains a data display screen in addition to the usual receiver tuning and audio controls. This data screen can be used to obtain information about the programming, news reports, sports scores, advertising, or any other useful data sent by the station or an originating network. Also, external interfaces could be used to provide a software link to personal computer systems or other digital information and productivity devices.

16.2.6 Audio Compression and Source Encoding

The development of digital audio encoding started with research into pulse-code modulation (PCM) in the late 1930s and evolved, shortly thereafter to include work on the principles of digital PCM coding. Linear predictive coding (LPC) and adaptive delta pulse-code modulation (ADPCM) algorithms had evolved in the early 1970s and later were adopted into standards such as C.721 (published by the CCITT) and CD-I (Compact Disc-Interactive). At the same time, algorithms were being invented for use with phoneme-based speech coding. Phonetic coding, a first-generation “model-based” speech-coding algorithm, was mainly implemented for low bit-rate speech and text-to-speech applications. These classes of algorithms for speech further evolved to include both code excited linear predictive (CELP) and vector selectable excited linear predictive (VSELP) algorithms by the mid-1980s. In the late 1980s, these classes of algorithms were also shown to be useful for high-quality audio music coding. They were put to commercial use from the late 1970s to the latter part of the 1980s.

Subband coders evolved from the early work on quadrature mirror filters in the mid-1970s and continued with polyphase filter-based schemes in the mid-1980s. Hybrid algorithms employing both subband and ADPCM coding were developed in the latter part of the 1970s and standardized (e.g., CCITT G.722) in the mid- to late 1980s. Adaptive transform coders for audio evolved in the mid-1980s from speech coding work done in the late 1970s. By employing psychoacoustic noise-masking properties of the human ear, perceptual encoding evolved from early work of the 1970s and where high-quality speech coders were employed. Music quality bit-rate reduction schemes such as motion picture expert group (MPEG), precision adaptive subband coding (PASC), and adaptive transform acoustic coding (ATRAC) have been developed. Further refinements to the technology will focus attention on novel approaches such as wavelet-based coding and the use of entropy coding schemes.

Audio coding for digital broadcasting in the early days employed one of the many perceptual encoding schemes previously mentioned or some variation thereof. Fundamentally, they depend on two basic psychoacoustic phenomena: (1) the threshold of human hearing, and (2) masking of nearby frequency components. In the early days of hearing research, Harvey Fletcher, a researcher at Bell Laboratories, measured the hearing of many human beings and published the well-known Fletcher-Munson threshold-of-hearing

FIGURE 16.12 An example of the masking effect. Based on the hearing threshold of the human ear (dashed line), a 500-Hz sinusoidal acoustic waveform, shown at A on the left graph, is easily audible at relatively low levels. However, it can be masked by adding nearby higher-amplitude components, as shown on the right. (Source: CCI.)

chart. Basically it states that, depending on the frequency, audio sounds below certain levels cannot be heard by the human ear. Further, the masking effect, simply stated, is when two frequencies are very close to each other and one is higher in acoustic level than the other, the weaker of the two is masked and will not be heard. These two principles allow for as much as 80% of the data representing a musical signal to be discarded.

Figure 16.12 shows how introduction of frequency components affects the ear’s threshold of hearing vs. frequency. Figure 16.13 shows how the revised envelope of audibility results in the elimination of components that would not be heard.

The electronic implementation of these algorithms employs a digital filter that breaks the audio spectrum into many subbands, and various coefficient elements are built into the program to decide when it is permissible to remove one or more of the signal components. The details of how the bands are divided and how the coefficients are determined are usually proprietary to the individual system developers. Standardization groups and system proponents have spent many worker-hours of evaluation attempting to determine the most accurate coding system for given compression ratios or data transfer rates.

During recent years, the algorithms used for encoding music signals have improved greatly, even though the fundamental methods remain as outlined above. Experience in the art of producing both hardware and software encoders and the frequent use of listening test panels has brought about great improvements. “Tweaking” of the overall technology has improved sound quality while keeping the compression and transfer rates as needed for the broadcast service to which it is applied. This optimization has benefited the prospects for high quality sound in digital transmission and broadcasting systems.

FIGURE 16.13 Source encoders use an empirically derived masking threshold to determine which audio components can be discarded (left). As shown on the right, only the audio components with amplitudes above the masking threshold are retained. (Source: CCI.)

Some examples of coding schemes that have been considered for use in broadcasting channels are: perceptual audio coder (PAC) that extends the idea of perceptual coding to stereo pairs. It uses both L/R (left/right) and M/S (sum/difference matrixing to abate noise generation) coding, switched in both frequency and time in a signal dependent fashion. The adaptive transform acoustic coder (ATRAC) has been developed for portable digital audio, but because of its robust coding scheme and availability of commercial integrated circuits, it also lends itself to broadcast use. This coder uses hybrid frequency mapping employing a signal splitting scheme that breaks the band into three sub-bands (0–5.5, 5.5–11, and 11–22 kHz) followed by a suitable dynamically windowed modified discrete cosine transform (MDCT). Advanced audio coding (AAC) is a high-quality perceptual audio coding technology appropriate for many broadcast and electronic music-distribution applications. Coding efficiency is superior to that of MP3, providing higher quality audio at lower transmitted bit rates. Developed and standardized as an ISO/IEC specification by industry leaders, AAC is supported by a growing number of hardware and software manufacturers as the logical successor to MP3 for consumer and computer products, as well as for broadcasting (See www.aac-audio.com and <http://www.iis.fraunhofer.de/amm/techinf/aac/> and <http://www.mp3prozone.com>).

Broadcast studios must have available in their facilities the necessary transforms to convert the many digital formats to their broadcast algorithm of choice. Hence, within the broadcast community, expert knowledge of all types and generations of audio compression formats is necessary. If an audio signal passes through several successive compression or bit reduction algorithms, there may be unexpected audible artifacts produced. It is the responsibility of the broadcast engineers to learn the compatibility issues and adjust the signal processing methods to make the necessary conversions with minimum degradation of audio quality. Consideration must be given to the format of the source audio program content and its legacy and compatibility with the coder being used for the final transmission or download. In the case of Internet streaming or downloading, the source coding used may sound best when listened to on a particular software decoder. Hence, there are many choices in the marketplace, each claiming certain improvements over its competitors.

An interesting modern source coding example is CT-aacPlus audio compression. CT-aacPlus is the combination of AAC, a highly efficient global standard based on the collaborative work of several experts on perceptual audio encoding, and additional coding from Coding Technologies' Spectral Band Replication (SBRTM) technology. SBR creates additional bitrate efficiency and utilizes subjective improvements worked out by the German Fraunhofer Institute, the inventor of MP3 (See <http://www.codingtechnologies.com> and <http://www.xradio.com>). With this combination of AAC and SBR, CT-aacPlus has been tested by audio experts and found to provide certain audio improvements. In a double-blind listening test, AAC alone was 33% more efficient when compared to previous generations of competing algorithms. Double-blind listening tests have established that the CT-aacPlus combination is as much as 30% more efficient than AAC. As a result of these tests, CT-aacPlus has been adopted by the DRM consortium and accepted by the MPEG standardization group as the "reference model" for the upcoming versions of MPEG-4 (a standard for a new form of audio and video compression) (See http://www.ebu.ch/trev_291-dietz.pdf).

16.2.7 System Example: Eureka-147/DAB

Eureka-147/DAB was the first fully developed DAB system that has demonstrated a capability to meet virtually all the described system goals. Developed by a European consortium, it is an out-band system in that its design is based on the use of a frequency spectrum outside the AM and FM radio broadcast bands. Out-band operation is required because the system packs up to 16 stereophonic broadcast channels (plus auxiliary data) into one contiguous band of frequencies, which can occupy a total bandwidth of several megahertz. Thus, overall efficiency is maintained, with 16 digital program channels occupying about the same total bandwidth as 16 equivalent analog FM broadcast channels. System developers have promoted Eureka-147/DAB for satellite transmission, as well as for terrestrial applications in locations that have a suitable block of unused spectrum in the L-band frequency range or below.

The ISO/MPEG-2 source encoding/decoding system has been defined for use with the Eureka-147/DAB system. Originally developed by IRT (Institut für Rundfunktechnik) in Germany as MUSICAM (Masking

pattern-adapted Universal Subband Integrated Coding And Multiplexing), the system works by dividing the original digital audio source into 32 subbands. As with the source encoders described earlier, each of the bands is digitally processed to remove redundant information and sounds that are not perceptible to the human ear. Using this technique, the original audio, sampled at a rate of 768 kilobits/sec per channel, is reduced to as little as 96 kilobits/sec per channel, representing a compression ratio of 8:1.

The Eureka-147/DAB channel encoder operates by combining the transmitted program channels into a large number of adjacent narrowband RF carriers, which are each modulated using QPSK and grouped in a way that maximizes spectrum efficiency known as orthogonal frequency-division multiplex (OFDM). The information to be transmitted is distributed among the RF carriers and is also time-interleaved to reduce the effects of selective fading. A guard interval is inserted between blocks of transmitted data to improve system resistance to intersymbol interference caused by multipath propagation. Convolutional coding is used in conjunction with a viterbi maximum-likelihood decoding algorithm at the receiver to make constructive use of echoed signals and to correct random errors (Alard and Lassalle, 1988).

RF power levels of just a few tens of watts per program channel have been used, providing a relatively wide coverage area, depending on the height of the transmitting antenna above surrounding terrain. This low power level is possible because the system can operate at a C/N ratio of less than 10 dB, as opposed to the more than 30 dB that is required for high-fidelity demodulation of analog FM broadcasts.

Another demonstrated capability of the system is its ability to use “gap filler” transmitters to augment signal coverage in shadowed areas. A gap filler is simply a system that directly receives the DAB signal at an unobstructed location, provides RF amplification, and retransmits the signal, on the same channel, into the shadowed area. Because the system can make constructive use of signal reflections (within a time window defined by the guard interval and other factors), the demodulated signal is uninterrupted on a mobile receiver when it travels between an area served by the main signal into the service area of the gap filler.

16.2.8 System Example: iBiquity FM IBOC

As disclosed in recent public FCC proceedings, the iBiquity FM IBOC DAB system provides a novel proprietary method for the transition from analog FM broadcasting to a hybrid digital/analog technology, and finally to an all-digital system, using existing broadcast spectrum in the 88–108 MHz FM broadcast band. Source coding uses a proprietary method known as high definition coder (HDC), which like CT-aacPlus has its roots in AAC. The present implementation operates at 96 kilobits/sec for both stereo channels, representing a compression ratio of 16:1, or even greater if the stream is split to allow both audio and data transmission or transmission of two or more separate but simultaneously delivered audio programs.

As shown in Figure 16.14, groupings of primary low level OFDM carriers are added to the FM analog signal, both below and above the host signal. Optional extended carriers also may be added, although their presence is not required for basic system operation. In addition to the FM analog host carrier frequency, reference subcarriers (used by the receiver/decoder for synchronization) are included with the IBOC carriers. As illustrated, the injection level of the individual carriers is quite low, and is easily contained within the spectral emission mask specified by the U.S. FCC Rules.

Because the ultimate system goal is for a transition to an all-digital broadcast system, the methodology and spectrum loading has been predefined to be compatible with receivers marketed to operate using the hybrid system. Figure 16.15 shows the spectral content of the defined all-digital system. Note that the power of the primary carrier groupings, previously adjacent to the analog FM signal, have been increased, and groupings of secondary carriers have been added in the location of the former FM analog signal spectrum. The higher level OFDM carriers are maintained in an approximate 100 to 200 kHz offset from the carrier frequency so that interference to or from co-channel and adjacent-channel stations is not degraded subsequent to the all-digital broadcasting transition.

For the hybrid (analog compatible) system, the IBOC DAB signal can be combined with the analog FM signal by way of a number of potential methods. Three of the more common combining methods

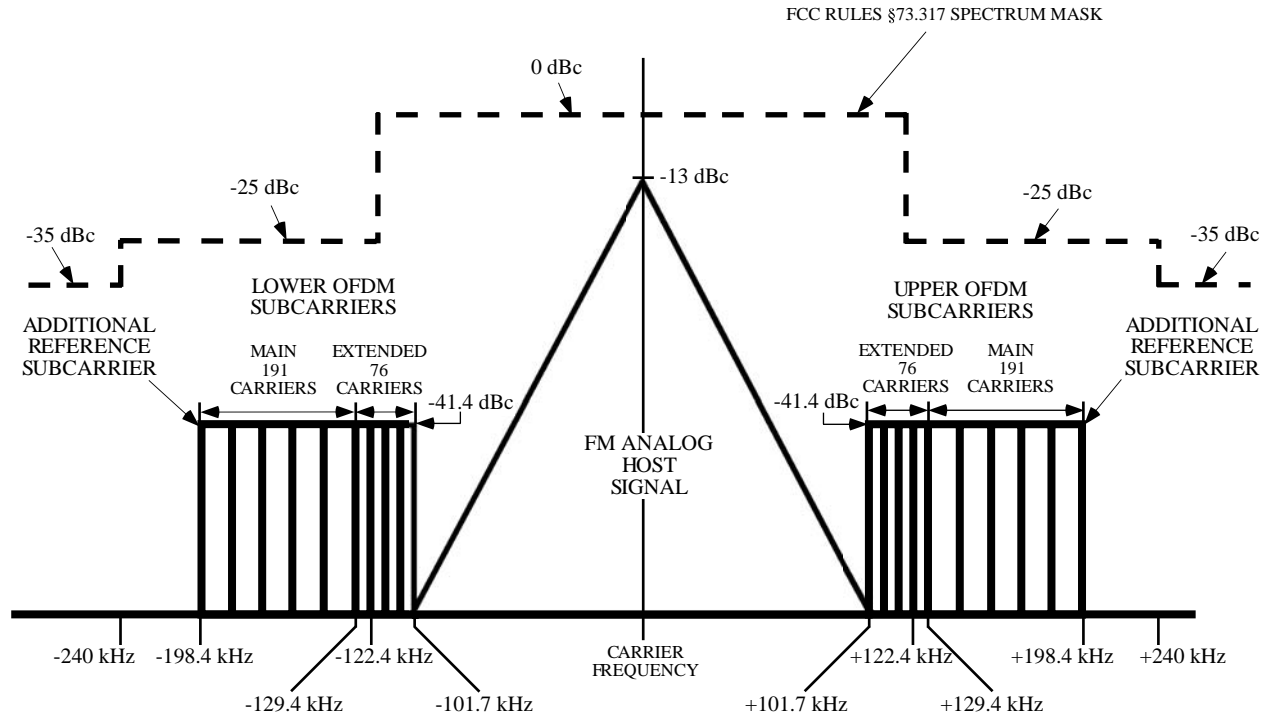

FIGURE 16.14 Spectral content of the iBiquity hybrid FM analog/IBOC DAB system (dBc = decibels relative to carrier level). (Source: Hammett & Edison, Inc., Consulting Engineers.)

FIGURE 16.15 Spectral content of the iBiquity all-digital IBOC DAB system intended for use in the present FM broadcast band allocation. The injection level of the secondary carriers is variable, depending on carrier loading. (Source: Hammett & Edison, Inc., Consulting Engineers.)

FIGURE 16.16 High level combining of IBOC DAB and analog FM signals. (Source: Hammett & Edison, Inc., Consulting Engineers.)

are illustrated in the following block diagrams. In all cases, the FM transmitter analog audio is delayed by several seconds to achieve time alignment with the recovered digital audio signal in the receiver. Thus, the system can automatically and seamlessly return to analog audio demodulation in locations where digital demodulation becomes impaired.

Figure 16.16 depicts the high level combining method, by which full-power analog and digital transmission systems operate in parallel, and the two signals are combined just prior to the input of the transmitting antenna system. This method has the benefit of maintaining high linearity of the IBOC DAB signal, since it never passes through the same active stages as the analog FM signal. However, the combiner must be carefully designed to minimize losses, particularly to the analog FM signal, which for many FM stations operates at power levels of 10 kilowatts or more. Thus, in order to increase the analog combining efficiency, the digital combining efficiency must be decreased, requiring much higher DAB power than is actually transmitted, often on the order of 10 dB higher. For example, to achieve 100 watts of DAB power at the input to the antenna system, 1000 watts of DAB power must be generated. This method is most popular with moderate power FM stations, since the amount of DAB power wasted in the combining process remains reasonable.

One alternative to high level combining is low level combining, shown in Figure 16.17. This method combines the low power output signals of the analog FM and IBOC exciter units and applies the composite signal to the transmitter. This method requires exceptional linearity in the transmitter RF amplifier stages to prevent distortion of the IBOC carriers. It is generally suitable for transmitters operating at an FM analog output power of 10 kilowatts or less.

A third method of combining analog FM and IBOC carriers is to employ separate transmitting antennas, as depicted in Figure 16.18. Field testing has shown this method to be acceptable, provided that the transmitting antennas have similar radiation patterns, are located close to each other, and are installed at comparable radiation center heights. This method is of significant interest to stations that operate with very high analog FM transmitter power of generally more than 30 kilowatts, where the high level combining method is impractical due to efficiency issues and low level combining is not possible due to the prohibitive cost of producing a high power linear transmitter to operate at VHF frequencies. The use of separate antennas is also of interest to many other FM broadcasters, since the method allows the existing analog FM facility to be left in place.

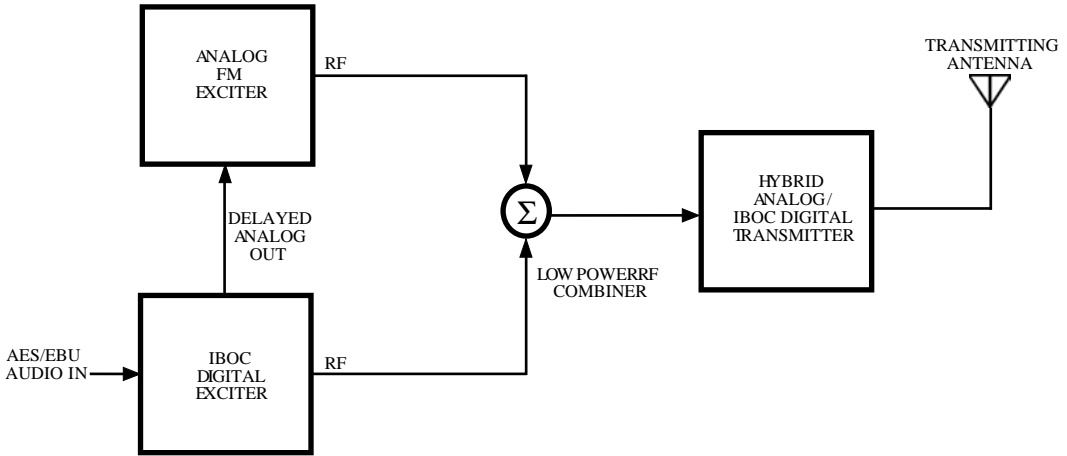

FIGURE 16.17 Low level combining of IBOC DAB and analog FM signals. (Source: Hammett & Edison, Inc., Consulting Engineers.)

16.2.9 System Example: iBiquity AM IBOC

As with the FM IBOC system, the proprietary iBiquity AM IBOC transmission system is capable of operating in two modes, hybrid and all-digital, with only the hybrid mode exhibiting interoperability with existing analog broadcasting. As with the FM IBOC system, source coding employs HDC, operating at 36 kilobits/sec for both stereo channels, representing a compression ratio of almost 43:1. A 400 bit/sec data stream is reserved for receiver program identification, but the data path can be expanded further at

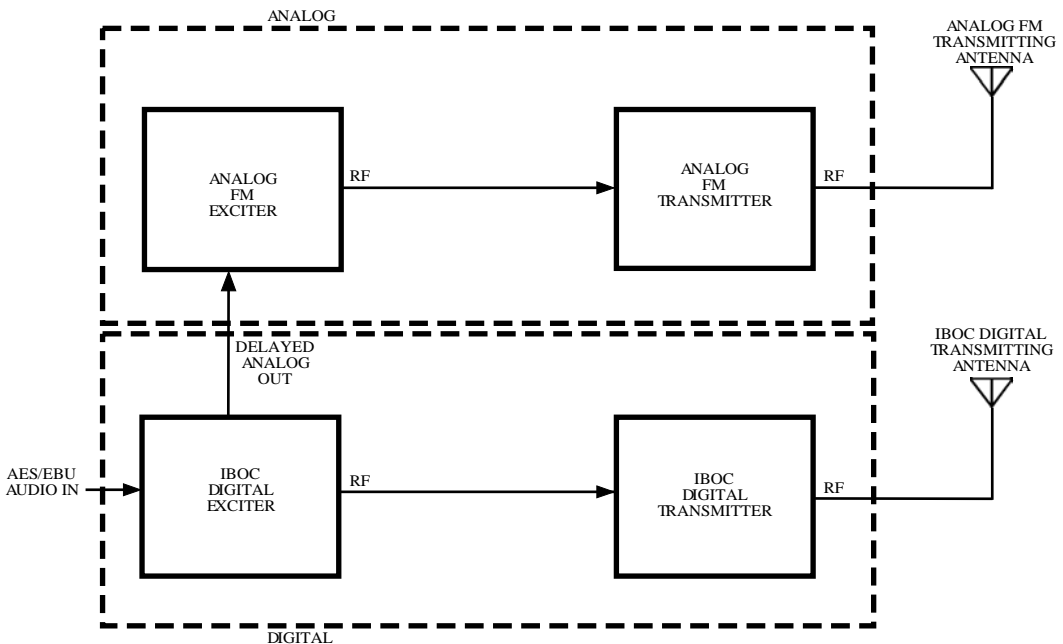

FIGURE 16.18 Combining of IBOC DAB and analog FM signals using separate transmitting antennas. (Source: Hammett & Edison, Inc., Consulting Engineers.)

FIGURE 16.19 Spectral content of the iBiquity hybrid AM analog/IBOC DAB system. (Source: Hammett & Edison, Inc., Consulting Engineers.)

the expense of using a higher audio compression ratio. According to the developers, HDC is capable of producing acceptable audio quality at bit rates as low as 20 kilobits/sec.

Accompanying Figure 16.19 provides a drawing of the spectrum occupancy of the hybrid AM IBOC transmission system. Similar to the related FM IBOC system, transmissions are carried by a series of OFDM carriers, separated into primary, secondary, and tertiary groupings. The primary digital carrier groupings are offset ± 10 to ± 15 kHz from the carrier frequency, while the secondary digital carrier groupings are offset ± 5 to ± 10 kHz of the carrier frequency. The tertiary carriers are located within ± 5 kHz of the carrier frequency, sharing same spectrum as the AM analog host sidebands. As shown by the dashed line, this arrangement of digital carriers fits within the U.S. FCC Rules spectrum mask.

In general, the system requires that the analog audio bandwidth be limited to 5 kHz, to protect the secondary digital carriers. An alternate mode of the system allows up to 7.5 kHz analog audio bandwidth, which generates some interference to the secondary digital carriers. Because the digital sidebands carry duplicative information that is inverted about the carrier frequency, recovery of the lower portion of the lower secondary digital subcarriers, along with the upper portion of the upper secondary digital subcarriers, still results in full recovery of the secondary digital information. The drawback is that recovery of both secondary sidebands is required for use of 7.5 kHz analog audio bandwidth, while recovery of just one secondary sideband is required for use of 5 kHz analog audio bandwidth. Thus, IBOC digital service area for 7.5 kHz analog audio bandwidth may be impaired in the presence of adjacent-channel interfering signals.

Accompanying Figure 16.20 provides a representation of the spectrum occupancy for the defined all-digital IBOC AM system. As with the FM IBOC system, it is anticipated that a transition to this system would take place after most stations have implemented the hybrid IBOC system and when market indicators have shown IBOC receiver penetration exceeding a defined threshold.

Note that the unmodulated carrier signal is retained in the all-digital system, but the primary digital carrier groupings now immediately surround the carrier, replacing the hybrid system tertiary digital carriers. Defined secondary and tertiary carriers occupy the former positions of the hybrid system secondary digital carrier groupings, and no information is transmitted beyond ± 10 kHz of the center carrier frequency.

FIGURE 16.20 Spectral content of the iBiquity all-digital IBOC DAB system intended for use in the present medium wave AM broadcast band allocation. (Source: Hammett & Edison, Inc., Consulting Engineers.)

As a result of its design, it is anticipated that the eventual migration to all-digital transmission will enhance station digital coverage over the hybrid system and exhibit improved performance on transmitting antenna systems exhibiting narrow bandwidth.

Figure 16.21 provides a block diagram of a typical AM IBOC installation. The conversion of an analog station requires the addition of an exciter, an auxiliary service unit (ASU), and appropriate audio processing.

FIGURE 16.21 Combining of IBOC DAB and analog AM signals. (Source: Hammett & Edison, Inc., Consulting Engineers.)

The auxiliary service unit (ASU) accepts AES/EBU digital audio as input, handles sampling rate conversions, and feeds the digital audio inputs of separate AM and IBOC audio processors. The ASU also contains a GPS-synchronized clock to generate the carrier reference and other synchronizing signals used by the exciter. The DAB audio processor controls and levels audio of the IBOC digital transmission, while the analog audio processor controls analog audio. The exciter contains a delay circuit for the analog audio path so that digital-to-analog transitions in receivers are time-aligned, similar to the FM IBOC system.

The exciter DAB path encodes the source audio, introduces error correction and interleaving overhead, and generates the coded OFDM carriers. The DAB and analog paths are then summed and converted to magnitude/phase signals that feed the broadcast transmitter. The exciter output signals feed the transmitter analog audio input and frequency-determining stages of the transmitter. The hardware topology of an all-digital conversion is the same as that shown, except that the analog audio processor and related exciter circuitry is not used.

Defining Terms

Channel encoder: A device that converts source-encoded digital information into an analog RF signal for transmission. The type of modulation used depends on the particular digital audio broadcasting (DAB) system, although most modulation techniques employ methods by which the transmitted signal can be made more resistant to frequency-selective signal fading and multipath distortion effects.

In-band on-channel (IBOC): A method of combining digital audio broadcasting signals, intended for reception by radio listeners, with the signals of existing analog broadcast services operating in the medium wave AM and VHF FM broadcast bands.

Gap filler: A low-power transmitter that boosts the strength of transmitted DAB RF signals in areas which normally would be shadowed due to terrain obstruction. Gap fillers can operate on the same frequency as DAB transmissions or on alternate channels that can be located by DAB receivers using automatic switching.

Source encoder: A device that substantially reduces the data rate of linearly digitized audio signals by taking advantage of the psychoacoustic properties of human hearing, eliminating redundant and subjectively irrelevant information from the output signal. Transform source encoders work entirely within the frequency domain, while time-domain source encoders work primarily in the time domain. Source decoders reverse the process, using various masking techniques to simulate the properties of the original linear data.

Further Information

The National Association of Broadcasters (See <http://www.nab.org>) publishes periodic reports on the technical, regulatory, and political status of DAB in the U.S. Additionally, their Broadcast Engineering Conference proceedings published since 1990 contain a substantial amount of information on emerging DAB technologies.

IEEE Transactions on Broadcasting, typically published quarterly by the Institute of Electrical and Electronics Engineers, Inc., periodically includes papers on digital broadcasting (See <http://www.ieee.org>).

Additionally, the periodic newspaper publication *Radio World* (See <http://www.rwonline.com>) provides continuous coverage of DAB technology, including proponent announcements, system descriptions, field test reports, and broadcast industry reactions.

16.3 Audio Interconnection

Roy W. Rising

16.3.1 Introduction

System interfacing problems have existed since the first audio engineer tried to wire two pieces of equipment together. Devices that work flawlessly alone can fail miserably when connected. Initially, transformers were required to correct for differences in ground potentials between pieces of equipment and to eliminate electrical noise picked up in cabling. Transformers also interfaced the internal unbalanced high-impedance characteristics of active devices with balanced transmission lines having much lower impedances. Transformers added significant cost, weight, and sometimes distortion to the equipment.

As the performance of electronic equipment improved, transformers kept pace with reduced distortion and broadened frequency response. Their physical size and weight, however, made them inconvenient for use in the ever shrinking chassis' of transistorized equipment. As solid-state technology became standard, designers sought ways to eliminate transformers. The result was electronically (active) balanced inputs and outputs (I/O).

The move away from transformers introduced several unexpected problems. Installation practices that provide acceptable performance with transformer-isolated equipment may not work for active balanced I/O equipment. Active balanced circuits can be less forgiving of wiring faults and short circuits; some output stages will self-destruct if shorted. Avoidance of ground loops is more important with an active balanced system than with transformers. Active balanced input circuits can provide excellent noise rejection under ideal conditions. In the real world, however, their noise rejection can deteriorate rapidly. Transformers remain the best choice for the toughest situations.

16.3.2 Balanced and Unbalanced Systems

Nearly all professional audio systems use balanced inputs and outputs because of the noise immunity they afford. Figure 16.22 shows a basic source and load connection. No grounds are present, and both the source and load float. This is the optimum condition for equipment interconnection.

Either the source or the load may be tied to ground with no problems, provided only one ground connection exists. Unbalanced systems are created when each piece of equipment has one of its connections tied to ground, as shown in Fig. 16.23. This condition occurs if the source and load equipment have unbalanced (single-ended) inputs and outputs. This type of equipment uses chassis ground for one of the audio conductors. This is a common practice in consumer audio products. Equipment with unbalanced inputs and outputs is cheaper to build but when various pieces of audio gear are tied together, trouble often results. These problems are compounded when the equipment is separated by a significant distance.

As shown in Fig. 16.23, a difference in ground potential causes current flow in the ground wire. This current develops a voltage across the wire resistance, and the ground noise voltage adds directly to the signal itself. Because the ground current usually results from leakage in power transformers and line filters, the 60-Hz signals give rise to hum. Reducing the wire resistance through a heavier ground wire helps reduce the hum, but cannot eliminate it completely.

By amplifying both the high side and the ground side of the source and subtracting the two to obtain a *difference signal*, it is possible to cancel the ground loop noise (see Fig. 16.24). This is the basis of the **differential input** circuit. Unfortunately, problems still can exist with the unbalanced source to balanced load system shown in the drawing. The reason centers around the impedance of the unbalanced source. One side of the line will have a slightly lower amplitude because of impedance differences in the output lines.

By creating an output signal that is out of phase with the original, a balanced source can be created to eliminate this error (see Fig. 16.25). As an added benefit, for a given maximum output voltage from the source, the signal voltage is doubled over the unbalanced case.

FIGURE 16.22 A basic source and load connection. No grounds are indicated and both the source and the load float.

FIGURE 16.23 An unbalanced system in which each piece of equipment has one of its connections tied to ground.

FIGURE 16.24 Illustration of how ground loop noise can be canceled by amplifying both the high side and the ground side of the source and subtracting the two signals.

FIGURE 16.25 A balanced source configuration where the inherent amplitude error of the system shown in Fig. 16.24 is eliminated.

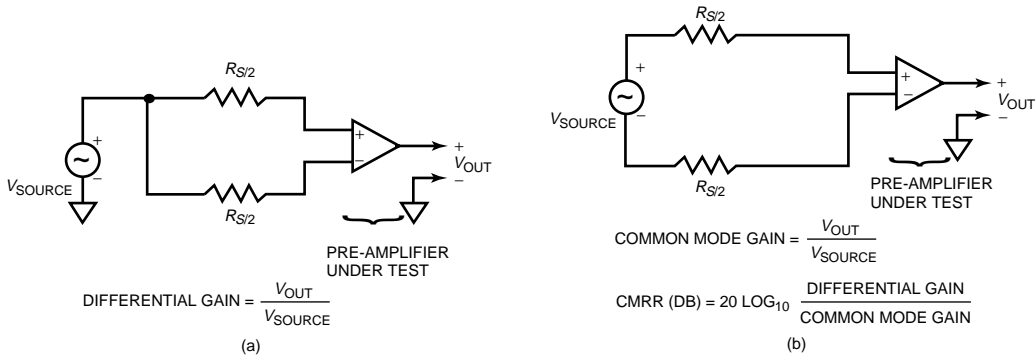

FIGURE 16.26 Common mode rejection ratio for an active balanced input circuit.

Common Mode Rejection Ratio

Common mode rejection ratio (CMRR) is the measure of how well an input rejects ground noise. The concept is illustrated in Fig. 16.26. The input signal to a differential amplifier is applied between the plus and minus amplifier inputs. The stage will have a certain gain for this signal condition, called the **differential gain**. Because the ground noise voltage appears on both the plus and minus inputs simultaneously, it is common to both inputs. The amplifier subtracts the two inputs, giving only the difference between the voltages at the input terminals at the output of the stage. The gain under this condition should be zero, but in practice it is not. CMRR is the ratio of these two gains (the differential gain and the **common mode gain**) in decibel. The larger the number, the better is the performance of the circuit. For example, a 60-dB CMRR means that a ground signal common to the two inputs will have 60 dB less gain than the desired differential signal. If the ground noise already is 40 dB below the desired signal level, the output noise level will be 100 dB below the desired signal level. If, however, the noise is already part of the differential signal, the CMRR will do nothing to improve the signal.

Although active balanced I/O circuits are not as effective as transformers in rejecting ground noise and radio frequency interference (RFI), they usually are adequate if well designed. Because of their advantages in cost, weight, and low distortion, active balanced I/O circuits generally are the best choice for all but the most demanding environments.

Active Balanced Input Circuits

A wide variety of circuit designs have been devised for active balanced inputs. All have the common goal of providing high CMRR and adequate gain for subsequent stages. All also are built around a few basic principles. Figure 16.27 shows the simplest and least expensive approach using a single operational amplifier (op-amp). For a unity gain stage all of the resistors are the same value, typically 10 kΩ. This circuit presents an input impedance to the line that is different for the two sides. The positive input impedance will be twice that of the negative input. The CMRR is dependent on the matching of the four resistors and the balance of the source impedance. The noise performance of this circuit, which usually is limited by the resistors, is a tradeoff between low loading of the line and low noise.

FIGURE 16.27 The simplest and least expensive active balanced input op-amp circuit. Performance depends on resistor matching and the balance of the source impedance.

Another approach, shown in Fig. 16.28, uses a buffering op-amp stage for the positive input. The positive signal is inverted by the op-amp and then added to the negative input of the second inverting amplifier

stage. Any common mode signal on the positive input (which has been inverted) will cancel when it is added to the negative input signal. Both inputs have the same impedance. The matching of resistors limits the CMRR to about 50 dB. With the addition of an adjustment pot, it is possible to achieve 80-dB CMRR, but component aging will degrade this value over time.

Adding a pair of buffer amplifiers before the summing stage results in an instrumentation grade circuit, as shown in Fig. 16.29. The input impedance is increased substantially, and floating source signal imbalance effects are eliminated. Additional noise is introduced by the added op-amp, but the resistor noise usually can be decreased by reducing impedances, causing a net improvement in system noise.

Both instrumentation and operational amplifiers are available as single-package devices. These incorporate laser-trimmed resistors that are critically matched for optimum performance. Fixed and adjustable gain units are offered with gains up to 1000 (60 dB), equivalent input noise of -128 dB, and total harmonic distortion (THD) of 0.0001% at 20 kHz.

CMRR performance for active balanced input circuits is highly dependent on the source balance. The ideal figure of 120 dB is achieved with a shorted input or perfectly balanced source. Source imbalances of 0.2–20 Ω are not uncommon. Figure 16.30 compares these effects at 60 Hz for transformer vs. active balanced inputs. At high frequencies, capacitance tolerance between the conductors and shield in typical wiring is ±5% resulting in similar CMRR deterioration.

Another potential problem with active balanced inputs is their maximum input voltage limit. While easily handling the signal voltage, common-mode voltages in broadcasting environments can drive the sum of the two into clipping. Precisely matched input attenuation can help this, but makeup gain increases the circuit's noise. For installations near broadcast transmitters, the common mode range should be ±50 V from DC through the significant harmonics of the transmitter. Transformer inputs easily withstand this and more.

Active Balanced Output Circuits

The classic active balanced output circuit used an approach similar to that shown in Fig. 16.31. The signal is buffered to provide one phase of the

FIGURE 16.28 An active balanced input circuit using two op-amps, one to invert the positive input terminal and the other to buffer the difference signal. Without adjustments, this circuit will provide about 50-dB CMRR.

FIGURE 16.29 An active balanced input circuit using three op-amps to form an instrumentation-grade circuit. The input signals are buffered and then applied to a differential amplifier.

FIGURE 16.30 CMRR as a function of source imbalance. (Source: Pacific Research & Engineering Corp., Carlsbad, CA. With Permission.)

balanced output signal. This signal is then inverted with another op-amp to provide the other phase of the output signal. Because the load is driven from the two outputs, the maximum output voltage is double that of an unbalanced output. The outputs are taken through two resistors, each of which is half of the desired source impedance. Matched 33- Ω resistors have been found to provide best frequency response for transmission lines up to 2000 ft.

The circuit in Fig. 16.31 works reasonably well if the load is always balanced, but it suffers from two problems when the load is not balanced. First, if the negative output is shorted to ground by an unbalanced load connection, the first op-amp is likely to distort. This produces a distorted signal at the input to the other op-amp. Even if the circuit is arranged so that the second op-amp is grounded by an unbalanced load, the distorted output current probably will show up in the audio output from coupling through grounds or circuit board traces. Equipment that uses this type of balanced output often provides a second set of output jacks that are wired to only one amplifier for unbalanced applications.

The second problem with the circuit in Fig. 16.31 is that the output does not float. If any voltage difference (such as power line hum) exists between the local ground and the ground at the device receiving the signal, it will appear as an addition to the signal. The only ground-noise rejection will be from the CMRR of the input stage at the receive end.

The preferred output stage is the electronically balanced and floating design shown in Fig. 16.32. The circuit consists of two op-amps that are cross-coupled with positive and negative feedback. The output of each amplifier is dependent on the input signal and the signal present at the output of the other amplifier. These designs may have gain or loss depending on the selection of resistor values. The output impedance is set via appropriate selection of resistor values. Some resistance is needed from the output terminal to ground to keep the output voltage from floating to one of the power supply rails. Care also must be taken to properly compensate the devices or stability problems may result.

FIGURE 16.31 A basic active balanced output circuit. This configuration works well when driving a single balanced load.

FIGURE 16.32 An electronically balanced and floating output circuit. A stage such as this will perform well even when driving unbalanced loads.

16.3.3 Interconnecting Audio Equipment

Susceptibility to RFI is a common problem with active-balanced circuits. Strong radio signals often can be rectified by nonlinearities in the input operational amplifiers or transistors. Although wideband, low-distortion circuits are less prone to this problem, they are not immune to it. Therefore, signals outside the range of the active circuits must be filtered before they are inadvertently amplified or demodulated.

To reduce this problem, most manufacturers add small series resistors and capacitors to ground at the input terminals. Inductors also may be added, but they are susceptible to external magnetic fields. If package shielding is inadequate, the inductors may, in fact, pick up as much noise as they are supposed to filter out. Another RFI defense consists of placing donut-shaped ferrite beads on the input leads of affected stages.

Successful equipment interfacing is a function of how well the I/O circuits were designed and the care taken by the equipment installer. Mixing of balanced and unbalanced inputs and outputs can be done if care is taken in planning where signals go and how wiring is to be performed. It is important to remember that the ground potential of one device may not be the same as the ground potential of another.

Wiring Guidelines

When it comes to interconnecting audio systems, theory and practice often go in divergent directions. A system design may look elegant on paper, yet turn out to be a nightmare when all of the hardware is installed and turned on. Strict adherence to some basic wiring conventions will help prevent equipment interfacing problems:

- The microphone is the starting point for most audio work. Microphones are considered to be floating sources. Use only shielded twisted-pair cable for all microphone wiring. Connect the microphone shield only to the microphone case and input chassis (see Fig. 16.33). If a grounded-shell XLR connector is used, the shell pin may be connected to the ground (shield) wire. The shell ground provides complete RFI shielding at the point where two cables join. This allows users to serially connect several microphone cables and maintain complete shielding. Be certain, however, that the XLR shells are not allowed to come in contact with any grounded metallic structures or fixtures. For this reason, most microphone cables are wired with the shells not grounded. Special microphone cables containing two twisted pairs have proven effective for reducing induced hum pickup in problem locations. This cable is also useful for stereo microphones.
- For audio equipment other than microphones, use only two-conductor shielded cable and tie the shield of each cable to the signal ground point at the respective destination equipment chassis. Do not connect the source end of the shield. Do not use the shield of an audio cable to provide safety (AC) grounding under any circumstances. Instead, build a separate ground system to tie the equipment together.

FIGURE 16.33 Interconnection arrangement for a floating source such as a microphone. Note that the microphone shield is bonded to the microphone case. It should also be bonded to the microphone preamplifier chassis.

Equipment Grounding

It is a common misconception that the only way for an audio system to be free from hum and buzz is to secure a good Earth ground. While this certainly will help, it is only one part of the picture. The term *grounding* when applied to audio often refers loosely to the interconnection of individual chassis with the Earth. It is better, however, to view grounding as an entire system. One ground system mistake can seriously impair the performance of an otherwise perfect arrangement. Grounding schemes can range from simple to complex, but any system serves three primary purposes:

- It provides for operator safety.
- It protects electronic equipment from damage caused by transient disturbances.
- It diverts stray radio frequency energy away from sensitive audio equipment.

Many engineers view grounding mainly as a method to protect equipment from damage or malfunction. However, the most important element is operator safety. The 120-V AC line current that powers most audio equipment can be dangerous, even deadly, if improperly handled. Grounding of equipment and structures provides protection against wiring errors or faults that could endanger human life.

Several different approaches can be taken to designing a studio or facility ground system. But some conventions should always be followed to ensure a low resistance (and low inductance) ground that will perform as required. Proper grounding is important whether or not the facility is located in an RF field.

Figure 16.34 shows the recommended grounding arrangement for a typical broadcast facility. The configuration is referred to as a **star ground system** because of the way the various pieces of equipment are connected in a radial pattern around the central ground point. For larger systems, a star of stars system is used, as illustrated in Fig. 16.35.

Distribution Amplifiers

Often it is necessary in an audio system to connect a single source to several different loads. Although this can be accomplished simply by tying the inputs in parallel, it may be a risky solution. The parallel arrangement is simple but leaves the audio system vulnerable to problems caused by changing levels, ground loops, and wiring faults. With a parallel hookup, shorting one of the input lines will result in a complete loss of signal to all of the other inputs.

Distribution amplifier (DA) systems have been developed to solve these problems. DAs are available in stand alone and modular configurations. Stand-alone DAs are appropriate if only a small number of

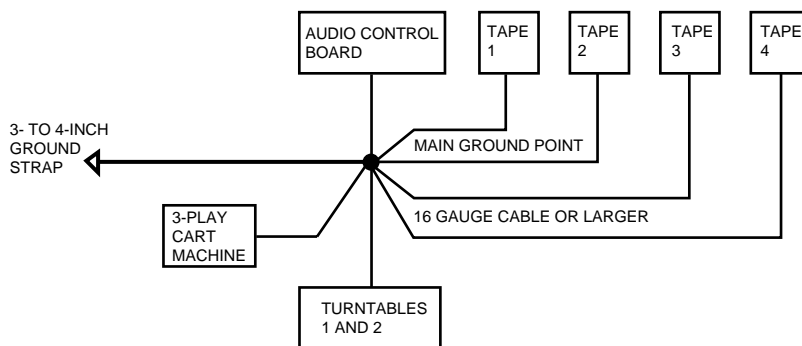

FIGURE 16.34 A typical grounding arrangement for a broadcast studio facility. The *main station ground point* is the reference from which all grounding is done at the facility.

FIGURE 16.35 A typical grounding arrangement for individual equipment rooms at a broadcast facility. The ground strap from the station ground point establishes a *local ground point* in each room, to which all source and control equipment is bonded.

sources need to be distributed. Modular DAs are better suited to multisource distribution. Generally, the modular approach is best if more than five channels must be distributed and they all can be fed conveniently from the same physical location. DAs are available with either fixed or adjustable output levels. If all of the devices being fed require approximately the same input level, then a fixed output DA with an overall gain control will be adequate. If, on the other hand, the expected destination levels vary, individual output adjustments are recommended.

DAs use transformer and active balanced inputs. Active balanced outputs may use one of two basic approaches: a resistive divider network or individual driver amplifiers. Figure 16.36 shows the resistive

FIGURE 16.36 A distribution amplifier output stage using resistive dividers. This system relies on a single high-current driver stage to feed all outputs.

FIGURE 16.37 A distribution amplifier output stage using individual driver amplifiers. With this arrangement, the failure of one driver will not cause the entire system to fail.

divider concept, whereas Fig. 16.37 shows the individual amplifier arrangement. Each approach has its benefits to users. Some engineers prefer the redundancy provided by having an amplifier for each output terminal. Such a design prevents a single component failure from crashing the entire system, but the cost is higher than for a comparable resistive divider circuit.

Audio Patch Bays

Designing patch bays into an audio system can provide a number of benefits to the users. Without patch bays, interconnections between the devices in a system are fixed, permanent, and difficult to access. If troubleshooting or setup adjustments are required, it usually is necessary to access the connections on the equipment itself. With patch bays, access to equipment inputs or outputs readily is available.

Most patch bays are configured with paired horizontal rows of vertically aligned three-conductor **tip, ring, sleeve (TRS)** jacks. The jacks on the top row are connected to the equipment outputs or sources. The bottom row of jacks are connected to the inputs or destinations. Although similar in appearance, PJ-051 patch plugs are not the same as $\frac{1}{4}$ -in. stereo phone plugs. The latter has a larger tip diameter and will damage the patch bay jacks.

If the signal path changes frequently, patch cords are used to complete the circuit between the desired jacks in the patch bay. Where parts of the system's circuit path are relatively permanent, switching jacks can be used. These jacks incorporate TRS terminals that are an integral part of the contacts that mate with the patch cord plug. When a pair of jacks is **normaled** (connected) to each other, the signal is routed through the pair; see Fig. 16.38. When a patch cord is inserted in either of the two normaled jacks, the circuit path is broken and the signal is routed through the cord. A more flexible approach, made possible by newer source and destination equipment (which does not require termination, typically $600\ \Omega$), is the *half-normaled* arrangement shown in Fig. 16.39. The source jack is wired to monitor the source without breaking its path to the destination jack's normaling contacts. The destination jack is wired as before. The insertion of a plug breaks the path and introduces a new source.

FIGURE 16.38 Schematic and symbol for *full-normaled* jacks.

FIGURE 16.39 Schematic and symbols for *half-normaled* jacks.

Defining Terms

Common mode gain: The gain of a differential amplifier fed by an unbalanced output signal (one referenced to ground).

Common mode rejection ratio (CMRR): A measure of how well a balanced input circuit rejects ground noise; it is the ratio of the differential gain and the common mode gain in decibels.

Differential gain: The gain of a differential amplifier fed by a balanced output signal.

Differential input: An amplifier input in which the signal is applied two complementary terminals that are not referenced to ground.

Normaled: The condition when, by design, two circuits are connected when a plug is absent from a patch panel point. The circuit is interrupted with the plug inserted, resulting in a new signal path.

Star ground system: A ground network constructed around a single, reference ground point so as to represent a star pattern.

Tip, ring, sleeve (TRS): The connection nomenclature for a three-conductor plug of the type used in patch bays.

16.4 Television and Video Production Systems

Curtis J. Chan

16.4.1 Introduction

Significant advances in television technology have been made since the early days of broadcasting. Present day television incorporates a multitude of diverse technological improvements in digital signal processing, tape and disk media recording, optical and electronic imaging, and distribution and transmission technologies. In its simplest form, the technology of television is based on the conversion of light rays from still or moving scenes and pictures into electronic signals for transmission, manipulation, or storage, and subsequent reconversion into visual images on a viewing or display device. A similar function is provided in the production of motion picture film; however, where film records the brightness variations of a complete scene on a single frame in a short exposure no longer than a fraction of a second, the elements of a television picture must be **scanned** one segment at a time. In the television system, a scene is dissected into a frame composed of a mosaic of picture elements (**pixels**). A picture element is the smallest area of a television picture capable of being delineated by an electrical signal passed through the system or part thereof. The number of picture elements or pixels in the completed picture, and their geometric characteristics of vertical height and horizontal width, provide information on the total amount of detail that the **raster** can display and on the sharpness of that detail. A pixel is defined as the smallest area of a television image that can be transmitted within the parameters of the system. This process is accomplished by

- Analyzing the image with a photoelectric device in a sequence of horizontal scans from the top to the bottom of the image to produce an electrical signal in which the brightness and color values of the individual picture elements are represented as voltage levels of a video waveform
- Transmitting the values of the picture elements in sequence as voltage levels of a video signal
- Reproducing the image of the original scene in a video signal display of parallel scanning lines on a viewing screen

Conceptually, the processing of a television signal starts with a camera whose lens focuses an image of a scene onto a photoelectric (charge-coupled device (CCD)) imager, which converts the optical signal into an electrical signal. The photosensitive surface of the imager is scanned with an electron beam, converting the represented optical image into an electrical signal in which variations in brightness are converted into their electrical voltage equivalent. The signal from the camera is then input to a processing amplifier that adds horizontal and vertical synchronizing pulses to time the picture tube scanning in synchronism with the camera. The processing amplifier also readies the signal for transmission where it is amplified and used to modulate a radio frequency (RF) carrier, using amplitude modulation (AM) for broadcasting.

The end user's receiver then receives the transmitted signal through a bandwidth-limited transmission channel, which consists of any one or combination of coaxial cable, microwave, satellite, fiber optic, or broadcast transmitter. In the television receiver, the modulated RF carrier is amplified and detected to restructure the video signal and synchronizing pulses. These signals are then used to drive the display device, usually a cathode-ray tube (CRT) or other display device, which reproduces an image of the original scene.

In the same way, the information content of a color picture produced by a compatible color television system can be described by the following:

- The information content consists of a combination of monochrome and color information since it is brought to the picture by the monochrome signal and by an auxiliary coloring signal called the chrominance signal.
- The information content consists of a combination of luminance and chromaticity information since it describes the distribution of luminance levels and chromaticity values in the picture.
- The information also consists of red, green, and blue primaries.

The information content of a video signal can be broken down into basic component definitions consisting of (1) luminance level, (2) monochrome level, (3) chromaticity value, (4) raster coordinates, (5) point image, (6) line image, and (7) picture element. Various recording, delivery, and playback systems can be developed through the use of the following.

The *luminance level* at a given point in a picture is the ratio of the luminance at that point to the maximum luminance occurring anywhere in the picture during an interval in time. Its value is between zero and unity. The reciprocal of the lowest luminance level in the scene is called the *contrast level* of that scene and the reciprocal of the luminance range is called the *contrast range*.

The *monochrome level* at a given point in a color television image is the luminance level in the monochrome picture, which appears in the absence of the chrominance signal.

The *chromaticity value* at a given point in a color television picture is the quantitative specification of the chromaticity at that point in terms of a suitable set of chromaticity coordinates.

The *raster coordinates* of a given point in a picture are a pair of numbers specifying the position of that point with respect to a suitable set of reference axes. The horizontal and vertical axes may be chosen along the upper edge and left-hand edge of the raster, respectively, and a distance equal to the raster height may be designated as unity along both axes. Therefore, raster coordinates of a point in a raster with a 4/3 aspect ratio would range between zero and unity for the vertical coordinate and between zero and 1.33 for the horizontal one.

The *point image* is the pattern of light formed on a television display in response to light received by a television camera from a single object point in its field of view. The position of any given point image on a display raster is determined by the position of the corresponding object point together with whatever geometric distortions may exist in the raster. Its position is also impacted by the line structure in the scanning raster unless its size is large in comparison with the distance between adjacent scanning lines, as happens when the object point lies beyond the camera field of focus.

The *line image* is the pattern of light formed on a television display in response to light received by a television camera from a uniformly illuminated ideally narrow line in the field of view. The position of any given line image on a reproducing raster is determined by the position of the corresponding object line in a manner analogous to that for a point image. A line image oriented perpendicular to the scanning path may be called a *transverse* line image, and one parallel to this path may be called a *longitudinal* line image.

As described earlier, a *picture element* is the smallest area of a television picture capable of being delineated by an electrical signal passed through the system or part thereof. The number of picture elements (pixels) in a complete picture and their geometric characteristics of vertical height and horizontal width provide information on the total amount of detail that the raster can display and on the sharpness of that detail, respectively.

Limiting Horizontal and Vertical Resolution

The image detail perceived by the eye is determined by the resolution capability of the reproducing system or the number of basic elements that can be reproduced. The overall *limiting resolution* of a television picture is expressed as the maximum number of alternate black and white lines that can be distinguished in a dimension equal to the height of the picture where both the black and white lines are counted. The detail of a scanned television picture is defined in terms of both **horizontal (H)** and vertical resolution.

The vertical resolution is determined by the number of horizontal scanning lines, which is the total number of horizontal black and white lines that can be distinguished or resolved in the picture height. Similarly, the horizontal resolution, the number of vertical lines that can be distinguished in a dimension equal to the picture height, is twice the number of cycles of the highest frequency in the video bandwidth in the time interval required for the scanning beam to traverse this dimension.

The *horizontal limiting resolution* of a television system is usually determined by its electrical bandwidth. Assuming that the aperture response (a universal criterion for specifying picture definition and other aspects of imaging system performance) of the system components is adequate to make the black-and-white line pair (two television lines) visible, the equation for horizontal resolution R_H is, therefore

$$R_H = 2C_H B_W / A_R N_L F_R$$

TABLE 16.5 Horizontal Resolution of the NTSC and PAL Broadcast Systems

B_W , MHz	4.2	5.0
N_L	525	625
C_H	0.85	0.80
Aspect ratio A_R	1.33 (4:3)	1.33 (4:3)
F_R , frames/s	29.97	25
R_H , lines	340	409

where

R_H = horizontal resolution

C_H = fraction of time in each scanning line devoted to the transmission of picture information after subtracting the time required for horizontal blanking

B_W = system bandwidth

A_R = aspect ratio

N_L = total number of scanning lines per frame

F_R = frame rate per second

For comparison, the horizontal resolution R_H of two broadcast systems discussed later are compared in Table 16.5. They are the National Television Systems Committee (NTSC) broadcast systems (U.S. and Japan) and phase alternate line (PAL) broadcast systems (Europe).

The *vertical limiting resolution* of a television system is the number of horizontal lines that can be distinguished in a dimension equal to the picture height and is limited by the number of active (visible) scanning lines. However, the actual value is lower because the vertical detail in the image is randomly located with respect to the scanning lines. The ratio of the vertical resolution to the number of scanning lines is called the *Kell factor* (K_F). It is not a precise number because it is subjective and depends on the width of the scanning lines. From 1934 to 1940, the Kell factor was given a value from 0.53 to 0.85. However, through earlier tests, K_F has been given an approximate value of 0.7.

The vertical resolution R_V is given by

$$R_V = C_V K_F N_L$$

where

R_V = vertical resolution

C_V = fraction of scanning lines that are visible after subtracting the lines that are removed by vertical blanking

K_F = Kell factor

N_L = total number of scanning lines

Table 16.6 compares the vertical resolutions of the NTSC and PAL broadcast systems.

TABLE 16.6 Vertical Resolution of the NTSC and PAL Broadcast Systems

	NTSC	PAL
C_V	0.92	0.92
N_L	525	625
K_F	0.7	0.7
R_V (lines)	343	408

Picture Elements (Pixels)

A television raster can be described as a grid of picture elements or pixels. The height of each pixel is the spacing between scanning lines divided by the Kell factor, and its width is the space on a scanning line occupied by one-half the cycle of the highest frequency in the transmission bandwidth. The number of pixels, which is equal to the product of the bandwidth and the fraction of time occupied by visible scanning lines, is a rough indicator of the information content of the image. The number of pixels (N_P) in a given image is

$$N_P = 2CK_F B_W/R_F$$

where

C = fraction of time occupied by active scanning after subtracting vertical and horizontal blanking periods

K_F = Kell factor

B_W = bandwidth of the system, Hz

R_F = frame rate, frames/s

For normal broadcast systems as described previously, the approximate number of pixels equals 148,000–150,000 for NTSC, 210,000 for PAL and 250,000 for sequential color with memory (SECAM).

Bandwidth Requirements

The bandwidth required by a television signal is one-half the number of pixels transmitted per second. The bandwidth B_W is given by the equation

$$B_W = 0.8F_R N_L R_H$$

where

B_W = system bandwidth

F_R = number of frames or complete pictures transmitted each second

N_L = number of scanning lines

R_H = horizontal resolution

The numerical constant of 0.8 is derived by the following:

$$B_W = (\text{cycles per frame}) (F_R)$$

$$\text{Cycles per frame} = (N_L) (\text{cycles per line})$$

$$\text{Cycles per line} = (0.5) (\text{aspect ratio}) (R_H)/0.84 = 0.8R_H$$

The factor 0.5 is the ratio of the number of cycles to the number of lines resolved. The aspect ratio in the equation is required because the horizontal resolution is measured in lines per picture height. The factor 0.84 is the fraction of the horizontal scanning interval that is devoted to signal transmission where the remainder is utilized for horizontal blanking. Choosing the optimum combination of B_W , F_R , N_L , and R_H for NTSC involved a series of tradeoffs. However, it can be said that the spectrum requirements of present day television systems required a wide bandwidth to resolve the fine detail of the picture while maintaining a high enough picture repetition rate to avoid objectionable flicker. As explained in the following text, the use of *interlace scanning* was devised to effectively reduce image flicker.

Scanning Lines and Fields

The image pattern of electrical charges on a camera tube target, corresponding to the brightness levels of a scene, are converted to a video signal in a sequential order of picture elements in the scanning process (see Fig 16.40). At the end of each horizontal line sweep, the video signal is blanked while the beam returns rapidly to the left side of the scene to start scanning the next line. This process continues until the image has been scanned from top to bottom to complete one field scan. That is why the television system employs a uniform linear scanning system. In other words, the camera sees the scene at a uniform rate and the receiver reconstructs the picture at the same rate as the camera scans it.

FIGURE 16.40 The interlace scanning pattern (raster) of the television image. (Source: Electronics Industries Association.)

After completion of this first field scan, at the midpoint of the last line, the beam again is blanked as it returns to the top center of the target where the process is repeated to provide a second field scan. The spot size of the beam as it impinges upon the target must be fine enough to leave unscanned areas between lines for the second scan. The pattern of scanning lines covering the area of the target, or the screen of a picture display, is called a raster. The ratio of the width of the raster and the resulting image is known as the picture ratio or more correctly, *aspect ratio*.

In general, countries with a 60-Hz power line standard use 525 horizontal lines laid down in sequence to form one complete picture, or frame, and there are 30 frames reproduced in every second. Countries with a 50-Hz power line standard, in general, produce a 625-line picture frame with 25 frames reproduced every second.

Interlaced Scanning

While 30 frames presented in rapid sequence will present an illusion of motion, flicker will be quite noticeable, particularly at the levels of illumination used on the television display device. Therefore, a repetition rate of 60 is more desirable to reduce the perception of flicker. However, signal bandwidths present a problem. Thus, to increase the rate, **interlaced** scanning is used. In so doing, the television frame is then divided into two parts, or **fields**, with each field presenting half of the information.

The net effect of the two fields is that the image repetition rate is increased by scanning all of the odd numbered lines and then scanning all of the even numbered lines. Then 60 images are presented to the eye without having to increase the system bandwidth. Because of the half-line offset for the start of the beam return to the top of the raster and for the start of the second field, the lines of the second field lie in between the lines of the first field. Thus, the lines of the two are interlaced. The two interlaced fields constitute a single television **frame**. Therefore, the main purpose of interlace scanning is to effectively reduce image flicker.

Reproduction of the camera image on a CRT is accomplished by a reversing of the process, with the scanning beam modulated in intensity by the video signal applied to an element of the electron gun. This control voltage to the CRT varies the brightness of each picture element on the phosphor screen. As a result of the retentivity of human vision, the eye perceives the rapidly repeated sequential display of scanning lines and rasters on the receiver display device as a continuous image.

Blanking of the scanning beam during the return trace is provided for in the video signal by a blacker-than-black pulse waveform. In addition, in most receivers and monitors another blanking pulse is generated from the horizontal and vertical scanning circuits and applied to the CRT electron gun to ensure a black screen during scanning retrace.

In conclusion, the interlaced scanning format, standardized for monochrome and compatible color, was chosen primarily for two partially related and equally important reasons:

- To eliminate viewer perception of the intermittent presentation of images, known as flicker
- To reduce video bandwidth requirements for an acceptable flicker threshold level

Perception of flicker is dependent primarily on two conditions:

- The brightness level of an image
- The relative area of an image in a picture

The 30-Hz transmission rate for a full 525-line television frame is comparable to the highly successful 24-frame-per-second rate of motion-picture film. However, at the higher brightness levels produced on television screens, if all 483 lines (525 less blanking) of a television image were to be presented sequentially as single frames, viewers would observe a disturbing flicker in picture areas of high brightness. For a comparison, motion-picture theaters on average produce a screen brightness of 10–25 fL, whereas a direct-view CRT may have a highlight brightness of 50–80 fL.

Through the use of interlaced scanning, single field images with one-half the vertical resolution capability of the 525-line system are provided at the high flicker-perception threshold rate of 60 Hz. Higher resolution of the full 490 lines (525 less vertical blanking) of vertical detail is provided at the lower flicker-perception threshold rate of 30 Hz. The result is a relatively flickerless picture display at a screen brightness of well over 50–75 fL, more than double that of motion-picture film projection. Both 60-Hz fields and 30-Hz frames have the same horizontal resolution capability.

The second advantage of interlaced scanning, compared to progressive scanning, is a reduction in video bandwidth for an equivalent flicker threshold level. Progressive scanning of 525 lines would have to be completed in 1/60 sec to achieve an equivalent level of flicker perception. This would require a line scan to be completed in half the time of an interlaced scan. The bandwidth then would double for an equivalent number of pixels per line.

The standards adopted by the Federal Communications Commission (FCC) for monochrome television in the U.S. specified a system of 525 lines per frame, transmitted at a frame rate of 30 Hz, with each frame composed of two interlaced fields of horizontal lines. Initially in the development of television transmission standards, the 60-Hz power line waveform was chosen as a convenient reference for vertical scan. Furthermore, in the event of coupling of power line hum into the video signal or scanning/deflection circuits, the visible effects would be stationary and less objectionable than moving **hum bars** or distortion of horizontal-scanning geometry. In the United Kingdom and much of Europe, the 50-Hz interlaced system was chosen for many of the same reasons. With improvements in television receivers, the power line reference was replaced with a stable crystal oscillator.

The existing 525-line monochrome standards were retained for color in the recommendations of the NTSC for compatible color television in the early 1950s. The NTSC system, adopted in 1953 by the FCC, specifies a scanning system of 525 horizontal lines per frame, with each frame consisting of two interlaced fields of 262.5 lines at a field rate of 59.94 Hz; 42 of the 525 lines in each frame are blanked as black picture signals and reserved for transmission of the vertical scanning synchronizing signal. This results in 483 visible lines of picture information.

Synchronizing Video Signals

In monochrome television transmission, two basic synchronizing signals are provided to control the timing of picture-scanning deflection: horizontal sync pulses at the line rate and vertical sync pulses at the field rate in the form of an interval of wide horizontal sync pulses at the field rate. Included in the interval are equalizing pulses at twice the line rate to preserve interlace in each frame between the even and odd fields (offset by a half-line).

In color transmissions, a third synchronizing signal is added during horizontal scan blanking to provide a frequency and phase reference for color signal encoding circuits in cameras and decoding circuits in receivers. These synchronizing and reference signals are combined with the picture video signal to form a composite video waveform.

The scanning and color-decoding circuits in receivers must follow the frequency and phase of the synchronizing signals to produce a stable and geometrically accurate image of the proper color **hue** and **saturation**. Any change in timing of successive vertical scans can impair the interlace of the even and odd fields in a frame. Small errors in horizontal scan timing of lines in a field can result in a loss of resolution

in vertical line structures. Periodic errors over several lines that may be out of the range of the horizontal scan automatic frequency control circuit in the receiver will be evident as jagged vertical lines.

16.4.2 Television Industry Standards

There are three primary analog color transmission standards in use today:

- *NTSC* is used in the U.S., Canada, Central America, most of South America, and Japan. In addition, *NTSC* is used in various countries or possessions heavily influenced by the U.S.
- *PAL* is used in England, most countries and possessions influenced by the British Commonwealth, many western European countries, and China. Variation exists in *PAL* systems.
- *SECAM* is used in France, countries and possessions influenced by France, and the former USSR, including former East Germany, and other areas influenced by Russia.

The three standards are incompatible for a variety of reasons.

Television transmitters in the U.S. operate in three frequency bands:

- Low-band VHF, channels 2–6
- High-band VHF, channels 7–13
- UHF, channels 14–83 (UHF channels 70–83 currently are assigned to mobile radio services)

Table 16.7 shows the frequency allocations for channels 2–83. Because of the wide variety of operating parameters for television stations outside the U.S., this section will focus primarily on TV transmission as it relates to the U.S.

TABLE 16.7 Frequency Bands for Television Broadcasting in the U.S.

Channel Designation	Frequency Band, MHz	Channel Designation	Frequency Band, MHz	Channel Designation	Frequency Band, MHz
2	54–60	29	560–566	56	722–728
3	60–66	30	566–572	57	728–734

22	518–524	49	680–686	76	842–848
23	524–530	50	686–692	77	848–854
24	530–536	51	692–698	78	854–860
25	536–542	52	698–704	79	860–866
26	542–548	53	704–710	80	866–872
27	548–554	54	710–716	81	872–878
28	554–560	55	716–722	82	878–884
				83	884–890

Maximum power output limits are specified by the FCC for each type of service. The maximum **effective radiated power (ERP)** for low-band VHF is 100 kW, for high-band VHF it is 316 kW, and for UHF it is 5 MW. The ERP of a station is a function of transmitter power output (TPO) and antenna gain. ERP is determined by multiplying these two quantities together, and subtracting transmission line loss.

The second major factor that affects the coverage area of a TV station is antenna height, known in the broadcast industry as *height above average terrain* (HAAT). HAAT takes into consideration the effects of the geography in the vicinity of the transmitting tower. The maximum HAAT permitted by the FCC for a low- or high-band VHF station is 1000 ft (305 m) east of the Mississippi River, and 2000 ft (610 m) west of the Mississippi. UHF stations are permitted to operate with a maximum HAAT of 2000 ft (610 m) anywhere in the U.S. (including Alaska and Hawaii).

The ratio of visual output power to **aural** output power can vary from one installation to another; however, the aural is typically operated at between 10 and 20% of the visual power. This difference is the result of the reception characteristics of the two signals. Much greater signal strength is required at the consumer's receiver to recover the visual portion of the transmission than the aural portion. The aural power output is intended to be sufficient for good reception at the fringe of the station's coverage area, but not beyond. It is of no use for a consumer to be able to receive a TV station's audio signal, but not the video.

Two classifications of **low power TV (LPTV)** stations have been established by the FCC to meet certain community needs. They are

- **Translator.** A low-power system that rebroadcasts the signal of another station on a different channel. Translators are designed to provide fill-in coverage for a station that cannot reach a particular community because of the local terrain. Translators operating in the VHF band are limited to 100-W power output (ERP), and UHF translators are limited to 1 kW.
- **Low-Power Television.** A service recently established by the FCC designed to meet the special needs of particular communities. LPTV stations operating on VHF frequencies are limited to 100-W ERP and UHF stations are limited to 1 kW. LPTV stations originate their own programming and can be assigned by the FCC to any channel, as long as sufficient protection against interference to a full-power station is afforded.

The **composite video** waveform is shown in Fig. 16.41. The actual radiated signal is inverted, with modulation extending from the synchronizing pulses at maximum carrier level (100%) to reference picture white at 7.5%. Because an increase in the amplitude of the radiated signal corresponds to a decrease in picture brightness, the polarity of modulation is termed negative.

Composite Video

The term composite is used to denote a video signal that contains: picture luminance and chrominance information and timing information for synchronization of scanning and color signal processing circuits (blanking, sync, and color burst). The television waveform is a complex combination of pulses and sine waves conveying seven different types of information necessary to satisfactorily reconstruct a television picture. The seven components, when properly combined into one continuous electrical wave, form a television *composite video waveform* or simply, composite video. The seven components of the composite video signal are

- Horizontal line synchronizing pulses
- Color sync (burst)
- Setup (black) level
- Picture elements
- Color hue (tint)
- Color saturation (vividness)
- Field synchronizing pulses

Referring to Fig. 16.42, nearly one-third of the total peak-to-peak voltage amplitude range of the composite video waveform is used for synchronizing information (horizontal, color burst, field synchronizing pulses).

FIGURE 16.41 The principle components of the NTSC color system. (Source: Electronics Industries Association.)

FIGURE 16.42 Sync pulse widths for the NTSC color system. (Source: Electronics Industries Association.)

If the remaining two-thirds of the composite video is removed (**setup** level, picture elements, color hue, and saturation), only a series of pulses will remain. The series of pulses are called *composite sync*. This may be further defined as follows:

Line, or *horizontal sync*, occurs once every $63.5 \mu\text{s}$, or at approximately a 15-kHz rate and is used to synchronize the movement of the scanning electron beam from left to right in the receiver to that in the camera.

Field, or *vertical sync*, occurs once every 16.6 ms, or at approximately a 60-Hz rate and is used to synchronize the movement of the scanning electron beam from bottom to top of the picture between subsequent fields of information.

Color sync, or *burst*, a 3.58-MHz occurs one per line for a specific duration and at a specific time and is used to ensure that the color information displayed by the receiver is identical to that picked up by the camera.

The nominal video and sync levels (in IRE units) are listed in Table 16.8

The Horizontal Blanking Interval

As shown in Fig. 16.42, the *horizontal blanking interval* includes *front porch*, *leading edge of sync*, *horizontal sync*, *breezeway*, *color burst*, and *back porch*. The total time duration of the interval is approximately $11.1 \mu\text{s}$. The definitions of the various components are described next.

Front Porch

The primary function of the front porch period is to blank the television receiver just before the start of horizontal retrace, the time during which the electron beam is returned to the left side of the raster to begin tracing the next picture line. In the days of quadruplex videotape recorders, the reproduce heads were switched during this time and the switch time was called *front porch switch*, *switch time pulse* or *blanking switch pulse*.

Horizontal Sync

The leading edge of the pulse synchronizes horizontal line sweeps of the receiver and camera. In videotape recorders, this edge is used to identify electronically the start of the blanking interval.

Back Porch

In the television receiver, the back porch interval provides picture blanking until the start of the active portion of the line. In some videotape recorders, the interval is used to re-establish the DC level of the signal after detection.

Color Sync or Burst

The color burst signal is normally included only during color transmission and is the color sync portion of the horizontal blanking interval. It provides a fixed reference of constant phase and amplitude to the receiver to enable it to decode correctly the varying phase and amplitude of the color information on the line that follows.

There are a number of other timing signals in the television system that are either derived from horizontal rate information or have a definite relationship to it. They are the following:

TABLE 16.8 Video and Sync Levels in IRE Units

Signal Level	IRE Level
Reference white	100
Blanking level width measurement	20
Color burst sine wave peak	+20 to -20
Reference black	7.5
Blanking	0
Sync pulse width measurement	-20
Sync level	-40

Horizontal Drive

This is a pulse approximately $6.35 \mu\text{s}$ long whose leading edge coincides with the leading edge of horizontal sync.

Burst Flag or Burst Key

This is a pulse approximately $2.3 \mu\text{s}$ long whose leading edge is delayed approximately $5 \mu\text{s}$, from the leading edge of sync. It is used to gate in the correct amount of color subcarrier on the back porch of the composite video signal.

Color Subcarrier

To minimize the visual effects of the color subcarrier signal on black and white (B/W) televisions, it was decided that the line pattern should be stationary and cross the picture at 45° from the horizontal. This was achieved by making the subcarrier frequency an odd multiple of half the horizontal line frequency. In that case, alternate lines in the same field have the subcarrier 180° out of phase or the line ends at half a subcarrier cycle. Because of the odd number of lines in the raster, the interlaced field has a $\frac{1}{4}$ cycle shift. One of the results of this system is that it takes two frames (four fields) for the color signal to get back to where it started with regard to sync. Thus, there are four fields in the complete color picture. Also, the beat between the color signal and the sound carrier was considered. To make this beat stationary, it was decided to alter the subcarrier and the scanning frequencies. The final value for the subcarrier signal was decided to be 3.579545 MHz and horizontal sync is $2/455$ times this value or 15,734.3 Hz, changing vertical sync to 59.94 Hz. The color subcarrier of 3.579545 MHz is an odd multiple of half-line frequency to produce minimum sound and picture interference on B/W receivers and minimum sound interference on color televisions.

Initial calculations indicated that a frequency 455 times half-line rate would be ideal.

$$F_{sc} = (15,750/2)(455) = 3.583125 \text{ MHz}$$

However, this frequency when beat with the sound carrier of 4.5 MHz produced an even harmonic of the line rate resulting in visible picture artifacts as a function of audio content. Instead, the horizontal frequency was changed from 15,750 to 15,734.3 Hz (actually 15,734.264 Hz) and the vertical line rate was changed from 60 to 59.94 Hz. Taking the 455th harmonic of half the new line frequency resulted in

$$F_{sc} = (15,734.264)(455)/2 = 3.579545 \text{ MHz.}$$

Thus, a continuous RF signal of exactly $3.579545 \text{ MHz} \pm 5 \text{ Hz}$ is used to define phase and amplitude of the coloring information in the video waveform. The relationship between color subcarrier and the prime timing signals are

$$\text{Horizontal rate} = (2) (3.579545 \text{ MHz})/455 = 15,734.3 \text{ Hz}$$

$$\text{Horizontal period} = 63.55 \mu\text{s}$$

$$\text{Vertical rate} = \text{H Rate}/262.5 = 15,734.3/262.5 = 59.94 \text{ Hz}$$

$$\text{Vertical period} = 16.68 \text{ ms}$$

$$\text{Frame rate} = \text{H Rate}/525 = 15,734.3/525 = 29.97 \text{ Hz}$$

$$\text{Frame period} = 33.36 \text{ ms} = 1/29.97 \text{ Hz}$$

Composite Blanking

This is a signal that contains both vertical and horizontal rate timing pulses. The pulse width for horizontal blanking is $11.1 \mu\text{s}$ in duration and 21 lines in duration for vertical blanking. The vertical blanking period is approximately 21 lines in duration for NTSC. The most important area of the vertical interval is the nine-line period comprising the pre-equalizing pulses, the serrated vertical sync pulse, and the postequalizing pulses. The balance of the interval is used in transmission systems for the insertion of active test signal information and other resetting or calibration signals for videotape recording.

Pre-equalizing Pulses

The function of the six pre-equalizing pulses present at the start of the vertical blanking interval is to ensure that the television picture maintains proper interlace. There are six of these pulses, each approximately $2.4 \mu\text{s}$ wide, occurring during a period of three television lines, and so they are said to occur at *twice line rate* or *half-line period*, a frequency of approximately 31.5 kHz. The way in which these pulses maintain interlace is determined by the fact that although there are always six pulses present at the start of the vertical interval, the timing relationship of these six pulses differ on succeeding intervals.

Vertical Sync

The vertical sync pulse portion of the vertical blanking interval is called the serrated pulse, since it is broken into six equal parts, or serrations, each approximately $4.5 \mu\text{s}$ wide. The vertical sync has a much greater average negative value than the equalizing pulse period. This large negative-to-positive value ratio is widely used in television equipment to develop a single pulse, which provides the vertical time reference for the system.

Post-equalizing Pulses

These six pulses, which are identical to the pre-equalizing pulses, have no current use in modern day television systems.

Back Porch

The balance of the vertical blanking interval from the end of the nine-line synchronizing period to the start of the first active scanning line is called the back porch and contains the correct number of horizontal sync pulses and line intervals to complete the interval. In a color signal, burst is also present in its proper relationship to horizontal sync. The back porch period is also used for the insertion of special test and reference signals to check the quality of television transmission and recording devices.

Field and Frame Identification

All modern day videotape recorders, editing systems and other processing devices place great reliance on some means of identifying a television frame or field in the reproduced picture so that the playback may be electronically compared to the station synchronizing signals. Each television picture is formed from two interlaced fields, which are then called a frame. There is one complete vertical blanking interval associated with each field. Although each blanking interval contains the same type of information, they are different from each other by the following.

If we consider the vertical interval to be the start of the field, and compare the intervals for fields one and two, six differences become apparent:

1. The start of field one is preceded by a full line of video; the start of field two is preceded by one-half line of video.
2. The leading edge of vertical sync of field one is time coincident with the leading edges of horizontal sync pulses; for field two, it is half-way between.
3. The first active scanning line in field one starts at the top left corner raster; in field two, it starts at the top center.
4. The last active scanning line in field one ends at the bottom center of the raster; in field two, it ends at the bottom right corner.
5. The scanning lines for field one are numbered beginning with the first equalizing pulse, in field two with the second equalizing pulse.
6. The first horizontal sync pulse in the interval for field one occurs one-half line after the last post-equalizing pulse; in field two, it occurs a full line after the last post-equalizing pulse.

Color Signal Encoding

To facilitate an orderly introduction of color television broadcasting in the U.S. and other countries with existing monochrome services, it was essential that the new transmissions be compatible. In other words, color pictures would provide acceptable quality on unmodified monochrome receivers. In addition,

because of the limited availability of RF spectrum, another related requirement was the need to fit approximately 2-MHz bandwidth of color information into the 4.2-MHz video bandwidth of the existing 6-MHz broadcasting channels with little or no modification of existing transmitters. This is accomplished using the band-sharing color signal system developed by the NTSC and by taking advantage of the fundamental characteristics of the eye regarding color sensitivity and resolution.

The video-signal spectrum generated by scanning an image consists of energy concentrated near harmonics of the 15,734-Hz line scanning frequency. Additional lower amplitude sideband components exist at multiples of 60 Hz (the field scan frequency) from each line scan harmonic. Almost no energy exists halfway between the line scan harmonics, that is, at odd harmonics of one-half line frequency. Thus, these blank spaces in the spectrum are available for the transmission of a signal for carrying color information and its sideband. In addition, a signal modulated with color information injected at this frequency is of relatively low visibility in the reproduced image because the odd harmonics are of opposite phase on successive scanning lines and in successive frames, requiring four fields to repeat. Furthermore, the visibility of the color video signal is reduced further by the use of a subcarrier frequency near the cutoff of the video bandpass.

In the NTSC system, the red, green, blue (RGB) outputs from the camera are fed to an encoder whose functions are the following and can be seen in Fig. 16.43.

The first function is to derive the brightness or luminance signal E_Y by suitable combinations of E_R , E_G , and E_B . The luminance signal is derived from components of the three primary colors, red, green, and blue in the proportions for *reference white* E_Y as follows:

$$E_Y = 0.299E_R + 0.587E_G + 0.114E_B$$

Rounding off becomes

$$E_Y = 0.30E_R + 0.59E_G + 0.11E_B$$

These transmitted values equal unity for white and thus result in the reproduction of colors on monochrome receivers at the proper luminance level. This is known as the constant-luminance principle. *Luminance*, therefore, is the portion of the signal that will be used by B/W receivers to display the brightness information of the color camera signal and consists of the proportions of the three camera pickup tubes already stated. It will be combined with the decoded color difference signals in the color receiver to give the original RGB signals that existed at the color camera outputs before encoding.

The second function of the encoder is to derive the I (in phase) color difference signal E_I by suitable combinations of E_R , E_G , and E_B in the proportion

$$E_I = 0.60E_R - 0.28E_G - 0.32E_B$$

and to pass this signal through a 1.5-MHz low-pass filter to the I channel input of a balanced modulator.

The third encoder function is to derive the Q (quadrature) color difference signal E_Q by suitable combinations of E_R , E_G , and E_B in the proportion

$$E_Q = 0.21E_R - 0.52E_G - 0.31E_B$$

and to pass this signal through a 0.5-MHz low-pass filter to the Q channel input of a balanced modulator.

FIGURE 16.43 Vectorscope representation for vector and chroma amplitude relationships in the NTSC system. (Source: Electronics Industries Association.)

The fourth encoder function is to use the bandlimited I and Q signals to modulate a suppressed subcarrier balanced modulator, the output phase of which represents hue and the output amplitude of which represents saturation. This is the chrominance signal and consists of sideband information generated by a suppressed subcarrier modulator, which is quadrature modulated by a wide-band color difference signal (I) and a narrow-band color difference signal (Q). The instantaneous phase of the chroma signal defines hue; the instantaneous amplitude of chroma defines saturation. The chroma signal cancels out in a B/W receiver because of the half line offset between subcarrier and line rate causing the chroma phase to reverse itself at the frame rate. The chroma signal in a color receiver is decoded to its original ($R-Y$) and ($B-Y$) components; the missing ($G-Y$) is developed by combining portions of $R-Y$ and $B-Y$ and the three color difference signals ($R-Y$), ($B-Y$) and ($G-Y$) are combined with the luminance signal $+Y$ to give R , G , and B signals to drive the individual guns of the CRT.

The fifth function is to combine the luminance (E_Y) signal with the chrominance signal.

The last encoder function is to add sync and color burst to the combined luminance and chrominance signal. Color burst consists of 8–11 cycles of the 3.579545-MHz subcarrier inserted in the back porch of horizontal blanking at an amplitude of 40-IRE divisions peak-to-peak where IRE is a unit named for the Institute of Radio Engineers. Its function is to phase lock a complementary crystal oscillator in the color receiver to the encoder to permit correct resultant hue on the color receiver after decoding. The final composite color video output of the encoder consists of the combination of luminance, chrominance, sync, and color burst.

In conclusion, the color signal consists of two chrominance components, $I(E_I)$ and $Q(E_Q)$, transmitted as amplitude modulated sidebands of two 3.579545-MHz subcarriers in quadrature (differing in phase by 90°). The subcarriers are suppressed, leaving only the sidebands in the color signal. Suppression of the carriers permits demodulation of the color signal as two separate color signals in a receiver by reinsertion of a carrier of the phase corresponding to the desired color signal. This system for recovery of the color signals is called *synchronous demodulation*.

Chrominance Bandwidth Requirements

Extensive research done by NTSC members in the late 1940s and early 1950s proved that the color acuity of human vision was at maximum for certain colors and minimum for others. By placing colored chips in a random pattern and having individuals with normal color vision identify the colors and then repeating the test by rearranging the chips and doubling the distance each time, these studies showed that in the region of yellow-orange the eye could distinguish color differences when the detail was quite small, whereas in the region of green-cyan, small objects were perceived as shades of gray.

On the basis of these tests, it was decided to shift the $R-Y$ and $B-Y$ signals 33° counterclockwise to place the shifted $R-Y$ signal on the axis of maximum acuity and the shifted $B-Y$ signal on the axis of minimum acuity. The bandwidth of the shifted $R-Y$ signal was limited to 1.5 MHz by a low-pass filter and this bandlimited shifted $R-Y$ signal was referred to as the I signal (in phase). The bandwidth of the shifted $B-Y$ signal was limited to 0.5 MHz by a low-pass filter and this bandlimited shifted $B-Y$ signal was referred to as the Q signal (quadrature).

As both signals were shifted the same amount, their original 90° relationship was maintained and the previous analysis of $R-Y$ and $B-Y$ to generate saturation and hue information still applied. Therefore, the values of E_I and E_Q as stated previously with the reduction factors are

$$E_I = 0.60E_R - 0.28E_G - 0.32E_B$$

$$E_Q = 0.21E_R - 0.52E_G - 0.31E_B$$

The vectorial in Fig. 16.43 shows the location of the primary and complementary colors with respect to the I and Q axis for 100% saturated corrected signals.

Color-Signal Decoding

Each of the two chroma signal carriers (E_I and E_Q) can be recovered individually by means of **synchronous detection** (using quadrature synchronous detectors), followed by suitable filtering. The E_I and

FIGURE 16.44 Matrix for obtaining color difference signals E_I and E_Q signals.

E_Q components can be used in a simple matrix to derive the needed $R-Y$, $B-Y$, and $G-Y$ signals. The equations that form the matrix are

$$\begin{aligned}
 E_B - E_Y &= 1.7E_Q - 1.10E_I \\
 E_R - E_Y &= 0.62E_Q + 0.96E_I \\
 E_G - E_Y &= -0.65E_Q - 0.28E_I
 \end{aligned}$$

In performing the matrix operation, the E_I and E_Q signals are time coincident by adding delay in the wide-band E_I channel. Following such delay equalization, the preceding matrix operation might be performed by using a pair of phase splitters, to obtain plus and minus E_I and E_Q signals, and then combining these signals through suitable resistive networks (see Fig. 16.44). A set of quadrature demodulators may be used to obtain directly the desired color difference signals $R-Y$ and $B-Y$. If needed, a third demodulator can be employed to obtain the remaining color difference signal $G-Y$. Primary color signals of the form E_R , E_G , and E_B are required to operate a three gun color display in a television receiver. These signals may be obtained by combining the respective color difference signals with the luminance signal. This combining function may occur in external adding circuits, so that the primary color signals E_R , E_G , and E_B are applied, respectively, to one control electrode of each gun of the display. These signals can also be combined in the picture tube by applying a negative polarity luminance signal $-E_Y$ to each of the cathodes and by applying the appropriate color difference signals $E_R - E_Y$, $E_B - E_Y$, and $E_G - E_Y$ to the respective control grids of the picture tube electron guns. The former operation can be then called *RGB operation* and the latter *color-difference operation*.

16.4.3 Transmission Equipment

Television transmitters are classified in terms of their operating band, power level, final-tube type, translators, and cooling method. The transmitter is divided into two basic subsystems: The *visual* section accepts the video input, amplitude modulates a radio frequency (RF) carrier, and amplifies the signal to feed the antenna system. The *aural* section accepts the audio input, frequency modulates a separate RF carrier and amplifies the signal to feed the antenna system. In the U.S., the ratio of aural power permitted by FCC Rules and Regulations may be between 10 and 20% of the peak signal power. The visual and aural signals are combined to feed a single radiating system.

The differences in transmitter design between low VHF, high VHF, and UHF are mainly in the up-converter and the output power level. Low VHF are channels 2–6, and high VHF are channels 7–13. UHF are channels 14–83, except for channels 70–83, presently assigned to mobile radio service. Present-day practice is to use an exciter operating at or near the intermediate frequency (IF) followed by an up-converter, which translates the IF signal to the desired channel frequency. In most cases, distortion corrections can be done at IF, although some are done at baseband and RF (see Table 16.9).

TABLE 16.9 Power and Height Limitations

Band	Channels	ERP, kW	Height, ft (m)	Zone
Low VHF	2–6	100	1000 (305)	1
			2000 (610)	2, 3
High VHF	7–13	316	1000 (305)	1
			2000 (610)	2, 3
UHF	14–69	5000	2000 (610)	1, 2, 3

Transmitter Classification

- *Power Output.* Output power refers to the peak power of the visual transmitter.
- *Modulation Level.* Transmitters classified by level are of the IF type. Some of the reasons for using IF modulation are ease of correcting distortions, ease in vestigial sideband shaping, and economic advantages to the manufacturer. This is because only one type of exciter is required for the VHF band, and only one basic design is required for the UHF band.
- *Final-Stage Type.* Solid-state devices generally are used for VHF transmitters and for lower level UHF transmitters, and **klystrons** are used for UHF above about 10 kW. The choice is dictated by the device that will best operate at the required frequency, factoring in initial cost, operating cost per hour, and the cost of the auxiliary equipment.
- *Cooling.* Cooling can be by water, air, vapor, or a combination of these. Again, operating frequency, operating costs, device life, noise, and efficiency determine the final selection.
- *Translators.* Low-power stations, or translators, rebroadcast another station's programs on another frequency, usually in the grade B service area of the mother station. They do not originate their own programs and their power output is limited to 100-W VHF and 100-W UHF.
- *Low-Power Stations.* These are translators, except that they originate programs and can be assigned to any channel meeting the FCC rules. The power limitations are 100-W VHF and 1000-W UHF with the stipulation that they do not interfere with other television stations even if it requires reducing their power output to a few watts.

Transmitter Design Considerations

Each manufacturer has a particular philosophy with regard to the design and construction of a broadcast TV transmitter. Some generalizations can, however, be made with respect to basic system design.

When the power output of a TV transmitter is discussed, the visual section is the primary consideration. Output power refers to the peak power of the visual section of the transmitter (peak of sync). The FCC-licensed effective radiated power is equal to the transmitter power output minus feedline losses times the power gain of the antenna.

A low-band VHF station can achieve its maximum 100-kW power output through a wide range of transmitter and antenna combinations. A 35-kW transmitter coupled with a gain of 4 antenna would work, as would a 10-kW transmitter feeding an antenna with a gain of 12. Reasonable pairings for a high-band VHF station would range from a transmitter with a power output of 50 kW feeding an antenna with a gain of 8, to a 30-kW transmitter connected to a gain of 12 antenna. These combinations assume reasonable feedline losses. To reach the exact power level, minor adjustments are made to the power output of the transmitter, usually by a front panel power trim control.

UHF stations, to achieve their maximum licensed power output, are faced with installing a very high-power transmitter. Typical pairings include a transmitter rated for 220 kW and an antenna with a gain of 25, or a 110-kW transmitter and a gain of 50 antenna. In the latter case, the antenna could pose a significant problem. UHF antennas with gains in the region of 50 are possible, but not advisable for most

installations because of the coverage problems that can result. High-gain antennas have a narrow vertical radiation pattern that can reduce a station's coverage in areas near the transmitter site.

At first examination, it might seem reasonable and economical to achieve licensed ERP using the lowest transmitter power output possible and highest antenna gain. Other factors, however, come into play that make the most obvious solution not always the best solution. Factors that limit the use of high-gain antennas include

- The effects of high-gain designs on coverage area and signal penetration
- Limitations on antenna size because of tower restrictions, such as available vertical space, weight, and windloading
- The cost of the antenna

The amount of output power required of a transmitter will have a fundamental effect on system design. Power levels dictate whether the unit will be of solid-state or vacuum tube design; whether air, water, or vapor cooling must be used; the type of power supply required; the sophistication of the high-voltage control and supervisory circuitry; and many other parameters.

Elements of the Transmitter

The design of a television transmitter may differ widely from manufacturer to manufacturer depending upon the frequency band and power rating. All transmitters, however, must include the following components:

1. Aural pre-emphasis to pre-emphasize the high-frequency components in accordance with FCC requirements.
2. Processing amplifiers to correct deficiencies such as improper sync level, in the input visual signal and to provide DC restoration.
3. Visual and aural carrier generators with the frequency tolerances specified by the FCC.
4. Visual and aural modulators.
5. Filters to remove the lower sidebands of the modulated visual carriers and to remove spurious frequency components from both carriers.
6. Linearity correction devices in the visual chain to compensate for incidental phase modulation and differential gain. Ideally, these corrections should be made in both the video and RF domains.
7. Intermediate and final power amplifiers.

Figure 16.45 shows the audio, video, and RF paths for a typical television transmitter. Referring to Fig. 16.45, video is first input to a video processing amplifier and equalizer unit within the video processing block. The processing amplifier performs the following operations: (1) video input amplifications, (2) receiver delay equalization, (3) video clamping and hum cancellation, (4) phase-delay compensation, (5) white clipping, and (6) sync regeneration.

The processed video is converted to amplitude modulation of an IF frequency, either on a carrier generated by a crystal oscillator or by a frequency synthesizer. The modulated IF is band-shaped in a vestigial sideband filter using a surface-acoustic-wave (SAW) filter. Envelope delay correction is not required for the SAW filter because of the uniform delay characteristics of the device. Envelope-delay compensation may, however, be needed for other parts of the transmitter. The SAW filter provides many benefits to transmitter designers and operators because it requires no adjustments and is stable with respect to temperature and time. Envelope-delay compensation, however, might be required for other parts of the transmitter.

The modulated visual IF signal is processed for distortion corrections and subsequent RF transmission in the following stages: (1) power amplifier linearity correction, (2) power amplifier group delay correction, (3) driver amplifier linearity correction, (4) incidental phase modulation correction, (5) RF up-conversion, and (6) channel bandpass filtering.

The IF power amplifier and the final power amplifiers then raise the power level to the station license requirement. An RF sample, obtained from a directional coupler installed at the output of the transmitter,

FIGURE 16.45 Simplified block diagram of a VHF television transmitter.

is used in an automatic power-level control circuit located in the RF processor section. A color-notch filter is used to provide the necessary additional attenuation of the lower sideband at 3.58 MHz, and a harmonic filter is used to attenuate out-of-band radiation as required by the FCC. Additional sample couplers provide signals for the following monitoring facilities: (1) voltage standing wave ratio (VSWR) metering, (2) VSWR protection, (3) RF for the demodulator, and (4) RF for the spectrum analyzer and sideband units.

Concurrently with the processing of video, audio is input and pre-emphasized to the 75- μ s standard and used to frequency modulate the IF carrier generated in the oscillator section. The modulated signal is then up-converted to the final RF carrier frequency and passed to the intermediate power amplifier (IPA) and power amplifier (PA) stages. The PA raises the output energy of the transmitter to the desired RF operating level. Harmonic filters are employed to attenuate out-of-band radiation of the audio and video signals to ensure compliance with FCC requirements. Filter designs vary depending on the manufacturer, however, most are of coaxial construction utilizing L and C components housed within a pre-packaged assembly. Stubfilters are also used, typically adjusted to provide maximum attenuation at the second harmonic of the operating frequency of the video and the audio carriers.

In addition, a color notch filter is required at the output of the transmitter because imperfect linearity of the IPA and PA stages introduces unwanted modulation products. The filtered video and audio outputs are fed to a hybrid diplexer where the two signals are combined to feed the antenna. For installations that require dual-antenna feedlines, a hybrid combiner with quadrature-phased outputs is used. Depending on the design and operating power, the color notch filter, aural and visual harmonic filters, and diplexer may be combined into a single mechanical unit.

The transmitter block diagram of Fig. 16.45 also shows separate video and audio PA stages. This configuration is normally used for high-power transmitters. Low-power designs often use a combined mode in which the audio and video signals are added prior to the PA. This approach offers a simplified system, but at the cost of additional precorrection of the input video signal. PA stages often are configured so that

the circuitry of the video and audio amplifiers are identical, providing backup protection in the event of a visual PA failure. The audio PA could then be reconfigured to amplify both the audio and the video signals, at reduced power.

Antenna System

The main goal of the antenna is to couple the transmitter to space by converting its electrical output energy to coherent electromagnetic radiation. This coupling is accomplished in free space from one or more radiating-antenna element that is excited by modulated RF currents. Although, by definition, the radiated energy is composed of mutually dependent magnetic and electric vector fields, conventional practice in television engineering is to measure and specify radiation characteristics in terms of the electric field only. Additionally, other primary antenna specifications focus on vertical directivity and gain, horizontal directivity, polarization, input impedance and bandwidth, and power handling capacity.

The field vectors may be polarized, or oriented, horizontally, vertically, or circularly. Television broadcasting, however, has used horizontal polarization for the majority of installations worldwide. Both horizontal and circular polarization designs are suitable for tower-top or side-mounted installations. The latter option is dictated primarily by the existence of a previously installed tower-top antenna. On the other hand, in metropolitan areas where several antennas must be located on the same structure, either a stacking or candelabra-type arrangement is feasible. Another approach to TV transmission involves combining the RF outputs of two or more stations and feeding a single wide-band antenna. This approach is expensive and requires considerable engineering analysis to produce a combiner system that will not degrade the performance of either transmission system.

Vertical Directivity and Gain

Transmitting antennas increase the signal strength on the Earth's surface by minimizing the power that is radiated into space and concentrating it at angles toward or just below the horizon. This property, the antenna's *directivity*, is indicated by a radiation pattern, a plot of the radiation intensity at different elevations.

Radiation patterns can best be described by the Fig. 16.46, which depicts the vertical radiation patterns for three representative antennas. These are a low-band low-gain VHF antenna, a high-band medium-gain VHF antenna, and a high-gain UHF antenna.

The points on the pattern where the field strength is 70% of the maximum are known as the *half-power points*, and the angular separation of these points is the *beam width*. The gain of the antenna is increased by narrowing the beam width to concentrate the radiated power in the desired directions, and the product of the gain and beam width tends to be constant.

The *aperture*, an imaginary cylinder in space surrounding the radiating elements, is used to calculate the directivity of the antenna. The cylindrical aperture is illuminated by the radiating elements, and for

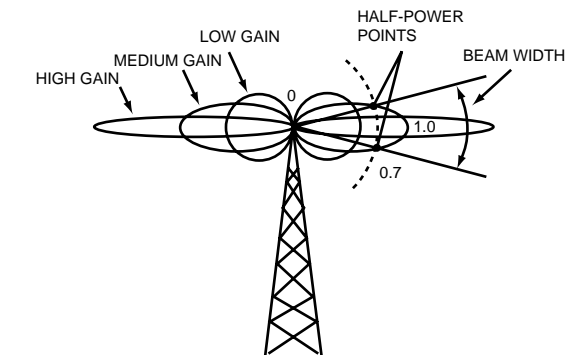

FIGURE 16.46 Vertical antenna radiation patterns.

analytic purposes, each point on the aperture can be considered to be a source of radiant energy. The antenna's directivity is based on the dimensions of the aperture and by the amplitude and phase of the radiant energy at each point on its surface. In the most basic assumption, all points on the aperture are illuminated by a field of the same phase and equal amplitude. The beam width, the angular separation between the half-power points at which the radiation intensity is 70% of that at the beam maximum, is inversely proportional to the ratio of the aperture height (h) to the wavelength (λ). Assuming that the illumination of the aperture is uniform, the beam width can be calculated as

$$\text{beam width} = 48(\lambda/h)^\circ$$

This equation does not apply if the illumination of the aperture is not uniform. However, in general, it can be said that the longer the aperture relative to the wavelength, the taller the antenna and the narrower the radiated beam of energy.

Antenna's Horizontal Directivity

The FCC Rules make a distinction between antennas that are intentionally designed to be directional and those that are directional by virtue of unavoidable imperfections in design. As a result with the FCC's bad experiences with AM directional antennas, which were overused to increase the number of stations on each frequency, the FCC ruled that directional antennas cannot be used in television to reduce the spacing between stations. Also, the FCC ruled that the maximum ERP from directional antennas cannot exceed the maximum allowed for non-directional antennas. The major purpose of directional antennas is to avoid wasting energy over sparsely populated areas and to provide the maximum allowed ERP to densely populated areas with lower total power.

Antenna Bandwidth, VSWR, and Echoes

One of the early challenges of antenna design was to achieve the proper input impedance over the bandwidth of a single channel because antenna components are frequency sensitive. Since that time, modern antenna design has made it possible to achieve good response over multiple channels.

The indicator of antenna bandwidth is the range of frequencies at which its input impedance approximates the characteristic impedance of the transmission line. This is measured by the VSWR of the transmission line feeding the antenna, and a number of 1.05 or less is desirable from 750 kHz below to 5.45 MHz above the visual carrier. The VSWR at the color subcarrier 3.58 MHz above the carrier is very important. A low VSWR is not an absolute guarantee of a satisfactory match between antenna and transmission line, and reflections from the antenna may cause visible echoes and ghosts, even though the VSWR is within limits. Also, the visibility of the echoes depends on their amplitude and their separation from the primary signal. For example, echoes having an amplitude of 1.5% or more will be visible for a transmission line length of 1000 ft. For a 500 ft length, visibility begins for echoes having an amplitude of 3% or greater.

16.4.4 Television Reception

The broadcast channels in the U.S. are 6 MHz wide for transmission on conventional 525-line standards. The minimum signal level at which a television receiver will provide usable pictures and sound is called the *sensitivity level*. The FCC has set up two standard signal level classifications, grades A and B, for the purpose of licensing television stations and allocating coverage areas. Grade A refers to urban areas relatively near the transmitting tower; Grade B use ranges from suburban to rural, and other fringe areas a number of miles from the transmitting antenna.

Many sizes and form factors of receivers are manufactured. Portable personal types include pocket-sized or hand-held models with picture sizes of 2–4 in diagonal for monochrome and 4–6 in for color. Large screen sizes are available in monochrome where low cost and lightweight are prime requirements. However, except where portability is important, the majority of television program viewing is in color. The 19- and 27-in sizes dominate the market.

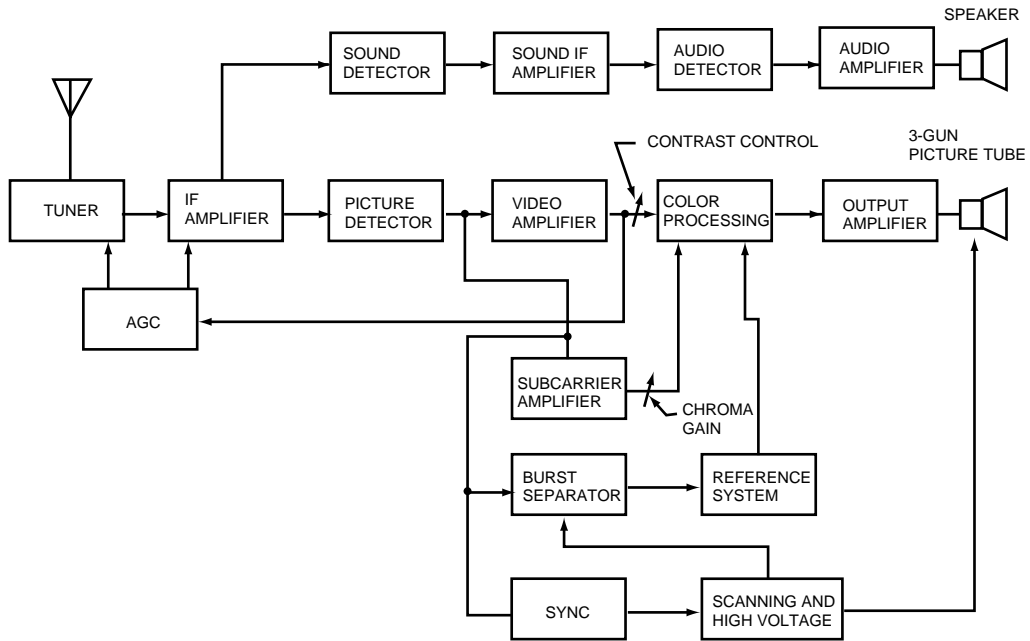

FIGURE 16.47 Simplified schematic block diagram of a color television receiver.

Television receiver functions may be broken down into several interconnected blocks. With the increasing use of very large-scale integrated circuits (VLSI), the isolation of functions has become less obvious in the design and service of television receivers. The typical functional configuration of a receiver using a tri-gun picture tube is shown in Fig. 16.47.

Display Systems

Color video displays may be classified under the following categories:

- Direct view CRT
- Large screen display, optically projected from a CRT
- Large screen display, projected from a modulated light beam
- Large area display of individually driven light-emitting CRTs or incandescent picture elements
- Flat panel matrix of transmissive or reflective picture elements
- Flat panel matrix of light-emitting picture elements

Cathode Ray Tube Display Designs

The direct-view CRT is the dominant display device in television. The attributes offered by CRTs include the following:

- High brightness
- High resolution
- Excellent gray scale reproduction
- Low cost compared to other types of displays

From the standpoint of television receiver manufacturing simplicity and low cost, packaging of the display device as a single component is attractive. The tube itself is composed of only three basic parts: an electron gun, an envelope, and a shadow-mask phosphor screen. The luminance efficiency of the electron optical

FIGURE 16.48 Color selection schemes (plan view): (a) three-beam focus grill, wires at 30–40% of screen voltage, (b) one-beam focus grill, wires at 30–40% of screen voltage, with 300–500 V color switching between alternate wires, (c) focus mask, three beams, mask at 30–40% of screen voltage, (d) index scheme, electron beam smaller than phosphor stripe, periodic index signal (secondary electrons or light) indicating beam position, (e) shadow mask at screen voltage, no focusing, three beams, can consist of holes and dots as shown, or slots and stripes. Note: in(a), (c), and (e) two additional beams approach at other angles to excite the other two colors. (Source: *Television Engineering Handbook*. 1986. K. Blair Benson, ed. McGraw-Hill, New York.)

system and the phosphor screen is high. A peak beam current of under 1 μA in a 25-in tube will produce a highlight brightness of up to 100 fL. The major drawback is the power required to drive the horizontal sweep circuit and the high accelerating voltage necessary for the electron beam. This requirement is partially offset through generation of the screen potential and other lower voltages by rectification of the scanning flyback voltage.

In retrospect, many CRT designs were researched during the early days of television. Figure 16.48 depicts five of the more important approaches. They can be categorized as follows.

Figure 16.48(a) shows a three-beam grill focusing design, which offers very high brightness because of minimal mask intercept. Figure 16.48(b) shows a one-beam grill focusing design, which offers less brightness but with the simplicity of a single beam operation. However, both designs suffer in their execution because secondary electrons generated at the grill and screen are all attracted without color selection to the high voltage of the screen where they reduce the contrast of the display. Screening process is another inherent problem with grill focusing designs due to the absence of an optical shadowing mask. Screening requires the use of printing masters and interchangeable parts, which presents a daunting task. For these reasons, focus-grill tubes are no longer built.

In Fig. 16.48(c), a large-hole focus mask, with the mask at a fraction of the screen potential, will focus the beamlets to permit increased mask transmission and screen brightness, but at the expense of reduced contrast. Figure 16.48(d) depicts an *index* color selection topology. This scheme makes it possible to monitor the position of a single beam and control which screen color is being excited at any instant through a periodic index signal generated by the beam, from either secondary electrons or from a fast response light-emitting phosphor. Again, two major drawbacks can be deduced from these early designs. First, high speed complex circuitry was needed to monitor the position of the beam and properly control it. Second, the beam itself must be no wider than a phosphor stripe, even when deflected over the full area of the picture tube.

In recent years, the shadow mask design as depicted in Fig. 16.48(e) has become a dominant player because of its improvements in brightness and contrast over previous designs, but without having to contend with the complex design issues of previous designs.

As consumer demands drive manufacturers to produce larger picture sizes, the weight and depth of the CRT and the higher power and voltage requirements become serious limitations. These are reflected in sharply increasing receiver costs. To withstand the atmospheric pressures on the evacuated glass envelope, CRT weight increases exponentially with the viewable diagonal. Nevertheless, manufacturers have

continued to meet the demand for increased screen sizes with larger direct-view tubes. Improved versions of both tri-dot delta and in-line guns have been produced. The tri-dot gun provides small spot size at the expense of critical convergence adjustments for uniform resolution over the full tube faceplate. In-line guns permit the use of a self-converging deflection yoke that will maintain dynamic horizontal convergence over the full face of the tube without the need for correction waveforms. The downside is slightly reduced resolution.

Defining Terms

Aural: The sound portion of a television signal.

Beam pulsing: A method used to control the power output of a klystron in order to improve the operating efficiency of the device.

Blanking: The portion of a television signal that is used to blank the screen during the horizontal and vertical retrace periods.

Composite video: A single video signal that contains luminance, color, and synchronization information. NTSC, PAL, and SECAM are all examples of composite video formats.

Effective radiated power: The power supplied to an antenna multiplied by the relative gain of the antenna in a given direction.

Equalizing pulses: In an encoded video signal, a series of 2X line frequency pulses occurring during vertical blanking, before and after the vertical synchronizing pulse. Different numbers of equalizing pulses are inserted into different fields to ensure that each field begins and ends at the right time to produce proper interlace. The 2X line rate also serves to maintain horizontal synchronization during vertical blanking.

Field: One of the two (or more) equal parts of information into which a frame is divided in interlace video scanning. In the NTSC system, the information for one picture is divided into two fields. Each field contains one half of the lines required to produce the entire picture. Adjacent lines in the picture are contained in alternate fields.

Frame: The information required for one complete picture in an interlaced video system. For the NTSC system, there are two fields per frame.

H (horizontal): In television signals, H may refer to any of the following: the horizontal period or rate, horizontal line of video information, or horizontal sync pulse.

Hue: One of the characteristics that distinguishes one color from another. Hue defines color on the basis of its position in the spectrum (red, blue, green, yellow, etc.). Hue is one of the three characteristics of television color. Hue is often referred to as *tint*. In NTSC and PAL video signals, the hue information at any particular point in the picture is conveyed by the corresponding instantaneous phase of the active video subcarrier.

Hum bars: Horizontal black and white bars that extend over the entire TV picture and usually drift slowly through it. Hum bars are caused by an interfering power line frequency or one of its harmonics.

Interlaced: A shortened version of *interlaced scanning* (also called *line interlace*). Interlaced scanning is a system of video scanning whereby the odd- and even numbered lines of a picture are transmitted consecutively as two separate interleaved fields.

IRE: A unit equal to 1/140 of the peak-to-peak amplitude of a video signal, which is typically 1 V. The 0 IRE point is at blanking level, with the sync tip at -40 IRE and white extending to $+100$ IRE. IRE stands for *Institute of Radio Engineers*, an organization preceding the IEEE, which defined the unit.

Klystron: An amplifier device for UHF and microwave signals based on velocity modulation of an electron beam. The beam is directed through an input cavity, where the input RF signal polarity initializes a *bunching effect* on electrons in the beam. The bunching effect excites subsequent cavities, which increase the bunching through an energy flywheel concept. Finally, the beam passes an output cavity that couples the amplified signal to the load (antenna system). The beam falls onto a collector element that forms the return path for the current and dissipates the heat resulting from electron beam bombardment.

- Low power TV (LPTV):** A television service authorized by the FCC to serve specific confined areas. An LPTV station may typically radiate between 100 and 1000 W of power, covering a geographic radius of 10 to 15 m.
- Pixel:** The smallest distinguishable and resolvable area in a video image. A pixel is a single point on the screen. The word pixel is derived from *picture element*.
- Raster:** A predetermined pattern of scanning the screen of a CRT. Raster may also refer to the illuminated area produced by scanning lines on a CRT when no video is present.
- Saturation:** The intensity of the colors in the active picture; the voltage levels of the colors. Saturation relates to the degree by which the eye perceives a color as departing from a gray or white scale of the same brightness. A 100% saturated color does not contain any white; adding white reduces saturation. In NTSC and PAL video signals, the color saturation at any particular instant in the picture is conveyed by the corresponding instantaneous amplitude of the active video subcarrier.
- Scan:** One sweep of the target area in a camera tube, or of the screen in a picture tube.
- Setup:** A video term relating to the specified base of an active picture signal. In NTSC, the active picture signal is placed 7.5 IRE units above blanking (0 IRE). Setup is the separation in level between the *video blanking* and *reference black* levels.
- Synchronous detection:** A demodulation process in which the original signal is recovered by multiplying the modulated signal by the output of a synchronous oscillator locked to the carrier.
- Translator:** An unattended television or FM broadcast repeater that receives a distant signal and retransmits the picture and/or audio locally on another channel.
- Vectorscope:** An oscilloscope-type device used to display the color parameters of a video signal. A vectorscope decodes color information into *R-Y* and *B-Y* components, which are then used to drive the *X* and *Y* axis of the scope. The total lack of color in a video signal is displayed as a dot in the center of the vectorscope. The angle, distance around the circle, magnitude, and distance away from the center indicate the phase and amplitude of the color signal.

16.5 ATSC Video, Audio, and PSIP Transmission¹

Jerry C. Whitaker

16.5.1 Overview of the ATSC Digital Television System

The digital television (DTV) standard has ushered in a new era in television broadcasting. The impact of DTV is more significant than simply moving from an analog system to a digital system. Rather, DTV permits a level of flexibility wholly unattainable with analog broadcasting. An important element of this flexibility is the ability to expand system functions by building upon the technical foundations specified in ATSC standards such as the ATSC digital television standard (A/53) [1] and the digital audio compression (AC-3) standard (A/52) [2].

With NTSC, and its PAL and SECAM counterparts, the video, audio, and some limited data information are conveyed by modulating an RF carrier in such a way that a receiver of relatively simple design can decode and reassemble the various elements of the signal to produce a program consisting of video and audio, and perhaps related data (e.g., closed captioning). As such, a complete program is transmitted by the broadcaster that is essentially in finished form. In the DTV system, however, additional levels of processing are required after the receiver demodulates the RF signal. The receiver processes the digital bit stream extracted from the received signal to yield a collection of program elements (video, audio, and/or data) that match the service(s) that the consumer has selected. This selection is made using system and service information that is also transmitted. Audio and video are delivered in digitally compressed form and must be decoded for presentation. Audio may be monophonic, stereo, or multi-channel. Data may supplement the main video/audio program (e.g., closed captioning, descriptive text, or commentary) or it may be a stand-alone service (e.g., a stock or news ticker).

The nature of the DTV system is such that it is possible to provide new features that build upon the infrastructure within the broadcast plant and the receiver. One of the major enabling developments of digital television, in fact, is the integration of significant processing power in the receiving device itself. Historically, in the design of any broadcast system—be it radio or television—the goal has always been to concentrate technical sophistication (when needed) at the transmission end and thereby facilitate simpler receivers. Because there are far more receivers than transmitters, this approach has obvious business advantages. While this trend continues to be true, the complexity of the transmitted bit stream and compression of the audio and video components require a significant amount of processing power in the receiver, which is practical because of the enormous advancements made in computing technology. Once a receiver reaches a certain level of sophistication (and market success) additional processing power is essentially “free.”

DTV System Overview

The DTV standard describes a system designed to transmit high quality video and audio and ancillary data over a single 6 MHz channel. The system can deliver about 19 Mbps in a 6 MHz terrestrial broadcasting channel and about 38 Mbps in a 6 MHz cable television channel. This means that encoding high-definition (HD) video sources at 885² Mbps (highest rate progressive input) or 994³ Mbps (highest rate interlaced picture input) requires a bit rate reduction by about a factor of 50 (when the overhead numbers are added, the rates become closer). To achieve this bit rate reduction, the system is designed to be efficient in utilizing available channel capacity by exploiting complex video and audio compression technology.

¹This section is based on: ATSC, “Guide to the Digital Television Standard, Doc. A/54A, Advanced Television Systems Committee, Washington, D.C., 2003.

² $720 \times 1280 \times 60 \times 8 \times 2 = 884.736$ Mbps (the 2 represents the 4:2:2 or color subsampling, an RGB with full bandwidth would be a 3)

³ $1080 \times 1920 \times 29.97 \times 8 \times 2 = 994.333$ Mbps (the 2 represents the 4:2:2 or color subsampling, an RGB with full bandwidth would be a 3)

FIGURE 16.49 Block diagram of functionality in a transmitter/receiver pair.

The compression scheme used for DTV service optimizes the throughput of the transmission channel by representing the video, audio, and data sources with as few bits as possible while preserving the level of quality required for the given application.

The RF/transmission subsystems described in the DTV standard are designed specifically for terrestrial and cable applications. The structure is such that the video, audio, and service multiplex/transport subsystems are useful in other applications as well.

System Block Diagram

A basic block diagram representation of the DTV system is shown in Figure 16.49. According to this model, the digital television system consists of four major elements, three within the broadcast plant plus the receiver.

Application Encoders/Decoders

The *application encoders/decoders* as shown in Figure 16.49, refer to the bit rate reduction methods (also known as data compression) appropriate for application to the video, audio, and ancillary digital data streams. The purpose of compression is to minimize the number of bits needed to represent the audio and video information. The DTV system employs the MPEG-2 video stream syntax for the coding of video and the ATSC standard *digital audio compression (AC-3)* for the coding of audio [2].

Transport (de)Packetization and (de)Multiplexing

Transport (de)packetization and (de)multiplexing refers to the means of dividing each bit stream into “packets” of information, the means of uniquely identifying each packet or packet type, and the appropriate methods of interleaving or multiplexing video bit stream packets, audio bit stream packets, and data bit stream packets into a single transport mechanism. The structure and relationships of these essence bit streams is carried in service information bit streams, also multiplexed in the single transport mechanism. In developing the transport mechanism, interoperability among digital media—such as terrestrial broadcasting, cable distribution, satellite distribution, recording media, and computer interfaces—was a prime consideration. The DTV system employs the MPEG-2 transport stream syntax for the packetization and multiplexing of video, audio, and data signals for digital broadcasting systems. The MPEG-2 transport stream syntax was developed for applications where channel bandwidth or recording media capacity is limited and the requirement for an efficient transport mechanism is paramount.

In the DTV standard, the carriage of program and system information is specified in ATSC standard A/65, *Program and System Information Protocol* [3].

RF Transmission

RF Transmission refers to channel coding and modulation. The channel coder takes the digital bit stream and adds additional information that can be used by the receiver to reconstruct the data from the received signal that, due to transmission impairments, may not accurately represent the transmitted signal. The modulation (or physical layer) uses the digital bit stream information to modulate a carrier for the transmitted signal. The modulation subsystem offers two modes: an 8-VSB mode and a 16-VSB mode.

Receiver

The ATSC receiver must recover the bits representing the original video, audio, and other data from the modulated signal. In particular, the receiver must

- Tune the selected 6 MHz channel
- Reject adjacent channels and other sources of interference
- Demodulate (equalize as necessary) the received signal, applying error correction to produce a transport bit stream
- Identify the elements of the bit stream using a transport layer processor
- Select each desired element and send it to its appropriate processor
- Decode and synchronize each element
- Present the programming

16.5.2 Video System

The MPEG-2 specification is organized into a system of profiles and levels, so that applications can ensure interoperability by using equipment and processing that adhere to a common set of coding tools and parameters [4]. The DTV standard is based on the MPEG-2 main profile. The main profile includes three types of frames (*I*-frames, *P*-frames, and *B*-frames), and an organization of luminance and chrominance samples (designated 4:2:0) within the frame. The main profile does not include a scalable algorithm, where scalability implies that a subset of the compressed data can be decoded without decoding the entire data stream. The high level includes formats with up to 1152 active lines and up to 1920 samples per active line, and for the Main Profile is limited to a compressed data rate of no more than 80 Mbps. The parameters specified by the DTV standard represent specific choices within these constraints.

Compatibility with MPEG-2

The DTV video compression system does not include algorithmic elements that fall outside the specifications for MPEG-2 main profile. Thus, video decoders that conform to the MPEG-2 MP@HL can be expected to decode bit streams produced in accordance with the DTV standard. Note that it is not

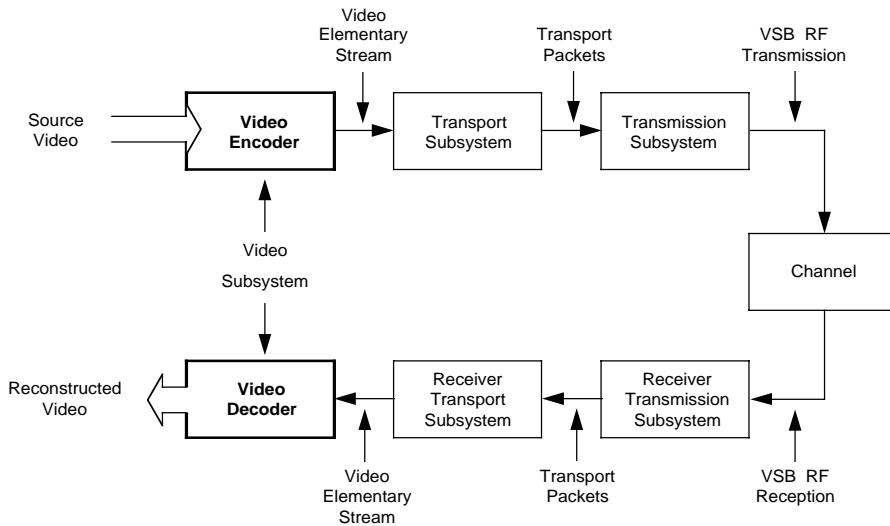

FIGURE 16.50 Video coding in relation to the ATSC DTV system.

necessarily the case that all video decoders which are based on the DTV standard will be able to properly decode all video bit streams that comply to MPEG-2 MP@HL.

Overview of Video Compression

The DTV video compression system takes in an analog video source signal and outputs a compressed digital signal that contains information that can be decoded to produce an approximate version of the original image sequence. The goal is for the reconstructed approximation to be imperceptibly different from the original for most viewers, for most images, for most of the time. In order to approach such fidelity, the algorithms are flexible, allowing for frequent adaptive changes in the algorithm depending on scene content, history of the processing, estimates of image complexity, and perceptibility of distortions introduced by the compression.

Figure 16.50 shows the overall flow of signals in the ATSC DTV system. Note that analog signals presented to the system are digitized and sent to the encoder for compression, and the compressed data then are transmitted over a communications channel. On being received, the compressed signal is decompressed in the decoder, and reconstructed for display (following error-correction, as necessary).

Video Preprocessing

Video preprocessing converts the analog input signals to digital samples in the form needed for subsequent compression. The analog input signals are typically composite for standard-definition signals or components consisting of luminance (Y) and chrominance (Cb and Cr) signals.

Video Compression Formats

Table 16.10 lists the compression formats allowed in the DTV standard.

In Table 16.10, “vertical lines” refers to the number of active lines in the picture. “Pixels” refers to the number of pixels during the active line. “Aspect ratio” refers to the picture aspect ratio. “Picture rate”

TABLE 16.10 DTV Compression Formats

Vertical Lines	Pixels	Aspect Ratio	Picture Rate
1080	1920	16:9	60I, 30P, 24P
720	1280	16:9	60P, 30P, 24P
480	704	16:9 and 4:3	60P, 60I, 30P, 24P
480	640	4:3	60P, 60I, 30P, 24P

TABLE 16.11 Standardized Video Input Formats

Video Standard	Active Lines	Active Samples/Line	Picture Rate
SMPTE 274M-1998	1080	1920	24P, 30P, 60I
SMPTE 296M-2001	720	1280	24P, 30P, 60P
SMPTE 293M-2003	483	720	60P
ITU-R BT.601-5	483	720	60I

refers to the number of frames or fields per second. In the values for picture rate, “P” refers to progressive scanning and “I” refers to interlaced scanning. Note that both 60.00 and 59.94 ($60 \times 1000/1001$) Hz picture rates are allowed. Dual rates are allowed also at the picture rates of 30 and 24 Hz.

Designers should be aware that a larger range of video formats is allowed under SCTE 43 [5], and that consumers may expect receivers to decode and display these as well. One format likely to be frequently encountered is 720 pixels by 480 lines, matching the format of ITU-R BT. 601-5 [6].

Possible Video Inputs

While not required by the DTV standard, there are certain digital television production standards, shown in Table 16.11, that define video formats which relate to compression formats specified by the standard.

The compression formats may be derived from one or more appropriate video input formats. It may be anticipated that additional video production standards will be developed in the future that extend the number of possible input formats.

Sampling Rates

For the 1080-line format, with 1125 total lines per frame and 2200 total samples per line, the sampling frequency will be 74.25 MHz for the 30.00 frames per second (fps) frame rate. For the 720-line format, with 750 total lines per frame and 1650 total samples per line, the sampling frequency will be 74.25 MHz for the 60.00 fps frame rate. For the 480-line format using 704 pixels, with 525 total lines per frame and 858 total samples per line, the sampling frequency will be 13.5 MHz for the 59.94 Hz field rate. Note that both 59.94 fps and 60.00 fps are acceptable as frame or field rates for the system.

For both the 1080- and 720-line formats, other frame rates, specifically 23.976, 24.00, 29.97 and 30.00 fps rates are acceptable as input to the system. The sample frequency will be either 74.25 MHz (for 24.00 and 30.00 fps) or 74.25/1.001 MHz for the other rates. The number of total samples per line is the same for either of the paired picture rates. (See SMPTE 274M [7] and SMPTE 296M [8]).

The six frame rates noted here are the only allowed frame rates for the DTV standard. In this discussion, any references to 24 fps include both 23.976 and 24.00 fps, references to 30 fps include both 29.97 and 30.00 fps, and references to 60 fps include both 59.94 and 60.00 fps.

For the 480-line format, there may be 704 or 640 pixels in the active line. The interlaced formats are based on ITU-R B.T 601-5 [6]; the progressive formats are based on SMPTE 294M [9].

If the input is based on ITU-R BT.601-5 or SMPTE 294M, it will have 483 active lines with 720 pixels in the active line. Only 480 of the 483 active lines are used for encoding. Only 704 of the 720 pixels are used for encoding; the first eight and the last eight are dropped. The 480-line, 640 pixel picture format is not related to any current video production format. It does, however, correspond to the IBM VGA graphics format and may be used with ITU-R BT.601-5 sources by using appropriate resampling techniques.

Colorimetry

For the purposes of the DTV standard, “colorimetry” means the combination of color primaries, transfer characteristics, and matrix coefficients. Video inputs conforming to SMPTE 274M and SMPTE 296M have the same colorimetry. Video inputs corresponding to ITU-R BT.601-5 should have SMPTE 170M colorimetry [10].

Active Format Description (AFD)

The DTV standard makes provisions for conveying *active format description* (AFD) data [1]. The term “active format” in this context refers to that portion of the coded video frame containing “useful information.” For example, when 16:9 aspect ratio material is coded in a 4:3 format (such as 480i), letterboxing may be used to avoid cropping the left and right edges of the widescreen image. The black horizontal bars at the top and bottom of the screen contain no useful information, and in this case the AFD data would indicate 16:9 video carried inside the 4:3 rectangle. The AFD data solve a troublesome problem in the transition from conventional 4:3 display devices to widescreen 16:9 displays, and also address the variety of aspect ratios that have been used over the years by the motion picture industry to produce feature films.

There are, of course, a number of different types of video displays in common usage—ranging from 4:3 CRTs to widescreen projection devices and flat-panel displays of various design. Each of these devices may have varying abilities to process incoming video. In terms of input interfaces, these displays may likewise support a range of input signal formats—from composite analog video to IEEE 1394.

Possible video source devices include cable, satellite, or terrestrial broadcast set-top (or integrated receiver-decoder) boxes, media players (such as DVDs), analog or digital VHS tape players, and personal video recorders.

Although choice is good, this wide range of consumer options presented two problems to be solved:

- First, no standard method had been agreed upon to communicate to the display device the “active area” of the video signal. Such a method would be able, for example to signal that the 4:3 signal contains within it a letterboxed 16:9 video image.
- Second, no standard method had been agreed upon to communicate to the display device, for all interface types, that a given image is intended for 16:9 display.

The AFD solves these problems and, in the process, provides the following benefits:

- Active area signaling allows the display device to process the incoming signal to make the highest-resolution and most accurate picture possible. Furthermore, the display can take advantage of the knowledge that certain areas of video are currently unused and can implement algorithms that reduce the effects of uneven screen aging.
- Aspect ratio signaling allows the display device to produce the best image possible. In some scenarios, lack of a signaling method translates to restrictions in the ability of the source device to deliver certain otherwise desirable output formats.

Active Area Signaling

A consumer device such as a cable or satellite set-top box cannot reliably determine the active area of video on its own. Even though certain lines at the top and bottom of the screen may be black for periods of time, the situation could change without warning. The only sure way to know active area is for the service provider to include these data at the time of video compression and to embed it into the video stream.

Figure 16.51 shows 4:3- and 16:9-coded images with various possible active areas. The group on the left is either coded explicitly in the MPEG-2 video syntax as 4:3, or the uncompressed signal provided in NTSC timing and aspect ratio information (if present) indicates 4:3. The group on the right are coded explicitly in the MPEG-2 video syntax as 16:9, provided with NTSC timing and an aspect ratio signal indicating 16:9, or provided uncompressed with 16:9 timing across the interface.

As can be seen in the figure, a pillar-boxed display results when a 4:3 active area is displayed within a 16:9 area, and a letterboxed display results when a 16:9 active area is displayed within a 4:3 area. It is also apparent that double-boxing can also occur, for example when 4:3 material is delivered within a 16:9 letterbox to a 4:3 display. Or, when 16:9 material is delivered within a 4:3 pillar-box to a 16:9 display.

For the straight letter- or pillar-box cases, if the display is aware of the active area it may take steps to mitigate the effects of uneven screen aging. Such steps could, for example, involve using gray instead of black bars. Some amount of linear or nonlinear stretching and/or zooming may be done as well using the knowledge that video outside the active area can safely be discarded.

FIGURE 16.51 Coding and active area.

16.5.3 Audio System

As illustrated in Figure 16.52, the audio subsystem comprises the audio encoding/decoding function and resides between the audio inputs/outputs and the transport subsystem. The audio encoder(s) is (are) responsible for generating the audio elementary stream(s), which are encoded representations of the baseband audio input signals. The flexibility of the transport system allows multiple audio elementary

FIGURE 16.52 Audio subsystem within the DTV system.

streams to be delivered to the receiver. At the receiver, the transport subsystem is responsible for selecting which audio streams(s) to deliver to the audio subsystem. The audio subsystem is responsible for decoding the audio elementary stream(s) back into baseband audio.

An audio program source is encoded by a digital television audio encoder. The output of the audio encoder is a string of bits that represent the audio source, and is referred to as an *audio elementary stream*. The transport subsystem packetizes the audio data into PES packets, which are then further packetized into transport packets. The transmission subsystem converts the transport packets into a modulated RF signal for transmission to the receiver. At the receiver, the signal is demodulated by the receiver transmission subsystem. The receiver transport subsystem converts the received audio packets back into an audio elementary stream, which is decoded by the digital television audio decoder. The partitioning shown is conceptual, and practical implementations may differ. For example, the transport processing may be broken into two blocks; one to perform PES packetization, and the second to perform transport packetization. Or, some of the transport functionality may be included in either the audio coder or the transmission subsystem.

Audio Encoder Interface

The audio system accepts baseband audio inputs with up to six audio channels per audio program bit stream. The channelization is consistent with ITU-R recommendation BS-775, "Multi-channel stereophonic sound system with and without accompanying picture." The six audio channels are: left, center, right, left surround, right surround, and low frequency enhancement (LFE). Multiple audio elementary bit streams may be conveyed by the transport system.

The bandwidth of the LFE channel is limited to 120 Hz. The bandwidth of the other (main) channels is limited to 20 kHz. Low frequency response may extend to DC, but is more typically limited to approximately 3 Hz (−3 dB) by a DC blocking high-pass filter. Audio coding efficiency (and thus audio quality) is improved by removing DC offset from audio signals before they are encoded.

Input Source Signal Specification

Audio signals that are input to the audio system may be in analog or digital form. Audio signals should have any DC offset removed before being encoded. If the audio encoder does not include a DC blocking high-pass filter, the audio signals should be high-pass filtered before being applied to the audio encoder. For analog input signals, the input connector and signal level are not specified. Conventional broadcast practice may be followed. One commonly used input connector is the 3-pin XLR female (the incoming audio cable uses the male connector) with pin 1 ground, pin 2 hot or positive, and pin 3 neutral or negative.

For digital input signals, the input connector and signal format are not specified. Commonly used formats such as the AES 3-1992 two-channel interface may be used [11]. When multiple two-channel inputs are used, the preferred channel assignment is

- Pair 1: Left, Right
- Pair 2: Center, LFE
- Pair 3: Left Surround, Right Surround

Sampling Frequency

The system conveys digital audio sampled at a frequency of 48 kHz, locked to the 27 MHz system clock. If analog signal inputs are employed, the A/D converters should sample at 48 kHz. If digital inputs are employed, the input sampling rate should be 48 kHz, or the audio encoder should contain sampling rate converters that convert the sampling rate to 48 kHz. The sampling rate at the input to the audio encoder must be locked to the video clock for proper operation of the audio subsystem.

In general, input signals should be quantized to at least 16-bit resolution. The audio compression system can convey audio signals with up to 24-bit resolution.

Summary of Service Types

The following service types are defined in the digital audio compression (AC-3) standard [2] and in the ATSC digital television standard [1]:

- **Complete main audio service (CM):** This is the normal mode of operation. All elements of a complete audio program are present. The audio program may be any number of channels from 1 to 5.1⁴.
- **Main audio service, music and effects (ME):** All elements of an audio program are present except for dialogue. This audio program may contain from 1 to 5.1 channels. Dialogue may be provided by a D associated service (that may be simultaneously decoded and added to form a complete program).
- **Associated service: visually impaired (VI):** This is typically a single-channel service, intended to convey a narrative description of the picture content for use by the visually impaired, and intended to be decoded along with the main audio service. The VI service also may be provided as a complete mix of all program elements, in which case it may use any number of channels (up to 5.1).
- **Associated service: hearing impaired (HI):** This is typically a single-channel service, intended to convey dialogue that has been processed for increased intelligibility for the hearing impaired, and intended to be decoded along with the main audio service. The HI service also may be provided as a complete mix of all program elements, in which case it may use any number of channels (up to 5.1).
- **Associated service: dialogue (D):** This service conveys dialogue intended to be mixed into a main audio service (ME) that does not contain dialogue.
- **Associated service: commentary (C):** This service typically conveys a single-channel of commentary intended to be optionally decoded along with the main audio service. This commentary channel differs from a dialogue service, in that it contains optional instead of necessary program content. The C service also may be provided as a complete mix of all program elements, in which case it may use any number of channels (up to 5.1).
- **Associated service: emergency message (E):** This is a single-channel service, which is given priority in reproduction. If this service type appears in the transport multiplex, it is routed to the audio decoder. If the audio decoder receives this service type, it will decode and reproduce the E channel while muting the main service.
- **Associated service: voice-over (VO):** This is a single-channel service intended to be decoded and added into the center loudspeaker channel.

Multi-Lingual Services

Each audio bit stream may be in any language. In order to provide audio services in multiple languages a number of main audio services may be provided, each in a different language. This is the (artistically) preferred method, because it allows unrestricted placement of dialogue along with the dialogue reverberation. The disadvantage of this method is that as much as 384 kbps is needed to provide a full 5.1-channel service for each language. One way to reduce the required bit-rate is to reduce the number of audio channels provided for languages with a limited audience. For instance, alternate language versions could be provided in 2-channel stereo with a bit-rate of 128 kbps or, a mono version can be supplied at a bit-rate of approximately 64–96 kbps.

Another way to offer service in multiple languages is to provide a main multi-channel audio service (ME) that does not contain dialogue. Multiple single-channel dialogue associated services (D) can then be provided, each at a bit-rate of approximately 64–96 kbps. Formation of a complete audio program requires that the appropriate language D service be simultaneously decoded and mixed into the ME service. This method allows a large number of languages to be efficiently provided, but at the expense of artistic limitations. The single-channel of dialogue would be mixed into the center reproduction channel,

⁴5.1 channel sound refers to a service providing the following signals: right, center, left, right surround, left surround, and low frequency effects (LEF).

TABLE 16.12 Typical Audio Bit Rate

Type of Service	Number of Channels	Typical Bit Rates
CM, ME, or associated audio service containing all necessary program elements	5	384–448 kbps
CM, ME, or associated audio service containing all necessary program elements	4	320–384 kbps
CM, ME, or associated audio service containing all necessary program elements	3	192–320 kbps
CM, ME, or associated audio service containing all necessary program elements	2	128–256 kbps
VI, narrative only	1	64–128 kbps
HI, narrative only	1	64–96 kbps
D	1	64–128 kbps
D	2	96–192 kbps
C, commentary only	1	64–128 kbps
E	1	64–128 kbps
VO	1	64–128 kbps

and could not be panned. Also, reverberation would be confined to the center channel, which is not optimum. Nevertheless, for some types of programming (sports, etc.) this method is attractive due to the savings in bit rate it offers. Some receivers may not have the capability to simultaneously decode an ME and a D service.

Stereo (two-channel) service without artistic limitation can be provided in multiple languages with added efficiency by transmitting a stereo ME main service along with stereo D services. The D and appropriate language ME services are simply combined in the receiver into a complete stereo program. Dialogue may be panned, and reverberation may be placed included in both channels. A stereo ME service can be sent with high quality at 192 kbps, while the stereo D services (voice only) can make use of lower bit-rates, such as 128 or 96 kbps per language. Some receivers may not have the capability to simultaneously decode an ME and a D service.

Note that during those times when dialogue is not present, the D services can be momentarily removed, and their data capacity used for other purposes.

Audio Bit Rates

The information in Table 16.12 provides a general guideline as to the audio bit rates that are expected to be most useful. For main services, the use of the LFE channel is optional and will not affect the indicated data rates.

The audio decoder input buffer size (and thus part of the decoder cost) is determined by the maximum bit rate that must be decoded. The syntax of the AC-3 standard supports bit rates ranging from a minimum of 32 kbps up to a maximum of 640 kbps per individual elementary bit stream. The bit rate utilized in the DTV system is restricted in order to reduce the size of the input buffer in the audio decoder, and thus the receiver cost. Receivers can be expected to support the decoding of a main audio service, or an associated audio service that is a complete service (containing all necessary program elements), at a bit rate up to and including 448 kbps. Transmissions may contain main audio services, or associated audio services that are complete services (containing all necessary program elements), encoded at a bit rate up to and including 448 kbps. Transmissions may contain single-channel associated audio services intended to be simultaneously decoded along with a main service encoded at a bit rate up to and including 128 kbps. Transmissions may contain dual-channel dialogue associated services intended to be simultaneously decoded along with a main service encoded at a bit rate up to and including 192 kbps. Transmissions have a further limitation that the combined bit rate of a main and an associated service that are intended to be simultaneously reproduced is less than or equal to 576 kbps.

16.5.4 DTV Transport

The transport subsystem employs the fixed-length transport stream packetization approach defined in ISO/IEC13818-1 [12], which is usually referred to as the MPEG-2 systems standard. This approach is well-suited to the needs of terrestrial broadcast and cable television transmission of digital television. The use of relatively short, fixed-length packets matches well with the needs and techniques for error protection in both terrestrial broadcast and cable television distribution environments.

The ATSC DTV transport may carry a number of television programs. The MPEG-2 term “program” corresponds to an individual digital TV channel or data service, where each program is composed of a number of MPEG-2 program elements (i.e., related video, audio, and data streams). The MPEG-2 systems standard support for multiple channels or services within a single, multiplexed bit stream enables the deployment of practical, bandwidth-efficient digital broadcasting systems. It also provides great flexibility to accommodate the initial needs of the service to multiplex video, audio, and data while providing a well-defined path to add additional services in the future in a fully backward-compatible manner. By basing the transport subsystem on MPEG-2, maximum interoperability with other media and standards is maintained.

Referring to Figure 16.49, the transport subsystem resides between the application (e.g., audio or video) encoding and decoding functions and the transmission subsystem. At its lowest layer, the encoder transport subsystem is responsible for formatting the encoded bits and multiplexing the different components of the program for transmission. At the receiver, it is responsible for recovering the bit streams for the individual application decoders and for the corresponding error signaling. The transport subsystem also incorporates other higher-level functionality related to identification of applications and synchronization of the receiver.

PSIP

The *Program and system information protocol* (PSIP) is data that are transmitted along with a station’s DTV signal that tells DTV receivers important information about the station and what is being broadcast. Described in ATSC Standard A/65 [3], the most important function of PSIP is to provide a method for DTV receivers to identify a DTV station and to determine how a receiver can tune to it. PSIP identifies both the DTV channel and the associated NTSC (analog) channel. It helps maintain the current channel branding because DTV receivers will electronically associate the two channels, making it easy for viewers to tune to the DTV station even if they do not know the RF channel number.

In addition to identifying the channel number, PSIP tells the receiver whether multiple program channels are being broadcast and, if so, how to find them. It identifies, for example, whether the programs are closed-captioned, conveys V-chip information, and if data are associated with the program.

PSIP Structure

PSIP is a collection of tables, each of which describes elements of typical digital television services [13]. Figure 16.53 shows the primary components and the notation used to describe them. The packets of the base tables are all labeled with a base *packet identifier* (PID). The base tables are

- System time table (STT)
- Rating region table (RRT)
- Master guide table (MGT)
- Virtual channel table (VCT)

The event information tables (EITs) are a second set of tables, whose packet identifiers are defined in the MGT. The extended text tables (ETTs) are a third set of tables, and similarly, their PIDs are defined in the MGT.

The system time table is a small data structure that fits in one transport stream packet and serves as a reference for time-of-day functions. Receivers can use this table to manage various operations and scheduled events, as well as display time-of-day.

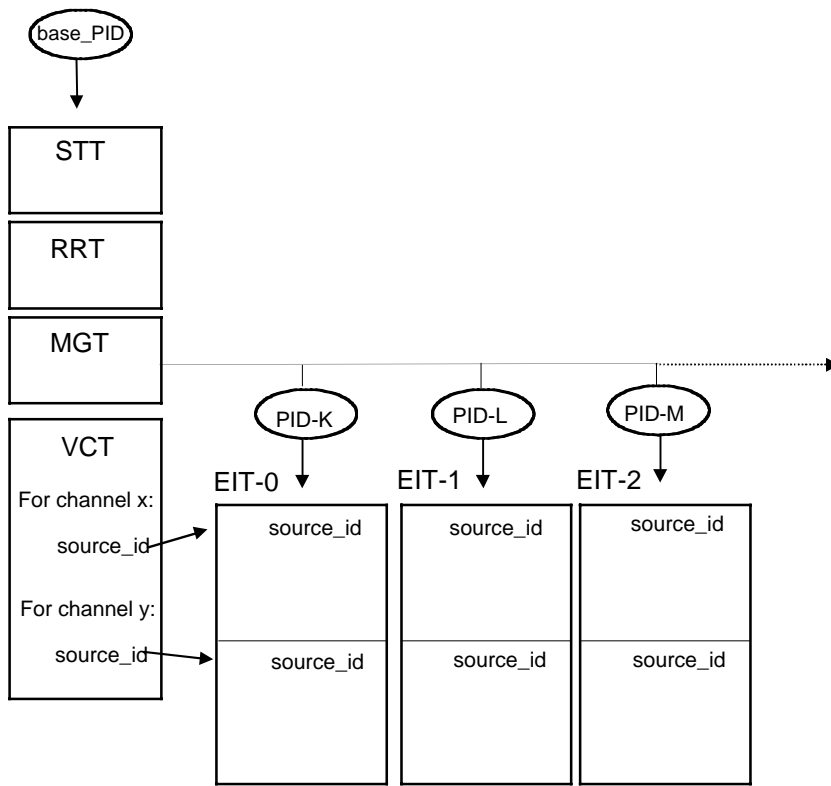

FIGURE 16.53 Overall structure of the PSIP tables.

The rating region table has been designed to transmit the rating system in use for each country using the ratings. In the U.S., this is incorrectly but frequently referred to as the “V-chip” system; the proper title is television parental guidelines (TVPG). Provisions have been made for multi-country systems.

The master guide table provides indexing information for the other tables that comprise the PSIP Standard. It also defines table sizes necessary for memory allocation during decoding, defines version numbers to identify those tables that need to be updated, and generates the packet identifiers that label the tables.

The virtual channel table, also referred to as the Terrestrial VCT (TVCT), contains a list of all the channels that are or will be on-line, plus their attributes. Among the attributes given are the channel name and channel number.

There are up to 128 event information tables, EIT-0 through EIT-127, each of which describes the events or television programs for a time interval of 3 h. Because the maximum number of EITs is 128, up to 16 days of programming may be advertised in advance. At minimum, the first four EITs must always be present in every transport stream, and 24 are recommended. Each EIT-k may have multiple instances, one for each virtual channel in the VCT.

As illustrated in Figure 16.54, there may be multiple extended text tables, one or more channel ETT sections describing the virtual channels in the VCT, and an ETT-k for each EIT-k, describing the events in the EIT-k. These are all listed in the MGT. An ETT-k contains a table instance for each event in the associated EIT-k. As the name implies, the purpose of the ETT is to carry text messages. For example, for channels in the VCT, the messages can describe channel information, cost, coming attractions, and other related data. Similarly, for an event such as a movie listed in the EIT, the typical message would be a short paragraph that describes the movie itself. Extended text tables are optional in the ATSC system.

FIGURE 16.54 Extended text tables in the PSIP hierarchy.

PSIP Requirements for Broadcasters

The three main tables (VCT, EIT, STT) contain information to facilitate suitably equipped receivers to find the components needed to present a program (event). Although receivers are expected to use stored information to speed channel acquisition, sometimes parameters must change and the VCT and EIT-0 are the tables that must be accurate each instant as they provide the actual connection path and critical information that can affect the display of the events. If nothing has changed since an EIT was sent for an event, then the anticipatory use of the data is expected to proceed, and when there is a change the new parts would be used. Additional tables provide TV parental advisory information and extended text messages about certain events. These relationships, and the tables that carry them, are designed to be kept with the DTV signal when it is carried by a cable system.

The Basics

There are certain “must have” items and “must do” rules of operation. If the PSIP elements are missing or wrong, there may be severe consequences, which vary depending on the design of receiver. The following are key elements that must be set and/or checked by each station:

- **Transport stream identification (TSID).** The preassigned TSIDs must be set correctly in all three locations (PAT, VCT common information, and virtual channel-specific information).
- **System time table (SST).** The STT time should be checked daily and locked to house time. Ideally, the STT should be inserted into the TS within a frame before each seconds-count increment of the house time with the to-be-valid value.
- **Short channel name.** This is a seven-character name that can be set to any desired name indicating the virtual channel name. For example, a station’s call letters followed by SD1, SD2, SD3, and SD4

TABLE 16.13 Mandatory PSIP Table Suggested Repetition Rates

PSIP Table	Transmission Cycle
MGT	Once every 150 ms
TVCT	Once every 400 ms
EIT-0	Once every 0.5 sec
EIT-1	Once every 3 sec
EIT-2 and EIT-3	Once every minute
STT	Once every second
RRT (not required in some areas ^a)	Once every minute

^aThe U.S. is one such area.

TABLE 16.14 Suggested Repetition Rates for Optional PSIP Tables

	PSIP Table	Transmission Cycle
	A/65A specifies the following repetition rates for DCC per specified conditions.	
DCCT	DCC request in progress	150 msec
	2 seconds prior to DCC request	400 msec
	No DCC	n/a
DCCSCT		Once per hour
ETT		Once every minute
EIT-4 and higher		Once every minute
DET		A later version of this Recommended Practice will address data services.

to indicated various SDTV virtual channels or anything else to represent the station’s identity (e.g., WNABSD1, KNABSD2, WNAB-HD, KIDS, etc.).

- **Major channel.** The previously assigned, paired NTSC channel is the major channel number.
- **Service type.** The service type selects DTV, NTSC, audio only, data, etc., and must be set as operating modes require.
- **Modulation mode.** A code for the RF modulation of the virtual channel.
- **Source ID.** The source ID is a number that associates virtual channels to events on those channels. It typically is automatically updated by PSIP equipment or updated from an outside vendor. Proper operation of this feature should be confirmed.
- **Service location descriptor (SLD).** Contains the MPEG references to the contents of each component of the programs plus a language code for audio. The PID values for the components identified here and in the PMT must be the same for the elements of an event/program. Some deployed systems require separate manual setup, but PID values assigned to a VC should seldom change.

The maximum cycle time/repetition rate of the tables should be set or confirmed to conform with the suggested guidelines given in Table 16.13 for mandatory PSIP tables and Table 16.14 for optional PSIP tables.

It is recommended that broadcasters send populated EITs covering at least three days. The primary cycle time guidelines are illustrated in Figure 16.55.

The recommended table cycle times given in this section result in a minimal demand on overall system bandwidth. Considering the importance of the information that these PSIP tables provide to the receiver, the bandwidth penalty is trivial.

FIGURE 16.55 Recommended PSIP table cycle times.

Chan	Name	6:00 PM	6:30 PM	7:00 PM	7:30 PM	8:00 PM	8:30 PM

FIGURE 16.56 Example electronic program guide.

Program Guide

Support for an electronic program guide (EPG) or interactive program guide (IPG) is another important function enabled by the PSIP standard. The concept is to provide a way for viewers to find out “what’s on” directly from their television sets, similar to the *guide channels* that are typically available for cable and satellite broadcast services. In a terrestrial broadcast environment, there is no single authority that determines what programs are on all the channels, so each broadcaster needs to include this type of information within the broadcast stream. Viewers’ receivers will be able to scan all the available channels and create a program guide channel from the consolidated information. The value of this type of guide information is high, and it will continue to increase in the DTV environment. Viewers will have the ability to choose not only what channel to watch, but also be able to select from multiple options within a broadcast. Examples include selecting from a set of alternative audio tracks in different languages, or choosing one of several SDTV programs shown at the same time on different virtual channels.

The more viewers rely on these guides, the more critical the accuracy and detail of the information they contain will become. Figure 16.56 shows what a typical electronic program guide might look like.

Building the On-Screen Display or EPG

The EPG has the dual functionality of announcing future programs and providing critical information about the current program. It contains program names and planned broadcast times as well as other information about an event. The data can be combined to build a receiver on-screen display such as that shown in Figure 16.57.

16.5.5 RF Transmission

The ATSC VSB system offers two basic operational modes: a terrestrial broadcast mode (8-VSB) and a high data rate mode (16-VSB) intended for cable applications. Both modes provide a pilot, segment syncs, and a training sequence (as part of data field sync) for acquisition and operation. The two system modes can use the same carrier recovery, demodulation, sync recovery, and clock recovery circuits. Adaptive equalization for the two modes can use the same equalizer structure with some differences in the decision feedback and adaptation of the filter coefficients. Furthermore, both modes use the same Reed-Solomon (RS) code and circuitry for *forward error correction* (FEC). The terrestrial broadcast mode is optimized for maximum service area and provides a data payload of approximately 19.4 Mbps in a 6 MHz channel. The high data rate mode, which provides twice the data rate at the cost of reduced robustness for channel degradations such as noise and multipath, provides a data payload of 38.8 Mbps in a single 6 MHz channel.

In order to maximize service area, the terrestrial broadcast mode incorporates trellis coding, with added precoding that allows the data to be decoded after passing through a receiver comb filter, used selectively to suppress analog co-channel interference. The high-data-rate mode is designed to work in a cable environment, which is less severe than that of the terrestrial system. It is transmitted in the form

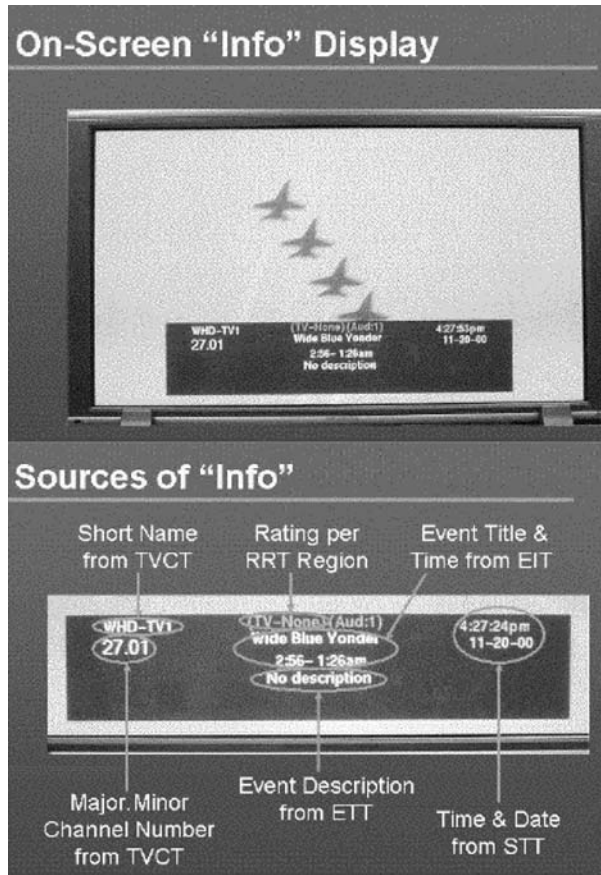

FIGURE 16.57 Illustration of how the various PSIP tables could combine to produce the on-screen display at the receiver.

of more data levels (bits/symbol). No trellis coding or precoding for an analog broadcast interference rejection (comb) filter is employed in this mode.

VSB transmission with a raised-cosine roll-off at both the lower edge (pilot carrier side) and upper edge (Nyquist slope at 5.38 MHz above carrier) permits equalizing just the in-phase (I) channel signal with a sampling rate as low as the symbol (baud) rate. The raised-cosine shape is obtained from concatenating a root-raised cosine in the transmitter with the same shape in the receiver. Although energy in the vestigial sideband and in the upper band edge extends beyond the Nyquist limit frequencies, the demodulation and sampling process aliases this energy into the baseband to suppress intersymbol interference (ISI) and thereby avoid distortion. With the carrier frequency located at the -6 dB point on the carrier-side raised-cosine roll-off, energy in the vestigial sideband folds around zero frequency during demodulation to make the baseband DTV signal exhibit a flat amplitude response at lower frequencies, thereby suppressing low-frequency ISI. Then, during digitization by synchronous sampling of the demodulated I signal, the Nyquist slope through 5.38 MHz suppresses the remnant higher-frequency ISI. With ISI due to aliasing thus eliminated, equalization of linear distortions can be done using a single A/D converter sampling at the symbol rate of 10.76 Msamples/s and a real-only (not complex) equalizer also operating at the symbol rate. In this simple case, equalization of the signal beyond the -6 dB points in the raised-cosine roll-offs at channel edges is dependent on the in-band equalization and cannot be set independently. A complex equalizer does not have this limitation, nor does a fractional equalizer sampling at a rate sufficiently above the symbol rate.

TABLE 16.15 Parameters for VSB Transmission Modes

Parameter	Terrestrial Mode	High Data Rate Mode
Channel bandwidth	6 MHz	6 MHz
Excess bandwidth	11.5%	11.5%
Symbol rate	10.76 Msymbols/s	10.76 Msymbols/s
Bits per symbol	3	4
Trellis FEC	2/3 rate	None
Reed-Solomon FEC	T = 10 (207, 187)	T = 10 (207, 187)
Segment length	832 symbols	832 symbols
Segment sync	4 symbols per segment	4 symbols per segment
Frame sync	1 per 313 segments	1 per 313 segments
Payload data rate	19.39 Mbps	38.78 Mbps
Analog co-channel rejection	Analog rejection filter in receiver	N/A
Pilot power contribution	0.3 dB	0.3 dB
C/N threshold	14.9 dB	28.3 dB

The 8-VSB signal is designed to minimize interference and RF channel allocation problems. The VSB signal is designed to minimize peak-energy-to-average-energy ratio, thereby minimizing interference into other signals, especially adjacent and “taboo” channels. To counter the man-made noise that often accompanies over-the-air broadcast signals, the VSB system includes an interleaver that allows correction of an isolated single burst of noise up to 190 microseconds in length by the (207,187) RS FEC circuitry, which locates as well as corrects up to 10 byte errors per data segment. This was done to allow VHF channels, which are often substantially affected by man-made noise, to be used for DTV broadcasting. If soft-decision techniques are used in the trellis decoder preceding the RS circuitry, the location of errors can be flagged, and twice as many byte errors per data segment can be corrected, allowing correction of an isolated burst of up to 380 microseconds in length.

The parameters for the two VSB transmission modes are shown in Table 16.15.

Bit Rate Delivered to a Transport Decoder by the Transmission Subsystem

As outlined previously, all data in the ATSC DTV system is transported in MPEG-2 transport packets. The useful data rate is the amount of MPEG-2 transport data carried end-to-end including MPEG-2 packet headers and sync bytes. The exact symbol rate of the transmission subsystem is given by

$$\frac{4.5}{286} \times 684 = 10.7 \dots \text{million symbols/second (megabaud)} \quad (16.1)$$

The symbol rate must be locked in frequency to the transport rate.

The numbers in the formula for the ATSC symbol rate in 6 MHz systems are related to NTSC scanning and color frequencies. Because of this relationship, the symbol clock can be used as a basis for generating an NTSC color subcarrier for analog output from a set top box. The repetition rates of data segments and data frames are deliberately chosen not to have an integer relationship to NTSC or PAL scanning rates, to insure that there is no discernible pattern in co-channel interference.

The particular numbers used are

- 4.5 MHz = the center frequency of the audio carrier offset in NTSC. This number was traditionally used in NTSC literature to derive the color subcarrier frequency and scanning rates. In modern equipment, this may start with a precision 10 MHz reference, which is then multiplied by 9/20.
- 4.5 MHz/286 = the horizontal scan rate of NTSC, 15734.2657 + ... Hz (note that the color subcarrier is 455/2 times this, or 3579545 +5/11 Hz).
- 684: this multiplier gives a symbol rate for an efficient use of bandwidth in 6 MHz. It requires a filter with Nyquist roll-off that is a fairly sharp cutoff (11% excess bandwidth), which is still realizable with a reasonable surface acoustic wave (SAW) filter or digital filter.

In the terrestrial broadcast mode, channel symbols carry three bits/symbol of trellis-coded data. The trellis code rate is 2/3, providing 2 bits/symbol of gross payload. Therefore the gross payload is

$$10.76 \dots \times 2 = 21.52 \dots \text{ Mbps (megabits/second)} \tag{16.2}$$

To find the net payload delivered to a decoder it is necessary to adjust (16.2) for the overhead of the *data segment sync*, *data field sync*, and Reed-Solomon FEC.

To get the net bit rate for an MPEG-2 stream carried by the system (and supplied to an MPEG transport decoder), it is first noted that the MPEG sync bytes are removed from the data stream input to the 8-VSB transmitter and replaced with segment sync, and later reconstituted at the receiver. For throughput of MPEG packets (the only allowed transport mechanism), segment sync is simply equivalent to transmitting the MPEG sync byte, and does not reduce the net data rate. The net bit rate of an MPEG-2 stream carried by the system and delivered to the transport decoder is accordingly reduced by the data field sync (one segment of every 313) and the Reed-Solomon coding (20 bytes of every 208):

$$21.52 \dots \text{ Mbps} \times \frac{312}{313} \times \frac{188}{208} = 19.39 \dots \text{ Mbps} \tag{16.3}$$

The net bit rate supplied to the transport decoder for the high data rate mode is

$$19.39 \dots \text{ Mbps} \times 2 = 38.78 \dots \text{ Mbps} \tag{16.4}$$

Performance Characteristics of Terrestrial Broadcast Mode

The terrestrial 8-VSB system can operate in a signal-to-additive-white-Gaussian-noise (S/N) environment of 14.9 dB. The 8-VSB segment error probability curve including 4-state trellis decoding and (207,187) Reed-Solomon decoding in Figure 16.58 shows a segment error probability of 1.93×10^{-4} . This is equivalent to 2.5 segment errors/second, which was established by measurement as the *threshold of visibility* (TOV) of errors in the prototype equipment [14]. Particular product designs may achieve somewhat better performance for subjective TOV by means of error masking.

The *cumulative distribution function* (CDF) of the peak-to-average power ratio, as measured on a low power transmitted signal with no nonlinearities, is plotted in Figure 16.59. The plot shows that 99.9% of the time the transient peak power is within 6.3 dB of the average power.

FIGURE 16.58 Segment error probability, 8-VSB with 4 state trellis decoding, RS (207, 187).

FIGURE 16.59 Cumulative distribution function of 8-VSB peak-to-average power ratio (in ideal linear system).

Transmitter Signal Processing

A pre-equalizer filter is recommended for use in over-the-air broadcasts where the high power transmitter may have significant in-band ripple or significant roll off at band edges. Pre-equalization is typically required in order to compensate the high-order filter used to meet a stringent out-of-band emission mask, such as the U.S. FCC required mask [15]. This linear distortion can be measured by an equalizer in a reference demodulator (“ideal” receiver) employed at the transmitter site. A directional coupler, which is recommended to be located at the sending end of the antenna feed transmission line, supplies the reference demodulator a small sample of the antenna signal feed. The equalizer tap weights of the reference demodulator are transferred to the transmitter pre-equalizer for pre-correction of transmitter linear distortion. This is a one-time procedure of measurement and transmitter pre-equalizer adjustment. Alternatively, the transmitter pre-equalizer can be made continuously adaptive. In this arrangement, the reference demodulator is provided with a fixed-coefficient equalizer compensating for its own deficiencies in ideal response.

A pre-equalizer suitable for many applications is an 80 tap, feed-forward transversal filter. The taps are symbol-spaced (93 ns) with the main tap being approximately at the center, giving approximately ± 3.7 microsecond correction range. The pre-equalizer operates on the I channel data signal (there is no Q channel data signal in the transmitter), and shapes the frequency spectrum of the IF signal so that there is a flat in-band spectrum at the output of the high power transmitter that feeds the antenna for transmission. There is no effect on the out-of-band spectrum of the transmitted signal. If desired, complex equalizers or fractional equalizers (with closer-spaced taps) can provide independent control of the outer portions of the spectrum (beyond the Nyquist slopes).

The transmitter vestigial sideband filtering is sometimes implemented by sideband cancellation, using the phasing method. In this method, the baseband data signal is supplied to digital filtering that generates in-phase and quadrature-phase digital modulation signals for application to respective D/A converters.

This filtering process provides the root raised cosine Nyquist filtering and provides compensation for the $(\sin x)/x$ frequency responses of the D/A converters, as well. The baseband signals are converted to analog form. The in-phase signal modulates the amplitude of the IF carrier at zero degrees phase, while the quadrature signal modulates a 90° shifted version of the carrier. The amplitude-modulated quadrature IF carriers are added to create the vestigial sideband IF signal, canceling the unwanted sideband and increasing the desired sideband by 6 dB.

Upconverter and RF Carrier Frequency Offsets

Modern analog TV transmitters use a two-step modulation process. The first step usually is modulation of the data onto an IF carrier, which is the same frequency for all channels, followed by translation to the desired RF channel. The digital 8-VSB transmitter applies this same two-step modulation process. The RF upconverter translates the filtered flat IF data signal spectrum to the desired RF channel. For the same approximate coverage as an analog transmitter (at the same frequency), the average power of the DTV signal is on the order of 12 dB less than the analog peak sync power (when operating on the same frequency).

The nominal frequency of the RF upconverter oscillator in DTV terrestrial broadcasts will typically be the same as that used for analog transmitters (except for offsets required in particular situations).

Note that all examples in this section relate to a 6 MHz DTV system. Values may be modified easily for other channel widths.

Nominal DTV Pilot Carrier Frequency

The nominal DTV pilot carrier frequency is determined by fitting the DTV spectrum symmetrically into the RF channel. This is obtained by taking the bandwidth of the DTV signal—5,381.1189 kHz (the Nyquist frequency difference or one-half the symbol clock frequency of 10,762.2378 kHz)—and centering it in the 6 MHz TV channel. Subtracting 5,381.1189 kHz from 6,000 kHz leaves 618.881119 kHz. Half of that is 309.440559 kHz, precisely the standard pilot offset above the lower channel edge. For example, on channel 45 (656–662 MHz), the nominal pilot frequency is 656.309440559 MHz.

Requirements for Offsets

There are two categories of requirements for pilot frequency offsets:

1. Offsets to protect lower adjacent channel analog broadcasts, mandated by FCC rules in the U.S., and which override other offset considerations.
2. Recommended offsets for other considerations such as co-channel interference between DTV stations or between DTV and analog stations.

Upper DTV Channel into Lower Analog Channel

This is the overriding case mandated by the FCC rules in the U.S.—precision offset with a lower adjacent analog station, full service or low power television (LPTV).

The FCC Rules, Section 73.622(g)(1), states that

“DTV stations operating on a channel allotment designated with a “c” in paragraph (b) of this section must maintain the pilot carrier frequency of the DTV signal 5.082138 MHz above the visual carrier frequency of any analog TV broadcast station that operates on the lower adjacent channel and is located within 88 km. This frequency difference must be maintained within a tolerance of ± 3 Hz.”

This precise offset is necessary to reduce the color beat and high-frequency luminance beat created by the DTV pilot carrier in some receivers tuned to the lower adjacent analog channel. The tight tolerance assures that the beat will be visually cancelled, since it will be out of phase on successive video frames.

Note that the frequency is expressed with respect to the lower adjacent analog video carrier, rather than the nominal channel edge. This is because the beat frequency depends on this relationship, and therefore the DTV pilot frequency must track any offsets in the analog video carrier frequency. The offset in the

FCC rules is related to the particular horizontal scanning rate of NTSC, and can easily be modified for PAL. The offset O_f was obtained from

$$O_f = 455 \times \left(\frac{F_h}{2} \right) + 191 \times \left(\frac{F_h}{2} \right) - 29.97 = 5,082,138 \text{ Hz} \quad (16.5)$$

Where F_h = NTSC horizontal scanning frequency = 15,734.264 Hz.

The equation indicates that the offset with respect to the lower adjacent chroma is an odd multiple (191) of one-half the line rate to eliminate the color beat. However, this choice leaves the possibility of a luma beat. The offset is additionally adjusted by one-half the analog field rate to eliminate the luma beat. While satisfying the exact adjacent channel criteria, this offset is also as close as possible to optimal comb filtering of the analog co-channel in the digital receiver. Note additionally that offsets are to higher frequencies rather than lower, to avoid any possibility of encroaching on the lower adjacent sound. (It also reduces the likelihood of the automatic fine tuning (AFT) in the analog receiver experiencing lock-out because the signal energy including the pilot is moved further from the analog receiver bandpass.)

Other Offset Cases

The FCC rules do not consider other interference cases where offsets help. The offset for protecting lower-adjacent analog signals takes precedence. If that offset is not required, other offsets can minimize interference to co-channel analog or DTV signals.

In co-channel cases, DTV interference into analog TV appears noise-like. The pilot carrier is low on the Nyquist slope of the IF filter in the analog receiver, so no discernable beat is generated. In this case, offsets to protect the analog channel are not required. Offsets are useful, however, to reduce co-channel interference from analog TV into DTV. The performance of the analog rejection filter and clock recovery in the DTV receiver will be improved if the DTV carrier is 911.944 kHz below the NTSC visual carrier. In other words, in the case of a 6 MHz NTSC system, if the analog TV station is not offset, the DTV pilot carrier frequency will be 338.0556 kHz above the lower channel edge instead of the nominal 309.44056 kHz. As before, if the NTSC station is operating with a ± 10 kHz offset, the DTV frequency will have to be adjusted in the same direction. The formula for calculating this offset is

$$F_{\text{pilot}} = F_{\text{vis}(n)} - 70.5 \times F_{\text{seg}} = 338.0556 \text{ Hz (for no NTSC analog offset)} \quad (16.6)$$

Where

F_{pilot} = DTV pilot frequency above lower channel edge

$F_{\text{vis}(n)}$ = NTSC visual carrier frequency above lower channel edge

= 1250 kHz for no NTSC offset (as shown)

= 1240 kHz for minus offset

= 1260 kHz for plus offset

F_{seg} = ATSC data segment rate; = symbol clock frequency/832 = 12,935.381971 Hz

The factor of 70.5 is chosen to provide the best overall comb filtering of analog color TV co-channel interference. The use of a value equal to an integer +0.5 results in co-channel analog TV interference being out-of-phase on successive data segment syncs.

Note that in this case the frequency tolerance is plus or minus one kHz. More precision is not required. Also note that a different data segment rate would be used for calculating offsets for 7 or 8 MHz systems.

Co-channel DTV into DTV

If two DTV stations share the same channel, interference between the two stations can be reduced if the pilot is offset by one and a half times the data segment rate. This ensures that the frame and segment syncs of the interfering signal will each alternate polarity and be averaged out in the receiver tuned to the desired signal.

TABLE 16.16 DTV Pilot Carrier Frequencies for Two Stations (Normal offset above lower channel edge: 309.440559 kHz)

Channel Relationship	DTV Pilot Carrier Frequency Above Lower Channel Edge			
	NTSC Station Zero Offset	NTSC Station +10 kHz Offset	NTSC Station −10 kHz Offset	DTV Station No Offset
DTV with lower adjacent NTSC	332.138 kHz ±3 Hz	342.138 kHz ±3 Hz	322.138 kHz ±3 Hz	
DTV co-channel with NTSC	338.056 kHz ±1 kHz	348.056 kHz ±1 kHz	328.056 kHz ±1 kHz	
DTV co-channel with DTV	+19.403 kHz above DTV	+19.403 kHz above DTV	+19.403 kHz above DTV	328.8436 kHz ±10 Hz

The formula for this offset is

$$F_{\text{offset}} = 1.5 \times F_{\text{seg}} = 19.4031 \text{ kHz} \tag{16.7}$$

Where

$$F_{\text{offset}} = \text{offset to be added to one of the two DTV carriers}$$

$$F_{\text{seg}} = 12,935.381971 \text{ Hz (as defined previously)}$$

This results in a pilot carrier 328.84363 kHz above the lower band edge, provided neither DTV station has any other offset.

Use of the factor 1.5 results in the best co-channel rejection, as determined experimentally with the prototype equipment. The use of an integer +0.5 results in co-channel interference alternating phase on successive segment syncs.

Summary: DTV Frequency

Table 16.16 summarizes the various pilot carrier offsets for different interference situations in a 6 MHz system (NTSC environment). Note that if more than two stations are involved the number of potential frequencies will increase. For example, if one DTV station operates at an offset because of a lower-adjacent-channel NTSC station, a co-channel DTV station may have to adjust its frequency to maintain a 19.403 kHz pilot offset. If the NTSC analog station operates at an offset of plus or minus 10 kHz, both DTV stations should compensate for that. Cooperation between stations will be essential in order to reduce interference.

Frequency Tolerances

The tightest specification is for a DTV station with a lower adjacent NTSC analog station. If both NTSC and DTV stations are at the same location, they may simply be locked to the same reference. The co-located DTV station carrier should be 5.082138 MHz above the NTSC visual carrier (22.697 kHz above the normal pilot frequency). The co-channel DTV station should set its carrier 19.403 kHz above the co-located DTV carrier.

If there is interference with a co-channel DTV station, the analog station is expected to be stable within 10 Hz of its assigned frequency.

While it is possible to lock the frequency of the DTV station to the relevant NTSC station, this may not be the best option if the two stations are not at the same location. It will likely be easier to maintain the frequency of each station within the necessary tolerances. Where co-channel interference is a problem, that will be the only option.

In cases where no type of interference is expected, a pilot carrier-frequency tolerance of ±1 kHz is acceptable, but in all cases, good practice is to use a tighter tolerance if practicable.

Defining Terms

Anchor frame: In MPEG-2, a video frame that is used for prediction. I-frames and P-frames are generally used as anchor frames, but B-frames are never anchor frames.

Asynchronous transfer mode (ATM): A digital signal protocol for efficient transport of both constant-rate and bursty information in broadband digital networks. The ATM digital stream consists of fixed-length packets called “cells,” each containing 53 8-bit bytes—a 5-byte header and a 48-byte information payload.

Bidirectional pictures (or B-pictures or B-frames): In MPEG-2, pictures that use both future and past pictures as a reference. This technique is termed *bidirectional prediction*. B-pictures provide the most compression. B-pictures do not propagate coding errors as they are never used as a reference.

Bit rate: The rate at which the compressed bit stream is delivered from the channel to the input of a decoder.

Block: A block is an 8-by-8 array of pel values or DCT coefficients representing luminance or chrominance information.

Byte-aligned: A bit in a coded bit stream is byte-aligned if its position is a multiple of 8-bits from the first bit in the stream.

Compression: Reduction in the number of bits used to represent an item of data.

Constant bit rate: A mode of operation in a digital system where the bit rate is constant from start to finish of the compressed bit stream.

Conventional definition television (CDTV): This term is used to signify the *analog* NTSC television system as defined in ITU-R Recommendation 470. See also *standard definition television*.

CRC: The cyclic redundancy check to verify the correctness of data.

D-frame: A frame coded according to an MPEG-1 mode that uses DC coefficients only.

Data element: An item of data as represented before encoding and after decoding.

Decoded stream: The decoded reconstruction of a compressed bit stream.

Decoder: An embodiment of a decoding process.

Digital storage media (DSM): A digital storage or transmission device or system.

Discrete cosine transform: A mathematical transform that can be perfectly undone and which is useful in image compression.

Elementary stream (ES): A generic term for one of the coded video, coded audio, or other coded bit streams in a DTV system.

Encoder: An embodiment of an encoding process.

Entitlement control message (ECM): Entitlement control messages are private conditional access information that specify control words and possibly other stream-specific, scrambling, and/or control parameters.

Entitlement management message (EMM): Entitlement management messages are private conditional access information that specify the authorization level or the services of specific decoders. They may be addressed to single decoders or groups of decoders.

Entropy coding: Variable length lossless coding of the digital representation of a signal to reduce redundancy.

Entry point: Refers to a point in a coded bit stream after which a decoder can become properly initialized and commence syntactically correct decoding. The first transmitted picture after an entry point is either an I-picture or a P-picture. If the first transmitted picture is not an I-picture, the decoder may produce one or more pictures during acquisition.

Event: A collection of elementary streams with a common time base, an associated start time, and an associated end time.

Field: For an interlaced video signal, a “field” is the assembly of alternate lines of a frame. Therefore, an interlaced frame is composed of two fields, a top field and a bottom field.

Frame: A frame contains lines of spatial information of a video signal. For progressive video, these lines contain samples starting from one time instant and continuing through successive lines to the

bottom of the frame. For interlaced video, a frame consists of two fields, a top field and a bottom field. One of these fields will commence one field later than the other.

Group of pictures (GOP): In MPEG-2, a group of pictures consists of one or more pictures in sequence.

High-definition television (HDTV): A system that provides significantly improved picture quality with more visible detail, a wide screen format (16:9 aspect ratio), and may be accompanied by digital surround-sound capability.

High level: A range of allowed picture parameters defined by the MPEG-2 video coding specification that corresponds to high-definition television.

Huffman coding: A type of source coding that uses codes of different lengths to represent symbols which have unequal likelihood of occurrence.

Intra coded pictures (or I-pictures or I-frames): MPEG-2 pictures that are coded using information present only in the picture itself and not depending on information from other pictures. I-pictures provide a mechanism for random access into the compressed video data. I-pictures employ transform coding of the pel blocks and provide only moderate compression.

Level: A range of allowed picture parameters and combinations of picture parameters in the DTV system.

Main level: A range of allowed picture parameters defined by the MPEG-2 video coding specification with maximum resolution equivalent to ITU-R Recommendation 601.

Main profile: A subset of the syntax of the MPEG-2 video coding specification that is supported over a large range of applications.

Motion vector: A pair of numbers that represent the vertical and horizontal displacement of a region of a reference picture for MPEG-2 prediction.

MPEG: Refers to standards developed by the ISO/IEC JTC1/SC29 WG11, *Moving Picture Experts Group*. MPEG may also refer to the Group itself.

MPEG-1: Refers to ISO/IEC standards 11172-1 (Systems), 11172-2 (Video), 11172-3 (Audio), 11172-4 (Compliance Testing), and 11172-5 (Technical Report).

MPEG-2: Refers to ISO/IEC standards 13818-1 (Systems), 13818-2 (Video), 13818-3 (Audio), 13818-4 (Compliance).

Packet: A packet consists of a header followed by a number of contiguous bytes from an elementary data stream. It is a layer in the system coding syntax of the DTV system.

Payload: Payload refers to the bytes that follow the header byte in a packet. The transport stream packet header and adaptation fields are not payload.

PES packet: The data structure used to carry elementary stream data. It consists of a packet header followed by PES packet payload.

PES stream: A PES stream consists of PES packets, all of whose payloads consist of data from a single elementary stream, and all of which have the same stream ID number.

Picture: Source, coded, or reconstructed image data. A source or reconstructed picture consists of three rectangular matrices representing the luminance and two chrominance signals.

Pixel: "Picture element" or "pel." A pixel is a digital sample of the color intensity values of a picture at a single point.

Predicted pictures or P-pictures or P-frames: MPEG-2 pictures that are coded with respect to the nearest *previous* I or P-picture. This technique is termed *forward prediction*. P-pictures provide more compression than I-pictures and serve as a reference for future P-pictures or B-pictures. P-pictures can propagate coding errors when P-pictures (or B-pictures) are predicted from prior P-pictures where the prediction is flawed.

Profile: A defined subset of the syntax specified in the MPEG-2 video coding specification.

Program clock reference (PCR): A time stamp in the transport stream from which decoder timing is derived.

Program specific information (PSI): Normative data that are necessary for the demultiplexing of transport streams and the successful regeneration of programs.

Program: A program is a collection of program elements. Program elements may be elementary streams. Program elements need not have any defined time base; those that do have a common time base and are intended for synchronized presentation.

Quantizer: A processing step that intentionally reduces the precision of DCT coefficients.

Random access: The process of beginning to read and decode the coded bit stream at an arbitrary point.

Scrambling: The alteration of the characteristics of a video, audio, or coded data stream in order to prevent unauthorized reception of the information in a clear form. This alteration is a specified process under the control of a conditional access system.

Source stream: A single, nonmultiplexed stream of samples before compression coding.

Splicing: The concatenation performed on the system level or two different elementary streams.

Standard definition television (SDTV): This term is used to signify a *digital* television system in which the quality is approximately equivalent to that of NTSC. This equivalent quality may be achieved from pictures sourced at the 4:2:2 level of ITU-R Recommendation 601 and subjected to processing as part of the bit rate compression. The results should be such that when judged across a representative sample of program material, subjective equivalence with NTSC is achieved. Also called *standard digital television*.

Start codes: 32-bit codes embedded in the coded bit stream that are unique. They are used for several purposes including identifying some of the layers in the coding syntax.

STD input buffer: A first-in, first-out buffer at the input of a system target decoder for storage of compressed data from elementary streams before decoding.

System clock reference (SCR): A time stamp in the program stream from which decoder timing is derived.

System header: The system header is a data structure that carries information summarizing the system characteristics of the DTV multiplexed bit stream.

System target decoder (STD): A hypothetical reference model of a decoding process used to describe the semantics of the DTV multiplexed bit stream.

Time-stamp: A term that indicates the time of a specific action such as the arrival of a byte or the presentation of a presentation unit.

TOV: Threshold of visibility, used to judge the quality of an analog or digital video signal.

Variable bit rate: Operation in a digital system where the bit rate varies with time during the decoding of a compressed bit stream.

Video buffering verifier (VBV): A hypothetical decoder that is conceptually connected to the output of an encoder. Its purpose is to provide a constraint on the variability of the data rate that an encoder can produce.

8 VSB: Vestigial sideband modulation with 8 discrete amplitude levels.

16 VSB: Vestigial sideband modulation with 16 discrete amplitude levels.

16.6 Propagation Considerations for Mobile Radio Systems

Michel D. Yacoub

16.6.1 Introduction

Mobile communications systems have been driven to use high frequencies due to the congestion at the low portion of the frequency spectrum, where the available bandwidth was not adequate to satisfy the great demand for mobile services. Dealing with high frequencies, however, usually leads to intricate problems, which are severely aggravated by the mobility of the users. Any small-sized object may work as a scatterer, and the multiple reflections provoke multipath propagation. As a consequence, the received signal fades rapidly. With the users moving from one place to another, large variations on the mean signal level are experienced due to different environments. In addition to this, cochannel and adjacent channel interference and a number of different types of noise may influence the transmission quality. Other kinds of phenomena, such as Doppler shift, random frequency modulation, etc., are also present in the signal.

16.6.2 Basic Propagation Models

The propagation of energy in a mobile radio environment is strongly influenced by several factors, including natural and artificial relief, propagation frequency, antenna heights, and others. A precise characterization of the signal variability in this environment constitutes a hard task. Deterministic methods, such as those described by the *free-space*, *plane earth*, and *knife-edge diffraction* models, are restricted to very simple applications. They are useful, however, in providing the basic propagation mechanisms.

In radio propagation studies one measure of interest is the **path loss** l , defined as the ratio between the transmitted power w_t and the received power w_r . It is frequently expressed in decibel as

$$L = 10 \log l = 10 \log \frac{w_t}{w_r} \quad (16.8)$$

In the next subsections we describe the three mentioned propagation models with the aim of determining their respective path losses.

Free-Space Model

A free-space condition represents an ideal situation, characterized by a line-of-sight propagation between transmitter and receiver, in which the radio propagation phenomenon is basically affected by the distance d between transmitter and receiver and by the wavelength λ of the propagated wave. In such a condition, the ratio between the received power w_r and the transmitted power w_t is given by the Friis free-space transmission formula

$$\frac{w_r}{w_t} = G_t G_r \left(\frac{\lambda}{4\pi d} \right)^2 \quad (16.9)$$

where G_t and G_r are the transmitting and receiving antenna gain, respectively.

Using the relation $c = \lambda f$, where c is the wave propagation velocity assumed to be 3×10^8 m/s and f is the frequency, for isotropic and lossless antennas ($G_t = G_r = 1$) the path loss expressed in decibel is

$$L = 20 \log f + 20 \log d + 32.44 \quad (16.10)$$

In Eq. (16.10) f is given in megahertz and d in kilometers.

Plane Earth Model

When two elevated antennas within line of sight of each other are mounted over a flat terrain, the received signal will be the resultant of the vector sum of the waves traveling through a direct path and those reaching the antenna through indirect paths. The indirect signals comprise mostly the reflected and surface waves. Reflection effects must be considered whenever the dimension of the surface obstructing the signal is large compared to its wavelength. Surface waves are only effective at a few wavelengths above the ground and are usually neglected for mobile radio communications purposes. Accordingly, the ratio between received and transmitted powers can be written as

$$\frac{w_r}{w_t} = G_t G_r \left(\frac{\lambda}{4\pi d} \right)^2 |1 + \rho e^{j\Delta\varphi}|^2 \quad (16.11)$$

where $\Delta\varphi$ is the phase difference between direct and indirect paths and ρ is the reflection coefficient. For grazing angles or frequencies above 100 MHz and incidence angles less than 10° , ρ tends to -1 . Writing $\Delta\varphi$ as a function of the wavelength λ and taking the geometry shown in Fig. 16.60 into account we obtain

$$\Delta\varphi = \frac{2\pi d}{\lambda} \left\{ \left[\left(\frac{h_t + h_r}{d} \right)^2 + 1 \right]^{1/2} - \left[\left(\frac{h_t - h_r}{d} \right)^2 + 1 \right]^{1/2} \right\} \quad (16.12)$$

Using the approximations $(1 + x)^{1/2} \cong 1 + x/2$, for small x , and $\sin(\Delta\varphi/2) \cong \Delta\varphi/2$, we have

$$\frac{w_r}{w_t} = G_t G_r \left(\frac{h_t h_r}{d^2} \right)^2 \quad (16.13)$$

FIGURE 16.60 Flat terrain geometry.

FIGURE 16.61 Knife-edge diffraction geometry.

Assuming isotropic and lossless antennas ($G_t = G_r = 1$), the path loss is given by

$$L = 40 \log d - 20 \log(h_t h_r) \tag{16.14}$$

Knife-Edge Diffraction Model

If an obstruction exists that intercepts a radio wave propagated by the transmitter, the receiver may be reached by diffracted rays. In other words, even for situations in which receivers are placed in shadowed regions, radio communications can still be provided. The diffracted rays comprise the vector sum of the secondary waves resulting from the obstructing surface. Although the diffraction effects are usually more relevant for the obstructed conditions, they can also be sensed in a line-of-sight situation. This is illustrated in Fig. 16.61(a) and Fig. 16.61(b), respectively.

For a single and sharp obstruction, which characterizes the knife-edge condition, the diffracted field E can be calculated as a function of the radiated field E_0 using the classical diffraction theory, in which case

$$\frac{E}{E_0} = \frac{(1 + j)}{2} \int_x^\infty \exp\left(-j \frac{\pi}{2} t^2\right) dt = F \exp(j \Delta\varphi) \tag{16.15}$$

where F is the diffraction coefficient, $\Delta\varphi$ is the phase difference between the direct path and the indirect path, and x is the Fresnel–Kirchoff diffraction parameter given by

$$x = -h \sqrt{\frac{2(d_1 + d_2)}{\lambda d_1 d_2}} \tag{16.16}$$

In Eq. (16.16) λ is the wavelength and $h, d_1,$ and d_2 are the dimensions shown in Fig. 16.61.

Therefore, the loss due to diffraction is given by

$$L = 10 \log \left| \frac{E}{E_0} \right|^2 = 20 \log F \tag{16.17}$$

Figure 16.62 shows the diffraction loss as a function of the parameter x .

Some Considerations on the Basic Propagation Models

Free-Space Model

Note that, from Eq. (16.10), in free-space conditions the path loss rate due to the distance is 20 dB/decade or 6 dB/octave. Moreover, although it has been said that the free-space model describes an ideal propagation condition, it can indeed be accurately used in satellite communication systems and short line-of-sight radio links.

Plane Earth Model

Note that, from Eq. (16.14), the path loss rate due to the distance is 40 dB/decade or 12 dB/octave. In the same way, the loss rate due to the antenna heights is -20 dB/decade or -6 dB/octave. In other words, a gain is obtained with the increase of the antenna height. A flat terrain condition can be assumed for

FIGURE 16.62 Knife-edge diffraction loss.

distances less than a few tens of kilometers, in which case the Earth curvature is negligible. Moreover, in general, for mobile radio applications, because the antennas' heights are small compared to the distance separating the transmitter and receiver, the grazing angle assumption is also reasonable. Equation (16.13) is a valid approximation for situations in which the loss due to reflection exceeds that of the free space, this occurring when $d > 12h_t h_r / \lambda$. Because, in practice, a perfectly flat terrain condition does not exist, a measure of smoothness S is utilized. This measure is given by the Rayleigh criterion as a function of the standard deviation σ of the mean heights of the terrain irregularities, the incidence angle θ of the ray, and the wavelength λ , such that

$$S = \frac{4\pi\sigma \sin \theta}{\lambda} \quad (16.18)$$

A surface is considered to be smooth if $S < 0.1$, whereas it is considered as rough if $S > 10$.

Knife-Edge Diffraction Model

An element positioned at any given point between transmitter and receiver is said to produce diffraction effects at the receiver if its height h obstructs the Fresnel zones in the concerned radio path. It is recognized that the first Fresnel zone bounds the volume contributing significantly to wave propagation. Therefore, an obstruction should be considered as a diffracting element if

$$h > \sqrt{\frac{\lambda d_1 d_2}{(d_1 + d_2)}} \quad (16.19)$$

The simple knife-edge diffraction model applies to single obstructing elements only. In practical situations a radio path will certainly encounter several obstructions, and the exact computation of the total diffraction loss is cumbersome. Many approximate solutions are available, and their accuracy varies according to the application. The Bullington method (Bullington, 1947) replaces the obstructions by an equivalent

edge found at the intersection point between the line connecting transmitter-first-obstruction-from-transmitter and that connecting receiver-first-obstruction-from-receiver. The Deygout method (Deygout, 1966) selects a dominant obstruction and calculates the corresponding loss. The losses due to the remaining knife edges are determined with respect to this dominant edge.

16.6.3 Field Strength Prediction Models

Generally speaking, the best known field strength prediction models currently available arose as a combination of some of the previously described analytical models with data obtained in field measurements. The resulting empirical models include several adjustment parameters, most of them lacking theoretical explanations, and their applicability is restricted to situations in which the experiments were performed. Predictions for situations other than the original ones must be exercised with care and are, usually, not recommended, unless further adjustments can be performed with field measurements.

Okumura Model

The Okumura model (Okumura et al., 1968) is based on field measurements taken in the Tokyo area. It provides an initial excess path loss estimate $A(f, d)$ with respect to the free-space loss L_F , as a function of the operating frequency f , ranging from 100 to 3000 MHz, and of the distance d , ranging from 1 to 100 km. This initial estimate has been obtained for a quasismooth terrain and for a base station antenna height h_{tb} of 200 m and a mobile station antenna height h_{rb} of 3 m. Correction factors are then introduced to account for conditions other than the initial ones. In particular, a gain $G(\text{area}, f)$ as a function of the frequency f can be encountered for *suburban area*, *quasiopen area*, and *open area*. Moreover, gains $G(h_t)$ and $G(h_r)$ due to base station and mobile station antenna heights, h_t and h_r , respectively, must be computed. Accordingly, the general path loss formulation L , in decibels, of the Okumura model is

$$L = L_F + A(f, d) - G(\text{area}, f) - G(h_t) - G(h_r) \quad (16.20)$$

Apart from the free-space loss, which can be calculated in analytical form, all of the other parameters in Eq. (16.20) are provided in graph form. The plots show that there is a gain ranging from 5 to 13 dB as the frequency goes from 100 to 3000 MHz due to a change from urban to suburban area. In the same way, the gain is reasonably constant and approximately equal to 12 dB due to a change from suburban to quasiopen area, whereas this is approximately 6 dB for a change from quasiopen to open area. As far as the antenna heights are concerned, the gain is 20 dB/decade for the base station antenna and 20 dB/decade for the mobile station antenna height if $3 < h_r < 10$ m, but 10 dB/decade if $h_r < 3$ m.

The Okumura model is probably one of the most complete prediction models and has become a comparison standard for other models.

Hata Model

Because the Okumura model is totally based on information provided by empirical curves, its automated version can become cumbersome. Hata (1980) has proposed an empirical formulation that fits the Okumura curves within a useful range of application. Within such a range the Hata model gives predictions almost indistinguishable from those provided by Okumura. The general path loss L of the Hata formulation, in decibels, for distances d , in kilometers, and base and mobile antenna heights h_t and h_r , in meters, within the range

$$150 \leq f \leq 1000 \text{ MHz}$$

$$30 \leq h_t \leq 200 \text{ m}$$

$$1 \leq h_r \leq 10 \text{ m}$$

$$1 \leq d \leq 20 \text{ km}$$

is as follows:

Urban area

$$L_{\text{urban}} = 69.55 + 26.16 \log f - 13.82 \log h_t - A(h_r) + (44.9 - 6.55 \log h_t) \log d \quad (16.21)$$

where $A(h_r)$ is a correction factor computed according to the size of the city.

For a small or medium-sized city and $1 \leq h_r \leq 10$ m

$$A(h_r) = (1.1 \log f - 0.7)h_r - (1.56 \log f - 0.8) \quad (16.22)$$

For a large city and $f \leq 200$ MHz

$$A(h_r) = 8.29 \log^2(1.54h_r) - 1.1 \quad (16.23)$$

For a large city and $f \geq 400$ MHz

$$A(h_r) = 3.2 \log^2(11.75h_r) - 4.97 \quad (16.24)$$

Suburban area

$$L = L_{\text{urban}} - 2 \log^2(f/28) - 5.4 \quad (16.25)$$

Rural (quasiopen) area

$$L = L_{\text{urban}} - 4.78 \log^2(f) + 18.33 \log f - 35.94 \quad (16.26)$$

Rural area (open area)

$$L = L_{\text{urban}} - 4.78 \log^2(f) + 18.33 \log f - 40.94 \quad (16.27)$$

COST 231-Hata Model

This model (ETR 103 1995) has been developed by the European Cooperation in the Field of Scientific and Technical Research (Euro-Cost), COST 231 subgroup on propagation models. It has been derived from Okumura's propagation curves in the upper frequency band. It is, therefore, an extension of the Hata model for frequencies f in the range $1500 \leq f \leq 2000$ MHz. The application of this model is restricted to large and small cells.

The parameters considered here are the same as those defined previously in the subsection on the Hata model. The basic loss for rural areas are the those expressed in Eq. (16.26) and Eq. (16.27). The path loss is as follows:

Urban area

$$L = 46.3 + 33.9 \log f - 13.82 \log h_t - A(h_r) + (44.9 - 6.55 \log h_r) \log d \quad (16.28)$$

where $A(h_r)$ is a correction factor computed according to the urban environment.

For medium-sized and suburban centers with moderate tree density

$$A(h_r) = (1.1 \log f - 0.7)h_r - (1.58 \log f - 0.8) \quad (16.29)$$

For metropolitan centers

$$A(h_r) = (1.1 \log f - 0.7)h_r - (1.58 \log f + 2.2) \quad (16.30)$$

Lee Model

The Lee model (Lee, 1986) is based on the well-accepted assumption that the ratio between the powers received at two different distances from the base station is proportional to the ratio of these distances to the power of the path loss coefficient. Accordingly, the model is completely determined if the received power at a given distance and the path loss coefficient for the required environment are known. These two

parameters are easily obtained, for a given set of basic initial conditions, by carrying out field measurements. Or, alternatively, by using data already available in the literature. Correction factors are then included in order to account for conditions other than the basic initial ones. There are four correction factors, and they are related to the base station and mobile station antenna heights in addition to their respective gains.

This constitutes a simpler version of the model, known as the *area-to-area mode*. The model is further enhanced by incorporating the loss due to diffraction L_k , or reflection L_r , as applicable. In such a situation it assumes a *point-to-point mode*, in which case the terrain profile information is taken into account for a more accurate prediction. Assuming a basic path loss L_b for the initial conditions h_{tb} and h_{rb} (representing the base and mobile antenna heights) and G_{tb} , and G_{rb} (their respective gains), the total path loss L at a distance d and for the new base and mobile antenna heights h_t and h_r and gains G_t and G_r , respectively, is given by

$$L = L_b + 10\alpha \log\left(\frac{d}{d_b}\right) - C + m(oL_k - \bar{o}L_r) \tag{16.31}$$

where L, L_b, L_k , and L_r are given in decibels, α is the path loss coefficient, m is a binary parameter denoting a point-to-point mode ($m = 1$) or an area-to-area mode ($m = 0$), o is a binary parameter denoting obstructive path ($o = 1$) or nonobstructive path ($o = 0$) (the bar implies the NOT binary operation), d_b is an initial distance, and

$$C = 10 \log \left[\left(\frac{h_t}{h_{tb}} \right)^2 \left(\frac{h_r}{h_{rb}} \right)^x \left(\frac{G_t}{G_{tb}} \right) \left(\frac{G_r}{G_{rb}} \right) \right]$$

is the correction factor, with $x = 2$ for $h_r > 10$ m or $x = 1$ for $h_r < 10$.

Some values of L_b , for a transmission power of 10 W (40 dB(1 mW)) and for the basic initial conditions of $d_b = 1$ mi (1.6 km), $h_{tb} = 100$ ft (30.48 m), $h_{rb} = 10$ ft (3 m), $G_{tb} = 4$ (6 dB) with respect to $\lambda/2$ dipole, and $G_{rb} = 1$ (0 dB) also with respect to $\lambda/2$ dipole, are given in Table 16.17. Also shown are the values of α for the respective environment.

The loss due to diffraction may be computed by any of the methods available. On the other hand, the loss due to reflection is determined as

$$L_r = 20 \log\left(\frac{h_{te}}{h_t}\right) \tag{16.32}$$

where h_{te} is the effective base station antenna height, representing the imaginary height the base station antenna should have in order to touch the ground extended from the reflection point that is closer to the mobile station, as shown in Fig. 16.63. Accordingly, this can either represent a real loss ($h_{te} < h_t$) or a gain ($h_{te} > h_t$).

COST 231–Walfish–Ikegami Model

The COST 231 subgroup on propagation models (ETR 103 1995) has developed a prediction method in which street canyon propagation and radio paths obstructed by buildings are treated separately. It is based on measurements performed in the city of Stockholm, for the line-of-sight case, and on a combination of the Walfish and Bertoni (1988) and Ikegami et al. (1984) models, for the obstructed path situation. The model is applicable to large and small as well as micro cells for frequencies f , base station antenna height h_t , mobile station antenna height h_r , and distances d , within the following range:

$$800 \leq f \leq 2000 \text{ MHz}$$

$$4 \leq h_t \leq 50 \text{ m}$$

$$1 \leq h_r \leq 3 \text{ m}$$

$$0.02 \leq d \leq 5 \text{ km}$$

The Line-of-Sight (Street Canyon) Case

The path loss is given by

$$L = 42.6 + 26 \log d + 20 \log f \quad (16.33)$$

where $d \geq 0.020$ is given in kilometers, and f in megahertz.

The Obstructed Case

In the obstructed case the model also considers as parameters (1) the mean height of the buildings h_B , (2) the road width r_w , (3) the mean distance between the buildings d_B , and (4) the road orientation with respect to the direct radio path φ , with h_B , r_w , and d_B in meters and φ in degree. The total loss L , in decibels, is composed by three terms, all in decibels; namely, the free-space loss L_F , the roof top-to-street diffraction and scatter loss L_D , and the multiscreen loss L_S , as

$$L = L_F + L_D + L_S \quad (16.34)$$

The free-space loss is given by Eq. 16.10. The other losses are detailed next. The roof top-to-street diffraction and scatter loss is

$$L_D = -16.9 - 10 \log r_w + 10 \log f + 20 \log(h_B - h_r) + L_\varphi \quad (16.35)$$

where

$$L_\varphi = -10 + 0.354\varphi \quad 0 \leq \varphi < 35^\circ$$

$$L_\varphi = 2.5 + 0.075(\varphi - 35) \quad 35^\circ \leq \varphi < 55^\circ$$

$$L_\varphi = 4.0 - 0.114(\varphi - 55) \quad 55^\circ \leq \varphi < 90^\circ$$

If Eq. (16.35) gives a negative value, then L_D is assumed to be equal to zero. The multiscreen diffraction loss is

$$L_S = -18 \log(1 + h_t - h_B) - 9 \log d_B + k_a + k_d \log d + k_f \log f \quad (16.36)$$

where the first term after the equal sign is assumed to be zero if $h_t - h_B \leq 0$ and

$$\begin{aligned} k_a &= 54 & h_t - h_B &> 0 \\ k_a &= 54 - 0.8(h_t - h_B) & d \geq 0.5 \text{ and } h_t - h_B &\leq 0 \\ k_a &= 54 - 0.8(h_t - h_B) \frac{d}{0.5} & d < 0.5 \text{ and } h_t - h_B &\leq 0 \\ k_d &= 18 & h_t - h_B &> 0 \\ k_d &= 18 - 15 \left[\frac{(h_t - h_B)}{h_B} \right] & h_t - h_B &\leq 0 \\ k_f &= -4 + 0.7 \left(\frac{f}{925} - 1 \right) & \text{for medium-sized cities and suburban centers with moderate} & \\ & & \text{tree densities} & \\ k_f &= -4 + 1.5 \left(\frac{f}{925} - 1 \right) & \text{for metropolitan centers} & \end{aligned}$$

In case detailed data on the structure of buildings and roads are not available, the following default values are recommended: $d_B = 20, \dots, 50$ m, $r_w = d_B/2$, $h_B = 3 \times (\text{number of floors}) + \text{roof height}$, in meters, and $\varphi = 90^\circ$. The roof height is assumed 3 m for pitched roofs, or 0 m for flat roofs.

16.6.4 Statistical Distributions of the Received Envelope

The field prediction models give the mean value of the received power as a function of parameters that more strongly influence the propagation of the mobile radio signal. However, a countless number of variables exist that deviate the instantaneous signal from its mean value. For instance, different obstructions may attenuate, diffract, reflect, or scatter the signal differently, and an infinitude of obstacles are encountered by the signal on its way from transmitter to receiver. Accordingly, because it is not viable or practicable to take all of the phenomena influencing the mobile radio propagation into account the received signal is treated on a statistical basis.

The random variation in the signal level characterizes the fading phenomenon. There are two types of fading: (1) long-term or **slow fading** and (2) short-term or **fast fading**. The slow fading is related to the variability of the area mean signal level due to shadowing. The fast fading is associated with the variability of the local mean signal level due to multipath propagation.

In this section we describe the several distributions that better characterize the variability of received envelope. All of these distributions have proved to be satisfactory fits to data obtained by field measurements.

Lognormal Distribution

The lognormal distribution describes the long-term variation of the received envelope. The corresponding probability density function is given by

$$p(R) = \frac{1}{\sqrt{2\pi}\sigma_R} \exp \left[-\frac{1}{2} \left(\frac{R - M_R}{\sigma_R} \right)^2 \right] \quad (16.37)$$

where R is the signal envelope (the local mean), M_R is the area mean, and σ_R is the standard deviation, usually in the range 5–12 dB, all given in decibels.

Rayleigh Distribution

The Rayleigh distribution describes the short-term variation of the received envelope in a multipath propagation environment where the scattered waves are assumed to be uniformly distributed around the receiver. The corresponding probability density function is given by

$$p(r) = \frac{r}{\sigma_r^2} \exp\left(-\frac{r^2}{2\sigma_r^2}\right) \quad (16.38)$$

where r is the signal envelope and $\sqrt{\pi/2}\sigma_r$ is the local mean.

Rice Distribution

The Rice distribution describes the short-term variation of the received envelope in a multipath environment where a line of sight is also present. The corresponding probability density function is given by

$$p(r) = \frac{r}{\sigma_r^2} \exp\left(-\frac{r^2 + a^2}{2\sigma_r^2}\right) I_0\left(\frac{ar}{\sigma_r^2}\right) \quad (16.39)$$

where r is the signal envelope, $a^2/2$ is the power of the direct wave, σ_r^2 is the power of the scattered waves, and

$$I_0\left(\frac{ar}{\sigma_r^2}\right) = \frac{1}{2\pi} \int_0^{2\pi} \exp\left(\frac{ar \cos \theta}{\sigma_r^2}\right) d\theta$$

is the modified zeroth-order Bessel function. Note that if $a = 0$ in Eq. (16.39) the Rice distribution degenerates into the Rayleigh distribution.

Nakagami Distribution

The Nakagami distribution describes the short-term variation of the received envelope in a multipath environment where the scattered waves are assumed to reach the receiver in clusters. The corresponding probability density function is given by

$$p(r) = \frac{2}{\Gamma(m)} \left(\frac{m}{\Omega}\right)^m r^{2m-1} \exp\left(-\frac{m}{\Omega} r^2\right) \quad (16.40)$$

where r is the signal envelope, $\Omega = E(r^2)$ is the mean square value, $m = \Omega^2/\text{Var}[r^2] \geq 1/2$ is the fading factor, and $\Gamma(m) = \int_0^\infty x^{m-1} \exp(-x) dx$ is the gamma function.

The Nakagami distribution reduces to the Rayleigh distribution for $m = 1$. Moreover, the Nakagami and the Rice distributions are approximately coincident for the following relation:

$$k = \frac{\sqrt{m^2 - m}}{m - \sqrt{m^2 - m}} \quad m > 1$$

where $k = a^2/2\sigma_r^2$ is the Rician factor.

Combined Distributions

The overall variability of the signal, in which slow fading and fast fading are combined, can be described through several distributions. The basic idea used to obtain these distributions is to assume the mean value of the fast fading distributions to be lognormally distributed. Therefore, the overall density is calculated as

$$p(r) = \int_{-\infty}^{\infty} p(r|R) p(R) dR \quad (16.41)$$

where $p(r|R)$ is one of the fast fading densities given by Eqs. (16.38), (16.39), or (16.40), $p(R)$ is the lognormal density given by Eq. (16.37), and R is the mean value of the corresponding densities given in

a logarithmic form. The respective densities obtained are named shadowed-Rayleigh density, shadowed-Rice density, or shadowed-Nakagami density. In particular, the shadowed-Rayleigh density is also known as the Suzuki density (Suzuki, 1977). Unfortunately, it does not seem to be possible to put these densities in a closed-form expression. Accordingly, they appear in their integral form and are computed by numerical methods.

16.6.5 Radio Coverage

System specifications require that an adequate reception must be accomplished anywhere within the mobile radio service area; 100% coverage could be achieved if the phenomena affecting the radio propagation in a mobile radio environment were deterministic. The received signal is a random variable, however, and the problem of radio coverage must be treated on a statistical basis, such that the outcomes of the prediction calculations should be interpreted as random events occurring with a given probability. Therefore, coverage requirements are specified as the proportion of locations where the received signal must be greater than a certain threshold considered to be satisfactory.

Suppose that at a given distance from the base station the *mean signal strength* is considered to be known. We want to determine the service area radius such that the mobiles experience a received signal above a certain threshold with a stipulated probability. The mean signal strength can be determined either by any one of the prediction models quoted previously or by field measurements. In the same way, the corresponding statistics are those mentioned before. In the calculations that follow we assume a lognormal environment, in which case only the large-scale variations are accounted for. The other environments can be analyzed in a like manner (Yacoub, 1993; Leonardo and Yacoub, 1993a, 1993b), although this may not be of interest if some sort of diversity is implemented because, in this case, the effects of the small-scale variations are minimized.

Propagation Model

Define m_w and k as the mean powers at distances x and x_0 , respectively, such that

$$m_w = k \left(\frac{x}{x_0} \right)^{-\alpha} \tag{16.42}$$

where α is the path loss coefficient. Expressed in decibels, $M_w = 10 \log m_w$, $K = 10 \log k$ and

$$M_w = K - 10\alpha \log \left(\frac{x}{x_0} \right) \tag{16.43}$$

Define the received power as $w = r^2/2$, where r is the received signal envelope. Let $p(W)$ be the probability density function of the power W , where $W = 10 \log w$. In a lognormal environment r has a lognormal distribution and

$$p(W) = \frac{1}{\sqrt{2\pi}\sigma_w} \exp\left(-\frac{(W - M_w)^2}{2\sigma_w^2}\right) \tag{16.44}$$

where M_w is the mean and σ_w is the standard deviation, all given in decibels. Define w_T and $W_T = 10 \log w_T$ as the threshold above which the received signal is considered to be satisfactory. The probability that the received signal is below this threshold is its *probability distribution function*, $P(W_T)$, such that

$$P(W_T) = \int_{-\infty}^{W_T} p(W)dW = \frac{1}{2} + \frac{1}{2} \operatorname{erf} \left[\frac{(W_T - M_w)^2}{2\sigma_w^2} \right] \tag{16.45}$$

where $\operatorname{erf}(\cdot)$ is the error function, defined as

$$\operatorname{erf}(y) = \frac{2}{\sqrt{\pi}} \int_0^y \exp(-t^2)dt \tag{16.46}$$

Base Station Coverage

The problem of estimating the service area can be approached in two ways. In the first approach, we may wish to determine the proportion β of locations at x_0 where the received signal power w is above the threshold power w_T . In the second approach we may estimate the proportion μ of the circular area defined by x_0 where the signal is above this threshold. In the first case this proportion is averaged over the perimeter of the circumference (cell border), whereas in the second approach the average is over the circular area (cell area).

The proportion β equals the probability that the signal at x_0 is greater than this threshold. Hence

$$\beta = \text{prob}(W \geq W_T) = 1 - P(W_T) \tag{16.47}$$

Using Eq. (16.43) and Eq. (16.45) in Eq. (16.47) we obtain

$$\beta = \frac{1}{2} - \frac{1}{2} \text{erf} \left[\frac{W_T - K + 10\alpha \log(x/x_0)}{\sqrt{2}\sigma_w} \right] \tag{16.48}$$

This probability is plotted in Fig. 16.64, for $x = x_0$ (cell border).

Let $\text{prob}(W \geq W_T)$ be the probability of the received power W being above the threshold W_T within an infinitesimal area dS . Accordingly, the proportion μ of locations within the circular area S experiencing such a condition is

$$\mu = \frac{1}{S} \int_S [1 - P(W_T)] ds \tag{16.49}$$

FIGURE 16.64 Proportion of locations where the received signal is above a given threshold (the dashdot line corresponds to the β approach and the other lines to the μ approach).

where $S = \pi x_0^2$ and $dS = x dx d\theta$. Note that $0 \leq x \leq x_0$ and $0 \leq \theta \leq 2\pi$. Therefore, solving for $d\theta$, we obtain

$$\mu = 2 \int_0^1 u\beta du \tag{16.50}$$

where $u = x/x_0$ is the normalized distance.

With Eq. (16.48) in Eq. (16.50) we have the result

$$\mu = 0.5 \left\{ 1 + \operatorname{erf}(a) + \exp\left(\frac{2ab + 1}{b^2}\right) \left[1 - \operatorname{erf}\left(\frac{ab + 1}{b}\right) \right] \right\} \tag{16.51}$$

where $\alpha = (K - W_T)/\sqrt{2}\sigma_w$ and $b = 10\alpha \log(e)/\sqrt{2}\sigma_w$.

These probabilities are plotted in Fig. 16.64 for different values of standard deviation and path loss coefficients.

Application Examples

From the theory that has been developed it can be seen that the parameters affecting the probabilities β and μ for cell coverage are the path loss coefficient α , the standard deviation σ_w , the required threshold W_T , and a certain power level K measured or estimated at a given distance x_0 from the base station.

The applications that follow are illustrated for two different standard deviations: $\sigma_w = 5$ dB and $\sigma_w = 8$ dB. We assume the path loss coefficient to be $\alpha = 4$ (40 dB/decade), the mobile station receiver sensitivity to be -116 dB (1 mW), and the power level estimated at a given distance from the base station as being that at the cell border, $K = -102$ dB (1 mW). The receiver is considered to operate with a SINAD of 12 dB for the specified sensitivity. Assuming that cochannel interference levels are negligible and given that a signal-to-noise ratio S/N of 18 dB is required, the threshold W_T will be -116 dB (1 mW) + $(18 - 12)$ dB (1 mW) = -110 dB (1 mW).

Moreover, three cases will be explored, as follows:

Case 1: We want to estimate the probabilities β and μ that the received signal exceeds the given threshold, first, at the border of the cell (β approach) and, second, within the area delimited by the cell radius (μ approach).

Case 2: It may be interesting to estimate the cell radius x_0 such that the received signal be above the given threshold with a given probability (say 90%), first, at the perimeter of the cell and, second, within the cell area. This problem implies the calculation of the mean signal strength K at the distance x_0 (the new cell border) of the base station. Given K and given that at a distance x_0 (the former cell radius) the mean signal strength M_w is known (note that in this case $M_w = -102$ dB(1 mW)) the ratio x_0/x can be estimated.

Case 3: To fulfill the coverage requirement, rather than calculating the new cell radius, as in case 2, a signal strength at a given distance can be estimated such that a proportion of the locations at this distance (β approach) or within the area delimited by this distance (μ approach) will experience a received signal above the required threshold. This corresponds to calculating the value of the parameter K already carried out in case 2 for the various situations.

The calculation procedures are now detailed for $\sigma_w = 5$ dB. Results are also shown for $\sigma_w = 8$ dB.

Case 1

Using the given parameters we obtain $(W_T - K)/\sigma_w = -1.6$. With this value in Fig. 16.64 we obtain Table 16.18.

TABLE 16.18 Probability That the Received Signal Exceeds -116 dB (1 mW) for $S/N = 18$ dB Given That at the Cell Border the Mean Signal Power is -102 dB (1 mW)

Standard Deviation, dB	β Approach (border coverage), %	μ Approach (area coverage), %
5	97	100
8	84	95

TABLE 16.19 Normalized Radius of a Cell Where the Received Signal Power is Above -116 dB (1 mW) with 90% Probability for $S/N = 18$ dB, Given That at a Reference Distance from the Base Station (the Cell Border) the Received Mean Signal Power is -102 dB (1 mW)

Standard Deviation, dB	β Approach (border coverage)	μ Approach (area coverage)
5	1.10	1.38
8	0.88	1.27

Note, from Table 16.18, that the signal at the cell border exceeds the receiver sensitivity with 97% probability for $\sigma_w = 5$ dB and with 84% probability for $\sigma_w = 8$ dB. If, on the other hand, we are interested in the area coverage rather than in the border coverage, then these figures change to 100% and 95%, respectively.

Case 2

From Fig. 16.64, with $\beta = 90\%$ we find $(W_T - K)/\sigma_w = -1.26$. Therefore, $K = -103.7$ dB(1 mW). Because $M_w - K = -10\alpha \log(x/x_0)$, then $x_0/x = 1.10$. Again, from Fig. 16.64, with $\mu = 90\%$ we find $(W_T - K)/\sigma_w = -0.48$, yielding $K = -107.6$ dB (1mW). Because $M_w - K = -10\alpha \log(x/x_0)$, then $x_0/x = 1.38$. These results are summarized in Table 16.19.

Note, from Table 16.19, that in order to satisfy the 90% requirement at the cell border the cell radius can be increased by 10% for $\sigma_w = 5$ dB. If, on the other hand, for the same standard deviation the 90% requirement is to be satisfied within the cell area rather than at the cell border, a substantial gain in power is achieved. In this case the cell radius can be increased by a factor of 1.38. For $\sigma_w = 8$ dB and 90% coverage at the cell border the cell radius should be reduced to 88% of the original radius. For area coverage an increase of 27% of the cell radius is still possible.

Case 3

The values of the mean signal power K are taken from case 2 and shown in Table 16.20.

TABLE 16.20 Signal Power at the Cell Border such that 90% of the Locations Will Experience a Received Signal Above -116 dB (1 mW) for $S/N = 18$ dB

Standard Deviation, dB	β Approach, dB (1 mW) (border coverage)	μ Approach, dB (1 mW) (area coverage)
5	-103.7	-107.6
8	-99.8	-106.2

16.6.6 Summary and Conclusions

A precise characterization of the signal variability in the mobile radio environment constitutes a hard task. Deterministic methods, such as those described by the free-space, plane earth, and knife-edge diffraction models, are restricted to very simple applications.

Generally speaking, the best known field strength prediction models currently used arose as a combination of the deterministic methods with data obtained in field measurements. They include several adjustment parameters, most of them lacking theoretical explanations, and their applicability is restricted to situations in which the experiments were performed. Predictions for situations other than the original ones must be exercised with care.

Because it is not viable or practicable to take all of the phenomena influencing the mobile radio propagation into account the received signal is treated on a statistical basis. Several distributions exist that well characterize the variability of the received envelope and they have proved to have a satisfactory fit to data obtained by field measurements.

Hence, the problem of radio coverage must be treated on a statistical basis, such that the outcomes of the prediction calculations should be interpreted as random events occurring with a given probability. Coverage requirements are specified as the proportion of locations where the received signal must be greater than a certain threshold considered to be satisfactory.

Defining Terms

Fast fading (also short-term fading): Fading associated with the variability in the local mean signal level due to multipath propagation.

Large cells and small cells: Cells having their base station antennas installed above the roof tops. Large and small cells differ in maximum range, which is 1–3 km for the latter.

Microcells: Cells having their base station antennas installed below the roof tops. Microcells have a maximum range of 0.5–1 km.

Path loss: The ratio between the transmitted power and the received power.

Slow fading (also long-term fading): Fading related to the variability of the area mean signal level due to shadowing.

The Vehicular Technology Society and the Communications Society are very active in promoting conferences in the area.

16.7 Cellular Radio

Harry E. Young

16.7.1 Cellular Service Evolution

In 1946, two-way mobile service was introduced in St. Louis. The service had hardly begun when the inherent disadvantages of the two-way mobile service were recognized. The major disadvantage, of course, was the tremendous physical separation required for cochannel interference reasons. In 1947, Bell Telephone Laboratories began exploring a concept that would reuse frequencies by utilizing small cells with low-powered mobile units. These cells could be linked together using a computer to permit mobility while simultaneously greatly increasing the number of subscribers that could be served by the system. However, the necessary computer technology did not become available until the mid-1960s when electronic switching systems were developed.

In spite of the fact that the cellular concept was developed in the U.S., other countries introduced cellular as a commercial service before the U.S. This was largely due to the fact that it took almost 13 years from the time cellular service was technically possible until the first commercial cellular systems were actually activated in 1983. This delay was essentially due to the regulatory process in the U.S., and a study by AT&T later concluded that the U.S. economy lost about \$86 billion due to this regulatory delay. Consequently, commercial cellular service first became available in Japan in 1979, quickly followed by systems in the Scandinavian countries in 1980 and 1981. Many other countries have since implemented cellular service and it is now available in many countries throughout the world.

There is no worldwide compatibility for cellular service, however. The system in the U.S. is based on the original AT&T design, **advanced mobile phone service (AMPS)**. AMPS is used in approximately 70 other countries in the world and is the most widely used standard at this time. Some of the other more common standards used for cellular service include **nordic mobile telephone (NMT)**, total access communications service (TACS), and **global system for mobile (GSM)** communications.

The original NMT was designed for rather small systems of 20–30,000 subscribers and provides 180 channels, each of which utilizes 25 or 30 kHz of bandwidth in the 450-MHz band. A later version of NMT provides greater capacity in the 900-MHz band. NMT 900 provides 1000 channels, each using 25-kHz of bandwidth, or 2000 channels of 12.5 kHz each. NMT, in one form or another, is used in about 30 countries in the world.

TACS is used in Europe, the United Kingdom, and about two dozen other countries. A specialized form of TACS is used in Japan and is called Japan Total Access Communications System (**JTACS**). TACS provides 1320 channels of 25 kHz each.

Because different cellular standards were used by various countries in Europe, a single standard was required to provide roaming capability. Thus, the GSM system has evolved as an all-digital service that is used in Europe and many other countries. GSM is designed to work in the 900-MHz band and provides eight digital time slots for every 200-kHz channel.

Not only do the various standards use different protocols, they operate on different frequencies so that worldwide compatibility is not possible between the different systems.

16.7.2 Regulation and Competition

To promote competition, the **Federal Communications Commission (FCC)** issued two cellular licenses for each defined geographical area. These geographical areas are known as a **metropolitan statistical area (MSA)** and **rural service area (RSA)**. One of these licenses was awarded to a subsidiary of a company that provides landline telephone service in the given geographical area and is known as the *wireline* licensee, or B band. The other was issued to a company not associated with the landline **local exchange carrier (LEC)** in that area and is called the *nonwireline* licensee, or A band. Because of mergers and acquisitions in recent years, this distinction has become confusing because wireline companies often operate as nonwireline carriers outside of the franchised areas of their landline LEC.

A cellular licensee may serve all or just a portion of a designated MSA or RSA. Usually most of a MSA is served, although large portions of a RSA may be left unserved. The actual service area is defined by the cellular carrier and is called the **cellular geographic service area (CGSA)**. Debate continues as to whether the FCC's effort to promote competition has been successful because there is often little difference in the prices charged by the wireline and nonwireline licensees or in the quality of service. Nonetheless, the overall price of cellular service has continued to drop and the number of subscribers has increased dramatically since service began in 1983. As of January 1996, there were approximately 34 million cellular subscribers in the U.S. and it is expected that there will be almost 65 million by the end of 2005.

16.7.3 Cellular Radio Spectrum Requirements

Each cellular licensee in a MSA or RSA is authorized by the FCC to use 25 MHz of spectrum within the 800-MHz range. Originally, the FCC allocated 20 MHz to each carrier, which was obtained by deleting UHF television channels 70–83 because they were lightly used. An additional 5 MHz per carrier was authorized in 1985 due to growing capacity problems in some areas. This 25 MHz of spectrum is divided for use by base and mobile stations within each system so that different frequencies are used for base-to-mobile and mobile-to-base. This type of operation is called *full duplex* and permits simultaneous conversation or transmission. It must be remembered that two channels are required for each conversation in order to operate on a full-duplex basis.

The AMPS cellular systems in the U.S. are based on an analog technology that employs frequency modulation (FM). With this technology, each channel occupies 30 kHz of bandwidth yielding a total of 832 channels, or 416 channel pairs, for each cellular operator. Of these 416 channel pairs, 21 are dedicated to control functions for call setup and handoff purposes. This leaves 395 channel pairs available for voice services.

Existing cellular systems use **frequency division multiple access (FDMA)** multiplexing, which divides the total band allocated to a cellular operator (25 MHz) into discrete channels. Since each channel has a bandwidth of 30 kHz, the system has a total of 832 channels available. Each conversation requires the use of two pairs of frequencies, and so there are 416 pairs of frequencies available to each operator, each of which can potentially be assigned to a cellular user at any given time. Mobile equipment that utilizes FDMA is less complex than that used with other multiplexing techniques and is generally less expensive. Because each

channel requires the use of a separate transmitter and receiver, however, FDMA needs considerably more equipment at the nonmobile, or *base station* site. FDMA can be used with analog or digital transmission systems.

Introduction of Digital Cellular

Initially, the development of digital cellular was the result of major concerns by the cellular carriers about their ability to meet a rapidly growing subscriber base. With growth rates of over 40%, it did not appear that existing analog technology would be able to cope with the projected numbers of subscribers within a few years.

In an effort to hasten the development of digital cellular, the Cellular Telecommunications Industry Association (CTIA) issued a **user performance requirements (UPR)** document in 1988 that outlined the service requirements. Key elements of the UPR were

- A tenfold increase in capacity
- Dual mode during an undefined transition period
- New features (such as calling number identification and improved security)
- Equipment to be available by 1991
- Standards for high quality

A request was made to the **Telecommunications Industry Association (TIA)**, which is a standards body, to develop a digital specification based on the UPR. In 1991, the TIA released Interim Standard 54 (IS-54), which uses **time division multiple access (TDMA)** technology. In 1993 the TIA also approved IS-95, a digital standard based on **code division multiple access (CDMA)** technology. Debate continues within TIA over a third technology, **extended time division multiple access (E-TDMA)**, which has been promoted by Hughes Network Systems.

With TDMA, each radio channel is divided into time slots. Each individual conversation is converted to a digital signal, which is then assigned to one of these time slots. The number of time slots per radio channel can vary, because it is a function of the system design. There are at least two time slots per channel, and usually more, which means that TDMA has the potential of serving several times more customers with the same amount of bandwidth as FDMA techniques.

TDMA is a more complex system than FDMA because the voice has to be digitized, or coded, then stored in a buffer for assignment to a vacant time slot, and finally transmitted. Consequently, signal transmission is not continuous and the transmission rate must be several times greater than the coding rate. Also, because more information is contained within the same bandwidth, TDMA equipment must have more sophisticated techniques of equalizing the received signal in order to maintain signal quality. TDMA offers improved handoffs between cells because of a mobile-assisted feature called **mobile assisted handoff (MAHO)**, improved sound quality, greatly improved security since the transmission is digitally encoded, and the possibility of new features such as receipt of caller identification. These advantages are somewhat offset by higher power consumption in the set, more weight and complexity to the set, and a higher unit cost of the set.

CDMA was developed by the military to prevent communications channels from being detected, and then jammed, by the enemy. The signal intelligence (speech) is converted to a digital signal, which is then mixed with a randomlike code. The total signal, speech plus the randomlike code, is then transmitted over a wide band of frequencies through *spread spectrum* techniques. It is difficult for an outside party to detect the radio signal and intelligence when it is spread over a wide bandwidth in a randomlike manner. There is the further potential for multiple radio systems to share the same spectrum with only limited interference.

Unlike FDMA and TDMA, the spread spectrum transmission used by CDMA requires channels that have a relatively immense bandwidth. For example, the channels in the IS-95 digital cellular standard require 1.25 MHz of bandwidth but other CDMA schemes require an even greater amount of bandwidth. However, it is theorized that CDMA could accommodate perhaps 10–20 times as many users for the same

amount of total bandwidth as FDMA can. Until now, CDMA has been used for specialized purposes with a small numbers of users. A major question to be answered is whether one service, with tens of thousands of users employing CDMA devices, can function and not interfere with other wireless services.

CDMA provides the ability to keep an existing cell connection while the call is transferred to an adjacent cell. This feature, called soft handoff, is not available with TDMA or FDMA multiplexing. CDMA also allows the same frequencies to be used in adjacent cells, thus somewhat simplifying the system design. It also has the same disadvantages of TDMA in terms of sets that are more complex, require more power, and cost more. As of this writing production models of dual-mode CDMA and analog sets have just become available.

A finite limit for an analog cellular system is almost impossible to determine. Some additional capacities have been achieved by improving the throughput of the cellular switches. Other increases have resulted from increasingly expensive network solutions such as cell-splitting and the deployment of microcells that contain some call-processing abilities. In some instances, subscribers may simply be added to the system, which results in a reduction of service quality because the ability of the subscriber to access the network without being blocked is reduced. There is no magic number that determines when the capacity limits of the analog cellular system have been exceeded. There are simply too many variables, including market size, geography, usage patterns, and network design, to set a finite limit. The largest market in the U.S., Los Angeles, however, supported over 750,000 subscribers in 1993 without the implementation of digital. This implies that most markets in the country could support similar levels of subscribers without deploying digital cellular.

In spite of the fact that system capacity can be met using analog technology, increasing capacity by converting to digital can still be a more economical solution. The number of subscribers that may be served by a given amount of spectrum can be increased by a factor of 3 to almost 20, depending on the type of technology that is used. Capital costs are about \$1000 per subscriber for an analog-only system. Comparable capital costs for a TDMA-based system may be as low as \$247 per subscriber, whereas those for a CDMA-based system are predicted to be \$109 per subscriber. Moreover, digital also permits the carrier to offer new subscriber features, increase battery life for a portable unit, improve sound quality, provide increased voice security, and improve handoffs. CDMA technology, in particular, should help enhance the data capabilities of the cellular systems.

16.7.4 Basic Cellular Architecture

Instead of having a single large, powerful transmitter to cover a geographical area, cellular places transceivers in numerous small cells within an area. The transceivers are controlled by a central processor, or switch, so that the subscriber can move between cells and still maintain service. This provides the frequency reuse capability that gives cellular the potential for far greater capacity than early two-way mobile systems.

The central processor, or switch, is also referred to as the **mobile switching center (MSC)**. The MSC was formerly referred to as the **mobile telephone switching office (MTSO)**. It provides the switching and radio control functions. Links extend from the MSC to the **cell sites** and also provide connections to the **public switched telephone network (PSTN)**.

Figure 16.65 illustrates a typical cellular system. In this diagram, the cell arrangements are shown in a hexagonal pattern. Cellular systems are engineered using this hexagonal arrangement in order to determine the frequency reuse pattern. This method is used to ensure enough separation exists between any two cells using the same frequencies so that interference does not occur. Typically, the system may be designed using a 4-cell, 7-cell, or 12-cell reuse pattern. If the world were flat and there were no obstructions, the radio waves could be confined to these hexagonal cells, but in reality, the radio signals can, at best, only approximate the hexagonal shape. Special measures are needed for areas that are difficult to serve with normal antennas, like tunnels. Still, the use of hexagonal cells is a useful engineering tool.

Cell Sites

Early cellular systems used cell sites that typically covered a radius of 10 miles or more. As traffic increased, or better coverage was needed in certain areas, the size of the cell sites decreased. Presently, the average cell

FIGURE 16.65 Configuration of a typical cellular system.

site has a radius of about 3–5 mi but this is also diminishing. The cells can range in size from a radius of less than 1 to 25 mi or more with the range being determined by the transmitted signal power and height of the antenna.

As traffic grows in a cellular system, additional channels and cells are added until all of the available spectrum is in service. Metropolitan areas may use all of the spectrum but RSAs rarely need a full complement of channels.

The number of transceivers in a given cell depends on the traffic that the cell is expected to handle. The maximum number of radios in any given cell site, however, depends on the reuse pattern used in the system design. This can be determined by dividing the total number of channels by the reuse pattern. For example, if the system is designed for a reuse pattern of $N = 4$, and the maximum number of voice channel pairs is 395, then the maximum number of channels in any given cell cannot exceed 98.

Definitions

Figure 16.65 displays several microcells that are distributed between two separate cellular systems. There are larger cells, such as cell site A and cell site B, as well as smaller cells, such as cell site C. In addition, there are very small cells within cell site B.

In any discussion of wireless systems employing a cellular-type architecture, the terms *cell site*, *macrocell*, *microcell*, and even *picocell*, are often used. A precise definition of each term is not possible because even standards bodies, such as the Telecommunications Industry Association, or industry associations such as CTIA or the Personal Communications Industry Association (PCIA) have not officially defined each term. Macrocells, microcells, and picocells are all considered to be cell sites in the cellular network architecture and the following definition does exist for a cell site.

A cell site is a transmitter/receiver location, operated by the cellular carrier (or **wireless carrier**) through which radio links are established between the cellular system and the mobile units. The area reliably served by a given cell site is referred to as a cell.

The other terms generally relate to the size of the cell site, and this is where the ambiguity of terms occurs. Determining the precise term to use based on the radio frequency (RF) coverage area of the cell is not of critical importance because the term cell site can always be used. To add confusion to matters, the term *base station* is often considered to be synonymous with the term cell site. Nonetheless, in spite of

the lack of formal definition for the other terms, the following general definitions are usually accepted by most engineers or technicians in the industry:

- Macrocell: A cell site having an RF coverage area diameter of greater than 2000 ft.
- Microcell: A cell site having an RF coverage area diameter of greater than 400 ft but less than 2000 ft.
- Picocell: A cell site having an RF coverage area diameter of less than 400 ft.

In Fig. 16.65, all of the cell sites, except for the microcells, would probably qualify as macrocells. The cell sites within cell site B fit the definition for microcells.

Purpose of Microcells

Microcells are deployed in a network for a number of reasons, such as

- Increase system capacity: One of the methods used to increase capacity in a cellular system is to split the existing cells into smaller cells. Sometimes a large cell, or macrocell, is divided into several smaller cells. This, of course, increases the frequency reuse capability within the network to provide additional capacity.
- Improve signal reception: In many large buildings, penetration of the RF signal from an outdoor cell site location becomes very difficult. A similar problem exists with certain outdoor locations, such as tunnels or bridges. The use of microcells located within the building or tunnel provides a more direct route for the RF signal, especially those from lower powered portable units.
- Provide inconspicuous coverage: Cellular users expect their service to work in any location within their expected service area. Often, they are also among the more affluent residents of a community and are the first to protest any proposal to construct a cellular tower in their neighborhood. The use of a microcell provides a relatively inconspicuous means of correcting a service problem without constructing a large tower.
- Reduce handoff switching: In traditional cellular systems, most handoffs between cells are controlled by the MSC. Increasing the number of cells, as well as decreasing the size of the cells themselves, increases the load requirements of the MSC. Some microcells do not need to have handoffs controlled by the MSC, which can also help increase the overall system capacity.
- Provide temporary capacity: In some situations, such as sporting events or traffic congestion, additional capacity is needed in a certain location but only on a temporary basis. One method of achieving this capacity is to borrow capacity from an adjacent cell. This can be accomplished with a microcell connected to a donor cell.

Cellular Power Levels

By design, cellular systems operate at a lower signal power level than traditional two-way mobile systems. Base stations have a maximum power limitation of 100 W *effective radiated power* (ERP) except for those located in rural service areas, which can transmit as high as 500 W ERP. Mobile units designed for use in cars are capable of transmitting at 3 W ERP whereas portable, hand-held, units have a maximum power of 600 mW. Cellular is often perceived as a high-powered wireless service for vehicular traffic and sometimes viewed as not suitable for low-powered applications. These power levels, though, represents maximum levels. The actual levels for mobiles are automatically adjusted by instructions from the base stations. Mobiles can transmit using power levels as low as 7 mW. Base station levels are set according to system design parameters but are often much lower than the maximum of 100 W.

Number of Subscribers Served

The capacity of any wireless system is greatly affected by the number of voice channels that is available to serve subscribers. The number of subscribers that can utilize any given voice channel is a function of the traffic characteristics of the subscribers. These characteristics are the number of calls generated, as well as the length of each call. There are traffic tables available that can predict the number of channels required

to serve a given load of traffic, measured in the quantity *erlang*. One erlang is equal to the continuous occupancy of one channel.

Cellular systems are engineered to provide a B.01 grade of service, that is, 1 of every 100 call attempts may be blocked. Using this grade of service, a system can typically accommodate 20–30 subscribers for each voice channel in a set. For an analog system, only one subscriber can use a voice channel at any one time, but multiple subscribers can share a single channel since they do not all use the channel at the same time.

Cell Splitting

To minimize interference, a certain distance must be maintained between cells using the same frequencies. However, this distance can be reduced without disturbing the cell reuse pattern. As the size of the cells are reduced, the same frequencies can be utilized in more cells, which in turn means more subscribers can be accommodated on the system. Particularly in congested areas, the cellular operator often splits an existing cell into two or more smaller cells. New transceivers are placed and the power of the transmitters are reduced in order to confine the signals to the newly created cells. For example, a cell that originally had a radius of 8 mi could be split into four cells with each new cell having a 2 mi radius. For the existing analog systems, cell splitting is an effective way to increase system capacity, although some practical limitations are reached. Suitable locations for cell sites becomes more difficult and the processing load on the switch rapidly increases because handoffs are more frequent.

Cell Site to MSC Links

Several methods may be used to connect cell sites of any type back to an MSC. The links may use two-wire or four-wire analog circuits, digital, fiber, or microwave facilities. The choice often depends on the type of microcell used, the facilities available in a given area, and of course, cost.

Two-wire analog facilities using copper wires are often used for microcells having small capacities, such as stand-alone applications. These systems do not need to be connected to the MSC or switch, but do require a normal line-side connection to the LEC's switch for access to the PSTN. This connection employs a standard, two-wire circuit, which usually uses copper wire that is part of the LEC's local loop. The copper wire is normally 22–26 gauge wire and the loss of the loop may be as high as 8 dB at 1000 Hz. Four-wire analog circuits are not as common now as they were when cellular was first introduced in the U.S. This is because the LECs have modernized their facilities in the last decade so that digital capabilities are more widely available. There are still some instances where digital is not available, or the voice channel requirements are very small, that a four-wire analog link is used.

Digital links are quite common between cell sites and the MSC or switching center. These links may be several miles in length or contained within a building. Generally, a **line** at the DS1 rate (1.544 Mb/s) is chosen for these applications, which requires some care in facility selection for proper performance. For intrabuilding applications, 22-gauge shielded wiring is the preferred choice in order to reduce the possibility of interference. Nonshielded wire in other sizes will work but are more susceptible to interference. Digital links at the DS3 rate (45 Mb/s) are also used for configurations requiring large numbers of voice channels.

Fiber links are a common way of connecting microcells to a donor cell. Because of its wide bandwidth capabilities, the fiber facility can transport the entire cellular spectrum if necessary. A number of these links utilize an analog signal that modulates the entire RF signal with an optical signal for transmission. Other equipment is available that digitizes the signal before it enters the fiber facility. This equipment is a little more tolerant of signal degradation than the analog variety. Both types can usually use fiber facilities that are over 40 km in length without requiring an optical repeater.

Microwave links from the MSC to cell site locations are quite common in cellular systems for normal macrocells. Microcells, because of their size and location, are generally more difficult to serve with the 2- or 6-GHz microwave systems normally employed in these situations. As an alternative, some companies have used 23- or 38-GHz links to connect microcells. Because of the high frequency, a very small antenna may be used for the microwave. However, the range between the donor cell and microcell is very limited and is also subject to fading.

Mobile Switching Center

Only digital switches are now used for cellular service. This has been the case practically since the introduction of cellular service in the U.S. although there were a few switches initially that were based on an analog, electronic switch design. Digital switching, however, does not necessarily mean digital radio transmission in the cellular system. It simply refers to the manner in which calls are processed by the switch.

Like many landline switches, the MSCs are *stored program controlled* (SPC) devices whose functions are controlled by software instructions. The systems are usually full availability, nonblocking switches, meaning any input port can be connected to any output port.

In addition to completing connections from the radio portion of the system to the landline network, or other wireless networks, the MSC also performs the radio controller function in an AMPS-type cellular network. Because of this feature, it has been estimated that an MSC takes 4–10 times the processing of a landline switch for an equivalent number of subscribers.

In most digital switches, the number of ports are configured in multiples of 24 in order to accommodate a DS1-rate input or output channel. Not all of the channels may be activated in any single DS1. As shown in Fig. 16.65, some of the ports are connected to the cell sites by the MSC–cell site links, others are connected to the PSTN or other networks, whereas still others provide links between MSCs themselves.

Cellular switches may be connected to the PSTN using several different configurations. The initial connection offered to cellular carriers was a trunk-side connection to an end office and is known as a Type 1 connection. Later, as a result of an FCC order, cellular carriers were able to obtain connections from a tandem office, which are known as Type 2A. There are also other variants available, such as high-usage **trunks** to specific **end offices** (Type 2B), trunks to 911 tandems (Type 2C), trunks to operator services tandems (Type 2D), and 56 kb/s circuits used for **signaling system 7 (SS7)** applications (Type S).

Other functions that are often part of the MSC are the **home location register (HLR)**, *visitor location register (VLR)*, and the **authentication center (AC)**.

The HLR function is a major component of the seamless network so often discussed. It is often an inherent part of most switches, although it can also be located externally from the switch. The HLR stores registration and service profiles of the subscribers of that particular system.

VLRs are used to store information regarding subscribers who have roamed into another area. It also can be located externally from the MSC but is generally an inherent part of the MSC too. The AC is a new feature that is intended to provide additional authentication information. These data change with each call so the AC must be queried for each call in order to continue call processing. Like the HLR and VLR, the AC function can also be separated from the MSC. The MSC contains software and hardware for recording call detail information. This information is normally transmitted to a billing center over voice-grade data links, but magnetic tapes are also used for this function. The billing system itself is separate from the MSC and is often a service provided by a vendor to the cellular carrier.

Operational systems allow personnel to perform maintenance, change subscriber data, change software within the switch, and provide alarms.

IS-41 Standard

Initially the protocols for messages between MSCs were proprietary to each vendor. Unless this was changed, this fact would have greatly inhibited the development of the seamless network the cellular industry was seeking. As a result, the TIA developed a standard called *interim standard number 41* (IS-41).

IS-41 allows MSCs manufactured by different vendors to exchange information regarding subscribers. Using Fig. 16.65, this allows MSC 2 to query the HLR of MSC 1 when a subscriber from MSC 1 enters the service area of MSC 2.

The major functional entities of the IS-41 standard are the *mobile station*, which is also known as the *cellular subscriber station* (CSS), the *base station* (BS), MSC, HLR, VLR, and AC. An initial version of IS-41, called IS-41 revision 0, was approved in late 1987. It provided handoffs between different systems and user validation but the validation process was done off line. Revision 0 only used X.25 protocol and the

transaction capabilities application part (TCAP) messages were based on the Consultative Committee on International Telephony and Telegraphy (CCITT) standard.

In 1990, IS-41, revision A was approved. It is not compatible with revision 0 because it used TCAP messages based on the American National Standards Institute (ANSI), instead of the CCITT standard. Revision A also added the use of the SS7 protocol as well as X.25, but the SS7 links had to be point-to-point between the respective MSCs. Moreover, revision A also added the ability to transfer features such as call waiting, three-way calling, and call forwarding.

Revision B of IS-41 was approved in 1991. It added the ability to minimize the paths between MSCs and added *global title translation* (GTT) capability so that direct links were not required between MSCs. GTT allows routing of SS7 messages on an SS7 network such as the North American Cellular Network (NACN). It also added support for dual-mode sets using TDMA multiplexing.

The latest version of IS-41, revision C, was approved in 1995. It adds support for the AC, short messaging (which is like alphanumeric paging), support for dual-mode CDMA sets, and the *data message handler* (DMH). The DMH is equipment that will allow real-time billing, which should help with fraud management.

Digital Synchronization

When digital switches and/or digital facilities are interconnected, some means of synchronizing the clock rates must be used in order to avoid errors. The synchronization is obtained from the bit stream of a digital signal, such as a DS1 rate (1.544 Mb/s) channel, that is used to connect the two networks. An agreement must be reached between the LEC and the cellular carrier regarding the primary source of timing.

Glare Resolution

When switches are interconnected by two-way trunk-side connections, there is always the possibility that the trunk will be simultaneously seized by both switches. This results in a condition called *glare* and is resolved by the switches containing instructions known as a *glare bit*. The glare bit indicates which switch is to yield first in the event of a glare condition. The normal convention is for the lower ranked office to yield first and so in the LEC network, end offices normally yield to tandem offices and tandem offices yield to **interexchange carrier (IC)** offices. It does not really matter which office yields first as long as it is understood when the connection is made what the convention will be. Therefore, in cases where the cellular carrier is interconnected with the LEC, an understanding regarding glare resolution must be reached as part of the interconnection agreement so that the glare bit may be properly set in both switches.

Numbering Requirements

Each cellular set used in North America has a telephone number encoded in the set. This number conforms to the **North American numbering plan (NANP)** and serves as the **mobile identification number (MIN)**. If the telephone number is changed for any reason, the set must be physically altered to accommodate the new MIN.

Cellular carriers are entitled to telephone number assignments just like any LEC. They often have entire **NXX** codes (blocks of 10,000 numbers) dedicated to them for cellular service. This is particularly true when the cellular carrier has a tandem (Type 2) interconnection with the LEC. However, entire codes can also be used with other types of interconnection as well.

In addition to the MIN, the sets have an **electronic serial number (ESN)** and **system identification (SID)** number encoded in them. The ESN is assigned by the manufacturer of the set, whereas the SID is assigned by the FCC for sets used in the U.S. A unique SID was assigned for each wireline and nonwireline carrier in each MSA and RSA, but cellular carriers have consolidated many of these SIDs. For example, the Washington and Baltimore systems originally had unique SIDs but the wireline carrier serving those areas has combined them into a single SID.

16.7.5 Call Processing

To process calls in a cellular system, the location and identity of the mobile user must be known by the MSC. This is true regardless of whether the mobile unit is operating in its home system or has traveled to a distant location and is considered to be roaming. To accomplish this task, the mobile unit transmits certain information each time the power is turned on, and again each time a call is originated. Specifically, this information consists of the mobile unit's MIN, ESN, and SID. In many cases, the operation of the set is the same for the user whether the mobile unit is used in its home system or not. This was not always the case, and there are still areas where different operations are required of the user but the seamlessness provided by IS-41 and SS7 networks is quickly eliminating these differences.

Technically, there are differences in the manner in which calls are processed between a user in a home system and one who is roaming. The basic call processing operations are described in the following paragraphs but in a seamless network, these processes are transparent to the user.

Call Processing-Home System

Dialing from a cellular phone is different from a landline telephone. Instead of receiving dial tone and then dialing the desired number, the cellular user first determines if service is available by verifying the presence of a service available indicator. This indicator is displayed when the mobile unit can receive a signal from one of the control channels in the cellular system. The mobile unit knows whether it is in its home area or not because the base station periodically broadcasts its identity, including the SID. The mobile unit compares this SID with its own and if they are the same, the mobile unit is operating in its home area. If the two SIDs do not match, the roam light is illuminated on the mobile unit to indicate a roaming condition exists.

Mobile-Land Calls-Home System

Assuming service is available, the mobile user enters the digits of the party being called and presses the send button on the mobile unit. The mobile unit transmits these digits to the base station using the control channel. This information may be received by more than one cell site, and the MSC will determine which cell site should initially handle the call. After ensuring the availability of a voice channel to that cell site and a trunk connection to the PSTN, the MSC seizes a trunk, Type 1, 2A, or 2B, depending on the connection used and call type, and outpulses the required number of digits to the LEC office. When the call is answered, the MSC connects the mobile to the voice channel so that conversation can begin.

Land-Mobile Calls-Home System

To reach a mobile subscriber in a cellular system, the landline customer dials the 7- or 10-digit mobile number, depending on the local dialing plan. The call is directed to either the end office providing a Type 1 or Type 2B connection, or the tandem office if a Type 2A connection is employed. In either case, the 7- or 10-digit number of the mobile subscriber is outpulsed by the LEC office to the MSC. If the MSC has not recorded the presence of the mobile unit when the power was first turned on, the location of the mobile subscriber is determined by broadcasting a paging code that includes the mobile subscriber's MIN to all cell sites via a separate control channel. The cell site with the strongest signal strength from the responding sites is selected and a voice channel is assigned by the MSC. A code is then outpulsed over the signaling channel, which causes the mobile unit to initiate a ringing signal. When the mobile subscriber answers, the voice channel is connected so that conversation can begin.

Cellular Roaming Call Processing

Once a mobile unit moves outside of its home area (the point where the SIDs no longer match), the unit is usually considered to be a roamer and is then served by a *visited* system. The following paragraphs describe the basic call processing techniques used for these types of calls and assume the use of autoregistration features used in seamless networks such as those provided by the North American Cellular Network.

Mobile-Land Calls-Visited System

Assume a cellular subscriber in Seattle travels to Miami and is part of the NACN. Once the set is turned on in Miami, the Miami system recognizes the MIN being broadcast from the mobile unit is from Seattle. The Miami system then queries its VLR to see if the user is already registered. If the user has not been previously registered there will be no information resident in the VLR. That being the case, the Miami system sends a TCAP message to Seattle requesting the service profile of the roaming subscriber. The information returned from Seattle validates the user and provides a profile of the services used by the subscriber in Seattle. In addition, the Seattle system requests a Miami *temporary local directory number* (TLDN) so that calls for the Seattle subscriber can be routed to Miami over the PSTN. When the subscriber makes a mobile-land call in Miami, the call is then processed just as in a home system because the Miami system has validated the user and, using IS-41, will usually provide the same features the subscriber has available in Seattle. The validation process may occur in real-time or off line. If off line, calls will be permitted if a roaming agreement exists between the two carriers even if the validation response has not yet been received by the Miami system. In essence, the Seattle-based subscriber does not have to do anything special to utilize the mobile phone in Miami.

Calls made by the Seattle subscriber in Miami are recorded and, through a clearinghouse function that usually involves a third-party vendor, the Seattle system eventually receives the data so that a bill can be rendered to the customer. The Miami system is ultimately reimbursed for these calls as part of this clearinghouse function.

Land-Mobile Calls-Visited System

Continuing with the example of the Seattle-based cellular subscriber, calls made to the subscriber are routed first to the Seattle MSC. This happens regardless of whether the call is made from a landline phone in Seattle or a landline phone in Miami. Upon receiving the call, the Seattle MSC queries its HLR and determines that the subscriber is currently in Miami. Using the TLDN provided by the Miami system, the call is forwarded to Miami where it is received by the Miami MSC. The Miami MSC translates the TLDN into the Seattle subscribers normal MIN and uses a broadcast page over all control channels in Miami to locate the subscriber. If the Seattle subscriber's mobile unit is activated, a response is made and the call is processed just like any other land-mobile call at that point.

Call Handoffs

All cellular systems perform call handoffs in which a call in progress is transferred from one cell to another. Many of these handoffs occur within the same cellular system or cells controlled by the same MSC. Others take place between cells controlled by different MSCs, and the MSCs may belong to different cellular systems.

In the analog mode of an AMPS cellular system, the handoffs are initiated by the base station and controlled by the MSC. For example, if mobile unit in cell A in Fig. 16.65 were to move close to cell B, the base station equipment in cell A would signal the MSC that the signal quality was diminishing. The MSC would initiate orders to adjacent cell sites to make signal measurements and report the results. Once the results had been received and analyzed by the MSC, the MSC would make a determination as to which cell site would receive the handoff. In this example, a message would be sent to the mobile unit, over the current voice channel, to change channels. This momentary use of the voice channel for signaling purposes is called blank and burst because the voice signal is blanked for a brief instant while a burst of signaling information is transmitted. The mobile unit changes channels as directed and the call is now transferred to the assigned channel in cell B. There is also a brief period, up to 400 ms, when no signal is received while the connection from the first cell is dropped and the connection to the new cell is being established.

Digital cellular, as previously explained, uses mobile assisted handoff to begin the handoff process. With MAHO, the mobile unit may make measurements on as many as 12 channels from adjacent cell sites. On command, it will report these results to the base station. Based on those results, the MSC may order a handoff to another channel controlled by an adjacent base station. The advantage of this method is a more accurate evaluation of the signal actually being received by the mobile unit. As previously explained,

TDMA still experiences a brief period of the mobile not receiving a signal while the handoff is occurring. Because of its ability to do soft handoffs, CDMA systems do not lose the signal because the connection is maintained with the old cell until the connection to the new cell is established.

Handoffs between cells controlled by different MSCs also take place, and IS-41 messages are used between the MSCs to control the process. The mechanics are similar to the handoffs described earlier except that when there is an adjacent system IS-41 messages must be sent to the adjacent MSC requesting the measurements (and results) and then initiating the handoff. The messages are sent over signaling links while the voice channels are part of dedicated lines between the MSCs. With IS-41, revision B, the capability exists to minimize the number of connections when more than two MSCs are involved in any one call.

Call Processing-Other Types of Calls

There are other types of calls that are processed in a cellular system. These can originate from home or visiting subscribers but are processed by the home system. They include mobile-mobile, emergency, and operator-assisted calls.

Mobile-Mobile Calls

Mobile subscribers can also reach other mobile subscribers, including those that operate on other cellular systems. If the call is to a mobile subscriber in the same cellular system, the MSC sets up the call, via the control channels, between the cell sites serving the two mobile subscribers. If the call is to a mobile subscriber in another system that is not directly interconnected with the originating system, the call is normally processed like the mobile- to-land call already described. This type of call would occur when a mobile subscriber of a wireline system places a call to a mobile subscriber served by a nonwireline system, or vice versa.

Emergency Services Calls

In most cases, the cellular carrier must make arrangements with the local public safety agency that is responsible for handling emergency calls before they begin forwarding such traffic to the LEC. Normally, the mobile user dials 911, but those digits may be translated into a seven digit number by the MSC in order to complete the call.

A major problem with calls from a mobile unit is the fact that the precise location may not be known, and the number of the mobile unit is not forwarded to the emergency answering location. Because of existing technical limitations, it is possible to provide either a general geographical location or identify the mobile unit, but not both. Typically, the general geographical location is used, and it is identified by associating a 7-digit telephone number with a specific sector of the antenna that receives the initial call. The MSC is able to discern which cell, and which sector, receives the initial call and will use this information to translate the 911 digits to the proper 7-digit number that is forwarded to the LEC for completion to the emergency answering location.

Operator Services Traffic

Traffic destined for operator services provided by the LEC is usually routed by the MSC over a Type 1 connection or over special direct trunks (Type 2D) to a LEC operator services tandem. The direct connection to the operator services tandem provides greater flexibility because the actual identification of the mobile unit placing the call is provided with this connection, whereas the Type 1 connection does not receive this information from the MSC. For example, a Type 2D will allow the LEC to provide *directory assistance call completion* (DACC) service whereby a call to directory assistance can be completed to the requested number by the LEC operator.

Because of heavy fraud activity, cellular carriers sometime restrict mobile users to placing long distance calls by using either a calling card, collect, or third-number billing options. This is possible because of a service called *selective class of call screening* (SCCS) that is offered to the cellular carriers by the LECs.

The LECs are not the only entities with operator services. Many ICs provide their own operators and these may be accessed via direct connections from the MSC to the IC or by using Type 1 or Type 2A trunks in the LEC network to reach the IC network.

Defining Terms

Advanced Mobile Phone Service (AMPS): An analog air interface standard for cellular service developed in the U.S. by AT&T Bell Laboratories. It is also known as the EIA/TIA-553 standard.

Authentication center (AC): An entity that manages encryption information for a wireless carrier. It may be associated with the home location register or it may be a separate function.

Cell site: A transmitter/receiver location, operated by the cellular carrier, through which radio links are established between the cellular system and mobile units. The area reliably served as a given cell site is referred to as a cell.

Cellular geographic service area (CGSA): The geographic area served by the cellular system within which a CMC is authorized to provide service.

Cellular system: A high-capacity land mobile radio system in which an assigned frequency spectrum is divided into discrete channels that are assigned in groups to cells covering the cellular geographic service area. The discrete cells can be reused in different cells within the same service area. Calls are handed off automatically from a channel in one cell to a different channel in an adjacent cell as the mobile unit moves across cell boundaries.

Code division multiple access (CDMA): A multiplexing technique where the signal intelligence is mixed with a randomlike code and then spread over a wide range of frequencies.

DS0: The 64-kb/s zero-level signal in the digital transmission hierarchy.

DS1: The 1.544 Mb/s first-level signal in the digital transmission hierarchy. In the time-division multiplexing hierarchy of the telephone network, DS1 is the initial level of multiplexing. Traditionally, 24 DS0 channels have been multiplexed up to the DS1 rate with each DS0 channel carrying the digital representation of an analog voice channel.

DS3: The 45 Mb/s third-level signal in the digital transmission hierarchy. It contains 28 DS1 signals or the equivalent of 672 analog voice channels.

Electronic serial number (ESN): Information electronically encoded by the manufacturer in a cellular set for identification purposes.

End office (EO): A LEC switching system within a LATA or market area where customer station loops are terminated for purposes of interconnection to each other and to trunks.

Federal Communications Commission (FCC): The federal agency empowered by law to regulate all interstate and foreign radio and wire communications services in the U.S. including radio, television, facsimile, telegraph, mobile, and telephone systems. The agency was created under the Communications Act of 1934.

Frequency division multiple access (FDMA): A multiplexing method whereby each channel is assigned a specific frequency for its use.

Global System for Mobile (GSM) Communications: A digital cellular standard developed in Europe.

Home location register (HLR): The location register to which end user identity information is assigned for record purposes.

Interexchange carrier (IC): A common carrier that provides services to the public between local exchanges on an intra or interLATA basis in compliance with local or Federal regulatory requirements and that is not an end user of the services provided.

Line: A central office connection that usually connects the switching system to customer equipment.

Local exchange carrier (LEC): A company that provides intraLATA telecommunications within a franchised territory.

Metropolitan statistical area (MSA): Sometimes known as standard metropolitan statistical areas (SMSAs), MSAs are areas based on counties as defined by the U.S. Census Bureau that are cities of 50,000 or more population and the surrounding counties. Using data from the 1980 census, the FCC allocated two cellular licenses in each of the 305 MSAs in the U.S.

Mobile identification number (MIN): A 10-digit number that conforms to the North American numbering plan that is used for identification purposes in wireless sets (such as a cellular).

- Mobile switching center (MSC):** A cellular switching system that is used to terminate mobile stations for purposes of interconnection to each other and to trunks interfacing with the public switched network.
- Mobile telephone switching office (MTSO):** A synchronous, but obsolete, term for mobile switching center.
- North American numbering plan (NANP):** A 10-digit number address used for direct dialing within world zone 1 which includes the U.S., Canada, Puerto Rico, the Virgin Islands, Jamaica, and Bermuda.
- NPA code:** A unique 3-digit code in the N 0/1 X series that identifies a numbering plan area. A NPA is the first three digits of the 10-digit destination number for all inter-NPA calls within the NANP area.
- NXX code:** A code normally used as a central office code. It may also be used as an NPA code or special NPA code.
- Signaling System 7 (SS7):** An internationally standardized, general purpose CCS system.
- System identification (SID):** An identity assigned by the FCC for cellular systems used to identify a specific cellular system. Initially, these numbers were unique for each provider and each MSA or RSA. Some systems have since been combined and so MSAs and RSAs are no longer necessarily unique.
- Telecommunications Industry Association (TIA):** A standards body accredited by ANSI that addresses telecommunications equipment and systems.
- Time division multiple access (TDMA):** A multiplexing technique in which individual conversations are converted to a digital format and assigned to a specific time slot in a channel. There are usually two or more time slots per channel.
- Transaction capabilities application part (TCAP):** In the SS7 protocol, the application layer of the transaction capability protocol.
- Trunk:** In a network, a communication path connecting two switching systems.
- Wireless carrier (WC):** A generic term used to describe entities providing wireless service. Such entities include, but are not limited to, cellular carriers, radio common carriers, and private carriers.

16.8 Satellite Communications

Daniel F. DiFonzo

16.8.1 Introduction

The impact of satellites on world communications since commercial operations began in the mid-1960s is such that we now take for granted many services that were not available a few decades ago: worldwide TV, reliable communications with ships and aircraft, wide-area data networks, communications to remote areas, direct TV broadcast to homes, position determination, and Earth observation (weather and mapping). New and proposed satellite services include global personal communications to hand-held portable telephones and broadband voice, video, and data to and from small user terminals at customer premises around the world.

Satellites function as line-of-sight microwave relays in orbits high above the Earth which can see large areas of the Earth's surface. This unique feature ensures satellites' continued growth even as fiber optic cables capture a larger market share of high-density point-to-point traffic. Satellites provide cost-effective access for areas with low (thin-route) communications traffic because Earth terminals can be installed in locations where the high investment cost of terrestrial facilities might not be warranted. Satellites are particularly well suited to wide-area coverage for broadcasting, mobile communications, and point-to-multipoint communications.

16.8.2 Satellite Applications

Figure 16.66 depicts several kinds of satellite links and orbits. The geostationary Earth orbit (GEO) is in the equatorial plane at an altitude of 35,786 km with a period of one sidereal day (23 h 56 min 4.09 sec). GEO satellites appear to be almost stationary from the ground (subject to small perturbations) and the

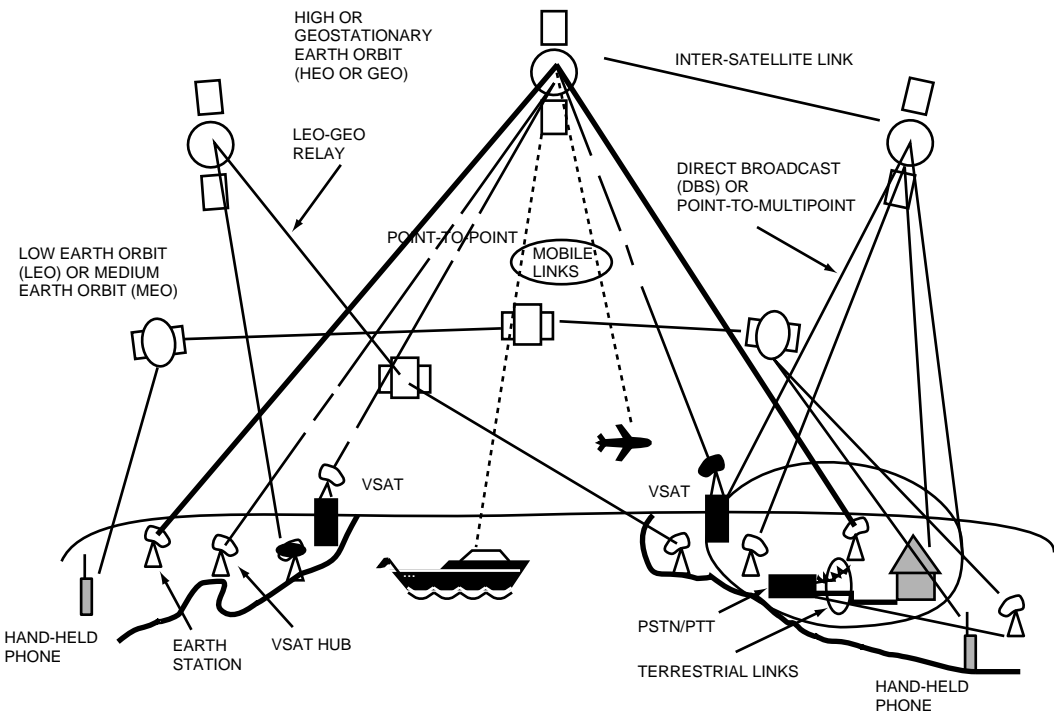

FIGURE 16.66 Several types of satellite links: illustrated are point-to-point, point-to-multipoint, VSAT, direct broadcast, mobile, personal communications, and intersatellite links.

Earth antennas pointing to these satellites may need only limited or no tracking capability. The orbits for which the highest altitude (apogee) is at or greater than GEO are sometimes referred to as high Earth orbits (HEO). Low Earth orbits (LEO) typically range from a few hundred km to about 2000 km. Medium Earth orbits (MEO) are at intermediate altitudes. Circular MEO orbits are sometimes called intermediate circular orbits (ICO). Several organizations have proposed MEO systems at an altitude of about 10,400 km for global personal communications at frequencies designated for mobile satellite services (MSS).

LEO systems for voice communications are called *big LEOs*. Constellations of so-called *little LEOs* operating below 1 GHz and having only limited capacity have been proposed for low data rate nonvoice services, such as paging and store and forward data for remote location and monitoring, for example, for freight containers and remote vehicles and personnel (Kiesling, 1996).

Initially, satellites were used primarily for point-to-point traffic in the GEO fixed satellite service (FSS), for example, for telephony across the oceans and for point-to-multipoint TV distribution to cable *head end* stations. Large Earth station antennas with high-gain narrow beams and high uplink powers were needed to compensate for limited satellite power. This type of system, exemplified by the early global network of the International Telecommunications Satellite Organization (INTELSAT), used Standard-A Earth antennas with 30 m diameters. Since then, many other satellite organizations have been formed around the world to provide international, regional, and domestic services (Rees, 1990).

As satellites have grown in power and sophistication, the average size of the Earth terminals has been reduced. High-gain satellite antennas and relatively high-power satellite transmitters have led to *very small aperture Earth terminals* (VSAT) with diameters of less than 2 m, modest powers of less than 10 W (Gagliardi, 1991) and to smaller *ultrasmall aperture terminals* (USAT) diameters typically less than 1 m. As depicted in Fig. 16.66, VSAT terminals may be placed atop urban office buildings, permitting private networks of hundreds or thousands of terminals, which bypass terrestrial lines. VSATs are usually incorporated into *star* networks where the small terminals communicate through the satellite with a larger *hub* terminal. The hub retransmits through the satellite to another small terminal. Such links require two *hops* with attendant time delays. With high-gain satellite antennas and relatively narrowband digital signals, direct single-hop *mesh* interconnections of VSATs may be used.

16.8.3 Satellite Functions

The traditional function of a satellite is that of a bent pipe quasilinear repeater in space. As shown in Fig. 16.67, *uplink* signals from Earth terminals directed at the satellite are received by the satellite's antennas, amplified, translated to a different *downlink* frequency band, channelized into *transponder channels*, further amplified to relatively high power, and retransmitted toward the Earth. Transponder channels are generally rather broad (e.g., bandwidths from 24 MHz to more than 100 MHz) and each may contain many individual or user channels.

The functional diagram in Fig. 16.67 is appropriate to a satellite using frequency-division duplex (FDD), which refers to the fact that the satellites use separate frequency bands for the uplink and downlink and where both links operate simultaneously. This diagram also illustrates a particular *multiple access* technique, known as frequency-division multiple access (FDMA), which has been prevalent in mature satellite systems.

Multiple access, to be discussed later, allows many different user signals to utilize the satellite's resources of power and bandwidth without interfering with each other. Multiple access systems segregate users by frequency division (FDMA) where each user is assigned a specific frequency channel, space-division multiple access (SDMA) by reusing the same frequencies on multiple spatially isolated beams, time-division multiple access (TDMA) where each user signal occupies an entire allocated frequency band but for only part of the time, polarization-division (PD) where frequencies may be reused on spatially overlapping but orthogonally polarized beams, and code-division multiple access (CDMA) where different users occupy the same bandwidth but use spread spectrum signals that contain orthogonal signaling codes (Sklar, 1988; Richharia, 1995).

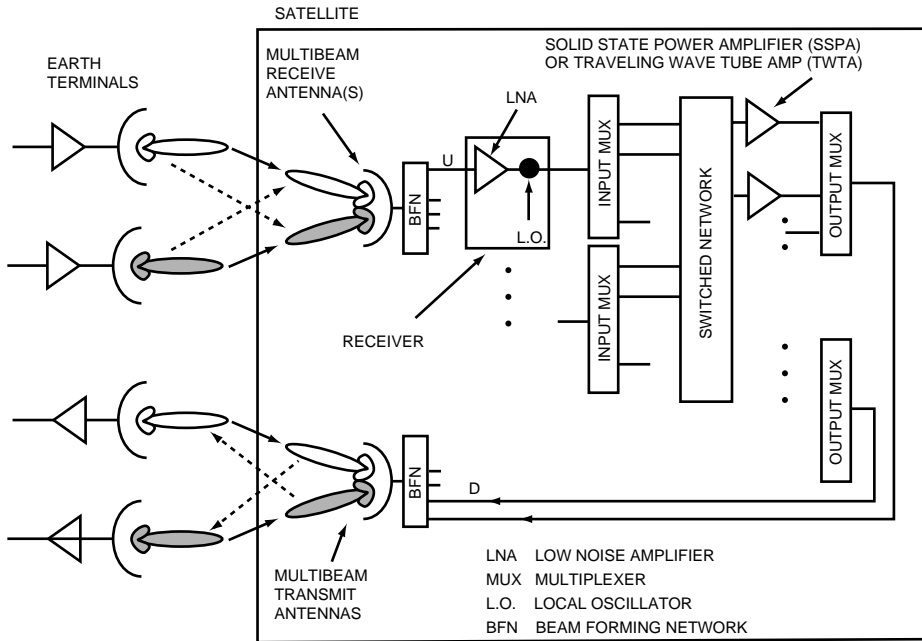

FIGURE 16.67 A satellite repeater receives uplink signals (U), translates them to a downlink frequency band (D), channelizes, amplifies to high power, and retransmits to Earth. Multiple beams allow reuse of the available band. Interference (dashed lines) can limit performance. Downconversion may also occur after the input multiplexers and several intermediate frequencies, and downconversions may be used.

Frequency modulation (FM) has been the most widely used modulation. However, advances in digital voice and video compression have led to the widespread use of digital modulation methods such as quadrature phase shift keying (QPSK) and quadrature amplitude modulation (QAM) (Schwartz, 1990; Sklar, 1988).

Newer satellite architectures incorporate digital modulations and onboard demodulation of the uplink signals to baseband bits, subsequent switching and assignment of the baseband signals to an appropriate downlink antenna beam, and remodulation of the clean baseband signals prior to downlink transmission. These *regenerative repeaters* or *onboard processors* permit flexible routing of the user signals and can improve the overall communications link by separating the uplink noise from that of the downlink. The baseband signals may be those of individual users or they may represent frequency-division multiplexed (FDM) or time-division multiplexed (TDM) signals from many users.

High-power *direct broadcast satellites* (DBS) or *direct-to-home* (DTH) satellites operate at Ku-band. In the U.S., satellites operating in the broadcast satellite service (BSS) with downlink frequencies of 12.2–12.7 GHz, deliver TV directly to home receivers having parabolic dish antennas as small as 46 cm (18 in) in diameter. DBS with digital modulation and compressed video is providing more than 150 National Television Systems Committee (NTSC) TV channels from a single orbital location having an allocation of 32 transponder channels, each with 24-MHz bandwidth.

Mobile satellite services operating at L-band around 1.6 GHz have revolutionized communications with ships and aircraft, which would normally be out of reliable communications range of terrestrial radio signals. The International Maritime Satellite Organization (INMARSAT) operates the dominant system of this type.

Links between LEO satellites (or the NASA Shuttle) and GEO satellites are used for data relay, for example, via the NASA tracking and data relay satellite system (TDRSS). Some systems will use intersatellite links (ISL) to improve the interconnectivity of a wide-area network. ISL systems would typically operate at frequencies such as 23 GHz, 60 GHz, or even use optical links.

16.8.4 Satellite Orbits and Pointing Angles

Reliable communication to and from a satellite requires a knowledge of its position and velocity relative to a location on the Earth. Details of the relevant astrodynamics formulas for satellite orbits are given in Griffin and French (1991) and Morgan and Gordon (1989). Launch vehicles needed to deliver the satellites to their intended orbits are described in Isakowitz (1994).

A satellite, having mass m in orbit around the Earth, having mass M_e , traverses an elliptical path such that the centrifugal force due to its acceleration is balanced by the Earth's gravitational attraction, leading to the equation of motion for two bodies:

$$\frac{d^2\mathbf{r}}{dt^2} + \frac{\mu}{r^3}\mathbf{r} = 0 \tag{16.52}$$

where \mathbf{r} is the radius vector joining the Earth's center and the satellite and $\mu = G(m + M_e) \approx GM_e = 398,600.5 \text{ km}^3/\text{sec}^2$ is the product of the gravitational constant and the mass of the Earth. Because $m \ll M_e$, the center of rotation of the two bodies may be taken as the Earth's center, which is at one of the focal points of the orbit ellipse.

Figure 16.68 depicts the orbital elements for a geocentric right-handed coordinate system where the x axis points to the first point of Aries, that is, the fixed position against the stars where the sun's apparent path around the Earth crosses the Earth's equatorial plane while traveling from the southern hemisphere toward the northern hemisphere at the vernal equinox. The z axis points to the north and the y axis is in the equatorial plane and points to the winter solstice. The elements shown are: longitude or right ascension of the ascending node Ω measured in the equatorial plane; the orbit's inclination angle i relative to the equatorial plane; the ellipse semimajor axis length a ; the ellipse eccentricity e ; the argument (angle) of perigee ω , measured in the orbit plane from the ascending node to the satellite's closest approach to the Earth; and the true anomaly (angle) in the orbit plane from the perigee to the satellite ν .

The mean anomaly M is the angle from perigee that would be traversed by a satellite moving at its mean angular velocity n . Given an initial value M_0 , usually taken as 0 for a particular epoch (time) at perigee, the mean anomaly at time t is $M = M_0 + n(t - t_0)$, where $n = \mu^{1/2}/a^{3/2}$. The eccentric anomaly E may then be found from Kepler's transcendental equation $M = E - e \sin E$, which must be solved numerically by, for example, guessing an initial value for E and using a root finding method. For small eccentricities, the series approximation $E \approx M + e \sin M + (e^2/2) \sin 2M + (e^3/8)(3 \sin 3M - \sin M)$ yields good accuracy

FIGURE 16.68 Orbital elements.

FIGURE 16.69 Geometry for a satellite in the plane defined by the satellite, the center of the Earth, and a point on the Earth's surface. The elevation angle el is the angle from the local horizon to the satellite. Shown to approximate scale are satellites at LEO, MEO (or ICO), and GEO.

(Morgan and Gordon, 1989, p. 806). Other useful quantities include the orbit radius r , the period P of the orbit (i.e., for $n(t - t_0) = 2\pi$), the velocity V , and the radial velocity V_v

$$r = a(1 - e \cos E) \quad (16.53)$$

$$P = 2\pi \sqrt{a^3/\mu} \quad (16.54)$$

$$V = \mu \left(\frac{2}{r} - \frac{1}{a} \right) \quad (16.55)$$

$$V_v = \frac{e(\mu a)^{1/2} \sin E}{a(1 - e \cos E)} \quad (16.56)$$

Figure 16.69 depicts quantities useful for communications links in the plane formed by the satellite, a point on the Earth's surface and the Earth's center. Shown to approximate scale for comparison are satellites at altitudes representing LEO, MEO (or ICO), and GEO orbits.

For a satellite at altitude h and Earth radius $r_e = 6378.14$ km, the slant range r_s , elevation angle to the satellite from the local horizon el , and the satellite's nadir angle θ are related by simple spherical trigonometry formulas. Note that $\theta + el + \gamma = 90^\circ$, where γ is the Earth central angle and the ground range from the subsatellite point is γr_e . Then

$$k = \frac{r_e + h}{r_e} = \frac{\cos(el)}{\sin \theta} \quad (16.57)$$

$$\tan(el) = \frac{(\cos \gamma - 1/k)}{\sin \gamma} \quad (16.58)$$

$$r_s = r_e \sqrt{1 + k^2 - 2k \cos \gamma} \quad (16.59)$$

The Earth station azimuth angle to the satellite measured clockwise from north in the horizon plane is given in terms of the satellite's declination δ , the observer's latitude ϕ , and the difference of the east longitudes of observer and satellite $\Delta\lambda$. Then

$$\tan A = \frac{\sin \Delta\lambda}{(\cos \phi \tan \delta - \sin \phi \cos \Delta\lambda)} \quad (16.60)$$

taking due account of the sign of the denominator to ascertain the quadrant.

The fraction of the Earth's surface area covered by the satellite within a circle for a given elevation angle el and the corresponding Earth central angle γ is

$$\frac{a_c}{a_e} = \frac{1 - \cos \gamma}{2} \quad (16.61)$$

16.8.5 Communications Link

Figure 16.70 illustrates the elements of the RF link between a satellite and Earth terminals. The overall link performance is determined by computing the link equation for the uplink and downlink separately and then combining the results along with interference and intermodulation effects.

The uplink received carrier-to-noise ratio at the satellite is

$$(C/N)_u = EIRP_u + (G_{su} - 10 \log T_{su}) + 228.6 - 10 \log (4\pi r_{su}^2) - 10 \log (4\pi/\lambda_u^2) - A_u + \Gamma_u - B \tag{16.62}$$

where each term is a quantity expressed in decibel, for example, P (dBW) = $10 \log(p)$ (W). The downlink equation has identical form with appropriate downlink quantities substituted in Eq. 16.62. The relevant quantities (without subscripts) are described next.

The carrier-to-noise ratio (C/N) is the decibel difference between carrier and noise powers expressed in decibel relative to one watt (dBW), that is, (C/N) dBW = $10 \log c - 10 \log n$. $EIRP = P + G$ dBW is the equivalent isotropically radiated power (EIRP) where the antenna gain G in decibels relative to isotropic (dBi) is the antenna gain *in the direction of the link*, that is, it is not necessarily the antenna's peak gain. The received noise power is $N = 10 \log(kTb)$ where $k = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant, $10 \log(k) = -228.6$ dBW/K/Hz, T is the system noise temperature in kelvins and $B = 10 \log(\text{bandwidth (Hz)})$ is the bandwidth in decibel hertz. Then, $(G - 10 \log T)$ dB/K is a figure of merit for the satellite or Earth receiving system. It is usually written as G/T and read as "gee over tee." The antenna gain and the noise temperature must be defined at the same reference point, for example, at the receivers input port.

The spreading factor $4\pi r_s^2$ is independent of frequency and depends *only* on the slant range distance r_{su} or r_{sd} . The gain of a 1-m^2 antenna is $10 \log(4\pi/\lambda^2)$, where the wavelength $\lambda = c/f$, where f is the frequency in hertz, and $c = 2.9979 \times 10^8$ m/sec is the velocity of light. The decibel sum of the spreading factor and the gain of a 1-m^2 antenna is the frequency-dependent path loss. A is the signal attenuation due to dissipative losses in the propagation medium.

Γ is the polarization mismatch factor in decibel between the incident wave and the receive antenna, that is, $\Gamma = 10 \log(\zeta)$ where $0 \leq \zeta \leq 1$. For nearly circularly polarized systems, having opposite senses of polarization, the decibel value of the polarization coupling term can be approximated as

$$\Gamma \approx 10 \log (R_w^2 + R_A^2 + 2R_w R_A \cos \delta) - 24.8 \tag{16.63}$$

where R_w and R_A are the axial ratios in decibel of the wave and antenna, respectively, and δ is the difference between the tilt angles of the two polarization ellipses. For ideal antennas and no *depolarization* due to antenna imperfections or precipitation (Gagliardi, 1991; Pratt and Bostian, 1986; Sciulli, 1986) the coupling would be zero or $-\infty$ dB. The copolarized coupling factor would normally be ≈ 1 , corresponding to $\Gamma = 0$ dB.

16.8.6 System Noise Temperature and G/T

The system noise temperature T incorporates contributions to the noise power radiated into the receiving antenna from the sky, ground, and galaxy, as well as the noise temperature due to circuit and propagation losses, and the noise figure of the receiver. The clear sky antenna temperature for an Earth station depends on the elevation angle since the antenna's sidelobes will receive a small fraction of the thermal noise power

FIGURE 16.70 Quantities for a satellite RF link: P = transmit power (dBW), G = antenna gain (dBi), C = received carrier power (dBW), T = noise temperature (K), L = dissipative loss (dB), r = slant range (m), f = frequency (Hz), u = uplink, d = downlink, e = Earth, s = satellite.

radiated by the Earth, which has a noise temperature $T_{\text{earth}} \approx 290$ K. At 11 GHz, the clear sky antenna noise temperature, T_{aclear} , ranges from 5 to 10 K at zenith ($el = 90^\circ$) to more than 50 K at $el = 5^\circ$ (Pratt and Bostian, 1986).

As shown in Fig. 16.71, the system noise temperature is developed from the standard formula for the equivalent temperature of tandem elements including the antenna in clear sky, propagation (rain) loss of A dB, circuit losses between the aperture and receiver of L_c dB, and receiver noise figure of F dB (corresponding to receiver noise temperature T_r K). The system noise temperature referred to the receiver input is approximated by the following equation where $T_{\text{rain}} \approx 270$ K is a reasonable approximation for the physical temperature of the rain:

$$T_{ed} = (T_{\text{aclear}} + 270(1 - 10^{-A/10})) / 10^{L_c/10} + 290(1 - 10^{-L_c/10}) + 290(10^{F/10} - 1) \text{ K} \quad (16.64)$$

The system noise temperature is defined at a specific reference point such as the input to the receiver. However, G/T is independent of the reference point when G correctly accounts for circuit losses. The satellite's noise temperature is generally higher than an Earth terminal's under clear sky conditions because the satellite antenna sees a warm Earth temperature of $\approx 150\text{--}300$ K, depending on the proportion of clouds, oceans, and land in the satellite antenna's beam, whereas a directive Earth antenna generally sees cold sky and the sidelobes generally receive only a small fraction of noise power from the warm Earth. Furthermore, a satellite receiving system generally has a higher noise temperature due to circuit losses in the beam forming networks, protection circuitry, and extra components for redundancy.

Figure 16.72 illustrates the link loss factors, maximum nadir angle θ , Earth central angle γ , and earth-space time delay as a function of satellite altitude. The path losses are shown for several satellite frequencies

FIGURE 16.71 Tandem connection of antenna, loss elements such as waveguide and receiver front end. The noise temperature depends on the reference plane but the G/T is the same for both points shown.

FIGURE 16.72 Satellite link losses, spreading factors, maximum nadir angle θ -max, Earth central angle γ , and one-way Earth-space time delay vs. satellite altitude, h km.

in use. The variation in path loss and Earth central angle is substantial. For example, L-band LEO personal communications systems to low cost handheld telephones with low gain (e.g., $G_u \approx 0\text{--}3$ dBi) need less link power than for MEO or GEO. On the other hand, more satellites are needed to provide full coverage since LEO satellites see much smaller fractions of the Earth.

The design for a constellation of satellites to serve communications needs, includes choices for the number of satellites, their orbital parameters, the satellite G/T and EIRP, etc. These mission analysis and design topics involve trades of many factors such as total communications capacity, link margins, space segment and Earth segment costs, reliability, interconnectivity, availability and cost of launch vehicles, mission lifetime, and system operations (Wertz and Larson, 1991).

16.8.7 Digital Links

For digital modulation systems, bit error rate (BER) is related to the dimensionless ratio (decibel difference) of energy per bit, E_b dB J to the total noise power density $N_o = 10 \log(kT)$ dB J (Sklar, 1988). For thermal noise

$$\begin{aligned} (E_b/N_o) &= (C/N) + B - R \\ &= (C/N_o) - R \text{ dB} \end{aligned} \quad (16.65)$$

where $R = 10 \log(\text{transmission bit rate in bit per second})$, B is the bandwidth (decibel hertz), and (C/N_o) is the *carrier-to-thermal noise density ratio*, that is, C/N normalized to unit bandwidth. Curves relating the communications performance measure of BER vs. E_b/N_o for different modulations may be found in Sklar (1988). The link equation may then be expressed in terms of (E_b/N_o) and transmission data rate R , without explicit reference to the bandwidth

$$(E_b/N_o) = EIRP + (G/T) + 228.6 - \left\{ 10 \log(4\pi r_s^2) + 10 \log\left(\frac{4\pi}{\lambda^2}\right) \right\} - A + \Gamma - R \text{ dB} \quad (16.66)$$

where the appropriate quantities are substituted depending on whether the uplink or downlink is being considered.

16.8.8 Interference and Total C/N and $E_b/(N_o + I_o)$

The C/N or $E_b/(N_o + I_o)$ for a complete transponder link combines the contributions of the uplink, downlink, and also the power sum of all interference signals due, for example, to intermodulation products generated in the output stages of the amplifiers, external interference from other systems, and intrasystem interference from reusing the same frequency band on spatially isolated or dual-polarized antenna beams to increase communications capacity. For most applications the total interference power may be taken as the power sum of interfering signals as long as they are not correlated with the desired carrier. The values for the interfering signals due to effects outside the satellite, for example, **frequency reuse** cross-polarization, multiple beam interferers, and other systems, must be obtained by carefully constructing the link equation for each case, taking into account the antenna gains for each polarization and beam direction of concern.

For an interference power i , and carrier power c (both in watt), the interference ratio c/i must be combined with the uplink and downlink c/n values to yield the total c/n . Here, the ratios are written in lower case to indicate they are *numerical power ratios* of quantities expressed in watts.

$$\left(\frac{c}{n}\right)_{\text{total}} = \frac{1}{\left(\frac{c}{n}\right)_u^{-1} + \left(\frac{c}{n}\right)_d^{-1} + \left(\frac{c}{n}\right)_i^{-1}} \quad (16.67)$$

Equation 16.67 applies to a bent pipe satellite. If onboard signal regeneration is used for digital transmission the uplink signal is demodulated and a *clean* set of baseband bits is remodulated. This has the effect of separating the accumulation of uplink and downlink noise contributions by causing the uplink noise to

be effectively modulated onto the downlink carrier with the desired signal (Gagliardi, 1991). In that case, only the uplink or the downlink term in the denominator of Eq. (16.67) would be used as appropriate. Remodulation is also useful for intersatellite links. In each case, a savings in power or antenna size may be obtained at the expense of circuit and processing complexity.

The degradation to a digital link from interference follows a form similar to that of Eq. (16.67) but in terms of e_b/n_o , where the lower case quantities refer to numerical ratios. For a link that is subject to a *given* additive white noiselike interference power expressed as a ratio of desired signal power to interference power c/i , and assuming digital modulation with m bits per symbol,

$$\frac{e_b}{i_o} = \frac{1}{m} \frac{c}{i} \quad (16.68)$$

The ratio of energy per bit to total thermal noise plus interference power density is

$$\left(\frac{e_b}{n_o + i_o} \right) = \frac{1}{\left(\frac{e_b}{n_o} \right)^{-1} + \left(\frac{e_b}{i_o} \right)^{-1}} \quad (16.69)$$

For a system employing frequency reuse via dual polarizations, the polarization coupling factor Γ between a wave and antenna determines the interference power. The C/I due to polarization is the ratio of desired (copolarized) receive power and undesired (cross polarized) powers and is called the **polarization isolation**.

16.8.9 Some Particular Orbits

A *geosynchronous* orbit has a period that is a multiple of the Earth's rotation period, but it is not necessarily circular, and it may be inclined. Therefore, a *geostationary* Earth orbit (GEO) is a special case of a geosynchronous orbit where $e = 0$, $i = 0$, $k = (r_e + h)/r_e = 6.61$, and $h = 35,786$ km. When $el = 0$ the maximum nadir angle $\theta = 8.7^\circ$, the maximum slant range is 41,680 km, and, from Eq. (16.58), $\gamma = 81.3^\circ$. Therefore, a GEO satellite cannot see the Earth above 81.3° latitude.

Molniya and Tundra orbits are critically inclined ($i = 63.4^\circ$) highly inclined elliptical orbits (HIEO) to cause the satellite's subsatellite ground trace to dwell at apogee at the same place each day. Such orbits whose subsatellite paths trace a repetitive loop (LOOPUS) allow several satellites to be phased to offer quasistationary satellite service at high latitudes. For full Earth coverage from a constellation of LEO satellites, circular polar constellations (Adams and Rider, 1987) and constellations of orbit planes with different inclinations, for example, Walker orbits (Walker, 1977) have received attention.

Table 16.21 compares the geometry, coverage, and some parameters relevant to the communications links for typical LEO, MEO (or ICO), and GEO systems. Reference should be made to Fig. 16.69 for the geometry and to the given equations for geometrical and link parameters.

16.8.10 Access and Modulation

Satellites act as central relay nodes, which are visible to a large number of users who must efficiently use the limited power and bandwidth resources. For detailed discussions of access issues see Gagliardi (1991), Pritchard et al (1993), Miya (1985), and Shimbo (1988). A brief summary of issues specific to satellite systems is now given.

Frequency-division multiple access has been the most prevalent access for satellite systems until recently. Individual users being assigned a particular frequency band may communicate at any time. Satellite filters subdivide a broad frequency band into a number of *transponder channels*, for example, the 500-MHz uplink FSS band from 5.925 to 6.425 GHz may be divided into 12 transponder channels of 36-MHz bandwidth plus guard bands. This limits the interference among adjacent channels in the corresponding downlink band of 3.7–4.2 GHz.

FDMA implies that several individual carriers coexist in the transmit amplifiers. To operate the amplifiers in a quasilinear region relative to their saturated output power to limit intermodulation products, the amplifiers, must be operated in a **backed off** condition. For example, to limit third-order intermodulation

TABLE 16.21 Comparison of Orbit and Link Parameters for LEO, MEO, and GEO for the Particular Case of Circular Orbits (Eccentricity $e = 0$) and for Elevation Angle $e_l = 10^\circ$.

Earth radius r_e , km	6378.14		
Earth surface area a_e , km ²	511.2×10^6		
Elevation angle e_l°	10		
Orbit	LEO	MEO/ICO	GEO
Example system	Iridium [®]	ICO-P	INTELSAT
Inclination i°	86.4	± 45	0
Altitude h , km	780	10,400	35786
Semimajor axis radius a , km	7159	16,778	42164
Orbit period, min	100.5	360.5	1436.1
$(r_e + h)/r_e$	1.1222	2.6305	6.6107
Earth central angle γ°	18.658	58.015	71.433
Nadir angle θ°	61.3	22	8.6
Nadir spread factor:			
$10 \log(4\pi h^2)$, dB m ²	128.8	151.3	162.1
Slant range r_s , km	2325	14,450	40,586
Earth-space time delay, ms	2.6	51.8	139.1
Maximum spread factor:			
$10 \log(4\pi r_s^2)$, dB m ²	138.3	154.2	163.2
$20 \log(r_s/h)$, dB	9.5	2.9	1.1
Ground coverage area, km ²	13.433×10^6	120.2×10^6	174.2×10^6
Fraction of Earth area	0.026	0.235	0.34

power for two carriers in a conventional traveling wave tube (TWT) amplifier to ≈ -20 dB relative to the carrier, its input power must be reduced (*input backoff*) by about 10 dB relative to the power that would drive it to saturation. The output power of the carriers is reduced by about 4–5 dB (*output backoff*). Amplifiers with fixed bias levels will consume power even if no carrier is present. Therefore, DC-to-RF efficiency degrades as the operating point is backed off. For amplifiers with many carriers, the intermodulation products have a noiselike spectrum and the noise power ratio is a good measure of multicarrier performance.

When reusing the available frequency spectrum by multiple spatially isolated beams (SDMA), interference can result if the sidelobes of one beam receives or transmits substantial energy in the direction of the other beams. Two beams that point in the same direction may reuse frequencies provided that they are orthogonally polarized, for example, vertical and horizontal linear polarizations or right- and left-hand circular polarizations. Typical values of sidelobe or polarization isolation among beams reusing the same frequency bands are from 27 to 35 dB.

Time-division multiple access users (TDMA) share a common frequency band and are each assigned a unique time slot for their digital transmissions. At any instant the DC—RF efficiency is high because there is only one carrier in the transmit amplifier, which may be operated near saturation. A drawback is the system complexity required to synchronize widely dispersed users in order to avoid intersymbol interference caused by more than one signal appearing in a given time slot. Also, the total transmission rate in a TDMA satellite channel must be essentially the sum of the users' rates, including overhead bits such as for framing, synchronization and clock recovery, and source coding. Earth terminal hardware costs for TDMA have been higher than for FDMA. Nevertheless, TDMA systems are gaining acceptance for some applications as their costs decrease.

Code-division multiple access (CDMA) modulates each carrier with a unique pseudorandom code, usually by means of either a direct sequence or frequency hopping spread spectrum modulation. As the CDMA users occupy the same frequency band at the same time, the aggregate signal in the satellite amplifier is noiselike. Individual signals are extracted at the receiver by correlation processes. CDMA tolerates noiselike interference but does not tolerate large deviations from average loading conditions. One or more very strong carriers could violate the noiselike interference condition and generate strong intermodulation signals.

User access is via assignments of a frequency, time slot, or code. Fixed assigned channels allow a user unlimited access. However, this may result in poor utilization efficiency for the satellite resources and may imply higher user costs (analogous to a leased terrestrial line). Other assignment schemes include *demand assigned multiple access* (DAMA) and *random access* (e.g., for the Aloha concept). DAMA systems require the user to first send a channel request over a common control channel. The network controller (at another Earth station) seeks an empty channel and instructs the sending unit to tune to it (either in frequency or time slot). A link is maintained for the call duration and then released to the system for other users to request. Random access is economical for lightly used burst traffic such as data. It relies on random time of arrival of data packets and protocols are in place for repeat requests in the event of collisions. (See Gagliardi (1991)).

In practice, combinations of multiplexing and access techniques may be used. A broadband may be channelized or *frequency-division multiplexed* and FDMA may be used in each subband, for example, FDM/FDMA.

16.8.11 Frequency Allocations

Table 16.22 contains a partial list of frequency allocations for satellite communications. The World Administrative Radio Conference, WARC-92 allocated L-band frequencies for LEO personal communications services and for LEO small satellite data relay. The World Radiocommunication Conference, WRC-95,

TABLE 16.22 Partial List of Satellite Frequency Allocations, Frequencies in Gigahertz

Band	Uplink	Downlink	Satellite Service
VHF		0.137–0.138	Mobile
VHF	0.3120–0.315	0.387–0.390	Mobile
L-Band		1.492–1.525	Mobile

Also, see Gagliardi, R.M. 1991. *Satellite Communications*, van Nostrand Reinhold, New York. Note that allocations are not always global and may differ from region to region in all or subsets of the allocated bands.

allocated S-band frequencies for mobile satellite services. Most of the other bands have been in force for years.

16.8.12 Satellite Subsystems

The major satellite subsystems are described in, for example, Griffin and French (1991). They are: propulsion, power, antenna, communications repeater, structures, thermal, **attitude** determination and control, telemetry, tracking, and command.

The satellite *antennas* typically are offset-fed paraboloids. Typical sizes are constrained by launch vehicles and have ranged from less than 1 m to more than 5 m for some applications. The Intelsat 6 satellite used a 3.2-m antenna at 4 GHz. Ku-band satellites may use a diameter > 2 m (i.e., $D > 80\lambda$). Multiple feeds in the focal region each produce a narrow *component beam* whose beamwidth is $\approx 65\lambda/D$ and whose directions are established by the displacement of the feed from the focal point. These beams are combined to produce a shaped beam with relatively high gain over a geographical region. Multiple beams are also used to reuse frequencies on the satellite. Figure 16.67 suggests that a satellite may have several beams for frequency reuse. In that case, the carriers occupying the same frequencies must be isolated from each other by either polarization orthogonality or antenna sidelobe suppression. As long as the sidelobes of one beam do not radiate strongly in the direction of another, both may use the same frequency band and increase the satellite's capacity.

The *repeaters* include the following main elements (see Fig. 16.67): A low noise amplifier (LNA) amplifies the received signal and establishes the uplink noise. The G/T of the satellite receiver includes the effect of losses in the satellite antenna, the noise figure of the LNA, and the noise temperature of the Earth seen from space (from 150 to 290 K depending on the percentage of the beam area over oceans and clouds). In a conventional repeater, the overall frequency band is downconverted by a local oscillator (LO) and mixer from the uplink band to the downlink band. It is channelized by an input multiplexer into a number (e.g., 12) of transponder channels. These channelized signals each are amplified by a separate high-power amplifier. Typically, a traveling wave tube amplifier (TWTA) is used with powers from a few watts to > 200 W for a DBS. Solid-state amplifiers can provide more than 15 W at C- and Ku-bands.

The *attitude determination and control system* (ADCS) must maintain the proper angular orientation of the satellite in its orbit in order to keep the antennas pointed to the Earth and the solar arrays aimed toward the sun (for example). The two prevalent stabilization methods are spin stabilization and body stabilization. In the former, the satellite body spins and the angular momentum maintains a gyroscopic stiffness. The latter uses momentum wheels to keep the spacecraft body orientation fixed. Components of this subsystem include the momentum wheels, torquers (which interact with the Earth's magnetic field), gyros, sun and Earth sensors, and thrusters to maintain orientation.

The *telemetry tracking and command* (TT&C) subsystem receives data from the ground and enables functions on the satellite to be activated by appropriate codes transmitted from the ground. This system operates with low data rates and requires omnidirectional antennas to maintain ground contact in the event the satellite loses its orientation.

The *power* subsystem comprises batteries and a solar array. The solar array must provide enough power to drive the communications electronics as well as the housekeeping functions and it must also have enough capacity to charge the batteries, which power the satellite during eclipse, that is, when it is shadowed and receives no power from the sun (Richharia 1995, 39). Typical battery technology uses nickel–hydrogen cells, which can provide a power density of more than 50 W-h/kg. Silicon solar cells can yield more than 170 W/m² at a satellite's beginning of life (BOL). Gallium arsenide solar cells (GaAs) yield more than 210 W/m². However, they are more expensive than silicon cells.

The space environment including radiation, thermal, and debris issues are described in Wertz and Larson (1991), and Griffin and French (1991). The structure must support all of the functional components and withstand the rigors of the launch environment. The thermal subsystem must control the radiation of heat to maintain a required operating temperature for critical electronics (Gilmore, 1994).

Defining Terms

- Attitude:** The angular orientation of a satellite in its orbit, characterized by roll (R), pitch (P), and yaw (Y). The roll axis points in the direction of flight, the yaw axis points toward the Earth's center, and pitch axis is perpendicular to the orbit plane such that $R \times P \rightarrow Y$. For a GEO satellite, roll motion causes north–south beam pointing errors, pitch motion causes east–west pointing errors, and yaw causes a rotation about the subsatellite axis.
- Backoff:** Amplifiers are not linear devices when operated near saturation. To reduce intermodulation products for multiple carriers, the drive signal is reduced or backed off. Input backoff is the decibel difference between the input power required for saturation and that employed. Output backoff refers to the reduction in output power relative to saturation.
- Beam and polarization isolation:** Frequency reuse allocates the same bands to several independent satellite transponder channels. The only way these signals can be kept separate is to isolate the antenna response for one reuse channel in the direction or polarization of another. The beam isolation is the coupling factor for each interfering path and is always measured at the receiving site, that is, the satellite for the uplink and the Earth terminal for the downlink.
- Bus:** The satellite bus is the ensemble of all of the subsystems that support the antennas and payload electronics. It includes subsystems for electrical power, attitude control, thermal control, TT&C, and structures.
- Frequency reuse:** A way to increase the effective bandwidth of a satellite system when available spectrum is limited. Dual polarizations and multiple beams pointing to different Earth regions may utilize the same frequencies as long as, for example, the gain of one beam or polarization in the directions of the other beams or polarization (and vice versa) is low enough. Isolations of 27–35 dB are typical for reuse systems.

17.1 Radar Principles

James M. Howell

17.1.1 Introduction

Radar is an acronym for radio detection and ranging as these were primary functions during the early use of radar. Radars can also measure other target properties such as range rate (Doppler), angular location, amplitude statistics, and polarization scattering matrix. In its simplest form, a radar propagates a pulse from an antenna to a target. The target reflects the pulse in many directions with some of the energy backscattered toward the radar. The radar return is received by the radar and subjected to processing to allow its detection. Since the pulse travels at approximately the speed of light, the distance to the target can be determined based on the round trip time delay. Reflections from undesired targets are known as *clutter* and often include terrain, rain, man-made objects, etc. Usually, the radar will have a narrow beam so that the angular location of the target (i.e., azimuth and elevation) can also be determined by some

technique such as locating the centroid of the target returns as the beam scans across the target or by comparing the signals received simultaneously or sequentially by different antenna patterns or overlapped beams. The radial velocity of the target can be determined by differencing the range measurements. Since the range measurements may not be very accurate, better range rate accuracy can be obtained by coherently measuring the Doppler frequency; that is, phase change from pulse-to-pulse in a given range cell. At microwave frequencies, the wavelength is quite small and, hence, small changes in range are readily detected. Generally, frequency is measured by using a **pulse Doppler** filter bank, pulse pair processing, or a CW frequency discriminator. Coherently measuring the frequency is also a good way for filtering moving targets from stationary or slowly moving clutter.

Radar parameters vary with the type of radar. Typically, the radar transmitted pulse width is 1 to 100 μs with a pulse repetition frequency (prf) of 200 Hz – 10 KHz. If the antenna is a mechanically rotated reflector, it generally rotates 360° in azimuth at about 12–15 r/min. If the two-way time delay is T , the range to the target is $R = 0.5T \times c$, where $c = 3 \times 10^8$ m/s is the velocity of light.

17.1.2 Applications

Radars can be classified by frequency band, use, or platform, for example, ground based, shipborne, airborne, or spaceborne. Radars generally operate in the microwave regime although HF over-the-horizon (OTH) radars such as JINDALEE, OTHB, and ROTH use similar principles in bouncing signals from the ionosphere to achieve long-range coverage. Radars are often denoted by the letter band of operation, for example, L-band (1–2 GHz), S-band (2–4 GHz), C-band (4–8 GHz), and X-band (8–12 GHz). Some classifications of radar are based on propagation mode (e.g., monostatic, bistatic, OTH, underground) or on scan method (mechanical, electronic, multibeam). Other classifications of radar are based on the waveform and processing, for example, pulse Doppler (PD), continuous wave (CW), FM/CW, synthetic aperture radar (SAR) or impulse (wideband video). Radars are often classified by their use: weather radar, police speed detection, navigation, precision approach radar, airport surveillance and air route surveillance, radio astronomy, fire control and weapon direction, terrain mapping and avoidance, missile fuzing, missile seeker, foliage penetration, subsurface or ground penetrating, acquisition, orbital debris, range instrumentation, imaging (e.g., SAR/ISAR), etc.

Search (or surveillance) radars are concerned with detection of targets out to long range and low-elevation angles to allow adequate warning on pop-up low-flying targets (e.g., sea skimmers). Since the search radar is more concerned with detection (i.e., presence or absence of targets) and can accommodate cruder accuracy in estimating target parameters such as azimuth angle, elevation angle, and range, search radars tend to have poorer range and angle accuracy than tracking radars. The frequency tends to be lower than track radars since RF power and antenna aperture are less expensive and frequency stability is better. Broad beams (e.g., *fan beam*) allow faster search of the volume. To first order, the radar search performance is driven by the *power-aperture* product (PA) to search the volume with a given *probability of detection* (PD) in a specified frame time. PA actually varies slightly in that to maintain a fixed false alarm rate per scan, more beam positions offer more opportunities for false alarms and, hence, the detection threshold must be raised, which increases the power to achieve the specified PD. With a phased-array antenna (i.e., electronically scanned beam), the probability of false alarm can be optimized by setting a high false alarm in the search beam and using a verify beam with higher threshold to confirm whether a search detection was an actual target or just a false alarm. The lower threshold in search allows less search power with some fraction of beams requiring the extra verify beams. The net effect on total required transmit power can be a reduction using this optimization technique. Search radars tend to use a fan beam or stacked receive beams to reduce the number of beam positions allowing more time in the beam for coherent processing to reduce clutter. Fill pulses are sometimes used to allow good clutter cancellation on second- or higher time-around clutter returns.

Track radars tend to operate at higher frequency and have better accuracy, that is, narrower beams and high range resolution. Simple radars track a single target with an early-late range tracker, Doppler speed gate, and conical scan or sequential lobing. More advanced angle trackers use monopulse or *conical scan on*

receive only (COSRO) to deny inverse modulation by repeater jammers. The multifunction phased-array radar can be programmed to conduct searches with track beams assigned to individual detected targets. The tracks are maintained in track files. If time occupancy becomes a problem, the track pulses can be machine gunned out at the targets in range order, and on receive they are gathered in one after the other since the track window on each target is quite small. In mechanically rotated systems, track is often a part of search, for example, *track-while-scan* (TWS). A plot extractor clusters the primitive returns in range Doppler angle from a given target to produce a single plot. The plots are associated with the track files using scan-to-scan correlation gates. The number of targets that can be handled in a TWS system is limited by data processing rather than track power.

17.1.3 Radar Configuration and Subsystems

A typical radar consists of a transmitter, *receiver-exciter* (REX), antenna, microwave components, signal processor, and data processor. Transmitters use solid-state or tubes (hollow state) as RF amplifiers. The solid-state power amplifier uses bipolar transistors at the lower frequencies, occasionally impact avalanche transit times (IMPATTs) at higher frequencies, and usually GaAs field effect transistors (FETs) at the higher frequencies. Solid-state transmitters have advantages of low voltage, high reliability due to graceful failure of multiple combined output stages, and maintainability, which can often be performed with the radar on-line. Since solid-state devices are peak power limited, long pulses are used to provide the required energy for detection with pulse compression on receive to provide the required range resolution. The long pulse sets the minimum range since the receiver generally cannot be receiving while the transmitter is transmitting. A short pulse at a different frequency is often transmitted before the long pulse and is used to provide coverage in the region blanked by the long pulse. A different frequency prevents longer range returns from the short pulse being detected when receiving the long pulse. Tube transmitters use either a traveling wave tube (TWT), magnetron, crossfield amplifier (CFA), klystron, or twystron. Good design of the transmitter includes, low spurious signals, low droop and timing jitter, etc.

The antenna is usually a reflector, lens, phased array, or some hybrid combination (e.g., limited scan applications). The antenna can be either rotated mechanically or scanned electronically (inertialess beam agility) using phase shifters and/or time-delay units. Cost considerations favor the low-cost reflector except in those cases where an array is essential, for example, rapidly switching between hundreds of targets. The cost of hundreds of reflectors would be even more expensive. Multiple beam lenses (e.g., R2R, RKR, **Rotman**, Ruze) are usually scanned with RF switches or *variable power divider* (VPD) networks. The antenna pattern is generally reciprocal on transmit and receive. The antenna pattern is created on transmit by radiation coming from different portions of the aperture with phase differences depending on direction. Mathematically, the pattern is a Fourier transform of the aperture illumination. Amplitude tapering (or space tapering/thinning the active elements of a phased array) lowers the sidelobes but increases the beamwidth. Common phased-array sum tapers include Taylor (either standard with $1/\mu$ sidelobe envelope or generalized with $1/\mu^n$ falloff), Tchebysheff, convolved Taylor (i.e., $\sin x/x$ convolved with Taylor to provide rapid falloff outside a given window), and Hamming weighting (i.e., optimum cosine-on-pedestal). Difference tapers include Bayliss, transmuted Taylor (i.e., linear weighting of Taylor sum with sidelobes about 10 dB higher), etc. Shaped antenna beam systems use **Woodward** and/or pattern-zero **synthesis** techniques. Phase-only synthesis can also be used to generate shaped beams. This approach uses the principle of stationary phase to scan different parts of the aperture toward different angles (i.e., similar to shaped reflector synthesis or the design of nonlinear frequency modulation (NLFM) waveforms). Phase synthesis can also be used to produce a notch in the elevation pattern near the horizon to minimize the effects of standoff jamming or low-angle multipath. Phase synthesis of planar arrays having uniform amplitude can also use checker-board synthesis where the phase of adjacent elements is adjusted to create the proper in-phase signal, and the sign of the quadrature signals are rotated successively from element-to-element. The in-phase signals add coherently producing the desired beam, whereas the quadrature signals add quasirandomly creating a sidelobe hashlevel that decreases with the number of elements. Performance is equivalent to using attenuators to produce an amplitude taper across the uniform amplitude aperture

with the exception that the lost energy is in the sidelobes rather than terminated in attenuators. The antenna beamwidth of an antenna is inversely proportional to both the aperture dimension and the RF frequency. Many antennas are rotated mechanically or scanned electronically, or use a hybrid combination of mechanical scan in azimuth and electronic scan in elevation. Phased arrays use diode or ferrite phase shifters for scanning the beam. The diode devices switch in nanoseconds, are reciprocal, and have small sensitivity to temperature. The ferrite devices switch in 10–100 μs and can be reciprocal or nonreciprocal as well as analog or digital. Ferrites have lower loss at the higher frequencies and can handle higher power levels. Flux drive is used for accurate phase setting. Frequency scan is sometimes used with slotted waveguide arrays for low cost, but it often limits frequency agility and makes each angle associate with a given frequency, which makes a jammer more effective against the radar.

The receiver–exciter (REX) provides precision timing and the high-quality frequency source, generates the waveform (digital synthesizer; waveform stored in programmable read-only memories (PROMs) and read out through a D/A converter), and provides the upconversion, amplification, and filtering needed for a drive signal to the transmitter. It provides timing signals for other subsystems and may include a test target generator for calibrating system performance. It also provides the downconversion on receive. The receiver should have good linearity over a wide dynamic range to prevent intermods and should have good image rejection (through the use of double downconversion). The front-end filtering (selectivity) provides rejection of interference and other undesired signals. The receiver can provide electronic counter-countermeasure (ECCM) features such as a Q-channel, sidelobe blanker, coherent sidelobe canceller loops, guard band blanking, Dicke-fix/log-fast time constant (FTC), etc. The receiver often provides sensitivity time control (STC) to prevent saturation at short ranges by clutter and undesired targets. Since RF STC at longer ranges can affect low sidelobe pulse compression waveforms, the STC can be performed digitally via threshold setting after pulse compression to prevent saturation by large objects. In a surveillance radar, such as an airport surveillance radar (ASR) or air route surveillance radar (ARSR), the antenna pattern should have a thumb at high-elevation angles to accommodate high-altitude detection when STC or a min-range short pulse is used. Pulse compression is sometimes accomplished in the receiver using analog **surface acoustic wave (SAW)** lines (e.g., **reflective array compressor (RAC)** or **impedance control (IMCON)** lines). The receiver local oscillators (LOs) should be stable, switchable from dwell-to-dwell for frequency diversity (decorrelate rain, chaff, and/or targets) or frequency jump burst (FJB) processing to allow wide-band waveforms to be passed through narrow-band receivers. A frequency swept local oscillator is needed for stretch processing, which enables wide-band waveforms to be passed through lower sampling rate A/D converters with high-range resolution over a narrow range window. The REX provides the analog anti-aliasing filter prior to A/D sampling. The receiver uses either direct sampling of the IF signal or coherent product detectors. An example of direct sampling is having the IF frequency at 4 times the sampling frequency. *I* and *Q* samples (i.e., in-phase and quadrature) are constructed by subtracting every other in-phase sample and every other quadrature sample. A Hilbert transform can be used to align the quadrature samples in time with the in-phase samples. Direct sampling avoids DC offsets from the A/D converter, and unlike the use of product detectors does not have to worry about amplitude and phase balance of the coherent product detectors. The video gain is set so that the thermal noise is set at one or two least significant bits (LSBs) of the A/D converter to provide a compromise between added noise due to A/D converter quantization, coherent extraction of signals below noise, and preservation of large dynamic range. Automatic gain control (AGC) can be used to protect the A/D converter from saturation. The A/D converter should have a low spurious level and the sample rate should be sufficient to reduce range straddling loss. If the sampling is at least Nyquist, the samples can be interpolated later for higher accuracy to minimize the peak sampling loss. The A/D converter often provides the interface to the signal processor.

Microwave components (IKEE) often include a circulator or gas transmit–receive (TR) switch (duplexer) or diplexer, RF filtering, pilot pulse injection, forward and backward couplers for monitoring power and voltage standing wave ratio (VSWR), rotary joint and associated slip rings, pressured waveguide for high power, arc detectors, etc.

The signal processor provides the digital processing for pulse compression, Doppler filtering, clutter map, constant false alarm rate (CFAR), and detection thresholding. In a *multifunction array radar* (MFAR), the

signal processor may also provide scheduling (adaptive or template) and generate beam steering commands. For a wider repertoire of waveforms, modern radars provide pulse compression in the signal processor using the fast Fourier transform (FFT). Linear frequency modulated (LFM) waveforms are often used because the compressed waveform is invariant with respect to Doppler frequency (other than the range-Doppler coupling due to the associated range-Doppler ambiguity) and allows a common compressor to be used for all Doppler filters. To prevent degradation due to Doppler sensitivity of phase-coded waveforms, a different pulse compressor may be required for each Doppler filter, which greatly increases processing throughput. Inverse filters can be used to compensate for the Fresnel ripples of low time-bandwidth waveforms or to compensate for system errors. Uncompensated correlated errors can lead to large range sidelobes (i.e., paired echoes). LFM waveforms in track are stretch processed to allow digital pulse compression of wide-band signals using relatively low sample rate A/D converters over a relatively small range window. The receive LFM signal is deramped to a CW tone, which is amplitude weighted in time and fast Fourier transformed to yield a compressed pulse with low range sidelobes. Since the weighting is applied in the time domain it may not be properly aligned with the uncompressed pulse, and range sidelobes will degrade. A better approach is to apply the weighting in the frequency domain so that it is independent of target position within the range window. This can be accomplished over a larger range window by using 3 cascaded FFTs rather than a single FFT. If the LFM bandwidth is not large, stretch processing is not needed and the pulse can be passed through A/D converter and compressed via an FFT, followed by phase conjugation and spectral weighting for reducing range sidelobes, followed by an inverse FFT. This allows all-range processing in search rather than pulse compression over only a small track window.

The data processor is a general or special purpose computer(s). The data processor processes the detected signals and includes plot extraction (i.e., reducing multiple returns from a single target (range-Doppler-angle) during a scan to a single report), associate a target return with a given track file, provides prediction/filtering to maintain track files with track initiation, drop, and promotion logic. The data processor can also correlate (data fusion) the target return with data from other primary surveillance radar (PSR) or secondary surveillance radar (SSR) sensors. An *extended Kalman filter* (EKF) is usually used for tracking since it is recursive and includes an optimal averaging of the measurements and predictions using a builtin plant (physics of motion) model. A generalized Kalman tracker can be used to combine the data from multiple sensors. Other approaches include acceleration detection or adaptive bandwidth based on innovations alarm, and interacting multiple models (IMM). Since EKF requires accurate tuning and optimal selection of coordinates (RVCC, RUV, etc.), simpler radars often use polynomial filters (alpha-beta-gamma or ghk) with fixed gains. Tracking filters require a compromise between smoothing out noise vs. responding to fast changes (i.e., minimize dynamic lag). An adaptive bandwidth helps in this regard.

Radar Range Equation

The signal-to-noise ratio (SNR) for a single pulse from a monostatic pulsed radar in free space is given as

$$2E/No = SNR = \frac{P_t \tau G_T}{4\pi R^2} (A) \left(\frac{\sigma}{4\pi R^2} \right) \left(\frac{1}{L} \right) \left(\frac{1}{kTs} \right)$$

where P_t is the peak power, τ is the uncompressed pulsewidth, G_t is the transmit antenna gain, A is the effective receive aperture, σ is the radar cross section (RCS) of the target, R is the range, $L > 1$ represents system losses, k is Boltzmann's constant, and T_s is the system noise temperature given by

$$T_s = T_a + 290 \times (LrNF - 1)$$

where T_a is antenna temperature, Lr is receive loss, and NF is the noise figure.

Since the receive antenna gain is given by

$$Gr = \frac{4\pi A}{\lambda^2}$$

SNR can be written as

$$SNR = \frac{P_t \tau G_T G_R \lambda^2}{(4\pi)^3 R^4 L k T_s}$$

As written, SNR is proportional to λ^2 . Expressed in other combinations of antenna aperture or gain, SNR varies inversely, directly, or independently of frequency. The units used in the radar range equation should be consistent. The system losses include transmit loss, signal processing losses (A/D converter quantization, range straddling, Doppler weighting and straddling, filter mismatch, constant false alarm rate (CFAR)), beamshape loss, scan loss, lens loss due to atmospheric divergence, atmospheric and rain attenuation, frequency squint over the bandwidth, etc. Range eclipsing and blind velocities associated with a given prf are assessed more accurately by their effect on probability of detection rather than treated simply as a loss. The signal and thermal noise should be calculated at the same point within the receiver chain with the system noise referenced to that location. For coherent integration and N pulses received in a coherent processing interval (CPI), the SNR can be increased by a factor of N with any additional losses placed in L . The product $P_t \tau$ accounts for the pulse energy and can be replaced in a pulse Doppler radar by $P_{ave} \times T_c$ where P_{ave} is the average power and T_c is the coherent integration time over the CPI.

In a search radar with a given prf, the number of pulses to be integrated in a beam depends on the search time over the volume and number of beam positions in that volume. Hence, N decreases linearly with aperture A since the beam area is inversely proportional to A . Since SNR depends on $G_t G_r$, radar sensitivity has an A^2 dependence. In search, however, the SNR has only a power-aperture dependence since N is inversely proportional to A . This would not be true, however, if the elevation coverage was quite small near the horizon and a large vertical beamwidth antenna were used. Doubling the vertical aperture would still provide the proper elevation coverage, but would increase the SNR in each beam by 6 dB since the horizontal beamwidth did not change. This would allow a 6-dB decrease in transmit power for the same performance rather than a 3-dB reduction as expected from the PA relationship. For a bistatic radar there are two ranges, G_t and G_r are different, and the bistatic radar cross section is used. To evaluate clutter-to-noise ratio (CNR), σ is replaced by the clutter coefficient and L is adjusted to show those losses particular to clutter (most signal processing losses, beam squint or beam shape loss are relevant only to the target). To include ground lobing effects, SNR is multiplied by a pattern factor F^4 where

$$F^4 = \left| 1 + D \rho \frac{E(\theta_R)}{E(\theta_d)} e^{j \frac{2\pi}{\lambda} \Delta r} \right|^4$$

where D is the spherical divergence factor and ρ factors into a diffuse term, shadowing term, and Fresnel specular reflection terms given by

$$\rho = \rho_{SHAD} \rho_s \rho_d$$

where the specular Fresnel reflection coefficient for horizontal and vertical polarizations are given by

$$\begin{aligned} \rho_h &= \frac{\sin \chi - \sqrt{\epsilon}}{\sin \chi + \sqrt{\epsilon}} \\ \rho_v &= \frac{\sqrt{\epsilon} \sin \chi - 1}{\sqrt{\epsilon} \sin \chi + 1} \\ \epsilon &= \epsilon_r - j60\sigma\lambda \\ \rho_d &= e^{-\left(\frac{4\pi\sigma_h \sin \chi}{\lambda}\right)^2} \end{aligned}$$

where χ is the grazing angle and σ_h is the RMS height of the rough surface.

To reduce ground lobing effects in search, one desires a tall vertical aperture with a sharp cutoff near the horizon (e.g., generated by Orchard synthesis). With ground lobing there is always a null near the horizon, which degrades the detection of low flyers. Ground lobing extends the coverage at elevation

angles corresponding to lobing peaks and reduces detection in the nulls. The target can have fades as it passes through the lobes of a two-dimensional surveillance radar. Height estimates can be crudely defined based on the aircraft velocity and the time between fades.

Various techniques can be used in search to improve detection performance. For example, if the target is large (e.g., a ship) and the pulse width is much shorter than the target, the return from a given transmitted pulse can be noncoherently integrated across the ship's length yielding essentially the same effect as if a number of pulses had been transmitted. Another approach is to perform detection on both the sum and difference receive beams. The thermal noise will be different in these channels providing independent looks. In most cases the target will be detected in the sum channel, but when the target is farther from the beam axis, detection in either the Azimuth (AZ) or Elevation (EL) difference channel may be more likely. The benefit in sensitivity might offset the higher cost associated with more processing throughput, particularly as computation become less expensive. Another approach is *track-before-detect* (TBD) where various trajectory threads are integrated noncoherently from scan-to-scan to allow detection of weaker targets. Many possible trajectories increase the processing. Detection on a given thread yields the track following detection.

In track, the angle accuracy is proportional to beamwidth $/\sqrt{\text{SNR}}$. One desires to size the radar system to achieve a given angle accuracy. The square of angle accuracy is proportional to beamwidth squared divided by SNR. Since beamwidth squared is proportional to aperture area, the angle accuracy is inversely proportional to PA^3 . If a radar (e.g., phased array) performs both search and track, the radar can be optimized in cost by recognizing that the transmit RF power costs so much per watt and the aperture costs so much per square foot (or per element). One desires a given PA in search and a given PA^3 in track (i.e., two performance constraints and two radar parameter variables). Simple differentiating gives the optimum power and aperture sizes to minimize cost. Bucket curves can be constructed to show cost sensitivity for departing from the optimum design.

Rain Clutter

The reflectivity of rain, snow, fog, wind blown sand, etc. is given by η where η has units such as square meter per cubic meter. Here η depends on the distribution of the particles (e.g., Marshall–Palmer). The radar resolution cell is given by

$$V_c = c_1(\Delta r)(R\theta_{AZ})(R\theta_{EL})$$

where the constant c_1 depends on the effective pulse width and beamwidth (e.g., 1-way vs. 2-way beamwidths, shapes). The average clutter cross section is given by $\sigma_c = \eta V_c$. The clutter amplitude will actually fluctuate according to a Rayleigh distribution (central limit theorem and large number of rain drops) or, perhaps, K distributed with a large number of degrees of freedom. The CNR is similar to SNR with σ replaced by σ_c , and losses L and pattern factor F^4 adjusted appropriately. Since the clutter is distributed, it does not experience the same losses as a point target. The rain clutter will also experience the attenuation associated with rain. If the rain does not completely fill the elevation beam, the rain height should be used in place of $R\theta_{EL}$ with a possible reduction in antenna gain since the rain may only be in the lower portion of the beam at longer ranges. A more rigorous approach is to integrate the rain in elevation with the 2-way pattern, varying attenuation, and rain rate with elevation angle. Rain rate generally decreases in a Gaussian fashion with height.

Surveillance antennas are generally designed with circular polarization (CP), which will reject the returns from a symmetrical (single bounce) object such as a rain drop. Since the antenna pattern is not perfectly polarized in all directions, the antenna rain rejection performance can be stated in terms of an *integrated cancellation ratio* (ICR), which is obtained by integrating the rain through the XPOL pattern over all angles and comparing that to the amount of rain received if the polarization were matched to the rain return. Practical values of antenna ICR are about 20 dB. Even if the antenna polarization were perfect, ICR is limited in practice by the increasingly nonspherical shape of the rain drops with rain rate, splashes from the ground that produce resonant dipolelike returns that are appreciably larger than the Mie scattering of the drops, and ground reflections at angles steeper than the Brewster angle, which tends to reverse the

sense of CP so that it will not cancel after directly returning from a rain drop. A sharp cutoff antenna pattern (i.e., vertical aperture) will minimize the latter two limitations.

Land or Sea Clutter

The average cross section of terrain or ocean is given by σ_o . The clutter will have both a spatial and temporal distribution. Spatially the clutter tends to have a distribution with long tails such as Weibull, K distributed, or log-normal (particularly at low grazing angles, high-range resolution, higher sea states, and horizontal polarization). Temporally, the distribution is often Rayleigh. A common value of $\sigma_o = \gamma \sin \chi$ where γ is a constant depending on frequency and polarization, whereas χ is the grazing angle. The resolution cell area is, generally,

$$A_c = c_2 \frac{(\Delta r)(R\theta_{AZ})}{\cos \chi}$$

but can be different if the elevation beamwidth intercepts less ground than the pulse width. The clutter cross section is given by $\sigma_c = \sigma_o A_c$. The clutter tends to be smaller for horizontal polarization and this polarization is often used by shipboard surveillance radars.

Radar Range Equation with Jamming

Jamming will often dominate over the receiver thermal noise and, hence, one is interested in the signal-to-jamming power ratio (S/J). This can be obtained from the previous SNR equation by replacing the $No = kTs$ term by

$$J = \frac{\text{EIRP} \left(\frac{1}{B_j} \right)}{4\pi R_j^2} \left(\frac{A_j}{L_j} \right)$$

where EIRP is the effective isotropic radiated power, i.e., product of jammer power and antenna gain toward the radar; B_j is the jammer bandwidth; R_j is the jammer range; A_j is the effective radar aperture in the direction of the jammer; and L_j are losses on the jammer. For a self-screening jammer, the target and jammer ranges are the same. Since $R_j = R$, S/J varies as $1/R^2$ rather than $1/R^4$ for thermal noise.

Radar Propagation

When the radar height is h and a spherical 4/3 effective Earth's radius is assumed, the range to the horizon is given by $d = 1.23\sqrt{h}$ where d is in nautical miles and h is in feet. The troposphere causes refractive bending according to Snell's law since the air density decreases with altitude bending the wave downward. This can be approximated in plotting coverage on a range–height (R–H) diagram by drawing rays as straight lines but using a 4/3 Earth radius. Anomalous propagation corresponds to a value larger than 4/3.

Ducting conditions can occur over land with temperature inversions over water causing energy to be trapped in the duct at elevation angles below a given critical angle. This causes strong clutter returns to arrive from ranges beyond the horizon since there is only energy spreading in the horizontal direction. These strong returns can appear at closer ranges (second time around) on a plan position indicator (PPI).

Plots of atmospheric attenuation can be found in many books. These curves are for a radar at the surface. Similar curves can be constructed for airborne radars by integrating the attenuation along the line of sight for an elevated radar. In general, atmospheric attenuation increases with frequency, lower radar heights, and lower elevation angles. There are atmospheric loss windows at 35, 94, and 140 GHz. An additional atmospheric loss is the lens loss due to the dispersive bending; that is, the bending is different at the upper and lower 3-dB points on the pattern spreading the energy out and reducing gain.

Attenuation also occurs with propagation through fog, dust, foliage, and missile plumes. At microwave frequencies, foliage attenuation is very severe, for example, about 1 dB/m. The loss is less for horizontal polarization (less tree trunk scatter) at lower frequencies. At long distances, the least loss propagation path through jungle is upward with diffraction along the canopy and diffraction back down into the foliage.

The attenuation through missile plumes can be severe and increases with engine thrust (more ionization) and metallic particles in the exhaust.

Rain and other particulate matter also cause attenuation through either scattering or absorption. The rain attenuation is given by $\alpha = ar^b$ where r is the rain rate in millimeter per hour. Rain can be both distributed (stratiform) and in convective cells. The diameter of the rain cells decrease with rain rate. Rainfall is generally classified as drizzle (0.25 mm/h), light (1.0 mm/h), moderate (4 mm/h), heavy (16 mm/h), and excessive (>40 mm/h).

The ionosphere produces Faraday rotation, which can cause polarization loss for a linearly polarized signal and can break the return waveform into two waveforms due to right-handed circular polarization (RHCP) and left-handed circular polarization (LHCP) having different propagation velocities. The time delay is frequency dependent and, hence, the ionosphere can change the ramp on an LFM waveform unless compensated.

Antenna temperature is a contribution to the radar system temperature and depends on where the antenna pattern is pointed. A narrow beam elevated high above the Earth will have a low temperature, whereas a broad elevation beamwidth illuminating much of the ground and low elevation angles will have a higher temperature. On transmit, energy is transmitted in various directions as defined by the antenna pattern, that is, toward ground, various regions of sky including stars, sun, etc., coupled into the radome as losses or into nearby structures. By reciprocity, all of these terminations are at various temperatures that radiate inband energy, which returns to the receive antenna via the same paths that occur during transmit. Hence, the antenna temperature is obtained by integrating the environmental temperatures through the receive pattern. The temperature contribution from the sky into a narrow beam can be approximated by

$$\text{Tan } t = 290 \left[1 - \frac{1}{\sqrt{L}} \right]$$

where L is the two-way atmospheric loss through the entire atmosphere at a given elevation angle.

The presence of the Earth creates lobing as the ground reflection interferes constructively or destructively with the direct signal. Ground roughness reduces the extent of the lobing, however. The elevation angle for the first lobe peak is $E = 0.25\lambda/h$ where h is the radar height. Other lobes occur at odd multiples of this angle, and nulls occur at even multiples. At the lower microwave frequencies, there is some diffraction over mountains, hills, buildings, and the Earth's horizon. These can be approximated by simple knife edge diffraction or diffraction formulas for a cylinder.

Diffuse scattering from rough ground comes primarily from a region called the glistening surface. The larger is the RMS slope of the surface, the larger is the region. At optical frequencies, the phenomena can be seen when the sun or moon rises over a slightly rough body of water.

17.1.4 Targets and RCS

The RCS of a target is the area assumed to intercept incident radiation on the target, which, when scattered isotropically, yields the actual power density received at the radar. A complex target is made up of many scatterers and, hence, the backscatter RCS varies with angular direction due to the constructive and destructive interference from the various scatterers. Similar to an antenna pattern, the lobes change more rapidly with angle when the target size is increased as measured in wavelengths. Changing frequency will cause the lobes to move when the frequency change is enough to make the phase difference along the target change by 180° . Frequency agility is used to make the RCS change so that if it happens to be in a null at one frequency it will probably be at a peak on another frequency. The bistatic RCS varies with angle for a given illumination angle of the target. When the angle between the incident and reflected angles is small, the bistatic cross section is approximately the backscatter RCS at the bisector angle since the scatter phasing is equivalent.

When a re-entry vehicle (RV) enters the atmosphere, an ionized sheath begins to form in front of the RV nose. An RCS dip can occur when the ionized layer is sufficiently thick that reflections from the nose

and front of the layer cancel. This will occur at a given altitude depending on the speed and entry angle of the RV and the wavelength of the radar.

Radar targets can be either fluctuating or nonfluctuating (steady). Particular models are Swerling targets SW0, SW1, SW2, SW3, and SW4. SW0 is a steady target. SW1 and SW2 have a probability density function (pdf) given by

$$p(\sigma) = \frac{1}{\sigma_{\text{ave}}} e^{-\sigma/\sigma_{\text{ave}}}$$

whereas the pdf for SW3 and SW4 are given by

$$p(\sigma) = \frac{4\sigma}{\sigma_{\text{ave}}} e^{-\frac{2\sigma}{\sigma_{\text{ave}}}}$$

SW1 and SW2 are chi square with $m = 1$, whereas SW3 and SW4 are chi square with $m = 2$. SW1 and SW2 are slow and fast fluctuating Rayleigh targets where *slow* means that the target RCS is essentially constant during the dwell but changes from scan-to-scan and *fast* means that the RCS fluctuates on a pulse-to-pulse basis. For a single pulse, SW1 and SW2 are the same and detection performance can be represented by

$$PD = PFA \frac{1}{1+SNR}$$

Note that if SNR is zero, probability of detection (PD) is simply the probability of false alarm (PFA) as expected. When SNR approaches infinity, PD approaches unity as expected. Frequency agility will convert an SW1 target into an SW2 target. SW3 and SW4 targets are slow and fast fluctuating targets whose RCS consists of several small scatterers plus a dominant scatterer. A fluctuating target can be compared to a steady target when they have the same mean value of RCS. At higher PDs (e.g., $PD > 33\%$), an increased RCS fluctuation does not help raise the PD since it is quite high anyway, but a decreased RCS fluctuation can greatly lower the PD. When averaged over the fluctuation values, the result is a net fluctuation loss that can be quite large (e.g., 8 dB at $PD = 0.9$ and $PFA = 10^{-6}$ for SW1 vs. SW0; i.e., SNR of 13 dB vs. 21 dB). The fluctuation loss for SW3 and SW4 is about half (e.g., 4 dB vs. 8 dB at $PD = 0.9$) that of SW1 and SW2 at all PDs above 33%, which is the same as 2 pulse frequency diversity with SW1 and SW2. At low PDs (e.g., $PD < 33\%$), the steady target has very low performance, but an increased fluctuation can greatly improve performance and a decreased RCS fluctuation has little damage. The result for low PDs is that fluctuation is actually a gain rather than a loss.

The complex target provides not only amplitude scintillation but also provides angle glint in that the phase center associated with backscatter from a target can wander all over and even off the target. If two dominant scatterers produce an out of phase but equal amplitude scattering, the pattern scattered back to the tracking radar has a field variation with a large phase gradient. If the tracker attempts to align with the phase front, there will be a large angle error. In effect, monopulse sum and difference patterns are interchanged and the ratio inverted. This is the strategy of the cross-eyed repeater jammer trying to defeat a monopulse system. A ground bounce jammer attempts to strongly illuminate the ground so that a missile will home onto the ground image instead of the target.

The RCS of a sphere is πa^2 and is independent of direction. The frequency region where the circumference of the sphere is less than one wavelength is defined as the Rayleigh region, and the RCS is proportional to λ^{-4} making the individual return from small scatterers such as a raindrop quite low. The region where the circumference of the sphere is much greater than a wavelength is the optical region. The region in between is marked by oscillations about the geometrical RCS and is termed the *resonance region*. A resonant dipole has an RCS given by $0.866\lambda^2$. The RCS of a flat plate is

$$\sigma = G \times A = \frac{4\pi A^2}{\lambda^2}$$

A typical small aircraft has a nose-on RCS of about 1 m^2 (comparable to that of a person). Larger aircraft have RCS from 10 to 100 m^2 depending on size and aspect angle. Ships can have RCS of several 1000 m^2 depending on displacement. At the other end of the RCS spectra are birds and insects having very small

individual RCS but often detected in the aggregate. Simple expressions are available for the geometrical optics RCS of simple targets such as a cylinder, dihedral, trihedral, cone, etc.

RCS patterns of radar targets can be obtained via the method of moments when the target is electrically small. The resonances of the mutual impedance matrix depend on the target type and are independent of angle of incidence making them potentially useful as angle-independent discriminants. For larger targets, physical diffraction can be used to compute the scattered pattern based on integrating the currents induced on the skin of the target via physical optics. Scattering can also be modeled using finite difference-time domain (FDTD), which is a discrete time-space representation of Maxwell's equations with increments chosen to satisfy the Courant stability criterion. For large targets, geometrical optics and geometrical theory of diffraction (GTD) are used to determine scattering from the contributing scatterers.

Stealth requires that scattering be minimized (e.g., absorbing or smoothly varying surfaces) or be redirected. External stores are avoided as are GTD edges and gaps. The fuselage is usually blended with the wings along curved contours. A metallic resonant radome can be used to hide large RCS objects such as antennas, and thin metalized foil can be used over the windshield with little visible attenuation. The backscatter from jet engine inlets can be analyzed using shooting and bouncing rays within the engine duct to establish the reflected field at the engine aperture. The RCS of fixed wing (aircraft) and rotary wing (helicopters) are often measured on scaled models. Propeller modulation can be seen in the Doppler spectrum and can be useful for classification or identification. There is, however, an ambiguity in determining the blade rotation unless the number of blades is known. HF or VHF frequencies are sometimes proposed for antistealth radars in that they resonate the target (target is like a resonant dipole) and shape has little effect on the RCS. In addition, RF absorber material is less effective at the lower frequencies.

Detection

Detection is a form of hypothesis testing where one asks: Is there a target present or not in this resolution cell? Generally, detection is based on exceeding a threshold and there are two types of errors (i.e., mis-detection where the target was present, but the signal plus noise did not exceed the threshold, and false alarms where the target was not present but the noise alone exceeded the threshold). The PFA depends only on the threshold level. The PD depends on both the threshold and the SNR. Raising the threshold reduces the PFA but also reduces PD for a given SNR. Increasing the SNR, however, can restore the PD. The effect of threshold on PFA and PD can be plotted as a receiver operating characteristic (ROC) curve. The Neyman–Pearson criterion requires that for a given PFA a test is used that minimizes the missed-detection probability. The optimal test is a likelihood ratio compared to a threshold.

Cumulative probability of detection gives the probability that a target approaching the radar will be detected at least once by a given range. P_{cum} increases rapidly due to both the SNR increasing as the target approaches and the multiple opportunities of detection. PD over n scans is given by: $P_{\text{cum}} = 1 - (1 - P_1) \times (1 - P_2) \times \dots \times (1 - P_n)$ where P_i is the probability of detection on the i th scan.

Binary integration can be used to prevent detections of n th-time-around targets. Each dwell has a different prf, and a detection is performed on each dwell based on a first threshold level. If the number of detections is m or greater out of n , then the target is declared to be present. Here, m is a second threshold and should be properly selected for optimum performance. Second time around targets and asynchronous pulsed interference will appear in different range cells and will most likely be rejected by the binary integration. The probability of detection with binary integration is given by

$$PD = \sum_{k=m}^n \binom{n}{k} P^k (1 - P)^{n-k}$$

where P is the probability of detection based on a single dwell. PFA can also be evaluated by replacing P with the PFA of a single dwell. Generally, $m = 0.5n$ is used to optimize performance.

Another type of detection is sequential detection where lower and upper thresholds are used. The likelihood function is computed based on all previous returns and is compared to the two thresholds.

If the likelihood function exceeds the upper threshold, a target present decision is declared. If it is less than the lower threshold, a no target decision is made. If the likelihood function is between the two thresholds, the decision is deferred and another return is included in the likelihood function and the process is repeated. The process can be forced to a decision if none has been made after N tries. The standard detection technique is merely a special case whereby the two thresholds approach each other. Hence, optimizing the two thresholds might improve some benefit over the single threshold. Another sequential detection approach uses a low threshold in search with detections confirmed by a verify pulse with higher threshold. The search-verify thresholds are optimized for lowest required power. The benefit of this approach is diminished when there are a large number of range cells at a given beam position.

Fluctuation loss is the increase in SNR to achieve the same PD and PFA for a fluctuating target as for a nonfluctuating target. This loss increases with PD, number of pulses noncoherently integrated, and correlation coefficient associated with the returns. As the correlation coefficient ρ approaches unity, the loss greatly increases. Even a small change of ρ from unity to 0.9 can reduce the fluctuation loss from 8 to 1.8 dB for a PD of 0.9. With frequency agility, the target backscatter is decorrelated, and the fluctuation loss in decibel is divided by Ne , the equivalent number of independent pulses. With two alternating frequencies and a SWI target, the returns are highly correlated and probabilities of detection of 1 out of 2, 2 out of 4, and 3 out of 6 would be the same if the antenna were not moving across the target.

There are several commonly used fluctuating models, which are related or approximate each other as limiting cases. These include chi square, log-normal, Rayleigh, Weibull, and Ricean probability density functions (pdf). Marcum derived the pdf for detection of a constant target with video integration in Gaussian (i.e., Rayleigh) noise in terms of the Q-function. Swerling considered 4 special cases of the chi-square distribution ($K = 1, N, 2,$ and $2N$) where K is the fluctuation parameter relating to the number of degrees of freedom. His results are actually general in that non-integer values of K can be used. The Weinstock fluctuation uses $0.4 < K < 0.7$. The log-normal pdf is Gaussian when the RCS is in decibels relative to a square meter (dBsm), which emphasizes the large and small values via the tails. The Weibull distribution is defined in terms of a slope parameter beta. A Weibull with beta = 1 reduces to Rayleigh ($K = 1$). Ricean is made up of a constant and fluctuating component with ratio given by S . As S approaches zero, the Ricean approaches Rayleigh and as S approaches infinity, it approaches the nonfluctuating case.

Estimation

Detection performance depends only on the energy in the waveform and not the type of waveform. Estimation of certain target parameters, however, is dependent on waveform parameters such as bandwidth, time duration, etc. Tracking is a particular type of estimation applied to a moving object. An optimal estimator might be unbiased, provide the best LMS estimate among all linear estimators, based on maximum likelihood or Bayesian algorithms, and come close to satisfying the Cramer-Rao bound on estimation performance. The Cramer-Rao inequality bound on accuracy is given by

$$E[(\hat{\theta} - \theta)^2] = \left\{ \frac{\frac{dm(\theta)}{d\theta}}{\int \int \left[\frac{\partial \log[p(x, \theta)]}{\partial \theta} \right]^2 p(x; \theta) dx} \right\}$$

where θ is the value, $\hat{\theta}$ is the estimate, and m is the mean. For an unbiased estimator, the expected value is the true value and the numerator is unity.

The signal has parameters θ , which are to be estimated, but the signal is also masked by additive noise, that is, the observation is $x(t) = As(t|\theta) + n(t)$. We assume $p(x|\theta)$ is known, but desire to estimate the most likely estimate of θ based on the observations, that is $\hat{\theta}(x)$. The maximum likelihood estimator (MLE) maximizes the *a posteriori* probability density function $p(\theta|x)$, which is related to the known *a priori* pdf $p(x|\theta)$ via Bayes' rule. Rather than use $p(\theta|x)$, one uses $\log(p(x|\theta))$ since it is a monotonic function yielding the same best estimate but simplifies the arithmetic. In the case of Gaussian noise, the MLE reduces to the problem of estimation by weighted LMS.

Accuracy and Resolution

Accuracy relates to a measurement or prediction being close to the true value of target parameters. Precision relates to the fineness of the measurements, which may not be very accurate, but could be quite precise. Target parameters for which accuracy is important include range, angle, Doppler, and amplitude. Accuracy varies as a function of range. At long range, thermal noise effects tend to dominate. At intermediate ranges, accuracy is dominated by the instrumentation errors (relatively constant vs. range). At short ranges, angle glint effects can dominate since the angular extent of the target increases inversely with range. The accuracy of a given measurement due to thermal noise is given by $\sigma = K/\sqrt{\text{SNR}}$ where K has the same dimensions as the measurement, but is also inversely proportional to the effective width in the other domain of a Fourier transform (FT) pair (i.e., range or time has frequency or bandwidth as its FT pair). Hence, the K for a range measurement is inversely proportional to bandwidth and the K for a Doppler frequency measurement is inversely proportional to time extent of the waveform, that is, takes a long time to discern small differences in frequency. Since an antenna pattern is the FT of its aperture distribution, the K for angle accuracy is inversely proportional to effective aperture width.

Resolution pertains to the question: Is there one target present or many? If two targets are resolved in range (i.e., well separated compared to the compressed pulsewidth), there will be two distinct returns. As the targets get closer together, the returns begin to merge such that it is difficult to tell if there is one or two since the thermal noise tends to distort the combination. The presence of a dip between them yielding two peaks will depend on the relative phases of the two pulses. Typical resolution algorithms include the classical inflection or dip approach, as well as template matching algorithms that look for differences compared to the known response of a single point target. Multipath and thermal noise will affect the probability of correctly resolving two targets in range when two targets are present as well as the probability of false splits (i.e., claiming that two targets are present when only one is actually present). Similar algorithms are used for resolution in angle when the beam scans past the target. If frequency diversity is used on different prfs, this will cause the amplitude to fluctuate as the beam scans past the target making it even more difficult to determine whether there is one or two targets present. With a monopulse radar, one can examine the imaginary part of the complex monopulse ratio to determine if more than one target is present. A single target creates a quadrature value of zero, and multiple targets can create a nonzero value.

Clutter

Radar clutter includes ground, sea, aurora, discretized structures, birds and insects, vehicles that are not of interest (e.g., automobiles are moving clutter for an airport surveillance radar and are often excized via a highway map), etc. At an altitude where the temperature is approximately 0°C, relatively large snowflakes begin to be covered with melting water producing large radar returns called bright band.

An airborne early warning (AEW) used in a look-down overland mode will encounter both mainlobe and sidelobe clutter. Modern designs use time-averaged-clutter coherent airborne radar (TACCAR), displaced phase center antenna (DPCA), or pulse Doppler techniques. Pulse Doppler approaches use a medium (ambiguities in both range and Doppler) or high prf (ambiguities in range) to provide sufficient Doppler space to detect targets overland.

A clutter fence is sometimes placed in front of a ground-based radar to reduce ground clutter with some loss on low-angle targets. The fence edge can be curved or serrated to minimize diffraction effects that will allow some of the ground clutter to propagate over the fence.

CFAR

There are many types of constant false alarm rate approaches that have been implemented. Early approaches used log-FTC or limiting to reduce clutter residue. Feedback was sometimes used for adjusting the detection threshold by counting the alarms per scan or simply adjusting by the operator, based on viewing a PPI display. More recent digital implementations use range (or range and Doppler) cell averaging (e.g., log-cell averaging (CA) CFAR) with leading and trailing windows used to estimate the clutter level. Greatest-of logic is used to prevent clutter breakthrough on clutter edges and smallest-of logic is sometimes

used to prevent adjacent targets or discretets from suppressing actual targets. Normally, a few guard cells are used around the center test cell to prevent a broad mainlobe or high near-in range sidelobes from contributing to the threshold. Sometimes a few largest returns are excised from the window to prevent large discretets from masking targets. To handle non-Rayleigh clutter distributions having large tails, a two-parameter threshold can be calculated. Increasing the number of samples in the window makes the estimate of the threshold better, reducing CFAR loss; but when the window is much larger than the spatial correlation of the clutter, the estimate may not be representative of the clutter in the test cell. More recently, ordered statistics approaches are being used; that is, test cell is compared to a threshold, which might be the 75% largest sample in the range window. This makes the approach somewhat insensitive to the tails of the distribution.

In many radars, a clutter map provides an adaptive threshold for the zero Doppler cell to allow super-clutter visibility as a target flies through clutter regions. A clutter map for a radar on a moving platform is somewhat difficult in that the measurements in polar coordinates must be slid along with the platform motion for averaging, but the resolution cell sizes are different.

Basically, a clutter map represents a temporal estimate of the clutter within a cell. A cell averaging CFAR represents a spatial average around a cell to estimate the clutter level within that cell.

Moving Target Indicator (MTI)

An MTI radar sends out several uniformly spaced pulses (sometimes staggered to minimize Doppler blindness) and generally uses a binomial canceller (or a generalized finite impulse response (FIR) filter or feedback filter) to cancel clutter. For stationary ground clutter, the phase difference from pulse-to-pulse is zero, and the weights are selected so that DC and very low frequency signals cancel. Moving targets will pass through the filter without canceling unless their velocity produces a pulse-to-pulse phase difference that is some multiple of 360° . This condition is known as a blind velocity and is given by $v = 0.5n\lambda(\text{prf})$. The performance of an MTI radar in canceling clutter is defined by the improvement factor given by

$$I = (S/C)_{\text{out}} / (S/C)_{\text{in}} = G(f) \times CA = V_o \times SCV$$

where $G(f)$ is the integration gain at a given target Doppler, CA is the clutter attenuation, V_o is the visibility factor (i.e., signal-to-clutter ratio (SCR) for a given detection performance), and SCV is the subclutter visibility (i.e., amount by which clutter can exceed the signal and still be detected).

Most modern surveillance radars use a *moving target detector* (MTD) consisting of an MTI canceler followed by a Doppler filter bank or simply FIR filters with super clutter visibility and clutter maps derived from the zero Doppler filter.

In the past, a limiter was used to provide CFAR performance in strong clutter. Limiting (a nonlinearity) spreads clutter into the passband of the canceler reducing the improvement factor. Birds traveling with the wind at 40–50 kn can also be in the passband. They are usually seen around dawn and dusk as flocks move between roosting areas and fields. Sensitivity time control (STC) is the best defense against birds.

Tracking

Tracking involves both data association and the process of filtering, smoothing, or predicting. Data association involves determining the origin of the measurements (i.e., determine whether a return is a false alarm, clutter, or a valid target and assess which returns go with which tracks or is this the first return from a given target). Given that the return is properly associated, an algorithm is needed to include this latest measurement in a manner that will improve the estimate of the next expected position of the target. Early trackers, such as the alpha-beta-gamma filter, used precomputed fixed gains that were sometimes changed based on maneuver detection. They were simple to code and required small amounts of memory and throughput. As tracking advanced, radars began to use the EKF. Many filter states were used in ballistic missile defense (BMD) and early warning trackers. More modern tracking approaches use nonuniformly scheduled pulses, Kalman filtering of multiple sensors, nonlinear filters, *interacting multiple model* (IMM), **joint probabilistic data association** (JPDA), and **multiple hypothesis tracking** (MHT).

Decision-directed techniques, such as MHT, can result in a growing memory that must be pruned as possibilities are deemed unlikely. As target density or clutter increases, many false tracks can initiate but over time it becomes obvious which are actual and which are bogus. The Hough transform can be used to track/detect straight line trajectories or those generalized for curvature.

Phased arrays provide flexibility for minimizing the energy to track targets with a given accuracy or impact point prediction (IPP). Options include revisit interval, dwell time, and beamwidth spoiling.

A tracking radar can use a high prf that avoids range blindness on the tracked target while providing ample Doppler space free of clutter. If a search radar is ambiguous in range, a different prf must be used on each dwell to resolve range ambiguities. If a target is within the unambiguous range interval, the range cell where the detection occurs does not change. If the target is beyond the range ambiguity distance, the range cell number changes due to the range foldover. The Chinese remainder theorem can be used to unravel the true range based on several ambiguous range measurements. The range estimate, however, can be grossly in error if an unambiguous range cell number is off by a single range cell due to measurement noise. Other approaches of resolving range ambiguities avoid this problem. For example, the entire instrumented range can be laid out for each dwell with a return placed at all corresponding ambiguous range cells. By summing the dwells in each range cell, the one with the highest count will be the true range since they all occur in this cell. To prevent errors due to a slight range error, one can sum both the range cell and its adjacent neighboring cells over all dwells. This will ensure that slight misses will be correctly counted in the summation. Methods that resolve range ambiguities for a point target are not very effective for a weather radar where the target is distributed. Multiple targets can produce ghosts when unraveling unambiguous ranges.

Classification

Many instrumentation and early warning/BMD radars perform object classification based on radar signature measurements, for example, sorting reentry vehicle (RV) vs. decoy. This is usually obtained through deceleration of the body by the atmosphere, wake effects (mean and spread), microdynamic motion (nosetip precession), polarization, range profile, inverse synthetic aperture radar (ISAR) imaging, radar cross-section (rcs) statistics, etc.

Typical estimators include Bayesian approaches. The K factor describes the ability to resolve two types of objects, that is, the separation of their probability density functions normalized to the spread of the density function. Many lightweight traffic decoys (e.g., balloons) can be placed on a postboost vehicle (PBV) by replacing an RV, but the ability of the lightweight decoy to penetrate the defense is less than that of a heavier replica decoy. Munkers algorithm can be used for optimally assigning objects seen on one sensor to those seen by another sensor, that is, handover or target object mapping (TOM).

Much work has been performed in the past in identifying or classifying battlefield vehicles (e.g., truck, jeep, tank) based on high-range resolution measurements. *A priori* measured range profiles at various angles can be stored to be matched against by an unknown object. Sometimes features are extracted from the data such as spacing between largest spikes, order of magnitude of spikes, etc. Some of the work has involved the use of neural networks.

Imaging

The simplest imaging radars use high range resolution with Doppler processing, that is, FFTs within the range cells. For a rotating object, the Doppler frequency increases with distance from the axis of rotation and hence, maps cross range into Doppler to produce two-dimensional ISAR images. Range walk will limit Doppler resolution since it determines how many pulses can be processed in the Doppler filter. The cross-range resolution is related to the angle through which the target rotates during the coherent processing. ISAR is similar to the conventional noncoherent tomography (radon transform, back projection) used in X-ray processing. Since it is only the relative motion between radar and target that is important, the turning object in ISAR is equivalent to a stationary target and a synthetic circular SAR, that is, aircraft flying a circle about the target. More advanced ISAR imaging radars use polar processing to avoid the range walk problem. The most advanced imaging radars use extended coherent processing where an image is created by coherently overlaying images for several complete rotations of the object. *Maximum entropy method* (MEM) techniques can be used to extend the bandwidth to provide sharper images for a given actual RF bandwidth.

Airborne synthetic imaging radars (i.e., conventional SAR) use a small aperture on a moving platform. By storing the pulses and coherently combining them, a large synthetic array can be constructed that is focused at all ranges. The effective synthetic pattern is actually a 2-way pattern and the cross-range resolution at every range is about the same as the size of the physical antenna on the aircraft. At each range, the phases from a scatterer produces a quadratic runout (i.e., LFM) that varies with range. Each range cell is match filtered yielding a pulse compression in the azimuth direction. Since Doppler frequency is mapping into cross range, moving objects such as a train create a range-Doppler coupling and may image off the tracks. Stereoscopic imaging can be performed by using SAR mapping from two aircraft or multiple displaced apertures on the same aircraft. The phase difference in a common pixel for the two apertures will provide height data within the pixel.

Ambiguity Function and Waveform Design

Whereas detection depends only on waveform energy, measurement accuracy and resolution also depend on waveform shape. As target parameters (e.g., angular location of two targets) approach each other there is an associated ambiguity function that was originally defined by Woodward. For an optimal detector, the optimal filter is the matched filter given by $H(f) = S^*(f)$. It can be shown by Schwarz's inequality that this filter provides the highest peak SNR of all filters. It filters white noise with little effect on filtering the signal. The phase conjugation of the filter's spectrum compensates for the wide-band phase of the signal spectrum allowing pulse compression. The impulse response of the matched filter is simply a time reversed version of the signal so that convolution becomes correlation. The ambiguity function is a surface that expresses the filter output for all possible Doppler offsets of the signal; that is

$$\chi(t, f_d) = \frac{1}{2\pi} \int S^*(\omega) S(\omega + 2\pi f_d) e^{j\omega t} d\omega = \int s(\tau + t) e^{j2\pi f_d \tau} s(\tau) d\tau$$

The ambiguity function (AF) is generally defined as $|\chi|^2$. The energy under the AF is constant for all waveforms suggesting that it can be shaped but not eliminated. Wide-band signals can have a thumbtack mainlobe but must have rather high sidelobes since very little of the energy is in the mainlobe. Pulse trains will have periodic clumps of ambiguity. Range-Doppler (i.e., time-frequency Fourier transform pair) ambiguity is ultimately related to the Heisenberg uncertainty principle of simultaneously measuring time and frequency. The value of the AF along its principle plane ($\tau = 0$ or $f = 0$) is related to the Fourier transform of the square of the magnitude of the waveform or spectrum. Tracking low RCS targets in a dense multiple target environment (e.g., RVs in the presence of a fragmented tank), requires low integrated range sidelobes (e.g., NLFM or weighted uniform burst (WUB)) having a good Q function where the Q function is the integration of the AF along range for a given Doppler offset.

Various waveforms have been designed for pulse compression. These include LFM with weighting, NLFM, and phase-coded waveforms. The use of phase-coded waveforms prevents a range gate pulloff repeater jammer from defeating a leading-edge tracker by taking advantage of range-Doppler coupling in a waveform such as LFM. A common phase-coded waveform is the Barker code. The Barker code is a biphasic code with autocorrelation function having unity sidelobes. There are no known codes with more than 13 elements. The known codes are $N = 2, 3, 4, 5, 7, 11, \text{ and } 13$. There are no known codes for $N < 12,000$ as verified by exhaustive search. Barker codes can be combined or nested. Frank codes are another type of phase-coded waveform. The Frank code consists of N^2 phases derived from an $N \times N$ phase matrix where the phases are given by $\phi = 2 \times \pi \times p \times m/N$ where $m = 0, 1, \dots, N - 1$ represents columns and $p = 0, 1, \dots, N - 1$ represents the rows. The phases are similar to that of a Butler matrix or FFT. When cascaded the phase is similar to a stepped LFM and Doppler sensitivity is similar to LFM. Frank codes have about 10 dB lower sidelobes than the best biphasic codes and have better Doppler tolerance. Another set of codes are the Kretschmer polyphase codes (P1, P2, P3, P4), which are related to Frank codes and stepped LFM. The P1 code is identical to Frank code for zero Doppler. P1 and P2 codes are more tolerant of receiver bandlimiting prior to pulse compression (e.g., antialiasing filter prior to A/D). Quadriphase codes are another phase-coded waveform. The quadriphase codes are derived from biphasic codes such as the combined Barker code. The subpulses are overlapped with cosine rise/fall times providing a constant envelope and good spectrum

rolloff to minimize electromagnetic interference (EMI). Complementary codes are another family. There exist waveforms whose autocorrelation functions are complementary in that when added together the sidelobes completely cancel for zero Doppler. Two approaches for using them consist of (1) transmit 2 waveforms separated in time, receive first pulse with its matched filter, switch receivers to receive the second pulse with its matched filter, delay the pulses so that they are aligned yielding a compressed waveform with zero sidelobes; and (2) separate the two transmit pulses and build a matched filter for the combination, which will cause near-in sidelobes to completely cancel but far-out sidelobes do not cancel since one of the pulses is going through the matched filter portion designed for the other pulse. Another wide-band waveform makes use of Costas codes where the waveform is frequency hopped pseudo-randomly during the pulse.

Weather radars frequently make use of pulse pairs. The returns are first processed through a clutter filter to remove ground clutter; then the phase difference of successive pulses is calculated (e.g. Rummeler pairs). Averaging the phase differences yields an estimate of the mean Doppler frequency and averaging the deviation above the mean provides an estimate of the variance of the weather spectrum. These parameters are often used for low-level wind shear detection since clear air microbursts are an aircraft landing hazard. Another waveform for measuring the Doppler frequency of a target in the presence of extended clutter at another Doppler frequency (e.g., target in chaff) is to use a Steudel quad waveform, which is a burst waveform consisting of a combination of 2-pulse MTI and pulse pairs. The first two pulses in the burst are processed through a single delay canceler providing an output signal where the clutter is canceled but the signal passes through. The next two pulses also pass through the canceler. Finally, the phase difference is taken between the outputs in the classical pulse pair fashion. The Steudel quad waveform has been proposed in BMD applications where a fast moving target is to be measured in the presence of lower velocity wake or pancaked chaff and debris.

Antennas

Antennas match the transmitter to free space and couple received signals from free space back into the radar. Hence, the antenna should have a good match over frequency, polarization purity, high gain, low sidelobes, etc.

A phased array consists of discrete radiators. The array is usually linear or planar, but can be cylindrical, spherical, or any conformal shape. Array design must consider mutual coupling, scan blindness effects, grating lobes, polarization purity, bandwidth, etc. Impedance match is a function of scan due to mutual coupling. The imbedded element pattern is given by

$$E(\theta) = \frac{4\pi A}{\lambda^2} \times \cos(\theta) \times (1 - \Gamma^2)$$

where Γ is the active reflection coefficient and is a summation of the coupling coefficients with phase shifter phasing. A is the unit cell area of a single element.

The ideal element pattern varies simply as $\cos(\theta)$ since Γ is matched to zero at all scan angles within real space. On receive, this ideal element's cell area collects all of the power incident on it from any angle without reflections. In a thinned array, dummy elements are generally used to ensure that the active element patterns are identical. In a thinned array, some elements can experience a reflection coefficient greater than unity at some scan angles since the reflection is made up of coupled power from other elements. On average, however, the reflection coefficient cannot exceed unity. In fact, the sum of the power radiated, dumped in dummy elements, and reflected back into the feed will add up to equal the total incident power. This is valid for any assumed coupling coefficients. The embedded element pattern in an array of open-ended waveguide radiators can be analyzed using modal analysis where the waveguide modes are matched to the free-space Floquet modes at the aperture-free-space interface. Performance in a large array can be evaluated using the periodic cell associated with an infinite array. Evaluation of element patterns in a finite array generally uses the Poisson summation or method-of-moment (element-by-element) techniques. The potential to form a scan blindness (i.e., complete reflection) can occur when the phase of the mutual coupling coefficient is approximately linear with distance and the mainbeam is scanned to an angle where a grating lobe begins to form at endfire. At this scan angle, the phase shifters are set so that all elements on

one side of a given element will couple in-phase into that element producing a large mismatch; that is, the phase lags of the coupling are offset by the phase advance of the phase shifter setting. Since the coupling is generally via a slow wave across the aperture, the scan angle creating the problem will occur slightly before the onset of the grating lobe. Ultralow sidelobe antennas (ULSA) have peak sidelobes below 40 dB and RMS sidelobes of below 55–60 dB.

Reflectors are often used in search radars and tracking radars. These are usually prime focus or employ a subreflector (Cassegrain or Gregorian). Design emphasis includes feed-strut blockage, offset geometries to avoid blockage, and attention to feed designs having low spillover. Subreflectors can be shaped for high gain or low sidelobes and can be made transparent to blockage using a twist reflector for the main reflector. Multibeam horns can be used for adaptive nulling, pattern shaping, or producing low sidelobes. The horns used with reflectors are generally sectorial, pyramidal, or conical. Multimodes, choke rings, corrugations, or dielectric lined walls can be used in feeds for pattern shaping. Search radars often use a doubly curved reflector with dual horns to create both a high beam and low beam. The signal is transmitted on the low beam for high gain at low elevation. Returns are initially received on the low beam to avoid near-in ground clutter and then switched to the high beam when ground clutter is reduced due to Earth's curvature.

A limited scan antenna achieves high gain and narrow beamwidth by using a low-cost large reflector and adds some limited beam scan with an array feed. One desires to design the antenna to achieve maximum gain over a given scan sector. On receive from a given angle, the array feed excitation should match that of the incident field on the array to achieve maximum gain, that is, matched filter with amplitude match and phase conjugation. If only phase shifters are available, performance may be slightly suboptimal. Design consists of shaping the main reflector surface, optimally locating the array and defining its size, and spacing the elements as far apart as possible for economy. Stangel's theorem is a powerful bound for assessing the optimal gain-scan product when combining different types of antennas (e.g., dishes combined with lenses and low-gain radiators) or array elements. In a given direction, each antenna has a different available gain. The optimal feed excitation for exciting this group of antennas is one where the amplitudes match the available gain in that direction and the phases are set for coherent addition of their patterns in that direction. If a given element has zero gain in a particular direction, then it is not excited when scanning in that direction. This approach provides maximum gain over the sector, but not necessarily low sidelobes. Phased arrays have generally been optimized for a given face, and the faces are usually oriented for good performance. True optimization, however, requires simultaneous excitation of multiple faces, which also provides a high degree of angular resolution, which can be useful for mainlobe nulling of jammers closely spaced near targets. When there are multiple array faces (e.g., 3), some element gain is not used effectively; for example, at an angle midway between two adjacent faces only one face is typically used throwing away 3 dB of available aperture. Tilting the array faces back by only 15° to favor long-range targets near the horizon causes almost half of the available element gain to be wasted since it is below the horizon. The dome antenna (i.e., a passive spherical lens fed by a zenith facing planar array) attempts to optimally redistribute the gain of each upward looking array element. The lens is designed to redistribute the element pattern; that is, take the high available gain near zenith and distribute it more toward the horizon. Since there is much more angular space near the horizon, however, the improvement is not drastic. For low sidelobes, all of the element patterns viewed through the lens should be similar, which requires that the lens be oversized. Hence, cost increases as sidelobe performance is increased. Several other peculiarities must be addressed with the design of the dome antenna; that is, AZ and EL difference patterns interchange and the polarization can rotate with azimuth scan direction. Most tradeoffs considering the added losses and costs associated with achieving good sum and difference patterns have shown that the dome has only a small advantage relative to an optimized set of planar faces.

17.1.5 ECCM

Jammers are typically barrage noise or repeater jammers. The former try to prevent all radar detections whereas the latter attempt to inject false targets to overload processing or attempt to pull trackers off the target. A standoff jammer attempts to protect a penetrating aircraft by increasing the level of noise

in the radar's receiver. In such an environment, the radar should be designed with electronic counter countermeasures. These can include adaptive receive antennas (e.g., adaptive array or sidelobe canceler), polarization cancelers (defeated easily by jammer using independent jamming on horizontal and vertical polarizations), sidelobe blankers to prevent false pulses through the sidelobes, frequency and prf agility to make life more difficult for the repeater jammer, low probability of intercept (LPI) waveforms, spread spectrum waveforms that will decorrelate CW jammers, spoofer waveform with a false frequency on the leading edge of the pulse to defeat set-on repeaters or a spoofer antenna having an EIRP that covers the sidelobes of the main antenna and masks the transmitted pulses in those directions, receiver uses CFAR/Dicke-fix, guard band blanking, excision of impulsive noise in time domain, and excision of narrow-band jammers via the frequency domain, etc. In stressing cases, the radar can employ burnthrough (i.e., long dwells with noncoherent integration of pulses). Bistatic radars can also be used to avoid jamming. For example, a standoff (*sanctuary*) transmitter can be used with forward-based netted receive-only sensors [avoid antiradiation missiles (ARMs) and responsive jammers] to located targets via multilateration. Ultralow sidelobe antennas can be complemented with remote ARM decoy transmitters that cover the radar's sidelobes.

Adaptive antennas include both adaptive arrays and sidelobe cancelers. The adaptive array includes a number of low-gain elements whereas the sidelobe canceler has a large main antenna and one or more low-gain auxiliary elements having sufficient gain margin to avoid carryover noise degradation. The processing algorithms are either analog (e.g., Applebaum or Widrow LMS feedback) that can compensate for nonlinearities or are digital (sample matrix inversion or various eigenvector approaches including Gram-Schmidt and singular valued decomposition (SVD)). Systolic configurations have been implemented for increased speed using Givens rotations or Householder (conventional and hyperbolic) transformations. In a sidelobe canceller (SLC) the jamming signal is received in the sidelobe of the main antenna as well as in the low-gain auxiliary element. By weighting the auxiliary signal to match that of the main antenna and setting the phase difference to 180° , the auxiliary signal can be added to the main channel yielding cancellation of the jammer. The weighting is determined adaptively since the main antenna is usually rotating. Target returns in the mainbeam are not canceled because they have much higher gain than their associated return in the auxiliary antenna. Since they are pulsed vs. the jammer being continuous, target returns have little effect in setting the adaptive weight. Since the closed-loop gain of an analog canceler is proportional to jamming level, the weights will converge faster on larger jammers creating an *eigenvalue spread*. To prevent the loop from becoming unstable, receiver gains must be set for a given convergence time on the largest expected jammer. Putting limiters or AGC in the loops will minimize the eigenspread on settling time. The performance of jammer cancellation depends on the nulling bandwidth since the antenna pattern is frequency sensitive and the receivers may not track over the bandwidth (i.e., weights at one edge of the band may not yield good nulling at the other end of the band). Broader bandwidth nulling is achieved through more advanced space-time processing; that is, channelize the spectrum into subbands that are more easily nulled or, equivalently, use adaptive tapped delay lines in each element to provide equalization of the bandpasses; that is, the adaptive filter for each element is frequency sensitive and can provide the proper weight at each frequency within the band. A Frost constraint can be included in digital implementations to maintain beamwidth, monopulse slope, etc., of the adapted patterns. If the jammers are closely spaced, mainlobe nulling may be required. Nulling the jammer will cause some undesired nulling of the target as the jammer-target angular separation decreases. This is limited by the aperture resolution. Difference patterns can be used as auxiliary elements with the sum beam. The adaptation will place nulls in the mainlobe of the sum pattern. They are actually more like conical scan where a difference pattern is added to a sum pattern to move the beam over. The mainbeam squints such that the jammer is placed in the null on the side of the mainbeam. Better angular resolution can be achieved by nulling with two separated array faces. The adaptive pattern can now have sharp nulls that cancel jammers with minimal target loss since the angular resolution is set by the much wider interferometric baseline.

Defining Terms

Conical scan: Angle estimate based on rotating an offset beam about the boresight axis.

Impedance control (IMCON): Bulk wave pulse compressor.

- Joint probabilistic data association (JPDA):** Updates a track with weighted sum of the various returns where the weights are proportional to the likelihood of being the correct association.
- Monopulse:** Angle estimate based on a single pulse using the ratio of the difference (odd) pattern to sum (even) pattern.
- Multiple hypothesis tracking (MHT):** Makes multiple hypotheses for track extension prior to a hard decision; generally uses all available data from the past.
- Pulse Doppler:** Radar processing of a coherent train of pulses usually with uniform spacing. Older versions implemented by analog filters; modern versions use fast Fourier transform or discrete Fourier transform processing.
- Reflective array compressor (RAC):** Pulse compressor built with reflecting grid of nonuniformly spaced grooves or reflectors.
- Rotman lens:** Microwave lens that forms multiple beams with the peaks fixed in space vs. frequency.
- RUV coordinates:** Natural phased-array tracking coordinates aligned with range and direction cosines.
- RVCC coordinates:** Radar tracking coordinates aligned with LOS, target velocity, and orthogonal to the other two.
- Sensitivity time control (STC):** Variation of attenuation (e.g., RF or IF) with range to minimize the returns from small objects at shorter ranges.
- Surface acoustic wave (SAW):** Pulse compressor built on an acoustic surface usually with interdigital transducers and/or reflective grooves.
- Woodward synthesis:** Constructing a signal or antenna pattern based on overlapping $\sin x/x$ subsignals.

17.2 Radar System Implementation

Melvin L. Belcher, Jr. and James A. Scheer

17.2.1 Radar System Design, Evaluation, and Assessment

Although there is no standard cookbook procedure to radar system design or analysis, there is a systematic approach, based on understanding the problem and all related issues, and using a base of experience to apply engineering solutions to the problem. Understanding the problem includes understanding the mission requirements, understanding the environment, understanding the limitations imposed by the platform, and understanding the technology being applied or at the disposal of the designer. Using the understanding of these elements, the design can be developed, or an analysis of a given design approach can be performed. [Figure 17.1](#) depicts a methodology for the design of a radar system, highlighting some of the significant driving elements.

The performance requirements given by the user are usually in terms of the probability that the sensor will perform a given task (e.g. P_d for probability of detection) and the probability that a false action will take place (e.g., P_{fa} for probability of false alarm on noise). It is not easy to express these parameters (P_d and P_{fa}) in terms of the radar characteristics, and so usually an intermediate calculation is performed.

FIGURE 17.1 Methodology for the design of a radar system.

In the case of the examples of detection and false alarm, the signal-to-noise ratio (SNR) is the intermediate measure of performance. This is easily calculated from the radar parameters, and then that value (SNR) is related to P_d and P_{fa} through subsequent analysis.

Usually there is a set of implementation related requirements that is given by the user, based on the platform on which the system is to be implemented. These may be size, weight, and power limits, as is the case with a missile-borne seeker or airborne interceptor system, or in the case of a remotely located land-based system, the requirements may not be size and weight related as much as reliability and maintainability related.

A key element to the proper design of a system is the understanding of the phenomenology associated with the radar characteristics of the target, clutter, and atmospheric propagation environment. Since these are usually time varying values, the distributions and spectral characteristics are important, both for the target and interference signals.

Almost always there will be a limit to the size of the aperture that can be employed. In a limited-space installation, the size limits are easily determined. In a land-based system, exposure to weather and effects of wind may be what determine the maximum size of an aperture. It is not always appropriate to use the largest aperture that is allowable, but it usually is.

It is not always easy to determine the best radar frequency band to use, unless a parametric study is performed to determine performance as a function of frequency. The typical radar bands (L-, S-, C-, X-,

Ku-, Ka-, and W-bands) should all be considered at first. Some of the bands will usually quickly drop out as potential candidates, due to propagation losses (for shorter wavelengths) or **beamwidth** issues (at longer wavelengths). In some applications, other (nonstandard) frequencies may be considered. For example, over-the-horizon or ground penetration related applications may require a very long wavelength, suggesting a frequency below L-band. Or, short-range or satellite-based systems may desire the low-probability-of-intercept features associated with wavelengths near the water vapor absorption line at 60 GHz.

Hardware/Software Mechanization

In principle, radar system design should be carried out in top-down fashion: user requirements are translated directly into system-level technical requirements which are then flowed down to the subsystem and component levels in increasing detail.

Subsystem/component-level testing can be used to assess system-level performance during the development of the radar system. The flow-down/flow-up approach can be effectively implemented using subsystem/component performance budgeting to track critical system performance parameters such as sensitivity and metric accuracy. This approach is highly recommended for large-scale radar systems where it is difficult to conduct full-scale system-level testing and where it is important to obtain leading-edge indicators of potential technical/cost/performance risks during development.

In practice, subsystem/component technology constrains the potential radar system architecture. Special-purpose radars have been essentially built around critical components such as millimeter wave **transmitter** tubes. Development efforts by both corporate and government organizations generally emphasize the use of hardware and software previously developed and fielded so as to mitigate cost and schedule demands. As described subsequently, this trend is particularly evident in digital signal processing where the major radar manufacturers have generally come to emphasize the use of commercially derived processors in recognition that there is inadequate funding resources to support specialized digital processor development of comparable performance. Even apparent exceptions to this trend, such as solid-state transmit/receive modules, generally derive core development and manufacturing assets from broad technology development efforts or commercial market capital investments.

The software engineering community argues that this technology trend forces a paradigm shift “in which hardware assumes the component implementation role and software assumes the systems implementation role” (Chittister and Haimes, 1994). In radar development with the emphasis on using existing hardware technology, software engineers are responsible for programming general purpose computers and generating embedded software so as to support the required real-time control or data collection functions. However, radar system engineering skills provide the core mechanism for deriving a radar system design that meets user requirements within the constraints of available software and hardware technology. Radar hardware engineering imposes unique requirements including wideband signal synthesis and processing and very wide **dynamic range**. Although requirements vary markedly with implementation, radar hardware architecture is remarkably consistent as described in the following section. In contrast, radar software engineering seems characterized by a great deal of variation depending on such particulars as digital platform, operating system, and higher order language. Independent of these considerations or the associated computer aided software development tools, it is essential to maintain a rigorous system engineering process to correctly specify software functions. Given that hardware design generally precedes software development, it is imperative for the software specification process to reflect in-depth understanding of radar hardware capabilities and requirements.

17.2.2 Radar Functions

Application Requirements—Mission Requirements

System implementation should be based on the user's requirements, not on the historical background and experience of the developer. Often, a contractor is selected based on success at previous radar programs, but the favorite solution may not be the appropriate solution. The designer must thoroughly understand the

mission requirements insofar as radar functions, target engagement scenario, and target and atmospheric characteristics are concerned.

A list of the most common mission related radar functions is given as follows:

Radar Functions. For a multimode phased array system, the radar resources must be divided among several functions. Long-range, high-altitude target defense requires a set of radar parameters that are somewhat diverse from those required for low-angle shorter range target defense. The long-range functions often consume nearly 100% of the radar resources, and so a separate system is often required for the other (short-range) threat.

Search/Surveillance/Detection. The search mode is usually the most demanding on the radar resources. Search parameters are usually specified in terms of the solid angle to be searched, the maximum range (sometimes as a function of elevation angle), and the revisit time allowed, for a given probability of detection and false alarm rate. The search mode usually requires that the direction of the antenna beam be changed to provide angular coverage. In general, the wider the beam, the less time it will take to search a given angular sector, out to some range. Also, it is usually the case that the larger the power/aperture product, regardless of wavelength, the faster the search can be conducted. Given a search volume, determined by the angular coverage and maximum range for each angular segment, for a given target radar cross section (RCS) characteristic, and revisit time, the so-called power-aperture product can be determined.

Acquisition. Acquisition refers to the process of declaring a detection to be a target and initiating the track mode on that target. It involves revisiting the detection and verifying its existence as a target of interest, and developing a preliminary set of tracking parameters on it. The ultimate function of the system is to track targets of interest. With a track-while-scan system, or a phased array radar in a track-while-search mode, it is not a trivial matter to determine when a target track should be initiated, particularly in the cases in which more than one target is in a given sector. Several samples of the target ensemble must be obtained before the target association process can be reliably conducted, in which case a track file can be initiated.

Track. Once a detection has been declared to be a target of interest, a (so-called) track file is established, which is a set of values defining its position in space (and Doppler) and its rate of change of these parameters with time. The longer a target is tracked, the better the estimate of its position, and velocity. Some systems are required to track multiple targets; 10 per face of a phased array radar or of a track-while-scan radar, is a typical number. The track function uses a small percentage of the radar resources. Typically, 1% of the time can be devoted to tracking a particular target. If there are 10 targets to be tracked, then this would consume only about 10% of the radar resources.

Target Identification. In a dense wartime environment, avoidance of fratricide has become an important consideration, making target recognition an additional function required of many fire control systems. This function can be performed cooperatively, by use of beacons and other identification-friend-or-foe (IFF) systems. However, sometimes these systems are not fully effective, and so noncooperative techniques must be considered. One technique involves imaging of the target, requiring a wide instantaneous **bandwidth** (to perform range profile of the target) and *inverse synthetic aperture radar* (ISAR) process, in which target motion is used to develop a cross-range image.

Fire Control. Once a target is identified by the search and track radar, often some form of engagement is required. This may be in the form of a missile or gun. The radar must provide some cueing and/or navigation information to the fire unit.

Illumination. Classically, this function is performed by a separate radar (illuminator) system, because a continuous wave (CW) signal has been required. Engagement of multiple targets has required cooperative timing of missile launch so that no two targets need be illuminated at a given time. Modification of the semiautonomous mode of defensive missiles can allow for a pulsed illuminator, which allows for multiple target illumination by a single system.

Damage Assessment. After a target of interest is engaged, sometimes the radar must determine the damage to that target. This requires a capability to image the target, providing a **high-resolution** description of the remains. The same features that are used to identify or classify the target are appropriate for the damage assessment task. The same techniques that are used for target recognition can be used to assess the damage

caused by a defensive system. Imaging of the area around the target, and a microscopic look at the Doppler signature of that area can provide a measure of the damage.

Scenario

Range, Altitude, Search Volume. The volume that has to be searched determines the architecture of the array. A sector search (no more than $\pm 60^\circ$ in azimuth) is achievable with a single array face, whereas more than that requires either mechanically scanning the array face or implementing more than one face.

Revisit Time. The revisit time required determines how well the radar can search the required search volume. Basically, the required power-aperture product can be determined from the target RCS characteristics, search volume, and revisit time parameters.

Target Density and Distribution in Angle (Sector). Given the multimode capability of a phase array system, the target density and angular distribution determines the scheduling parameters of the system. Multiple target tracks do not usually drive the system resources as much as the search function.

Target Characteristics

RCS and Fluctuation Model. The RCS and fluctuation statistics of the target are required to determine the detection performance of a given system. The probability density function of the (pdf) target plus noise plus clutter signal is compared to the pdf of the noise plus clutter to determine the receiver operating curves.

Speed. The speed of travel of a target determines the Doppler characteristics, as seen by the radar. This is important to determine the clutter suppression that is achieved in the target Doppler domain.

Height. The height of the target over the land or sea clutter determines the ability of the antenna system (beam characteristics) to separate some of the clutter from the received signal, at minimal loss of target signal. The remaining clutter must be removed by waveform and signal processing related approaches.

Moving Target Indication (MTI) and Stationary Target Indication (STI)

In a broad sense, a radar target is defined as the item the radar operator wants to detect, and other things that the radar may see are considered to be clutter. For a weather radar system, the target is the rain, hail, sleet, wind shear cell, etc., that may be detectable by the radar. In the case of a surface-to-air radar, one designed to detect aircraft, the weather is considered to be clutter.

This discussion relates to a system that is designed to detect hard, man-made targets, such as a vehicle, in the presence of ground clutter. This is generally the most taxing situation, particularly for the case in which the target of interest is not moving. It is often the case that the clutter signal is larger than the target signal, so the detection problem is one of determining what is target and what is clutter. This is often called *discrimination*, rather than detection, since the target is indeed detected, but not discriminated from the clutter.

There are two radar modes designed to detect such a target. The *moving target indication* (MTI) mode takes advantage of an identifying characteristic of a moving target, associated with the Doppler frequency offset imposed by the target motion. Since a moving target is at a different distance from the radar on a sample-to-sample (pulse-to-pulse) basis, the phase of the received signal is different on successive pulses, whereas the phase of the clutter signal is not. A coherent radar is designed to measure phase and can, therefore, detect a moving target in the presence of clutter, within the stability-imposed limits of the radar.

If the target of interest is not moving, the detection problem is considerably harder, requiring a *stationary target indication* (STI) technique. The radar must be designed to exploit some characteristic of the target that is different from that of the clutter. The basic techniques involve reducing the pulse width (range resolution) and beamwidth so that the range/azimuth resolution cell matches that of the expected target. This minimizes the clutter reflection, without losing any target signal. In this case, the target-to-clutter ratio is about optimum, which may not be good enough for reliable detection. Some other characteristic of the target must be exploited. Identification of the individual target scatterers by imaging (in range

and/or cross range) sometimes provides discrimination capability. If not, then sometimes the polarimetric properties (*polarization scattering matrix* (PSM)) of the target are measured. At the extreme, in state-of-the-art systems, a combination of imaging, with resolution less than 1 ft (0.3-m) in range and cross range, and measuring the PSM of each major scatterer is combined for target discrimination and classification applications.

17.2.3 Radar Subsystem Implementation

Figure 17.2 is an overall block diagram of a radar system, not including the **signal processor** and beyond. The system depicted in the figure is a coherent system in that it will measure the phase of the received signal (vector) in addition to the amplitude. This capability lies in the ability to maintain a stable phase reference, by means of the stable local **oscillator** (STALO), coherent oscillator (COHO), and intermediate frequency (IF) oscillator. These signals are generated in the exciter. Once the RF signal is developed, by mixing the stable signals with each other, the RF signal is amplified and applied to the antenna system. The received signal is down-converted to IF and synchronously detected to provide the baseband signal for processing, normally consisting of spectral analysis (filtering and Fourier transform processing) and data processing such as *constant false alarm rate* (CFAR) detection, and tracking, etc.

The state-of-the-art in component development for the major system components is discussed here, but first a few words concerning one of the more basic radar performance metrics, signal-to-noise ratio, and the performance of components as related to that metric. Since the radar range equation has a factor of R^4 in the denominator, the system SNR must improve by a factor of 16 relative to some baseline value, to improve the single-look detection range by a factor of 2. A 1-dB (25%) change in radar SNR performance results in a range performance increase of only about 6%; a 0.5-dB change results in about 3% increase in range.

For example, noise figure values on the order of 2–2.5 dB are readily achievable at most microwave frequencies from L-band through X-band. By tighter selection process, and narrow-band tuning, noise

FIGURE 17.2 Classical coherent radar system block diagram.

figure values of 1–1.5 dB might be achievable, but at considerable cost; with field degradation, these values may revert back to the more common 2–2.5 dB values, all for a 6% improvement in range. If it is important to achieve a little more range performance, it is often easier to cool the receiver. Reducing the temperature from 290 to 230 K has the same effect as reducing the noise figure by 1 dB, or increasing the transmit power by 1 dB.

As subtle as they are, these improvements are only true if the system range performance is noise limited, not clutter limited. In many modern applications, the range performance is not noise limited, but rather it is clutter limited. For example, air-to-surface, surface-to-surface, and ground penetration applications often result in a poor signal-to-clutter ratio. Therefore, it is not always practical to strive for the utmost in power or noise figure performance, if the system performance is clutter limited.

Seldom is a system required to perform its detection process in a single pulse. The system is usually allowed to process an ensemble of pulses to perform detection. In this case, it is the average power and dwell time that are important, not the peak power and instantaneous bandwidth. The system designer should choose a transmitter with sufficient average power capability, select a pulse repetition frequency (PRF) based on Doppler sampling and unambiguous range considerations, and select a pulse width that operates the transmitter at its maximum duty cycle. If that pulse width is too wide for the desired range resolution, then the pulse should be coded, using phase coding or linear FM (as examples). The receiver must then use matched filtering (**pulse compression**) to obtain the resolution desired.

Antenna Subsystem

The antenna is the transitional device between the transmitter/**receiver** and free space. Although such a general definition can be fulfilled by any number of radiating structures, most modern radar antennas can be classified as either reflectors or arrays. (However, for applications requiring only modest directivity, a horn or other aperture antenna may be utilized.) Maximization of system performance as a function of cost generally mandates that a substantial fraction of the total cost be devoted to the antenna. The antenna may consist of 20% of the total system cost for relatively undemanding applications to well over 50% for solid-state array systems. Large reflector antennas can be produced relatively cheaply though it may be difficult to maintain stringent tolerances associated with low-**sidelobe** performance for a reflector that spans many wavelengths.

As the interface between the radar and the external environment, the antenna pattern should generally be characterized by significant directivity in the nominal pointing direction in conjunction with suppressed response outside this region. The orientation of reflector antennas is controlled via some manner of one or two dimensionally rotating pedestal. The pointing direction is estimated by the radar controller to either probe for targets in a specified sector of space (search) or maintain cognizance of a previously detected target (track). System sensitivity is largely determined by the two-way antenna gain, which is the product of the transmit gain and receive gain as can be readily discerned from the radar range equation.

Reflector antennas typically employ a parabolic structure that is highly reflective at the carrier frequency of the radar so as to focus energy at either a feed or subreflector. The commonly used Cassegrain reflector antenna employs a hyperboloidal subreflector to focus energy on a feed located at the base of the parabolic reflector so as to minimize antenna aperture blockage. The feed is generally some manner of horn antenna designed to produce a specified illumination function across the reflector.

The feed provides an output for the transmitter and input to the receiver depending on which function the radar is performing. The principle of reciprocity dictates that the transmit and receive antenna patterns are identical. This condition generally holds true for radar antennas unless there are nonlinear components in the antenna (such as ferrite devices) or the illumination function described in the following is deliberately changed between transmit and receive. Hence, the antenna will generally have the same polarization on transmit and receive.

Array antennas must further be classified into mechanically and electronically scanned designs. Mechanically scanned corporate-feed array antennas are attractive for space-constrained applications such as airborne intercept radars, which cannot readily accommodate the depth required for a reflector antenna with its associated feed structure. Antennas of adequate directivity are fabricated from an array of

individual elements that can be formed with individual wire elements or fabricated as slots in a waveguide among other techniques. The elements are fed using a constrained beamformer typically consisting of waveguide or coaxial cabling.

In the case of an electronically scanned antenna, the relative phase of each individual element is controlled so that the pointing direction is determined by the element-to-element phase differential. Given an element spacing of d and a desired scan direction of θ_0 from the antenna boresight (defined as the direction orthogonal to the aperture plane), transmitted/received signals will be in phase if the interelement phase shift is $(2\pi d/\lambda) \sin(\theta_0)$. Phased arrays implement electronic beam scanning by controlling an individually phase shifter for each element. Diode or ferrite devices are used to implement the commanded phase shift. Phase shifters can potentially switch phase sets in less than $1 \mu\text{s}$ but the computation and control process necessary to command the phase shifter setting typically imposes beam switching times on the order of $5\text{--}25 \mu\text{s}$. This architecture can provide flexible one- or two-dimensional electronic beam scanning at the cost of a relatively complex element-level phase control subsystem.

The feed structure cost can be significantly lowered by illuminating the back face of the array with a feed horn rather than employing a corporate feed. This space-fed phased array sacrifices compactness and some degree of illumination function control. Feed scatter and aperture spillover degrades antenna sidelobe suppression.

Active arrays drive each radiating element or small groups of radiating elements with dedicated high-power amplifiers (HPAs) on transmit and low-noise amplifiers (LNAs) on receive. Modern active arrays package a HPA and LNA along with a phase shifter, precision attenuator, and control circuitry into a solid-state module that typically possesses an integrated radiating element. A radar antenna may be constructed from a few hundred such modules for short-range search applications up to several to tens of thousands for demanding long-range/high-resolution applications such as missile defense.

The beam pointing direction of frequency scanned arrays is determined by the carrier frequency of the radar. This architecture does not require element-level control as a fixed feed system is used that produces an element-to-element phase shift inversely proportional to wavelength. A serpentine feed feeding the elements in series is commonly used for this purpose. This technique affords one-dimensional electronic beam steering at relatively low cost but constrains waveform bandwidth and is susceptible to electronic countermeasures (ECMs) as the radar's scanning can be estimated from measurement of its carrier frequency.

The fundamental pattern and resolution characteristics of antennas are summarized in Fig. 17.3. Antenna response and performance is generally characterized by its far-field pattern, which is independent of range (REF). The antenna near-field pattern is a function of range and is equivalent to the Fresnel region

FIGURE 17.3 Aperture antenna characteristics.

encountered in optics, whereas the far field corresponds to the Fraunhofer region. The transition from near field to far field is generally defined as $2D^2/\lambda$ where D is the maximum extent of the antenna. In practice, the peak response regions are well formed at a range of D^2/λ but the antenna pattern nulls are not well defined until substantially greater ranges. In general, all radar operations will be associated with targets in the far field.

Gain is the product of both the directivity and the efficiency of the antenna. The corresponding directive gain is the ratio of the maximum radiation intensity produced by the antenna to that produced by an isotropic antenna given the same source. The efficiency of the antenna is degraded by a number of factors but the loss imposed by intentional tapering to suppress the antenna pattern outside the desired region is often the dominant source in radar applications. Major unintentional **loss** sources in the antenna and associated feed structure that degrade antenna efficiency include mismatch and ohmic losses. In addition, feed blockage is often a significant source of loss in reflector antennas.

As defined here and used in the radar range equation, gain is strictly due to passive components and does not include active component (amplifier) gain associated with the transmitter subsystem. This distinction is important in estimating the performance of solid-state active arrays.

The far-field antenna pattern is generally characterized in terms its **main lobe** and sidelobes. The main lobe extent denotes the far-field angular resolution of antenna along a given dimension. This value is approached by λ/L where λ is the radar carrier wavelength and L is the extent of the antenna in that dimension as illustrated in Fig. 17.3. As can be readily deduced, the directivity of the antenna is inversely proportional to the solid-angle extent of the main lobe. Radar antenna gain generally lies in the region of 25–45 dB inversely corresponding approximately to angular resolutions on the order of 1–10°.

Low sidelobe response is required to reject interference from clutter, electromagnetic countermeasures, and unintended electromagnetic interference that are resolved from the target. Peak sidelobe magnitude in most radar systems is at least 25 dB below the peak of the main lobe. In applications requiring detection of relatively small targets in the presence of strong clutter or active interference sources, the sidelobe level must be significantly lower. Given that the transmit and receive antenna patterns are identical, the composite rejection of sidelobe interference in decibels will be twice the nominal sidelobe level for clutter but active interference rejection is dependent solely on the receive pattern sidelobes.

Sidelobe suppression is highly dependent on the antenna illumination function, which characterizes the power distribution across the face of the antenna. The antenna illumination function and the resulting far-field pattern constitute a Fourier transform. Hence, illumination tapering can be used to suppress the sidelobe response of the antenna by implementing weighting techniques such as those delineated in Table 17.1. The Fourier transform of a smoothly tapering function such as a cosine-on-a-pedestal results in sidelobes suppressed below the nominal –13.3-dB peak value associated with the $\sin(x)/x$ far-field voltage

TABLE 17.1 Aperture Weighting

- Signal aperture (e.g., time duration for case of Doppler filtering)

that would otherwise characterize linear or rectangular aperture antenna's response along the principal plane. The cost of this enhanced rejection of sidelobe interference is broadened main lobe extent (degraded angular resolution) and loss in S/N.

Antenna sidelobe suppression is ultimately limited by the electrical and mechanical tolerances that can be maintained during manufacturing and operation. In the case of reflector antennas, feed blockage will further degrade the attainable degree of sidelobe suppression. Typical average sidelobe suppression relative to isotropic may be on the order of -3 dBi though specialized antennas with substantially lower sidelobe levels have been developed at the penalty of developing and maintaining tighter amplitude/phase/displacement tolerances.

One can interpret an antenna pattern as the Fourier transform of the sum of the desired antenna illumination function and an illumination error function that represents deviation from that function. The worst case consists of periodic errors across the antenna face that imposes a spatially coherent illumination error function that manifests as discrete sidelobes of significant magnitude. In modern antennas designed for good sidelobe suppression, the illumination error function can often be characterized by randomly disturbed amplitude, phase, and mechanical displacement errors resulting in randomly distributed sidelobes. Wang (1992) has provided useful expressions to estimate the resulting error sidelobe level for array antennas with such randomly distributed errors as well as random element failures. For example, adapting his expression yields the root-mean-square (rms) sidelobe magnitude in units of dBi as

$$\sim 10 \cdot \log[\pi \cdot [1 + [10^{(\frac{a}{20})} - 1]^2] \cdot e^{[\theta^2 + (\frac{2\pi}{\lambda} \cdot \sigma)^2]} - P_{go}]$$

where:

a = rms element-level amplitude error (dB)

θ = rms element-level phase error (radians)

σ = three-dimensional rms displacement error of element (m), and

P_{go} = probability of give element being functional.

The cross-range resolution afforded by a given antenna can be closely approximated using simple trigonometric identities as the product of the angular resolution and the range to the target. It is necessary to estimate a given target's position with significantly better **accuracy** than the nominal resolution to support precision tracking applications such as fire control and air traffic control. Most modern radar systems employ a monopulse beamformer for that purpose. In the three-dimensional measurement case, the receive antenna feed simultaneously produces a sum beam, azimuth-difference, and elevation-difference beams which requires three receiver channels but is much more efficient at estimating target position to a given accuracy than other available techniques. Monopulse operation can be conceived as essentially comparing the amplitude of a return received in two independent offset lobes. The voltage measured at the output of the two difference channels is a function of the target's angular position relative to the nose of the beam. Monopulse **accuracy** degrades as the target approaches the edge of the main lobe and the difference-beam slope becomes increasingly nonlinear.

Composite tracking accuracy is generally dominated by antenna performance. Accuracy is determined by instrumentation and propagation error sources as well as the noise-limited precision. Instrumentation errors include antenna illumination errors as well as amplitude and phase imbalance among the monopulse receiver channels. Propagation errors are generally dominated by multipath and tropospheric refraction. Both error sources decrease in severity as elevation angle increases.

As will be described subsequently, tracking accuracy can be improved substantially by estimating the target position and velocity from multiple measurements. Errors that are independent from measurement to measurement, such as induced by thermal noise, are efficiently smoothed by track filtering. However, performance is sometimes limited in practice by systematic residual errors that are highly correlated over multiple measurements and are not significantly smoothed by track filtering. These errors include coordinate registration error associated with translating radar measurement coordinates into other coordinate systems used by the track filter and the end user.

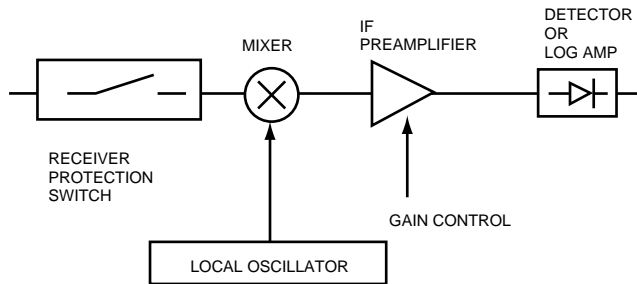

FIGURE 17.4 Simple superhetrodyne receiver block diagram.

Receiver Subsystem

Figure 17.2 showed the overall block diagram of a basic coherent radar system. The exciter develops all of the reference oscillator signals and the timing signals. The up converter stages generate the transmitted RF from the product of mixing the various reference oscillator signals. This signal is amplified to the desired transmit power level, and applied to the antenna system. The signal that comes back into the antenna, from the target scene, is directed to the receiver subsystem, which converts the RF back down to intermediate frequencies, which are convenient for amplifying and filtering the signal, and then to baseband (video). The in-phase/quadrature phase (I/Q) detector develops the in-phase and quadrature phase components of the received vector.

The receiver can be one of a variety of configurations. Complexity varies from a simple detector to a dual conversion superhetrodyne system. Figure 17.4 shows the block diagram of a relatively simple noncoherent (amplitude only) receiver. The RF signal is converted down to an intermediate frequency (IF) by means of a mixer, using a free running oscillator as the LO drive. The IF signal is amplified to an appropriate power level, and detected using a linear, square law, or log detector circuit. The log amplifier used in many of the latest noncoherent radar system provides the best dynamic range of the amplitude detectors.

Figure 17.5 is the block diagram of a typical log amplifier used in a non-coherent radar system receiver. It is configured as a series of limiting IF amplifiers, whose outputs are detected and added (summed) in a summing network/video amplifier circuit. For very low signal levels, none of the amplifier stages is saturated, and the circuit acts as a linear amplifier. As the signal level increases, successive stages of the circuit begin to saturate (beginning with the last stage) so that the marginal gain is decreased with increased signal level. The saturation characteristics are designed such that the output signal is proportional to the log of the input signal, producing the input–output characteristics shown in Fig. 17.6.

Figure 17.6 shows the output voltage as a function of input signal level, for a typical (hypothetical) log amplifier. At very low input signal levels, the curve is exponential when plotted on a log axis, but at some nominal input level the IF amplifiers begin to saturate, contributing less to the output, and the output

FIGURE 17.5 Log amplifier block diagram.

FIGURE 17.6 Typical log amplifier input–output characteristics.

FIGURE 17.7 Coherent radar receiver block diagram.

voltage becomes a linear function of the input power, up to the point at which the first stage saturates, at which time there is no increase in output signal level. An 80-dB dynamic range is usually achievable with this circuit.

Figure 17.7 shows the block diagram of a relatively simple coherent receiver. The received RF signal is down converted to IF in a mixer, in much the same way as the superhetrodyne, with the additional feature that the local oscillator is a sample of the LO used in the transmitter upconverter process. In this way, the phase integrity of the received signal (relative to that of the transmitted signal) is maintained. Measurement of the received signal vector (amplitude and phase) is commonly performed by means of an I/Q detector, which produces two orthogonal components of the vector, the *in-phase* and *quadrature-phase* components. The reference signal for this phase sensitive detection is a sample of the coherent oscillator signal that is used in the transmitter upconversion process.

Figure 17.8 is a block diagram of a typical I/Q detector network. The received down-converted IF signal is split and applied to the input to two double balanced mixers, whose reference (LO) inputs are quadrature

FIGURE 17.8 Coherent radar I/Q detector network block diagram.

TABLE 17.2 Double Sideband Noise Figure for Various Radar Bands, Achievable with Low-Noise RF Amplifiers

^aNo low-noise amps available, preferred configuration is mixer/preamplifier with 3-dB additional loss.

samples of the COHO signal. Usually, phase trimmers are used to ensure orthogonality between the I and Q components of the detected signal. Also, careful matching of the gain between the I and Q channels is required to properly reconstruct the nature of the received vector in spectral processing. Nonorthogonality and gain imbalance will create an artificial target at the image of the Doppler frequency of the actual target, presenting a false target.

Figure 17.9 depicts the relationships between the orthogonal components of the received vector (I and Q) to the original vector, which has an amplitude and a phase. The expressions for transforming from one to the other coordinate system are shown. Fortunately, the signal processor (MTI or fast Fourier transform (FFT)) often operates in the I/Q domain, so the transformations are not required.

FIGURE 17.9 Relationship between polar coordinate system variables (A, q) and rectangular coordinate system variables (I, Q).

Figure 17.10 is a block diagram of a coherent receiver configuration that has two downconversion stages preceding the I/Q detector network. This configuration is used with stepped frequency systems, since the second IF signal into the I/Q network can be of a constant frequency, while the RF is stepping in frequency on a pulse-to-pulse or dwell-to-dwell time frame.

Noise Figure

The sensitivity of the receiver depends on the thermal noise inherent at the input to the first stage of gain. The original system configurations did not have low noise RF amplifiers ahead of the mixer (down-converter) stage. In this case, the noise figure was the mixer loss plus the noise figure of the IF amplifier that followed. In modern systems, at frequencies up through Ka-band, the noise figure is established at a low noise RF amplifier preceding the mixer stage. Table 17.2 lists the double sideband noise figure obtainable using modern catalog-listed narrow-band (usually about 10%) low noise RF amplifiers. This does not include losses in the system prior to the amplifier, and does not include losses associated with built-in limiters if so configured. Since there is no noise RF amplifier available at W- band, the figure given represents that achievable with a mixer/preamplifier combination.

FIGURE 17.10 Dual conversion coherent receiver block diagram.

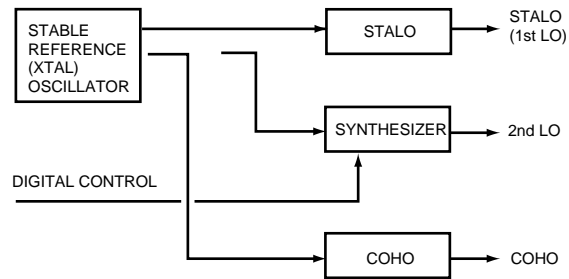

FIGURE 17.11 Coherent radar exciter subsystem block diagram.

In this case, there is an additional (approximate 3 dB) signal-to-noise ratio loss due to the fact that both noise sidebands are mixed to IF, while the signal appears in only one RF sideband.

Exciter Subsystem

One of the most stressing requirements for many radar systems is the requirement to detect a small (low RCS) target in the presence of a high clutter background. Detection of a cruise missile, near the surface of the ground or water, is a prime example. The most commonly applied technique involves performing a spectral analysis of the signal return from each range/azimuth cell, and determining whether the signal has a Doppler frequency offset indicative of the presence of a moving target.

The system exciter, which to a large extent is integrated with the receiver down-converter subsystem, develops the required IF and RF reference signals for the transmitter and receiver. Many of the components of the system **instabilities**, which lead to a limit to the clutter suppression performance, are derived in the exciter subsystem: timing jitter and oscillator phase noise being the two dominant contributors.

Figure 17.11 is a block diagram of a typical exciter subsystem that produces the coherent reference signals and stable oscillator signals used in the processes described previously. Typically three signals are required, a coherent oscillator signal, an *intermediate frequency local oscillator (IFLO)* signal, and a stable local oscillator signal, though there can be more (or fewer) as the system requirements dictate. The IFLO signal is often the one that is stepped in frequency to produce a stepped frequency RF signal to transmit. Usually all of the reference oscillators are phase locked or derived from a stable crystal oscillator as shown. Often the PRF and microtiming and control signals are also derived from this clock for system synchronization.

Transmitter Subsystem

To a large measure the performance of a radar system is determined by the parameters of the transmitter subsystem. Some of the primary factors to consider in transmitter selection and design are

- Frequency
- Bandwidth (instantaneous and tunable)
- Peak power
- Average power
- Pulse length
- Pulse repetition frequency
- Efficiency
- Coherence requirements
- Stability (amplitude and phase)
- Spurious outputs
- Cost
- Weight, volume, environmental sensitivity
- Reliability, maintainability

TABLE 17.3 Typical Transmitter Power Levels

Device	Frequency						
	L-band	S-band	C-band	P_{pk}/P_{avg} X-band	Ku-band	Ka-band	W-band

• Transistor	200 W/50 W	200 W/50 W	100 W/25 W	20 W/5 W	—	—	—

The two major categories of transmitters are coherent and noncoherent. A noncoherent radar system has the ability to measure the amplitude of the received signal, but has no ability to measure the phase (or at least the phase has no significance). A coherent system, on the other hand, can measure the phase of the received vector as well as its amplitude. Given this distinction, there is no need for the noncoherent transmitter to have particularly stable or predictable phase characteristics. The coherent radar transmitter must have a high degree of phase integrity.

The power requirements for the transmitter depend on the required detection range for a given target RCS, and other system parameters such as antenna size, receiver sensitivity, and dwell time. Short-range systems, or those with a large aperture and reasonable detection range requirements, may have the luxury of being able to employ solid-state technology for the transmitter. In this case, the device may be a transistor or diode, which provides a high degree of reliability. In general, solid-state devices can develop on the order of 100 mW of average power (at millimeter wave frequencies) to tens of watts of average power at microwave frequencies. Missile systems, close-in security systems, and automatic systems (including police speed timing radars) are examples of solid-state transmitters.

Longer range systems need power associated with thermionic (tube) type devices, such as magnetrons, cross-field amplifiers, traveling wave tube amplifiers (TWTAs), or klystron type devices. In general, tube type transmitters can develop up to hundreds of kilowatts of average power at microwave frequencies, though the most commonly used devices generate tens of kilowatts. At millimeter wave frequencies, the power is more modest, with tens of watts being a typical average power limit. Peak power levels can range from 100 W at millimeter wave frequencies to megawatts at microwave frequencies. Table 17.3 lists some typical power levels for different devices, at different frequencies. These are typical values, and do not represent the maximum levels achievable. In many cases, the table presents what has been done as opposed to “what could be done,” where the difference is based on the needs of a particular program with sufficient resources and need to pay for the development of a particular device. Also, the absence of an entry in the table does not necessarily mean that the technology does not or could not exist.

The selected frequency of the system depends on the application, available space, and the results of the trade-off analysis described in Sec. 17.2.2. Usually, long-range surveillance systems are best designed to operate at the lower microwave bands, such as L-band (1 GHz), S-band (3 GHz), or C-band (6 GHz). Airborne interceptors are usually at 10 or 16 GHz (X- or Ku-band) and missile seeker radars are at millimeter wave bands (35 or 95 GHz). The longer wavelength systems experience less atmospheric attenuation, and generally more power, less system losses, and lower noise figure is available at lower frequencies. The airborne systems would suffer from the relatively wide beamwidth associated with lower frequencies, given the limited space available for the aperture. Yet, millimeter wave systems for this application would suffer from excessive atmospheric loss and lower available power. The missile seekers have a limited required

range of operation and are driven more by beamwidth issues, particularly in the air-to-ground applications in which the target is in a severe clutter environment.

The bandwidth of the system determines the range resolution (δR). The wider the bandwidth, the finer the range resolution.

$$\delta R = \frac{\alpha c}{2B}$$

where

α = factor (about 1.3) determined by the processing weighting function

c = speed of electromagnetic energy (3×10^8 m/s)

B = bandwidth of the system, Hz

Using conventional signal processing, resulting in an α of about 1.3, about 650-MHz bandwidth is required for 1-ft (0.3-m) range resolution. In most cases this is adequate for target discrimination (in clutter) and in some cases it is sufficient for target classification and recognition.

The corresponding range-rate measurement resolution is

$$\delta R = \frac{\lambda \alpha}{2 T}$$

where T is the coherent signal duration.

The peak power determines the single pulse signal to noise ratio. Though in some systems, during the search mode, it is desired that a detection is made on a the basis of a single pulse, more often than not, there is more than one pulse available with which to make a detection decision. In this case, the average power capability of the transmitter is important.

The length of the transmitted pulse, coupled with the PRF, determines the average power developed by the transmitter. The bandwidth of the pulse determines the instantaneous range resolution. For a monochromatic pulse, the bandwidth is approximated by the reciprocal of the pulse width. Therefore, range resolution and detection range are conflicting requirements. In most modern systems, however, the pulse is coded, such that it contains high-resolution range information, without sacrificing average power.

The pulse repetition frequency of the system is the rate at which pulses are transmitted. If range ambiguity is undesired, then the maximum PRF (minimum pulse repetition interval (PRI)) is determined by the time delay to the farthest target of interest. If Doppler sampling satisfying the Nyquist sampling criterion is desired, then the PRF needs to be at least as high as the highest Doppler frequency expected, based on the fastest target of interest. (I and Q detection is equivalent to doubling the sample rate.) Sign ambiguity issues require twice that rate. Often, there is a conflict between the minimum and maximum PRF. In this case, there are bound to be ambiguities, in range and/or Doppler. These ambiguities can be resolved by staggering the interpulse period on a dwell-to-dwell basis, and analyzing the response. Any target that does not change apparent Doppler frequency or range when the PRI is somewhat changed is not in an ambiguity region. A target that does change apparent Doppler or range is in an ambiguity region. The amount of apparent change in the measured parameter relative to the amount of PRI change is an indication of which ambiguity region the target is in.

Reasons for employing a low PRF are elimination of range ambiguities, lower data rates for data acquisition, easier power supply development, etc. Higher PRF is desired for Doppler sampling requirements and average power and number-of-pulses-integrated considerations.

The unambiguous range R_u to a target, for a given PRF is found from

$$R_u = c/2\text{PRF}$$

and so the maximum PRF is

$$\text{PRF}_{\max} = c/2R_u$$

which is not wavelength dependent.

If the Doppler frequency characteristics of a target are to be determined, then the sampling rate (PRF) must be sufficient to satisfy the Nyquist sampling criterion, two samples per Doppler cycle. In this case, the minimum PRF is found from

$$\text{PRF}_{\min} = \frac{4V_r}{\lambda}$$

where V_r is the radial component of velocity.

As the wavelength becomes shorter, it is increasingly difficult to avoid a range or Doppler ambiguity, or both.

Digital Processing

Digital processing functions for radar applications can generally be divided into signal processing and data processing functions. Signal processing is essentially characterized by single-measurement processing operations such as pulse compression, Doppler filtering, and detection thresholding that exist over time scales of milliseconds to tens of milliseconds. These operations are characterized by relatively simple algorithm structures and generally do not involve extensive iteration or branching. These operations can be efficiently implemented on specialized high-throughput processors to accommodate the relatively wide processing bandwidths associated with radar signal processing. The signal processor must generally operate in close synchronization with the other radar subsystems to ensure that it does not bottleneck system-level capability.

In contrast, data processing functions are generally implemented on a general purpose computer, which often operates asynchronously from the other radar subsystems. Data processing algorithms are characterized by extensive data-dependent flexibility and operate over time scales of tens to hundreds of seconds. Typical data processing functions include top-level radar control, track filtering, and control and display support. In radars with modest throughput requirements, signal processing and data processing functions may be readily integrated in a single processor.

Signal processing functions can further be divided into matched filtering approximation and information extraction. The radar signal processor first attempts to maximize S/N subject to both unintentional and intentional mismatch terms. Unintentional mismatch is due to ohmic and nonohmic losses imposed by the hardware and software constraints. Pulse compression consists of pulse-level matched filtering, whereas Doppler filtering approximates a matched filter to a coherent sequence of pulses.

Signal Processing

As noted previously, typical radar bandwidths can range from 1 MHz to significantly in excess of 100 MHz. These bandwidths have historically stressed signal processing technology and so a number of analog technologies have been investigated for pulse compression and related functions. Current implementation trends strongly favor digital processing with analog processing largely limited to the receiver/exciter applications previously described. The principal advantages of digital processing over analog technologies, such as surface acoustic wave devices, are flexibility, long-duration signal processing, large dynamic range, and low perceived development risk. Accordingly, this subsection will focus on defining the parameters necessary to size a digital signal processor for radar applications.

As will be evident in the following subsections, a number of radar signal processing functions are implemented via the fast Fourier transform. The FFT is a computationally efficient implementation of a discrete Fourier transform. A number of high-throughput digital engines possess optimized hardware/software to perform FFTs.

Vendor claims of signal processing throughput, typically given in terms of complex operations per second or FFT butterflies per second, should be treated skeptically. Achieving peak throughput performance is often dependent on repetitively processing a given FFT size. In contrast, radar applications involving support of multiple waveforms and functions mandate an interleaved sequence of heterogeneous FFT sizes, which may result in peak performance significantly less than indicated by vendor literature. Instruction and data transfer operations may impose additional delays. Input-to-output processor latency for a typical mixture

of radar application software tasks is generally required to reliably evaluate a candidate signal processor without imposing unreasonable performance margin requirements.

Pulse Compression

Pulse compression consists of matched filtering waveforms designed to provide the requisite range/Doppler resolution and sensitivity. Matched filtering provides appropriate signal processing for the detection and amplitude estimation of signals embedded in Gaussian noise independent of the statistical criterion utilized in the detection processor. Matched filtering maximizes S/N so that it also determines the achieved lower bound on measurement precision. The matched filter, $h_m(t)$, to any baseband-referenced radar waveform is given simply by

$$s(t) = h_m^*(-t)$$

where * denotes the complex conjugate, or

$$S(f) = H^*(f)$$

in the frequency domain where the upper case letters denote the Fourier transform and f represents frequency.

Pulse compression requires a separate matched filter be supported for each waveform used by the radar system. In practice, this filter is implemented via fast convolution as illustrated in Fig. 17.12. From Fourier transform theory, frequency-domain multiplication is equivalent to time-domain convolution. Hence, receiver digitized output data is input to a FFT, multiplied by the Fourier transform of the matched filter response, and then passed through an inverse FFT (IFFT) to output time-domain data. The matched filter reference functions transforms are generally computed off-line and stored in memory to support real-time processing. Fast convolution significantly reduces the number of operations required compared to time-domain direct convolution of returns and the appropriate matched filter function.

Most programmable multiple function radar signal processors are optimized for performing FFTs. The FFT is ubiquitous in radar signal processing as it is used to support the fundamental operations of pulse compression and Doppler filtering. However, it is important for the signal processor to accommodate multiple size FFTs in a multiple tasking software environment necessary to satisfy the radar functional needs.

FFT sizing for fast convolution is illustrated in Fig. 17.13. Since a FFT implements a discrete Fourier transform, frequency-domain multiplication equates to circular convolution in the time domain. The desired

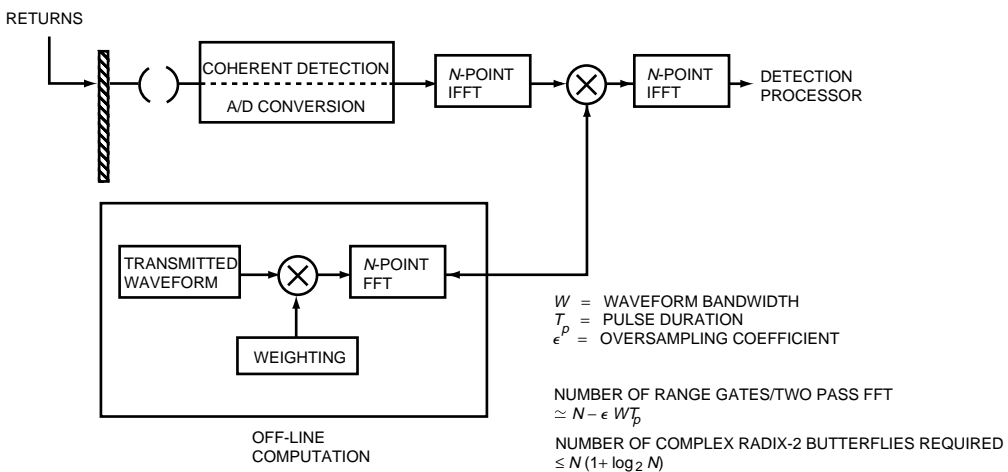

FIGURE 17.12 Pulse compression via fast convolution.

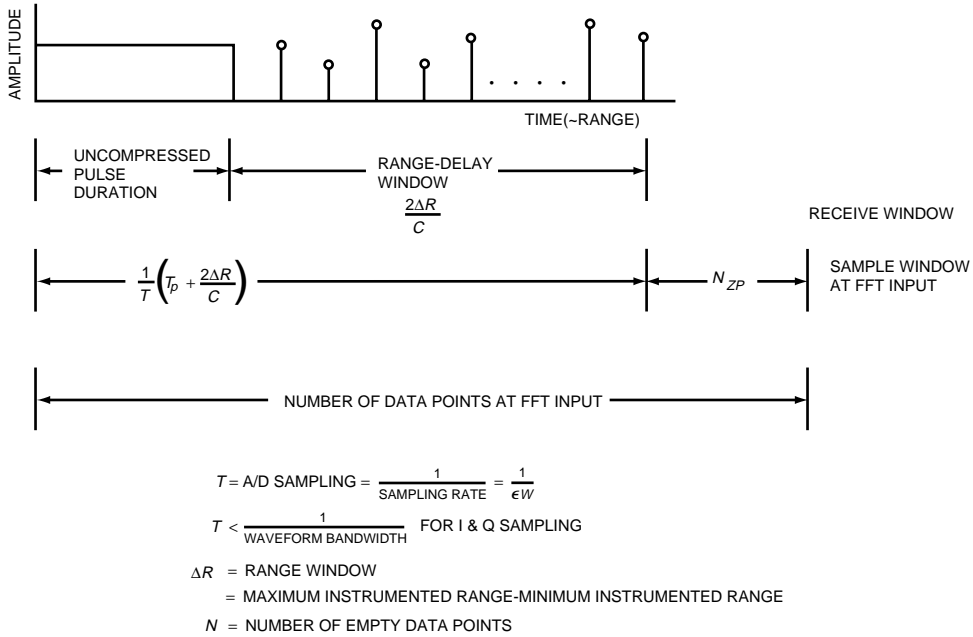

FIGURE 17.13 Fast convolution: FFT sizing.

time-domain linear convolution is achieved by increasing the size of the transform to accommodate the specified range window as illustrated. If the range window corresponding to the range interval over which target returns must be processed correspond to M range resolution cells, then the fast convolution transform size must be at least M points larger than the product of the sampling rate and pulse duration. For example, assuming a waveform bandwidth and complex sampling rate of 1 MHz and a pulse duration of 10 μ s would mandate an FFT size of 64 to achieve a range window of about 2-km extent. An FFT size of 512 points would be required to achieve a range window of some 69-km duration as would be typically required for search.

It is often desirable to tradeoff somewhat degraded mainlobe resolution and associated S/N mismatch loss for reduced range sidelobes or Doppler sidebands via windowing, as previously described in the context of antenna illumination tapering. Linear frequency modulation (LFM) is frequently used for pulse compression applications. The requisite bandwidth desired for range resolution is achieved by linearly sweeping the carrier frequency over the necessary bandwidth. A repertoire of waveforms can be created by using different swept bandwidths in conjunction with appropriate pulse durations. The linear relationship between time and frequency in LFM mandates that the matched filter response be relatively insensitive to Doppler mismatch. An offset in Doppler frequency induces a corresponding range-delay offset equal to the Doppler offset multiplied by the uncompressed pulse duration divided by the swept bandwidth.

For LFM waveforms with products of swept bandwidth and uncompressed pulse duration exceeding about 10, the shape of the pulse compressor output envelope can be closely approximated by the Fourier transform of the input. Hence, application of weighting to the signal at the pulse compressor input suppresses the range sidelobes at the cost of introducing mismatch loss and degraded mainlobe resolution. Typical pulse compression mismatch loss is on the order of 0.5–1.2 dB depending primarily on the degree of range sidelobe weighting used. In principal, weighting suppression could be attained without this penalty by weighting the pulse on transmit. In practice, it is necessary to operate the transmitter in saturation for maximum power conversion efficiency so that weighting on receive must be used.

Phased coded pulses may also be employed for pulse compression. A sequence of binary or polyphase samples is imposed on the uncompressed pulse duration at a specified bit rate corresponding approximately to the effective waveform bandwidth. For the commonly used linear recursive sequence (LRS) waveforms,

a binary sequence composed of antipodal phase states is used. The corresponding Doppler resolution is on the order of the inverse of the uncompressed pulse duration. The rms range-Doppler sidelobe level of match-filtered LRS waveforms relative to the peak response is given approximately by $10 \log(N)$ where N is the number of bits in the code sequence. For large N , the mainlobe-sidelobe range-Doppler response approximates a thumbtack shape.

Detection Processing

Automatic detection processing may be characterized as the decision-driven filtering operations that reduce the relatively wideband data stream of range-gate/Doppler-filter outputs to a series of target-return reports that can be accommodated by the radar data processor. Detection processors are generally designed to provide constant false alarm performance. The processor adjusts the detection threshold as a function of the local interference estimate based on the design false-alarm probability and the CFAR algorithm. CFAR thresholding prevents data processor and/or operator performance from being degraded with excessive return reports due to the combined effects of thermal noise, clutter returns, and other interference sources.

Detection-decision processing consists of a binary decision at the output of each range-gate/Doppler-filter output between two hypotheses: target-absent and target-plus-interference-present. This decision is generally implemented by comparing the cell output magnitude x_i , with a threshold value X_t , such that the presence of a target is declared if $x_i > X_t$.

Most operational CFAR processors employ some variation of cell-averaging CFAR (CA-CFAR). CA-CFAR provides an unbiased minimum-variance statistical estimate of homogeneous interference within the reference window. Interference is estimated by taking the mean across a local area termed the reference window, which is centered around the test cell. The CFAR window may be implemented across range, Doppler, angle, time, or some combination depending on the radar operational characteristics and design. An azimuth rotating radar may be designed to maintain a map of estimated local clutter and other interference sources estimated over multiple scans (time) as a function of range and azimuth. This mean interference is multiplied by a constant computed to provide a designated average probability of false alarm.

CA-CFAR performance is degraded by the presence of strong interfering signals within the CFAR window. The test cell is not included in the local interference estimation. A strong target return present in the reference window causes the local interference level to be overestimated, which elevates the detection threshold. The summation also omits one or more cells on each side of the test cell. These so-called guard cells prevent a cell straddling target return from contaminating the interference estimate.

CFAR loss is the incremental signal-to-interference (S/I) ratio required by a given CFAR threshold estimation scheme to achieve a specified detection probability over that required with full knowledge of the background interference. CFAR loss is effectively the S/I margin required to accommodate the error imposed by the local interference-estimation technique for an assumed interference PDF. The CFAR loss for a Swerling 1 target is plotted in Fig. 17.14 as a function of the number of independent reference cells for various false alarm probabilities. Note that CFAR loss can be kept below 1 dB at reasonable false-alarm probabilities by choosing a reference window affording in excess of 32 samples.

FIGURE 17.14 Swerling 1 CA-CFAR loss.

Alternative CFAR techniques are widely used to mitigate target masking effects at the cost of some increase in homogeneous CFAR loss. In general, these techniques are based on some manner of nonlinear processing the reference window samples prior to estimating the local interference level. Logarithmic rectification of the receiver output, rank ordering of reference window samples, and rejection of samples exceeding a given magnitude are common techniques for this purpose.

Data Processing

Radar Automation

Whereas operator effectiveness has been greatly enhanced by advances in controls and displays technology, radar system operation and control are increasingly automated. Modern workstation technology has allowed development of high-resolution color monitors capable of supporting three-dimensional perspective displays tailored to specific operational environment such as air traffic control. In a modern surveillance radar system, the **data processor** routinely initiates, maintains, and terminates tracks, drastically reducing the operator workload. Critical functions such as flightpath monitoring and projection coupled with multiple-source target identification monitoring affords the radar user the critical information needed to make decisions without overwhelming the operator with data.

To support applications with either very short timelines (such as point defense against low-flying missiles) or high-density multiple-target tracking, the radar control process must be automated as the requisite decision rate exceeds that which can be accommodated by an operator. Human operator intervention can be essential in coping with target and environmental parameters that are outside the nominal bounds implicit in the radar software.

Modern radars typically employ a general-purpose computer for these automation tasks. A real-time operating system is generally required to assure that the data processor performs critical functions within the latency constraints imposed by measurement rates and radar control requirements. A dedicated controller generally serves as the synchronizing interface from the data processor to the other subsystems such as the antenna steering unit, receiver, and transmitter. The implementation of this controller varies from a smart data bus to a dedicated digital processor of substantial capability depending on the design and sophistication of the radar. Multiple-function radar systems that interleave operations present the most challenging data processing requirements because of the associated need for deterministic run-time guarantees to assure that latency constraints are met across all combinations of conditions as well as the need to manage radar hardware resources such as duty cycle, occupancy, and beam pointing direction.

Target Tracking

Tracking essentially consists of maintaining cognizance of the position and course of a given target. This task is typically implemented using a tracking loop such as illustrated in Fig. 17.15. This tracking loop is implemented as a recursive digital filter in most modern tracking radars. The assumed equations of motion vary from a simple polynomial equation to high-order nonlinear models of the target flight characteristics. The track filter compares the update measurement with the value predicted by the track filter based on data smoothed from previous measurements. The weighted difference is used to update the estimated current position and velocity of the target. Tracking techniques such as Kalman filtering adapt this weight based on estimated measurement and track quality. Depending on target characteristics and processor capability, separate independent track filters may be implemented for each measurement dimension. However, significant enhancement in tracking accuracy can be used by employing a coupled coordinate system representation in the track filter, which better represents target maneuvering characteristics or sensor measurement performance.

If the measurement errors are independent look-to-look, the random error, after smoothing over the track interval σ_s , can be estimated as

$$\sigma_s = \sigma_m \cdot \sqrt{\frac{1}{N_m} \cdot \left(1 + \frac{3 \cdot (N_m - 1)}{N_m + 1}\right)}$$

where

σ_m = standard deviation of the measurement error

N_m = the number of measurements smoothed by the track filter

It is necessary to predict target motion over short periods for measurement updating and over long periods to satisfy user needs such as fire control or collision avoidance. The resulting prediction error for

FIGURE 17.15 Tracking loop implementation.

the first-order polynomial filter given a prediction period of T_p beyond the end of the tracking interval is

$$\sigma_p = \sigma_m \cdot \sqrt{\frac{1}{N_m} \cdot \left(1 + \frac{12 \cdot (T_p + \frac{(N_m-1)T}{2})^2}{T^2 \cdot (N_m - 1)(N_m + 1)} \right)}$$

where T is the interval between measurements. This expression effectively presupposes that the target equations of motion are known by the track filter designer. Obviously this is not the case against such targets as maneuvering aircraft but is indicative of the performance that can be achieved tracking targets on ballistic trajectories. Maneuvering targets can be modeled as possessing random acceleration of a given magnitude and time constant so as to tune the track filter and estimate associated smoothing/prediction performance.

Target tracking can essentially be broken down into two classes of problems: single target tracking (STT) and multiple target tracking (MTT). STT applications are characterized by applications where the radar seeks to implement a measurement rate significantly higher than the maneuver bandwidth of the target. Targets are presupposed to be separated by multiple resolution cells. Microwave-band range instrumentation radars employing mechanically scanned antennas typify this type of design. Such radars operate at a few hundred pulses per second and typically use simple first-order polynomial tracking filters to keep the antenna oriented at the target and keep the target return positioned in range and Doppler acceptance gates.

In applications such as air surveillance or air defense, there are multiple targets distributed throughout the spatial volume of interest to the user. Targets may be closely spaced so that association of measurements to track files can be problematic. Radar resources must be shared among the multiple targets resulting in two different approaches. Track-while-scan (TWS) radars illuminate a given angular sector by repeatedly scanning a fixed illumination with a typical revisit period on the order of 10 sec. Tracks are generated by correlating measurements across multiple scans. TWS radar performance is constrained from achieving highly accurate tracking by the associated constraints on the update rate. In the event of densely spaced targets, the track filtering process may misassociate returns with the wrong track file so as to further degrade tracking accuracy.

Track-during-scan (TDS) radars attempt to overcome this limitation by adaptively updating the measurement of high-priority targets at relatively frequent intervals while conducting a search operation to acquire new targets as they enter the search volume. Practically speaking, TDS mandates electronic scanning to achieve the beam agility required to multiplex multiple target tracks and search functions. To achieve substantial performance gains over a TWS radar, the TDS controller must efficiently partition resources among multiple independent track files and search rasters. Multiple-function phased array radars such as the PATRIOT AN/MPQ-53 or Aegis AN/SPY-1 provide examples of MTT operation.

Typically, fast (≥ 1 update per second) and slow (≤ 1 update per second) track rates are available corresponding to precision and maintenance tracking functions. The automated radar control process generally gives higher priority to track than to search functions. Multiple search rasters may be used to facilitate satisfaction of user requirements. In air defense applications, a horizon fence raster could be deployed with a revisit time of a few seconds to detect cruise missiles while a larger volumetric search raster for aircraft detection could be repeated at intervals of tens of seconds.

17.2.4 Driving Implementation Requirements

Noise-Limited Sensitivity

Though the radar transmitter/antenna generates and launches a high-power burst (or tone) of electromagnetic energy, the power level of the received signal is often very small, sometimes on the order of -100 dBm (10^{-10} mW, or 10^{-13} W). The noise that exists in a receiver, due to the random motion of the electrons in the circuits, is sometimes greater than this level, so there is a challenge in detecting a target signal in the presence of the thermal noise.

The noise power can be predicted with a high degree of accuracy from

$$P_n = kTBF$$

where

- k = Boltzmann's constant
- T = standard temperature
- B = receiver bandwidth
- F = the noise factor

The signal power is easily computed; however there are some variables with uncertainty, in particular, the losses.

The radar range equation was introduced in [Sec. 17.1](#). In practice, estimation of the composite system loss factor and the system noise temperature can be very demanding.

The composite system loss factor is generally tabulated from operational losses, propagation loss, transmit losses, and nonohmic receive losses. Operational losses are generally a consequence of target positional uncertainty and include beamshape loss and range-gate/Doppler-filter straddle. Propagation loss is imposed by multipath cancellation and atmospheric absorption. Transmit loss is due to ohmic heating and mismatch between the transmitter output and the antenna radiating structure.

Nonohmic receive loss is imposed by mismatch between RF and IF components as well as signal processing effects such as quantization noise, range sidelobe and Doppler filter weighting, and detection thresholding. Quantization noise is due to the finite number of bits in analog-to-digital conversion process. This source of loss is typically on the order of 0.1–0.3 dB.

Noise temperature is a more direct way of estimating the system noise floor than estimating the composite noise figure directly for low noise receiver chains. The **system noise temperature** incorporates ohmic receive loss since such components effectively raise the noise floor as well as attenuating the signal.

The process of estimating dynamic range and system noise temperature is illustrated in [Fig. 17.16](#). The process is delineated in terms of an active array but can be readily adapted to other radar configurations. To estimate the performance of a conventional passive array, G_2 and NF_2 would be set to unity in magnitude. The case of $N = 1$ corresponds to a conventional mechanically scanned antenna. This particular case was

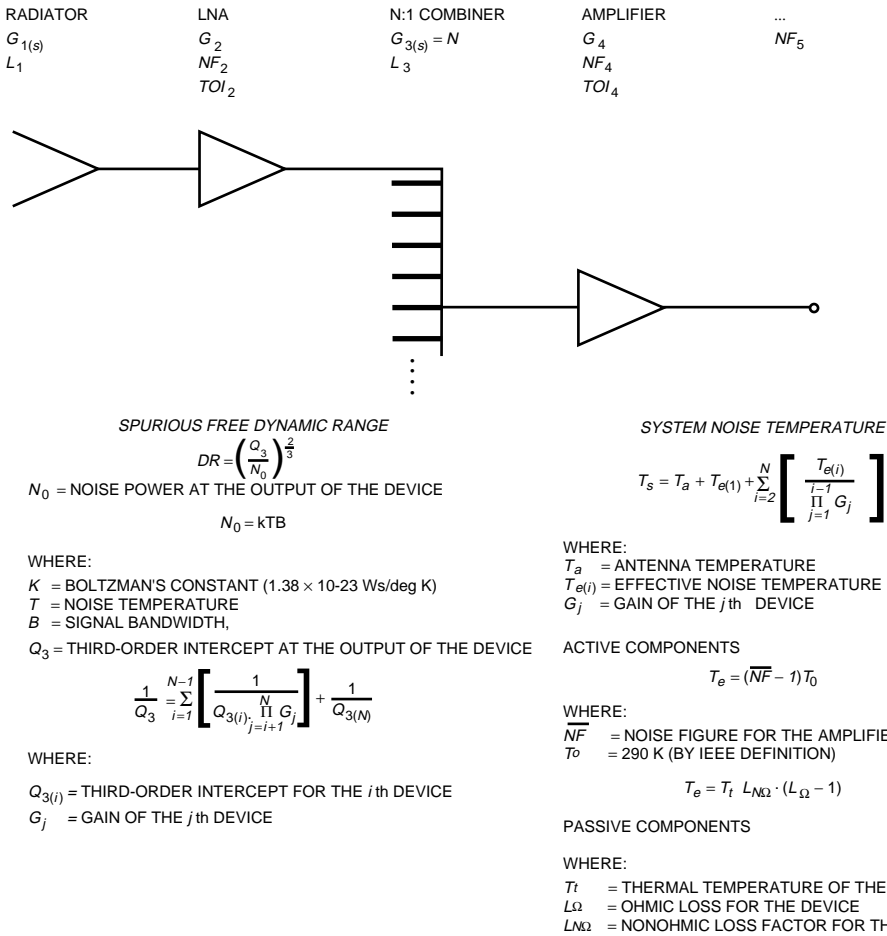

FIGURE 17.16 Computation of dynamic range and noise temperature. (Source: Robert Howard, Georgia Tech. Research Institute, Atlanta, GA.)

chosen since it illustrates the difference between spatial gain and amplifier gain in computing dynamic range; the former contributes directly to system dynamic range since the process of element combination effectively splits up the signal path.

Interference Environment

The radar system is designed to detect, track, and somehow treat targets of interest, in a nonideal environment. There are two major categories of environmental effects that limit the radar performance, propagation, and interference. Propagation effects influence the classical $1/R^4$ term in the radar equation by either attenuating the signal or enhancing it. Interference takes the form of noise, clutter (man-made and natural), and intention or unintentional signal jamming.

In addition to the mission requirements, a comprehensive understanding of the environmental conditions is required. The following sections describe some of the major factors.

Ducting

Surface-based ducting (over land and sea) and evaporation ducting (over sea) affect the propagation of electromagnetic energy in that the signal is bent toward the Earth (usually) to increase the power density at a given range, extending the distance over which targets and clutter will be detected. Though this effect

increases target signal, which may improve noise-limited detection performance, it also increases clutter signal, exacerbating a clutter limited performance limit.

Multipath

Multipath is a condition in which if a target is near a reflecting terrain of sea surface, the direct signal constructively or destructively interferes with the indirect signal, creating areas of enhanced or reduced signal, respectively. This condition varies with many parameters, such as sea state, ground moisture content, depression angle, wavelength, etc. Prediction of detection performance is highly dependent on accurate modeling of the multipath environment.

Clutter

In the past, for benign clutter conditions, radar detection performance has been limited by the presence of noise generated in the receiver. Low RCS targets flying near the Earth's surface create a problem in detection due to the interference of the clutter signal. So-called clutter limited performance analysis depends on a high-fidelity model of the clutter reflection characteristics.

- Sea clutter. The reflectivity (backscatter and forward scatter) from the sea depends on the sea state and wind conditions, as well as the relative angle between the look direction and the wind direction. The reflectivity is a strong function of wavelength, depression angle, and polarization of the EM wave.
- Land clutter. Land clutter reflectivity is also dependent on the wavelength, depression angle, and polarization of the EM wave. The type of land clutter (grass, desert, trees, urban, etc.) is a strong influence on the reflectivity as well.
- Propagation. Refraction of the RF signal across standard atmospheric conditions (apart from the ducting effect) causes the propagation of the signal to depart from straight line, line of sight. The effect varies for different standard conditions.
- Losses. Atmospheric losses result from water vapor and oxygen as well as other elements in the atmosphere. Though at most microwave frequencies, up to Ku-band, these effects are negligible, except at very long ranges, the additional effects of humidity, and worse, rain, sleet, and hail, are not.

Clutter Rejection

The system signal-to-interference ratio is determined by a variety of factors, in addition to the thermal noise. Therefore, it is more complete to say that the interference is noise plus clutter plus interference (such as jamming).

In many cases, the detection performance of the system is not limited by thermal ($kTBF$) noise but rather by clutter. The RCS of a clutter cell is estimated to be the average reflectivity of the clutter in that cell (σ^0) times the illuminated area, defined by the pulse width and the beamwidth,

$$\sigma_c = \sigma^0 R \theta c \tau / 2$$

This is the signal with which the target must compete.

The clutter signal is complicated by the effects of range folding, particularly with a medium or high PRF system. A far-away target may be competing with close-in clutter in the case of the ambiguous range effect. An example of the effect is presented here. For $\sigma^0 = -20$ dB (0.01), $\theta^\circ = 1^\circ$ and $\tau = 1 \mu\text{s}$, the effective clutter RCS at a range of 1 km is about 25.5 m², or 14 dBm². A small target, (such as a 0-dBm² target) will be hidden by the clutter signal. If, as is often the case, the system is ambiguous in range, then there may exist a condition in which the target at some far range appears in the same range cell as close-in clutter. In this case, the close-in clutter will experience a $1/R^4$ loss associated with a small R (say, 1000 m) and the target will experience a $1/R^4$ loss associated with a large R (say, 100 km). In this case, for the ranges given, the target is further reduced by a factor of 80 dB! The total clutter signal with which the target signal has to compete consists of two components, the clutter that is in the same cell as the target (at 50 km) and the

FIGURE 17.17 Phase noise characteristics (typical) for ultrastable sources at various frequencies.

clutter at 1 km. The clutter at 1 km has been calculated to be about 14 dBm², but its effect is increased by 68 dB because of the “close-in effect” to an equivalent RCS of 82 dBm², and the clutter at 50 km is 31 dBm². It is easy to see that the clutter may have to be suppressed by 100 dB or more to be able to reliably detect the target.

Doppler processing offers a means to suppress the clutter signal. Since the target is moving, it has a nonzero Doppler frequency offset, and the clutter has zero offset. A high-pass filter will reject the clutter signal and pass the target signal. As an alternative, an FFT process will separate the clutter signal from the target signal, and will also provide target velocity information.

An MTI filter is designed to remove the clutter signal, because it is nearly at DC (having no Doppler frequency offset), except that portion of the signal that makes it through the passband. The optimum filter shape depends on expected clutter spectrum.

Pulse Doppler (PD) processing generally provides better clutter rejection because the filters are narrower and farther away from the centroid of the clutter spectrum (in the frequency domain). The thermal noise is also reduced (relative to an MTI filter) because of the narrower bandwidth.

Unfortunately, in practice, the spectral analysis processing described previously does not work as well as desired. System instabilities reduce effectiveness of these processes by spreading the Doppler frequency of clutter, which is expected to be in the zero Doppler bin, into all of the other Doppler bins. Though a major portion of the clutter signal is in the first few bins, remembering that we want to reject the clutter by 100 dB, only a very small portion of the clutter is allowed in the Doppler bin of the target.

There are several primary contributors to system instability. The most prevalent is oscillator phase noise. Others include timing jitter, amplifier additive noise, A/D quantization, and I/Q detector effects.

Oscillator phase noise is one of the major contributors to this effect. Figure 17.17 shows the phase noise that can be expected from oscillators at a variety of common radar bands. The spectral spreading shown, modified by sampling effects and range ambiguity effects, is a measure of the subclutter visibility that can be achieved.

Electronic Countermeasures (ECM)

The ECM environment in which a radar system must operate is complicated by several factors. First, improvements in electronic warfare (EW) technology such as digital RF memory (DRFM) and solid-state amplifiers are making certain ECM techniques more feasible and effective. Second, EW technology and export systems are widely available to emerging nations as well as the rest of the world on the international market. Third, the performance demands placed on the area-defense and self-defense systems allow very little margin for ECM-induced degradation.

The ECM environment will potentially consist of active and passive techniques that attempt to achieve denial or deception against the radar in its various modes. Examples of possible ECM techniques include barrage noise, responsive spot noise, repeater noise, range false targets, angle false targets, Doppler false targets, range track error, angle track error, Doppler track error, active and passive decoys, chaff,

and high-power RF directed energy. The ECM platform geometry may be self-screening jamming (SSJ), stand-off jamming (SOJ), stand-in jamming (SIJ), or escort jamming (ESJ). ECM platforms include fighters, bombers, helicopters, unmanned aerial vehicles (UAVs), ships, and land-based jammers. The ECM environment parameters of interest include the number of jammers, their spatial distribution and motion, the ECM effective radiated power (ERPs), the ECM waveforms, the electronic support measures (ESM) sensitivity, and the ECM activation conditions, for example.

The potential effects of the ECM environment must be assessed for the candidate radar designs for different operational scenarios and radar functions. The operational scenarios are important because different radar waveforms may be used in open sea vs. littoral environments, against sea-skimmers vs. high divers, and against ballistic missiles vs. antiship cruise missiles. The radar functions to be considered include surveillance, verification, acquisition, track initiation, target tracking, target classification/identification, and target designation functions. For each operational scenario, the radar functions that are at risk of being degraded by the specified ECM environments must be identified. The extent of the degradation of each function must be assessed by characterizing effects such as: reduced probability of detection, increased probability of false alarm, delay in acquisition, delay in track initiation, false target acquisition, false data association, track error, increased occupancy requirements, increased integration time requirements, and track file overload.

Electronic counter-countermeasures (ECCM) requirements must be based on the assessment of ECM degradations for each radar function. These ECCM requirements may potentially impact hardware design, software design, or both. Examples of the ECCM techniques and radar system design features that may be considered include: adaptive digital beam forming, sidelobe cancellation, sidelobe blanking, polarization diversity, polarization purity, high-resolution range, high-resolution Doppler, superresolution, mainbeam nulling, mainbeam cancellation, frequency agility, waveform agility, passive environmental sensing, spoof waveforms, sidelobe reduction, target identification, interleaved antenna beam waveforms, range-Doppler correlation, angle gating, monopulse-in-search, burnthrough, and passive tracking. The ECCM requirements for each candidate radar design may differ based on bandwidth, peak power, and duty cycle associated with the respective radar technologies.

Defining Terms

Accuracy: The amount of error in the estimated value of a signal parameter.

Bandwidth: The range of frequencies over which a system instantaneously operates, i.e., passes a signal, usually taken as the difference between the upper -3 dB point in the response and the lower -3 dB point.

Beamwidth: The range of angles over which the antenna system has instantaneous response, usually taken as the difference between the -3 dB points in the one-way antenna pattern.

Data processor: That portion of a radar system designed to operate on the narrow-band signal out of the signal processor, e.g., thresholding, Kalman filtering, tracking, etc. Dwell-to-dwell processing is performed in the data processor.

Dynamic range: The ratio between the maximum signal power within the linear operating regime of the radar receiver and the minimum detectable signal.

Instability: Random variations in component parameters leading to undesired amplitude, phase, or frequency variations in the received signal.

Loss: Ohmic loss in S/N is due to signal dissipation across a resistive load imposed by a component, whereas while nonohmic loss is due to impedance mismatch so that the reflectance coefficient between adjacent components is greater than 0. In a radar system, loss can also occur as a less-than-ideal gain in the signal processing function.

Mainlobe: A signal response within the region (in time, angle, and/or frequency) within which the radar is attempting to maximize its sensitivity.

Oscillator: Device for producing a precise sinusoidal reference signal.

Pulse compression: The coding and processing of a pulse of long duration to one of short time duration and relatively fine range resolution while providing S/N commensurate with the long pulse duration.

Receiver: That portion of a radar system allocated the task of amplifying, filtering, and detecting the energy reflected from a target and captured by the antenna subsystem.

Resolution: The degree to which two signals of nearly equal value can be separated in some dimension, such as range, angle, and/or frequency

Sidelobes: An undesired signal response in time, frequency, or angle outside the extent where the radar is attempting to maximize sensitivity

Signal processor: The portion of a radar system that operates on the wideband (video) signal by employing some algorithm for a particular effect, e.g., integration, high-pass filtering, and fast Fourier transform (FFT) processing. Pulse-to-pulse and single-dwell processing is performed in the signal processor.

System noise temperature: The equivalent temperature of a passive device yielding the same thermal noise power per unit bandwidth as the system under test.

Transmitter: That portion of a radar system allocated the responsibility for generating the radio frequency (RF) signal that is launched in the desired direction.

17.3 Electronic Navigation Systems

Benjamin B. Peterson

17.3.1 Introduction

In an attempt to treat electronic navigation systems in a single chapter, one must either treat lightly or completely ignore many aspects of the subject. Before going into detail on some specific topics, I would like to point out what is discussed and what is not in this chapter and why, and where interested readers can go for missing topics or more details. The chapter begins with fairly brief descriptions of the U.S. Department of Defense satellite navigation system, NAVSTAR Global Positioning system (GPS), its Russian counterpart, Global Navigation Satellite System, (GLONASS), and LORAN C. For civil use of GPS and GLONASS there are numerous existing and proposed augmentations to improve accuracy and integrity which will be mentioned briefly. These include maritime Differential GPS, the FAA Wide Area Augmentation System (WAAS), and Local Area Augmentation System (LAAS) for aviation. The second half of the chapter looks in detail at how position is determined from the measurements from these systems, the relationships between

geometry, and the statistics of position and time errors. It also considers how redundant information may be optimally used and how information from multiple systems can be integrated.

GPS and its augmentations were chosen because they already are and will continue to be the dominant radionavigation technologies well into the next century. GLONASS, could potentially become significant, by itself, and potentially integrated with GPS. LORAN C is included while other systems were not for a variety of reasons. The combination of its long history and military significance dating back to World War II, and its large user base, has resulted in a wealth of research effort and literature. Because the basic principle of LORAN C, that is, the measurement of relative times of arrival of signals from precisely synchronized transmitters, is the same as that of GPS, it is both interesting and instructive to analyze the solution for position of both systems in a unified way. While the future of LORAN C in the U.S. is uncertain (DoD/DoT, 1999), it is expanding in Europe and Asia and may remain significant on a worldwide basis for many years. Since LORAN C has repeatable accuracy adequate for many applications, because it is more resistant to jamming, has failure modes independent of those of GPS, and because its low frequency signals penetrate locations like urban canyons and forests better than those of GPS, analysis of its integration with GPS is felt useful and is included.

Of other major systems, VHF omnidirectional range (VOR), instrument landing system (ILS), distance measuring equipment (DME), and microwave landing system (MLS) are relatively shorter range aviation systems that are tentatively planned to be phased out in favor of GPS/WAAS/LAAS beginning in 2008. (DoD/DoT, 1999). Due to space and because their principles of operation differ from GPS they are not included. The U.S. Institute of Navigation in its 50th Anniversary issue of Navigation published several excellent historical overviews. In particular, see Enge (1995) for sections on VOR, DME, ILS, and MLS, and Parkinson (1995) for the history of GPS.

Recently, there has been a significant and simultaneous reduction in the printing of U.S. Government documents and increased distribution of this information via the Internet. Details on Internet and other sources of additional information are included near the end.

17.3.2 The Global Positioning System (NAVSTAR GPS)

GPS is a U.S. Department of Defense (DoD) developed, worldwide, satellite-based radionavigation system that will be the DoD's primary radionavigation system well into the 21st century. GPS full operational capability (FOC) was declared on July 17, 1995 by the Secretary of Defense and meant that 24 operational satellites (Block II/IIA) were functioning in their assigned orbits and the constellation had successfully completed testing for operational military functionality.

GPS provides two levels of service—a standard positioning service (SPS) and a precise positioning service (PPS). SPS is a positioning and timing service, which is available to all GPS users on a continuous, worldwide basis. SPS is provided on the GPS L1 frequency, which contains a coarse acquisition (C/A) code and a navigation data message. The current official specifications state that SPS provides, on a daily basis, the capability to obtain horizontal positioning accuracy within 100 m (95% probability) and 300 m (99.99% probability), vertical positioning accuracy within 140 m (95% probability), and timing accuracy within 340 nanosec (95% probability). For most of the life of GPS, the civil accuracy was maintained at approximately these levels through the use of selective availability (SA) or the intentional degradation of accuracy via the dithering of satellite clocks. In his Presidential Decision Directive in 1996, President Clinton committed to terminating SA by 2006. On May 1, 2000, in a White House press release (White House, 2000) the termination of SA was announced and a few hours later it was turned off. Work is starting on a new civil GPS signal specification with revised accuracy levels. Very preliminary data, as this are begin written in late May 2000, indicate 95% horizontal accuracy of approximately 7 m will be possible under some conditions. When SA was on, it was the dominant error term; accuracy for all receivers with a clear view of the sky was easily predictable and independent of other factors. Now, it is expected that terms such as multipath and ionospheric delay, which vary greatly with location, time, and receiver and antenna technology will dominate, and exact prediction of error statistics will be more difficult.

The GPS L1 frequency also contains a precision (P) code that is not a part of the SPS. PPS is a highly accurate military positioning, velocity, and timing service which is available on a continuous, worldwide basis to users authorized by the DoD. PPS is the data transmitted on GPS L1 and L2 frequencies. PPS is designed primarily for U.S. military use and is denied to unauthorized users by the use of cryptography. Officially, P-code capable military user equipment provides a predictable positioning accuracy of at least 22 m (2 drms) horizontally and 27.7 m (2 sigma) vertically, and timing/time interval accuracy within 90 nanosec (95% probability).

The GPS satellites transmit on two L-band frequencies: L1 = 1575.42 MHz and L2 = 1227.6 MHz. Three pseudo-random noise (PRN) ranging codes are in use giving the transmitted signal direct sequence, spread spectrum attributes. The coarse/acquisition (C/A) code has a 1.023 MHz chip rate, a period of one millisecond (msec), and is used by civil users for ranging and by military users to acquire the P-code. Bipolar-phase shift key (BPSK) modulation is utilized. The transmitted PRN code sequence is actually the Modulo-2 addition of a 50Hz navigation message and the C/A code. The SPS receiver demodulates the received code from the L1 carrier, and detects the differences between the transmitted and the receiver-generated code. The SPS receiver uses an exclusive or truth table, to reconstruct the navigation data, based upon the detected differences in the two codes. Ward (1994–1995) contains an excellent description of how receivers acquire and track the transmitted PRN code sequence.

The precision (P) code has a 10.23 MHz rate, a period of seven days, and is the principle navigation ranging code for military users. The Y-code is used in place of the P-code whenever the antispoofing (A-S) mode of operation is activated. *Antispoofing* (A-S) guards against fake transmissions of satellite data by encrypting the P-code to form the Y-code. A-S was exercised intermittently through 1993 and implemented on January 31, 1994. The C/A code is available on the L1 frequency and the P-code is available on both L1 and L2. The various satellites all transmit on the same frequencies, L1 and L2, but with individual code assignments.

Each satellite transmits a navigation message containing its orbital elements, clock behavior, system time and status messages. In addition, an almanac is provided that gives the approximate data for each active satellite. This allows the user set to find all satellites once the first has been acquired. Tables 17.4 and 17.5 include examples of ephemeris and almanac information for the same satellite at approximately the same time.

The nominal GPS constellation is composed of 24 satellites in six orbital planes, (four satellites in each plane). The satellites operate in circular 20,200-km altitude (26,570 km radius) orbits at an inclination angle of 55° and with a 12-h period. The position is therefore the same at the same sidereal time each day, that is, the satellites appear four minutes earlier each day.

The GPS control segment consists of five monitor stations (Hawaii, Kwajalein, Ascension Island, Diego Garcia, Colorado Springs), three ground antennas, (Ascension Island, Diego Garcia, Kwajalein), and a master control station (MCS) located at Falcon AFB in Colorado. The monitor stations passively track all satellites in view, accumulating ranging data. This information is processed at the MCS to determine

Navigation Health Status is: All Data OK
Signal Health Status is: All Signals OK

satellite orbits and to update each satellite's navigation message. Updated information is transmitted to each satellite via the ground antennas.

The GPS system uses time of arrival (TOA) measurements for the determination of user position. A precisely timed clock is not essential for the user because time is obtained in addition to position by the measurement of TOA of four satellites simultaneously in view. If altitude is known (e.g., for a surface user), then three satellites are sufficient. If a stable clock (say, since the last complete coverage) is keeping time, then two satellites in view are sufficient for a fix at known altitude. If the user is, in addition, stationary or has a known speed then, in principle, the position can be obtained by the observation of a complete pass of a single satellite. This could be called the "transit" mode, because the old transit system used this method. In the case of GPS, however, the apparent motion of the satellite is much slower, requiring much more stability of the user clock.

The May 2000 GPS constellation consists of 28 satellites counting 27 operational and one recently launched and soon to become operational. Figure 17.18 and Figure 17.19 illustrate the history of the constellation including both the limiting dates of the operational periods, individual satellites, and the total number available as a function of time.

**FIGURE 17.18** Operational lifetimes of GPS satellites.

FIGURE 17.19 GPS history.

GPS Augmentations

Many augmentations to GPS exist to improve accuracy and provide integrity. These are both government operated (for safety of life navigation applications) and privately operated. This section will only deal with government operated systems. The recent termination of selective availability has sparked some debate on the need for GPS augmentation, but the most prevalent views are that stand-alone GPS will not satisfy all accuracy and integrity requirements, and that some augmentation will continue to be necessary. Since the dominant post-SA errors vary much more slowly than SA-induced errors did, the information bandwidth requirements to meet specified accuracy levels have certainly been reduced. Since integrity requirements specify maximum times to warn users of system faults, these warning times and time to first fix specifications will now drive information bandwidth requirements.

The simplest and first to become operational were maritime differential GPS stations. Existing radio-beacons in the 285 to 325 kHz band were converted to transmit differential corrections via a minimum shift keyed (MSK) modulation scheme. A base station receiver in a fixed, known location measures pseudo-range errors relative to its own clock and known position. Messages containing the time of observation, these pseudo-range errors, and their rate of change are then transmitted at either 100 or 200 baud. Parity bits are added, but no forward error correction is used. If the user receiver notes a data error, it merely waits for the next message. The user receiver uses the corrections extrapolated ahead in time based on the age of the correction and its rate of change. For a description of the message format the reader is referred to (RTCM, 1992.)

With SA on, satellite clock dithering was the dominant error and was common to all users. It is also assumed that over the few hundred kilometers or less where the signal can be received, that errors such as ephemeris and ionospheric and tropospheric delay are correlated between base station and user receiver as well and can be considerably reduced. The algorithms to predict these delays are disabled in both the base station and user receivers.

Because the corrections are measured relative to the base station clock, they are relative and not absolute corrections. This means they must have corrections for all satellites used for a position and all of these corrections must be from the same base station. For fixed position, precise time users, DGPS provides no improvement in accuracy. For moving users, their solution for time will track the base station clock, and

since this base station receiver is in a fixed known location, the time solution in the moving receiver will see improved accuracy as well.

The U. S. Coast Guard operates maritime DGPS along the coasts and rivers. In addition, the system is being expanded inland in support of the Federal Railroad Administration in the National DGPS project. Many foreign governments worldwide operate compatible systems primarily for maritime applications. RTCM type DGPS messages are also transmitted by modulating LORAN C transmitters in Europe. Additional details on this system known as EUROFIX are included in the later section on LORAN C.

Three satellite based augmentation systems (SBASs) for aviation users are in various stages of development. These include

1. the wide area augmentation system (WAAS) by the U.S. FAA
2. the European geostationary navigation overlay system (EGNOS) jointly by the European Union, the European Space Agency (ESA), and EUROCONTROL, and
3. MTSAT satellite based augmentation system (MSAS) by the Japan Civil Aviation Bureau (JCAB)

These systems are intended for the enroute, terminal, nonprecision approach, and Category I (or near Category I) precision approach phases of flight. All of these systems are designed to be compatible, and to the level of detail in this chapter, are equivalent. For additional details on all three systems the reader is referred to Walter (1999) and to RTCA (1999) for the WAAS signal specification. In SBASs corrections need to be applied over the very large geographic area in which the satellite signal can be received. In this case the errors due to satellite ephemeris and ionospheric delay are not the same for all users and cannot be combined into one overall correction. Separate messages are provided for satellite clock corrections, vector corrections of satellite position and velocity, integrity information, and vertical ionospheric delay estimates for selected grid points. These grid points are at 5° increments in latitude and longitude, except larger increments occur in extreme northern or southern latitudes. The user receiver calculates its estimates of ionospheric delay by first determining the ionospheric pierce point of the propagation path from satellite to user receiver, interpolating between grid points, and then correcting for slant angle.

These corrections are or will be transmitted from geostationary satellites at GPS L1 frequencies with signal characteristics similar to GPS. The SBASs will provide additional ranging signals and transmit their own ephemeris information to improve fix availability. Message symbols at 500 symbols/sec will be modulo 2 added to a 1023 bit PRN code. The baseline data rate is 250 bits/sec. These data are rate $1/2$ convolutional encoded with a forward error correction code resulting in 500 symbols per second. The data will be sent in 250-bit blocks or 1 block/sec. The data block contains an eight-bit preamble, a six-bit message type, a 212-bit message, and 24 bits of CRC parity.

For Category II and III precision approach, the U.S. FAA will implement the local area augmentation system (LAAS). The transmitted data will include pseudo-range correction data, integrity parameters, approach data, and ground station performance category. The broadcast will be in the 108 to 117.95 MHz band presently used for VOR and ILS systems.

The modulation format is a differentially encoded, eight-phase-shift-keyed (D8PSK) scheme. The broadcast uses an eight-time-slot-per-half-second, fixed-frame, time-division-multiple-access (TDMA) structure. The total data rate of the system is 31,500 bits/sec. After the header and cyclic redundancy check (CRC), the effective rate of the broadcast is 1776 bits (222 bytes) of application data per time slot, or a total of 16×1776 BPS equaling 28,416 application data bits/sec. For additional information on LAAS the reader is referred to Braff (1997) and Skidmore (1999).

17.3.3 Global Navigation Satellite System (GLONASS)

GLONASS is the Russian parallel to GPS and has its origins in the mid-1970s in the former Soviet Union. Like GPS, the system has been primarily developed to support the military, but in recent years has been broadened to include civilian users. In September 1993, Russian President Boris Yeltsin officially proclaimed GLONASS to be an operational system and the basic unit of the Russian Radionavigation Plan. The well-publicized political, economic, and military uncertainties within Russia have undoubtedly hampered the

FIGURE 17.20 Operational lifetimes of GLONASS satellites.

implementation and maintenance of the system. These issues combined with the poor reliability record of the early satellites, raised questions relative to its eventual success. Figure 17.20 and Figure 17.21 show data on the operational life of those satellites that became operational from the first one in 1982 through the present. It is also believed that attempts were made to place approximately 10 or more other satellites into operation resulting in failure for a number of reasons (Dale, 1989). However, in the mid-1990s, the reliability of the satellites considerably improved, and many more satellites were put in orbit such that in early 1960 there were 24 operational satellites. The triple launch on December 30, 1998 has been the only launch

FIGURE 17.21 GLONASS history.

since late 1995, and the constellation has degraded to only 10 operational satellites, again raising concerns on the future of the system. Publicly, the Russian Federation remains fully committed to the system. To date, GLONASS receivers have been quite expensive and have only been produced in limited quantities.

While similar in many respects to GPS, GLONASS does have important differences. While all GPS satellites transmit at the same frequencies and are distinguished by their PRNs, all GLONASS satellites transmit the same PRN and are distinguished by their frequencies. The L1 transmitted frequencies in MHz are given by $1602 + 0.5625 \times \text{Channel Number}$, which extends from 1602.5625 to 1615.5 MHz. L2 frequencies are $\frac{7}{9}$ L1 and in MHz are given by $1246 + 0.4375 \times \text{Channel Number}$ or from 1246.4375 to 1256.5 MHz. GLONASS satellites opposite to each other in the same orbit plane have been assigned the same channel number and frequency to limit spectrum use. Like GPS, the C/A code is transmitted on L1 only, and P code on both L1 and L2. The C/A code is 511 chips long at 511 KBPS for a length of 1 ms. The P code is at 5.11 MBPS. Like GPS, the actual modulation is the Modulo-2 addition of the PRN sequence and 50 BPS data and BPSK modulation is used.

The GLONASS planes have a nominal inclination of 64.8° compared to 55° for GPS, which gives slightly better polar fix geometry at the cost of fix geometry at lower latitudes. The 24 slots are in three planes of eight slots each. The orbital altitude is 25,510 km or 1050 km less than GPS. The orbit period is 11 h, 15 min.

Rather than transmitting ephemeris parameters as in GPS, GLONASS satellites transmit actual position, velocity, and acceleration in Earth centered, Earth fixed (ECEF) coordinates that are updated on half-hour intervals. The user receiver integrates using Runge-Kutta techniques for other times. All monitor sites are within the former Soviet Union, which limits accuracy of both ephemeris and time and would delay user notification of satellite failures. The system produces both high accuracy signals for Russian military use only and lesser accuracy for civilian use. The civilian use signals are not degraded to the same extent as GPS was with SA, which resulted in significantly better accuracy than civil GPS during the period GLONASS had a complete constellation. Military accuracy is classified. For more details the reader is referred to the GLONASS Interface Control Document (CSIC, 1998) available at http://www.rssi.ru/sfcsic/sfcsic_main.html

17.3.4 LORAN C History and Future

Early in World War II, both the U.S. and Great Britain recognized the need for an accurate, long range, radionavigation system to support military operations in Europe. As a result the British developed Gee and the U.S. developed LORAN (long range navigation). Both were pulsed, hyperbolic systems with time differences between master and secondary transmitters measured by an operator matching envelopes on a delayed sweep CRT. Gee operated at several carrier frequencies from 20 to 85 MHz and had a pulse width of 6 usec. Standard LORAN (or LORAN A) operated at 1.95 MHz and had a pulse width of 45 usec. The first LORAN A chain was completed in 1942 and by the end of the war 70 stations were operating. For details on the World War II LORAN effort see Pierce (1948).

It was recognized that lower frequencies would propagate longer distances, and near the end of the war testing began on a 180-kHz system. The pace of development slowed considerably after the war. The band from 90 to 110 kHz was established by international agreement for long-range navigation. In 1958, system tests started on the first LORAN C chain, which consisted of stations at Jupiter, FL, Carolina Beach, NC, and Martha's Vineyard, MA.

Over the next two decades LORAN C coverage was expanded by the U.S. Coast Guard in support of the Department of Defense to much of the U.S. (including Alaska and Hawaii), Canada, northwest Europe, the Mediterranean, Korea, Japan, and Southeast Asia. The Southeast Asia chain ceased operations with the fall of South Vietnam in 1975. In 1974 LORAN C was designated as the primary means of navigation in the U.S. Coastal Confluence Zone (CCZ), the cost of civilian receivers declined sharply, and the civil maritime use of the system became very large. In the late 1980s at the request of the Federal Aviation Administration, the Coast Guard built four new stations in the mid-continent and established LORAN C coverage for the entire continental U.S.

Other countries are developing and continuing LORAN C to meet their future navigational needs. Many of the recent initiatives have taken place as a result of the termination of the U.S. DoD requirement

for overseas LORAN C. This need came to an end as of December 31, 1994. With the introduction of GPS, many countries have decided that it is in their own best interests not to have their navigational needs met entirely by a U.S. DoD-controlled navigation system. Many of these initiatives have resulted in multilateral agreements between countries which have common navigational interests in those geographic areas where LORAN C previously existed to meet U.S. DoD requirements (e.g., northern Europe and the Far East). The countries of Norway, Denmark, Germany, Ireland, the Netherlands, and France established a common LORAN C system under the designation The Northwest European LORAN C System (NELS). Recently the governments of Italy and the United Kingdom have applied for membership. This system presently comprises eight stations forming four chains. In conjunction with this system, respective foreign governments took over operation of the former USCG stations of B0 and Jan Mayen, Norway; Sylt, Germany; and Ejde, Faroe Islands (Denmark) as of 31 December 1994. The two French stations formerly operated by the French Navy in the rho-rho mode were reconfigured and included and two new stations in Norway were constructed. A planned ninth station at Loop Head, Ireland has yet to be constructed. The former USCG stations at Angissoq, Greenland and Sandur, Iceland were closed.

An important feature of NELS is the transmission of DGPS corrections by pulse position modulation. This concept, called EUROFIX, was developed by Professor Durk Van Willigen and his students at Delft University of Technology in the Netherlands. The last six pulses in each group are modulated in a three-state pattern of prompt and 1 usec advance or retard. Of the possible 729 combinations, 142 of which are balanced, 128 balanced sequences are used to transmit a seven-bit word. Extensive Reed Solomon error correction is used resulting in a very robust data link, although at a somewhat lower data rate than the MSK beacons. With Selective Availability on, the horizontal accuracy was 2 to 3 m, 2 DRMS, or slightly worse than conventional DGPS due to the temporal decorrelation of SA. With SA off, the performance should be virtually comparable. EUROFIX has been operating at the Sylt, Germany transmitter since February, 1997, expansion to other NELS transmitters is planned for the near future. In a joint FAA/USCG effort, preliminary testing is underway of transmitting WAAS data via a much higher data rate LORAN communications channel. If LORAN C survives in the long term, it is likely to be both as a navigation system and as a communications channel to enhance the accuracy and integrity of GPS.

In the Far East, an organization was formed called the Far East Radionavigation Service (FERNS). This organization consists of the countries of Japan, The Peoples Republic of China, The Republic of Korea, and the Russian Federation. Japan took over operation of the former USCG stations in its territory and they are currently being operated by the Japanese Maritime Safety Agency (JMSA). In the Mediterranean Sea area, the four USCG stations were turned over to the host countries. The two stations in Italy, Sellia Marina and Lampedusa, are currently being operated. The stations at Kargaburun, Turkey and Estartit, Spain remain off air. Saudi Arabia and India are currently each operating two LORAN chains.

There is ongoing debate at high levels concerning the future of LORAN C in the U.S. According to the 1999 Federal Radionavigation Plan (DoD/Dot, 1999), "While the administration continues to evaluate the long term need for continuation of the LORAN-C navigation system, the Government will operate the LORAN C system in the short term. The U.S. Government will give users reasonable notice if it concludes that LORAN C is not needed or is not cost effective, so that users will have the opportunity to transition to alternative navigational aids."

LORAN Principles of Operation

Each chain consists of three or more stations, including a master and at least two secondary transmitters. (Each master-secondary pair enables determination of one LOP, and two LOPs are required to determine a position. The algorithms to convert these LOPs into latitude and longitude are discussed in a later section.) Each LORAN C chain provides signals suitable for accurate navigation over a designated geographic area termed a *coverage area*.

The stations in the LORAN chain transmit in a fixed sequence that ensures that time differences (TDs) between a receiving master and secondary can be measured throughout the coverage area. The length of time in usec over which this sequence of transmissions from the master and the secondaries takes place

FIGURE 17.22 LORAN C pulse pattern.

is termed the group repetition interval (GRI) of the chain. All LORAN C chains operate on the same frequency (100 kHz), but are distinguished by the GRI of the pulsed transmissions.

The LORAN C system uses pulsed transmission, nine pulses for the master and eight pulses for the secondary transmissions. Figure 17.22 shows this overall pulse pattern for the master and three secondary transmitters (X, Y, and Z). Coding delay is the time between when a secondary receives the master signal and when it transmits. The time differences measured on the baseline extension beyond the secondary should be coding delay. Emission delay is the difference in time of transmission between master and secondary and is the sum of coding delay and baseline length (converted to time). Shown in Fig. 17.23 is an exploded view of the LORAN C pulse shape. It consists of sine waves within an envelope referred to as a t-squared pulse. (The equation for the envelope is also included in Fig. 17.23.) This pulse will rise from zero amplitude to maximum amplitude within the first 65 usec and then slowly trails off or decays over a 200 to 300 usec interval. The pulse shape is designed so that 99% of the radiated power is contained within

FIGURE 17.23 Ideal LORAN pulse.

TABLE 17.6 LORAN C Phase Codes.

GRI Interval	Master	Secondary
A	+ + - - + - + - +	+ + + + + - - - +
B	+ - - + + + + + -	+ - + - + + - - -

the allocated frequency band for LORAN C of 90 to 110 kHz. The rapid rise of the pulse allows a receiver to identify one particular cycle of the 100 kHz carrier. Cycles are spaced approximately 10 usec apart. The third cycle of this carrier within the envelope is used when the receiver matches the cycles. The third zero crossing (termed the positive 3rd zero crossing) occurs at 30 usec into the pulse. This time is both late enough in the pulse to ensure an appreciable signal strength and early enough in the pulse to avoid sky wave contamination from those skywaves arriving close after the corresponding ground wave.

Within each pulse group from the master and secondary stations, the phase of the radio frequency (RF) carrier is changed systematically from pulse-to-pulse in the pattern shown in Fig. 17.23 and Table 17.6. This procedure is known as phase coding. The patterns A and B alternate in sequence. The pattern of phase coding differs for the master and secondary transmitters. Thus, the exact sequence of pulses is actually matched every two GRIs, an interval known as a phase code interval (PCI).

Phase coding enables the identification of the pulses in one GRI from those in an earlier or subsequent GRI. Just as selection of the pulse shape and standard zero crossing enable rejection of certain early sky waves interfering with the same pulse, phase coding enables rejection of late sky waves interfering with the next pulse. Since seven of the fourteen pulses that come immediately before another pulse have the same phase code and seven are different, late sky waves interfering with the next pulse will average to zero. Because the master and secondary signals have different phase codes, the LORAN receiver can distinguish between them.

17.3.5 Position Solutions from Radionavigation Data

In general, closed-form solutions that allow direct calculation of position from radionavigation observables do not exist. However, the inverse calculations can be done. Given one’s position and clock offset, one can predict GPS or GLONASS pseudo-ranges or LORAN TDs or TOAs. These expressions are nonlinear but can be linearized about a point and the problem solved by iteration. The basic approach can be summarized by

1. Assuming a position
2. Calculating the observables one should have seen at that point
3. Calculating rate of change of observables (partial derivatives) as position is varied
4. Comparing calculated to measured observables
5. Computing a new position based on differences between calculated and measured observables
6. Depending on exit criteria, either exit algorithm or return to “b” above using the calculated position as the new assumed position

We will look at the details of each of these steps and the expected statistics of the results for a number of cases. We will start with the example of processing three LORAN TOAs (or two TDs), but the basic principles apply to GPS as well. We will then consider overdetermined solutions and the techniques for assuring the solutions are optimal in some sense. We will also consider integrated solutions and Kalman filter based solutions.

For LORAN the calculated times of arrival (TOAs) are given by

For Master $TOA_m = d_i$
 and for secondaries $TOA_i = d_i + ED_i$, etc.

where d_m and d_i are the propagation times from the master and *i*th secondary stations to the assumed position and ED_i is emission delay. (Note: Secondary stations are designated by the letters *V, W, X, Y*,

and Z , but because we will also want to use x and y for position variables, in order to avoid confusion, we will use integer subscripts to denote secondaries.) The LORAN propagation times are the sums of three terms:

1. *Primary factor* (PF) or the geodesic distance to the station divided by a nominal phase velocity. See WGA (1982, 57–61) for an algorithm that will work to distances up to 3000 nautical miles.
2. *Secondary factor* (SF) which takes into account the additional phase lag due to the signal following a curved earth surface over an all-seawater path (see COMDT (G-NRN) 1992, II-14 for formula), and
3. *Additional secondary factor* (ASF) which takes into account the difference between the actual path traveled and an all-seawater path. This factor can be calculated based on conductivity maps, or can be obtained by tables (from the U.S. Defense Mapping Agency) or from charts published by the Canadian government. The latter two are based both on calculations and observations.

A typical LORAN receiver measures time differences (TDs) vs. TOAs and the receiver need not necessarily solve for time. In GPS or GLONASS, since the transmitters move rapidly with time, in order to know their location it is essential that an explicit solution for time be made. In GPS each satellite transmits ephemeris parameters which, when substituted in standard equations (NATO, 1991, A-3-26 and 27), give the satellite location as a function of time expressed in Earth centered, Earth fixed (ECEF) coordinates. In this system, the positive x axis goes from the Earth's center to 0° latitude and longitude, the positive y axis goes from the Earth's center to 0° latitude and 90°E longitude, and the positive z axis goes from the Earth's center to 90°N latitude. For GLONASS, the satellites transmit their location, velocity, and acceleration, in ECEF coordinates, and validate at half-hour intervals. The user is expected to numerically integrate the equations on motion to obtain position for a particular time.

The receiver measures the time of arrival of the satellite signal, and since the signal is tagged precisely in time, the difference in time of transmission and time of arrival (converted to distance) is a pseudo-range. "Pseudo" is used as the time of arrival is relative to the receiver clock, which cannot be assumed exact but must be solved for as part of the solution. These pseudo-ranges are then corrected for both ionospheric and tropospheric delay. In civil C/A code receivers, ionospheric delay parameters are transmitted and the delay calculated via an algorithm (NATO, 1991, p A-6-31). For dual frequency receivers, the ionospheric delay is assumed to be inversely proportional to frequency and the delay determined from the difference in pseudo-ranges at the two frequencies. For differential GPS, ionospheric delay is assumed to be the same at the reference station and the user's location and the algorithm is disabled at both locations.

Solution Using Two TDs (LORAN Only)

TDs at the assumed position are calculated (TD_p) and subtracted from observations (TD_o), i.e.,

$$\begin{aligned} \text{TD}_i &= \text{TOA}_i - \text{TOA}_m \\ \Delta\text{TD} &= \begin{bmatrix} \Delta\text{TD}_1 \\ \Delta\text{TD}_2 \end{bmatrix} = \text{TD}_o - \text{TD}_p \end{aligned}$$

This difference in TDs can be linearly related to a difference in position $\Delta P = \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}$ by

$$\begin{bmatrix} \sin(\phi_m) - \sin(\phi_1) & \cos(\phi_m) - \cos(\phi_1) \\ \sin(\phi_m) - \sin(\phi_2) & \cos(\phi_m) - \cos(\phi_2) \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} = c \begin{bmatrix} \Delta\text{TD}_1 \\ \Delta\text{TD}_2 \end{bmatrix}$$

where ϕ_m , ϕ_1 , and ϕ_2 are the azimuths to the transmitters measured in a clockwise direction from the north or positive y direction as shown in Fig. 17.24. While exact calculations taking into account the ellipsoidal nature of the shape of the Earth must be used in the calculation of predicted TDs, only approximate

FIGURE 17.24 Definition of LORAN azimuths.

expressions based on a spherical earth are necessary to determine azimuths. The expression above can be expressed in matrix form:

$$A_{TD} \Delta P = c \Delta TD$$

and solved by

$$\Delta P = c A_{TD}^{-1} \Delta TD$$

At this point a new assumed position would be calculated (using an appropriate conversion of meters to degrees), the predicted TDs at that location determined, and if they were within a selected tolerance of the measured, the algorithm would stop, otherwise a new solution would be determined. An alternative criteria based on the movement of the assumed position, $|\Delta P|$, can be used as well and will be more appropriate in an over-determined solution because exact match of TDs is not possible. Figure 17.25 and Figure 17.26 show typical convergence of this type of algorithm. Since the algorithm is based on the assumption that the TD grid is linear in the vicinity of the assumed position, we need to limit the step size so that the position does not jump to radically different geometry in one step. As can be seen in Fig. 17.25 all lines of constant TD between two transmitters are closed curves on the Earth's surface. Two of these curves intersect, either do not intersect, or intersect exactly twice. Since we assume we are starting with a set of TDs that exist, the latter applies. The initial assumed position is what determines to which of these two ambiguous positions the algorithm will converge. Essentially since the algorithm is based on the gradient of the TDs with respect to change in position and that gradient changes sign on the baseline extension, the position will move to the solution it can reach without crossing a baseline extension. The direction of the gradient, and hence the final solution also changes as the lines of constant TD become parallel as at 30°N and 10°E in Fig. 17.26.

FIGURE 17.25 Convergence of position solution algorithm.

Frequently, as shown in the Fig. 17.25, one of these ambiguous positions is well beyond the range the signals can be received and can easily be eliminated. This is not true when one of the solutions is near the baseline extension as shown in Fig. 17.26. In this example, it is necessary to have prior knowledge that the actual position is North or South of the master station.

FIGURE 17.26 Example of position solution with close by ambiguous position.

Solution Using TOAs

This method yields a solution for receiver clock bias (modulo one phase code interval) and even though not generally implemented in present receivers, is presented for a number of reasons:

1. It is functionally equivalent to the GPS position solution but is presented first because it is a two vs. three-dimensional and is somewhat easier to visualize.
2. For the exactly determined (two-TD or three-TOA) case it is exactly equivalent to the TD solution and therefore we can extend results from TOA or pseudo-range analysis to the TD case. Early LORAN TD analysis was typically done in scalar form before computer programs such as spreadsheets and MatLab™ made matrix calculations trivial. GPS fix analysis has typically been expressed in matrix form resulting in simpler expressions.
3. For over-determined solutions, since we can assume TOA errors are statistically independent, but cannot make the same assumption for TD errors, the solution is slightly easier to implement and analyze.
4. Solutions using Kalman filters, integrated GPS/LORAN, or a precise clock with only two TOAs, will typically be based on TOAs vs. TDs.

The vector difference between observed (TOA_o) and predicted (TOA_p) TOAs are calculated via

$$\Delta TOA = TOA_o - TOA_p$$

Equation is replaced by

$$- \begin{bmatrix} \sin(\phi_m) & \cos(\phi_m) & 1 \\ \sin(\phi_1) & \cos(\phi_1) & 1 \\ \sin(\phi_2) & \cos(\phi_2) & 1 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \\ c \Delta t \end{bmatrix} = c \begin{bmatrix} \Delta TOA_m \\ \Delta TOA_1 \\ \Delta TOA_2 \end{bmatrix}$$

or

$$a_{TOA} \Delta P = c \Delta TOA$$

and solved by

$$\Delta P = c A_{TOA}^{-1} \Delta TOA$$

It is useful to think of the sines and cosines in the matrix as the cosines of the angles between the positive direction of the coordinate axes and the directions to the transmitters. This concept can be easily extended to the three-dimensional case in GPS or GLONASS solutions. For a normal GPS-only solution it is usually more convenient to express both satellite and user positions in an Earth centered, Earth fixed (ECEF) coordinate system. In this case the direction cosines are merely the difference of the particular coordinate divided by the range to each satellite. After position solution, an algorithm is used to convert from (xyz) to latitude, longitude, and altitude. An alternative that will prove useful for meaningful dilution of precision (DOP) calculations or for integrated GPS/LORAN receivers is to use a East/North/altitude coordinate system and to solve for the azimuth (AZ) and elevation (EL) of the satellites. In this case the direction cosines for each satellite become

- East: $\sin(AZ) \cos(EL)$
- North: $\cos(AZ) \cos(EL)$
- Altitude: $\sin(EL)$

Error Analysis

With only three TOAs this solution will be exactly the same as the two-TD solution above. In both of these solutions after the algorithm has converged, we can consider ΔTOA or ΔTD as measurement errors and ΔP as the position error due to these errors. The covariance of the errors in position (and in time for TOA

processing) can be expressed as functions of the direction cosine matrix and the covariance of the TDs or TOAs.

$$\Delta P \Delta P^T = c^2 A_{\text{TD}}^{-1} \Delta \text{TD} \Delta \text{TD}^T (A_{\text{TD}}^{-1})^T$$

$$\text{cov}(\Delta P) = E \{ \Delta P \Delta P^T \} = c^2 A_{\text{TD}}^{-1} E \{ \Delta \text{TD} \Delta \text{TD}^T \} (A_{\text{TD}}^{-1})^T = c^2 A_{\text{TD}}^{-1} \text{cov}(\Delta \text{TD}) (A_{\text{TD}}^{-1})^T$$

$$\text{cov}(\Delta P) = c^2 A_{\text{TOA}}^{-1} \text{cov}(\Delta \text{TOA}) (A_{\text{TOA}}^{-1})^T$$

Given that the covariances of the measurements are known it becomes a simple task to evaluate the covariance of the position errors. We will first assume each TOA measurement is uncorrelated, that is,

$$\text{cov}(\Delta \text{TOA}) = \begin{bmatrix} \sigma_m^2 & 0 & 0 \\ 0 & \sigma_1^2 & 0 \\ 0 & 0 & \sigma_2^2 \end{bmatrix}$$

and

$$\text{cov}(\Delta \text{TD}) = \begin{bmatrix} \sigma_m^2 + \sigma_1^2 & \sigma_m^2 \\ \sigma_m^2 & \sigma_m^2 + \sigma_2^2 \end{bmatrix}$$

For simplicity we will also assume each TOA measurement has the same variance (σ_{TOA}^2). While this assumption is not in general valid, particularly for LORAN C, it is useful in that it allows us to separate out purely fix geometry from signal-in-space issues. Under this assumption

$$\text{cov}(\Delta \text{TOA}) = \sigma_{\text{TOA}}^2 I$$

and

$$\text{cov}(\Delta \text{TD}) = \sigma_{\text{TOA}}^2 \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$$

For the particular case of the same number of measurements and unknowns, these both yield the same results:

$$\text{cov}(\Delta P) = \begin{bmatrix} \sigma_x^2 & \sigma_{xy} & c\sigma_{xt} \\ \sigma_{xy} & \sigma_y^2 & c\sigma_{yt} \\ c\sigma_{xt} & c\sigma_{yt} & c^2\sigma_t^2 \end{bmatrix} = c^2 \sigma_{\text{TOA}}^2 A_{\text{TOA}}^{-1} (A_{\text{TOA}}^{-1})^T = c^2 \sigma_{\text{TOA}}^2 [A_{\text{TOA}}^T A_{\text{TOA}}]^{-1}$$

What is significant is that the matrix $G = [A_{\text{TOA}}^T A_{\text{TOA}}]^{-1}$ is a dimensionless multiplier that relates our ability to measure the range to a transmitter (LORAN station or GPS satellite). In GPS, (NATO GPS 1991) $\sqrt{\text{trace}(G)}$ is defined as the geometric dilution of precision (GDOP), which includes the time term. (NATO GPS 1991). In LORAN C, since convention has been not to explicitly solve for time, GDOP is normally considered as $\sqrt{G_{11} + G_{22}}$, which only contains horizontal position terms and is equivalent to horizontal dilution of precision (HDOP) in GPS. Since we want to consider both LORAN and GPS in a consistent, integrated way, we will use HDOP and reserve GDOP for expressions including time term. The scalar expression for this quantity is

$$\text{HDOP} = \frac{1}{\sqrt{2} \sin(C)} \sqrt{\frac{1}{\sin^2(A/2)} + \frac{1}{\sin^2(B/2)} + \frac{\cos(C)}{\sin(A/2) \sin(B/2)}}$$

where A and B are the angles from the Master to each secondary and $C = \frac{A+B}{2}$. Figure 17.27 shows contours of constant HDOP as functions of these two angles. While the horizontal accuracy in one dimension is well defined ($\sigma_x^2 = G_{11} c^2 \sigma_{\text{TOA}}^2$, for example), the two-dimensional accuracy is slightly more complex. Generally the terms drms and 2 drms accuracy are used to refer to the one-sigma and two-sigma accuracies. For example

$$2 \text{ drms horizontal accuracy} = 2 \text{ HDOP } c\sigma_{\text{TOA}}$$

FIGURE 17.27 HDOP as function of angles from master to secondaries.

A circle of this radius should contain between 95.4 and 98.2% of the fixes depending on the eccentricity of the error ellipse describing the distribution of the fixes. For example, if $\sigma_x = \sigma_y$ and $\sigma_{xy} = 0$, the error ellipse becomes a circle and one of radius 2 drms contains $(1 - \exp(-4)) = 98.2\%$. In the other extreme, when the ellipse collapses to a line ($\sigma_{xy} \cong \pm \sigma_x \sigma_y$) the 2 drms circle contains the probability within two standard deviations of the mean of a scalar normal variable or 95.4%.

The relationship between geometry and accuracy can best be explained via numerical example. Shown below are spreadsheet calculations for a master and two secondaries at 0, 80, and 300°, respectively.

Bearing	East (Sine)	North (Cosine)	Time
Master 0	0	1	1
Sec. #1 80	0.9848	0.1736	1
Sec. #2 300	-0.8660	0.5000	1
	INVERSE ($A^T A$)		
TOA	0.7122	0.6748	-0.4047
	0.6748	3.5258	-1.9937
	-0.4047	-1.9937	1.4616
TD	$\sin(M) - \sin(S)$	$\cos(M) - \cos(S)$	
	-0.9848	0.8264	
	0.8660	0.5000	
	R(TD)		
	2	1	
	1	2	
	INV(A) R INV(A^T)		
	0.7122	0.6748	
	0.6748	3.5258	

Assuming $\sigma_{\text{TOA}} = 100$ ns or equivalently $c\sigma_{\text{TOA}} = 30$ m, we can make specific calculations regarding repeatable accuracy. The standard deviations in the east and north directions and time are

$$\begin{aligned} \text{EDOP} &= \sqrt{0.7122} & \sigma_x &= 30 \text{ m EDOP} = 25.3 \text{ m}, \\ \text{NDOP} &= \sqrt{3.5258} & \sigma_y &= 30 \text{ m NDOP} = 56.3 \text{ m}, \\ \text{TDOP} &= \sqrt{1.4616} & \sigma_t &= 100 \text{ ns TDOP} = 120.9 \text{ ns}, \\ \text{HDOP} &= \sqrt{0.7122 + 3.5258} = 2.058 \end{aligned}$$

and the 2 drms accuracy = $2 \times 30 \text{ m} \times 2.058 = 123.5 \text{ m}$.

Error Ellipses (Pierce, 1948)

Frequently the scalar 2 drms accuracy does not adequately describe the position accuracy and the distribution of the error vector provides useful additional information. The probability density of two jointly normal random variables is given by

$$p(x, y) = \frac{1}{2\pi \sqrt{\sigma_x^2 \sigma_y^2 - \sigma_{xy}^2}} \exp \left[-\frac{\sigma_x^2 \sigma_y^2}{2(\sigma_x^2 \sigma_y^2 - \sigma_{xy}^2)} \left(\frac{x^2}{\sigma_x^2} - \frac{2xy\sigma_{xy}}{\sigma_x^2 \sigma_y^2} + \frac{y^2}{\sigma_y^2} \right) \right]$$

and the ellipses

$$\frac{x^2}{\sigma_x^2} - \frac{2xy\sigma_{xy}}{\sigma_x^2 \sigma_y^2} + \frac{y^2}{\sigma_y^2} = 2 \left(1 - \frac{\sigma_{xy}^2}{\sigma_x^2 \sigma_y^2} \right) c^2$$

are curves of constant probability density such that the probability a sample lies within the ellipse is $1 - \exp(-c^2)$. For algebraic simplicity this equation will be rewritten:

$$Ax^2 + 2Hxy + By^2 = C$$

which can be rotated by angle (Ω) into a (ξ, η) coordinate system aligned with the ellipse axes

$$\frac{\xi^2}{\alpha^2} + \frac{\eta^2}{\gamma^2} = C$$

where

$$\tan(2\Omega) = -\frac{2H}{B - A}$$

$$\alpha^2 + \gamma^2 = \frac{A + B}{AB - H^2}, \quad \text{and}$$

$$\alpha^2 - \gamma^2 = \frac{(B - A) \sec(2\Omega)}{AB - H^2}$$

Taking the sum and difference of the last two expressions

$$2\alpha^2 = \frac{A[1 - \sec(2\Omega)] + B[1 + \sec(2\Omega)]}{AB - H^2}, \quad \text{and}$$

$$2\gamma^2 = \frac{A[1 + \sec(2\Omega)] + B[1 - \sec(2\Omega)]}{AB - H^2}$$

In the example above, $\Omega = -12.8^\circ$. To draw an ellipse that contains $(1 - \exp(-4)) = 98.17\%$ of the samples, $\alpha = 63.4$ m and $\gamma = 162.8$ m. (Note: α is the length of the ellipse axis rotated by angle Ω from

FIGURE 17.28 Error ellipse and distribution of fix errors.

the original positive x axis.) Figure 17.28 and Figure 17.29 illustrate an example of 2000 fixes based on the above geometry and TOA statistics. In this example 1926 or 96.3% are contained in the 2 drms circle of radius 123.5 m.

Figure 17.30 is an illustration of error ellipses (not to scale) and lines of constant time difference for a typical triad. The main point is that when geometry becomes poor in the fringes of the coverage area, representing the accuracy by circles of increasing 2 drms radii does not truly reflect one's knowledge of accuracy. In many examples from both air and marine navigation, cross-track accuracy is far more important than along-track accuracy. Knowledge of the orientation of the error ellipse may be important.

In GPS or GLONASS, exactly the same error analysis and ellipses apply, the main difference being that the geometry at any particular point on the earth's surface has constantly changing geometry as satellites move and are added/subtracted from the available constellation. When we look at distributions of GPS or GLONASS fixes they tend to appear circularly symmetric, not because the instantaneous distributions are that way, but because the averaged distributions over long periods such as a day or longer become circularly symmetric.

FIGURE 17.29 Radial errors as a function of cumulative distribution.

17.3.6 Over-Determined Solutions

In the previous examples the issue of the distribution of measurement errors had no impact on the method used to find a solution, except only on the error analysis of that solution. We assumed a normal distribution on these errors not necessarily because we could guarantee that distribution, but because it allowed us to make meaningful predictions. When the number of observables exceeds the number of unknowns, we

FIGURE 17.30 Lines of constant time difference and error ellipses for typical triad.

FIGURE 17.31 Azimuth and elevation plot of GPS satellites for 1400Z, Aug. 28, 1995, New London, CT.

have choices in how to process the observations and the optimum choice depends both on the distribution of our measurement errors and what parameter we are trying to optimize. Since the GPS space segment now has 28 satellites, commonly there are more than the minimum of three or four required.

If the errors in the measured pseudo-ranges or TOAs are statistically independent and have the same variance, then the solution that minimizes the sum of the squares of the pseudo-range residuals is the linear least squares solution.

$$\Delta P = (A^T A)^{-1} A^T \Delta PR$$

where A is the matrix of direction cosines and ΔPR is the difference between measured and calculated pseudo-ranges. The covariance of the position error is now

$$\text{cov}(\Delta P) = (A^T A)^{-1} A^T \text{cov}(\Delta PR) A (A^T A)^{-1} = \sigma_{PR} (A^T A)^{-1}$$

where $\text{cov}(\Delta P) = \sigma_{PR} I$.

Figure 17.31 shows the azimuth and elevation plot of GPS satellites for 1400Z, August 28, 1995 in New London CT as a typical example. Eliminating the low elevation satellite (#18) due to potential multipath and using the nine remaining listed in table below, we can calculate expected accuracies.

SVN	Elevation	Azimuth
5	18°	317°
12	32°	232°
7	68°	73°
24	32°	249°
14	29°	50°
29	7°	94°

0.2533	-0.0192	0.0223	0.0239
-0.0192	0.5248	0.1160	-0.0466
0.0223	0.1160	1.6749	-0.8404
0.0239	-0.0466	-0.8404	0.5380

$$\text{GDOP} = \sqrt{\text{trace}(G)} = 1.73$$

$$\text{PDOP} = \sqrt{G_{11} + G_{22} + G_{33}} = 1.57$$

$$\text{HDOP} = \sqrt{G_{11} + G_{22}} = 0.88$$

$$\text{VDOP} = \sqrt{G_{33}} = 1.29$$

Exactly what these DOPs imply in terms of accuracy depends on what version of GPS/DGPS service one is using.

For the standard positioning service (SPS) with selective availability (SA) on, typically the value 32 m was used for the one sigma error. Since this value depended almost entirely on policy, advances in technology did not change its value. In Conley (1999) we can get a glimpse of what accuracies will be expected in the short term, and how they may improve in the future. They report less than 1.4 m rms for the on-orbit clocks and 59 cm for the ephemeris contribution to user range error (URE) in 1999. For SVN 43, the first operational Block IIR satellite, the combined clock and ephemeris errors were 70 cm RMS. This means that the errors in predicting ionospheric delay at about 5 m, the errors in predicting tropospheric delay at about 2 m, and multipath now dominate the statistics. DGPS will remove most of the residual errors due to satellite clock and ephemeris, and ionospheric and tropospheric delay leaving multipath as the most common dominant error source. The multipath errors are highly dependent on receiver and antenna design and antenna placement. Preliminary data after the termination of SA, from fixed sites, with high quality receivers, and where some care has been taken to minimize multipath, is indicating 7 m 2 drms accuracy may be achievable. The performance on typical installations with low cost receivers on moving platforms will be considerably worse. In the GPS modernization program to be implemented over the next decade, the addition of C/A code on L2 and third civil frequency, will mean civil receivers will measure ionospheric delay via differential pseudo-range as in dual frequency, military receivers. This combined with other improvements in technology is expected to improve civil GPS accuracy to better than 5 m 2 drms.

For precise positioning service users, NATO GPS (1991) specifies 13.0 m (95%) URE, which would imply a standard deviation of 6.5 m assuming a normal distribution. The actual performance, while classified, is generally acknowledged to be considerably better than this 1991 value, and will continue to improve with technology.

The negative correlation ($\rho = -0.8404/\sqrt{1.6749*0.5380} = -0.885$) between the altitude and time errors is common because the satellites used (by receivers on the Earth's surface) all must lie within a cone starting at some (elevation mask) angle above the horizon. Figure 17.32 shows the error ellipse for the joint time and altitude distribution. By using the first (East), second (North), and fourth (time) columns in the matrix A above we can calculate the expected DOPs for a GPS receiver in a fixed (known) altitude

FIGURE 17.32 Typical joint distribution of GPS altitude and time errors.

mode. HDOP is virtually unchanged but TDOP improves from 0.73 to 0.34. Similarly, if we assume we know time accurately and are only solving for three-dimensional position, we use the first three columns and VDOP improves from 1.29 to 0.60. Realistically, we will not know time exactly because we use the GPS to get time. We can improve vertical accuracy somewhat by propagating clock bias ahead via a Kalman filter as described in a later section, but can never get to zero clock error and this VDOP.

17.3.7 Weighted Least Squares

When the covariance of the measurement error is not a constant times an identity matrix, the optimum solution is a weighted vs. linear least squares solution.

$$\Delta P = (A^T W A)^{-1} A^T W \Delta P R$$

Now the covariance of the error is given by

$$E\{\Delta P \Delta P^T\} = E\{(A^T W A)^{-1} A^T W \Delta P R \Delta P R^T W^T A (A^T W A)^{-1}\}$$

This error is minimized if

$$W = R^{-1}$$

And this minimum error is given by

$$E\{\Delta P \Delta P^T\} = (A^T W A)^{-1}$$

For example, if we assume the standard deviation of each TOA measurement is the same for a three TD fix we should use a weighting matrix given by

$$W = R^{-1} = \begin{bmatrix} \sigma_m^2 + \sigma_1^2 & \sigma_m^2 & \sigma_m^2 \\ \sigma_m^2 & \sigma_m^2 + \sigma_2^2 & \sigma_m^2 \\ \sigma_m^2 & \sigma_m^2 & \sigma_m^2 + \sigma_3^2 \end{bmatrix}^{-1} = \frac{1}{\sigma_{\text{TOA}}} \begin{bmatrix} 0.75 & -0.25 & -0.25 \\ -0.25 & 0.75 & -0.25 \\ -0.25 & -0.25 & 0.75 \end{bmatrix}$$

When this matrix is multiplied times the TD observation vector, the correlation of the errors in the resulting vector is removed. It can be shown that weighted least squares processing of the TD measurements with the weighting matrix above is exactly equivalent to linear least squares processing of TOA measurements. For GPS, GLONASS, or DGPS there may be some advantages to weighted least squares processing. For example, low elevation satellites are subject to larger pseudo-range errors due to multipath and ionosphere delay modeling errors. The typical approach is to reject satellites below some elevation mask threshold of 5 to 10°. An alternative method using low elevation satellites with lower weights may help eliminate occasional spikes in GDOP. In integrated GPS/GLONASS, weighted least squares would have advantages in assigning different weights according to the relative accuracy of the two system's pseudoranges.

In LORAN, TOAs do not have same variance, TDs are not independent, and the position solution should be designed accordingly. Figure 17.33, Figure 17.34 and Figure 17.35 show the results of 1166 LORAN fixes over 6.5 h using the 9960 chain at a stationary location in New York Harbor. The LOCUST™ receiver used was modified to use a Cesium time standard and provided TOA data. The observed TOA standard

FIGURE 17.33 Example LORAN fixes (error +/- 20 m).

FIGURE 17.34 Example LORAN fixes (error ± 50 m).

FIGURE 17.35 Weighted error of example LORAN fixes.

deviations were

Seneca, NY	(175 nm)	7.6 ns
Caribou, ME	(452 nm)	100.6 ns
Nantucket, MA	(186 nm)	8.6 ns
Carolina Beach, NC	(438 nm)	21.1 ns
Dana, IN	(618 nm)	60.0 ns

(*Note:* Even though distances are comparable, the Carolina Beach TOAs are much better than those of Caribou because the path is seawater vs. land. In addition, Carolina Beach TDs are monitored and controlled using data from nearby Sandy Hook, NJ and Caribou is controlled using data from a monitor in Maine.)

The 2 drms repeatable accuracy is seen to be 21.8 m for linear least squares and 7.3 m for weighted least squares. Since for this particular data set, the Caribou and Dana signals are virtually ignored (Caribou is weighted $(7.6/100.6)^2 = 0.0057$ relative to Seneca), comparable accuracy to weighted least squares would have been obtained by totally ignoring Caribou and Dana data and doing three-TOA/two-TD fixes. In general using all data provides for a much more reliable solution. Figure 17.36 shows a histogram of time difference data of the 5930Y (Caribou/Cape Race) baseline as measured in New London, CT. What is seen for marginal signals like Cape Race at 875 nm from New London, is frequent cycle errors resulting in 10 and 20 usec TD errors. Any kind of standard least squares algorithm will not work. Assuming an over-determined solution, there are two basic alternatives; first, a maximum likelihood algorithm that takes into account the potential for local maxima in the likelihood function due to cycle errors, and second, receiver autonomous integrity monitoring (RAIM). In RAIM, a fix using all measurements is calculated and the residuals compared to a threshold. For RAIM to be valid, assuming N measurements, each of the N fixes available from each subset of $N - 1$ measurements must have acceptable geometry. For GPS, if we have two or more measurements than unknowns, the potential exists to identify and remove bad data

FIGURE 17.36 Histogram of time difference data of the 5930Y (Caribou/Cape Race) baseline measured in New London, CT.

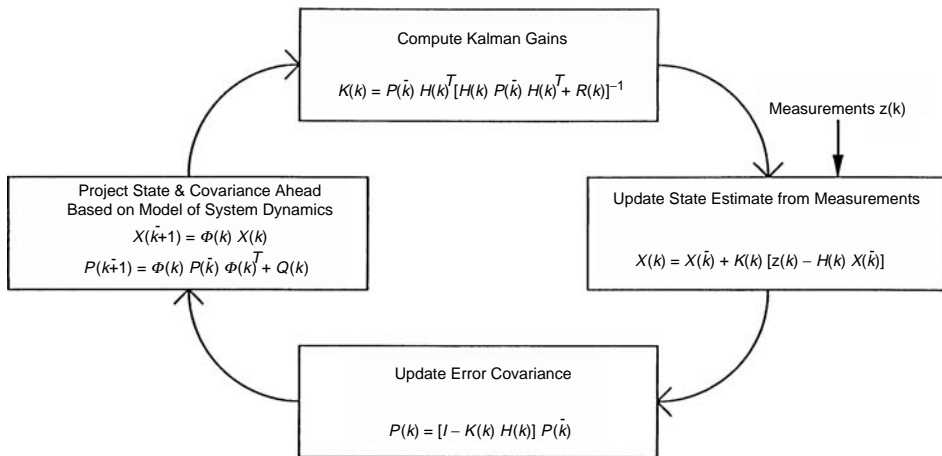

FIGURE 17.37 Kalman filter structure.

via residual analysis on these N over-determined fixes. Since for LORAN, cycle errors have predictable behavior, we may be able to identify and remove them with only one measurement more than the number of unknowns.

17.3.8 Kalman Filters

This section points out the basic principles of Kalman filters and specifically how they can be used in radionavigation systems. All of our analysis above has assumed we process each set of data independently. We know that parameters such as clock frequency and our velocity can only change at finite rates and therefore we ought to be able to do better using all past measurements. When we integrate LORAN TOAs or GLONASS pseudo-ranges with GPS pseudo-ranges we may not be able to assume the various systems are exactly synchronized in time. Therefore we cannot only solve for one time term, but we do know the drift between systems is extremely slow and need to somehow exploit that knowledge. Kalman filters allow us to use past measurements together with *a priori* knowledge of platform and clock dynamics to obtain optimum values of position and velocity. Typically, Kalman filters have found extensive use in the integration of inertial and electronic navigation systems. Here we will concentrate on stand-alone electronic navigation systems. The reader is referred to more extensive references such as Brown (1992) for more detail.

Figure 17.37 shows the basic structure of a discrete Kalman filter. The process starts with initial estimates of the state $[X(0)]$ and the error covariance $[P(0)]$. The other variables are

- $R(k)$ is the covariance of the measurement errors. (They are assumed white, this is not valid for SA-dominated pseudo-range errors, which are correlated over minutes. Strictly speaking this correlation should be modeled via additional state variables in system model, but normally it is not.)
- $H(k)$ Matrix of direction cosines and ones (as A above) that relate pseudo-range or TOA errors to positions and clock bias and Doppler's to velocity and frequency errors.
- $z(k)$ Pseudo-range (or TOA) and Doppler measurements
- $K(k)$ Kalman gains
- $\Phi(k)$ State transition matrix
- $Q(k)$ Covariance of noise driving state changes. This matrix controls allowed accelerations and clock frequency and phase variations. Smaller $Q(k)$ will result in smaller estimates of state error covariance and less weighting of measurements. Larger $Q(k)$ will result in faster system response to measurements. Conventional wisdom suggests using larger Q when uncertain of exact model.

A typical state space model for stand-alone GPS would have 8 states, the spatial coordinates and their velocities, and the clock offset and frequency. The individual pseudo-range measurements can be processed sequentially, which means that the Kalman gains can be calculated as scalars without the need for matrix inversions. There is no minimum number of measurements required to obtain an updated position estimate. The measurements are processed in an optimum fashion and if not enough for good geometry, the estimate of state error variance $[P(k)]$ will grow. If two satellites are available, the clock bias terms are just propagated forward via the state transition matrix.

The structure is ideal for integrated systems where the offset between GPS and GLONASS time may only be known approximately initially, but is known to be virtually constant. This offset would then be estimated as a state variable with some initial uncertainty but with very small $Q(k)$ driving changes. The same would be true for LORAN/GPS time offsets and the concept could be extended to ASFs for individual stations as well. The ASFs would be represented by very slowly varying states to be estimated. If GPS pseudo-ranges became unavailable such as in an urban canyon, mountain valley, or under heavy foliage cover, the LORAN would now be well calibrated.

Defining Terms

Accuracy: The degree of conformance between the estimated or measured position and/or velocity of a platform at a given time and its true position or velocity. Radionavigation system accuracy is usually presented as a statistical measure of system error.

Predictable: The accuracy of a radionavigation system's position solution with respect to the charted solution. Both the position solution and the chart must be based upon the same geodetic datum.

Repeatable: The accuracy with which a user can return to a position whose coordinates have been measured at a previous time with the same navigation system.

Relative: The accuracy with which a user can measure position relative to that of another user of the same navigation system at the same time.

Availability: The availability of a navigation system is the percentage of time that the services of the system are usable. Availability is an indication of the ability of the system to provide usable service within the specified coverage area. Signal availability is the percentage of time that navigational signals transmitted from external sources and are available for use. Availability is a function of both the physical characteristics of the environment and the technical capabilities of the transmitter facilities.

Block I and Block II Satellites: The Block I is a GPS concept validation satellite; it does not have all of the design features and capabilities of the production model GPS satellite, the Block II. The FOC 24 satellite constellation is defined to consist entirely of Block II/IIA satellites.

Coordinated Universal Time (UTC): UTC, an atomic time scale, is the basis for civil time. It is occasionally adjusted by one-second increments to ensure that the difference between the uniform time scale, defined by atomic clocks, does not differ from the earth's rotation by more than 0.9 sec.

Differential: A technique used to improve radionavigation system accuracy by determining positioning error at a known location and subsequently transmitting the determined error, or corrective factors, to users of the same radionavigation system, operating in the same area.

Dilution of precision (DOP): The magnifying effect on radionavigation position error induced by mapping ranging errors into position and time through the position solution. The DOP may be represented in any user local coordinate desired. Examples are HDOP for local horizontal, VDOP for local vertical, PDOP for all three coordinates, TDOP for time, and GDOP for position and time.

Distance root mean square (drms): The root-mean-square value of the distances from the true location point of the position fixes in a collection of measurements. As used in this Chapter 2 drms is the radius of a circle that contains at least 95% of all possible fixes that can be obtained with a system at any one place. Actually, the percentage of fixes contained within 2 drms varies between approximately 95.5 and 98.2%, depending on the degree of ellipticity of the error distribution.

Hyperbolic navigation system: A navigation system that produces hyperbolic lines of position (LOPs) through the measurement of the difference in times of reception (or phase difference) of radio signals from two or more synchronized transmitters.

Integrity: Integrity is the ability of a system to provide timely warnings to users when the system should not be used for navigation.

Multipath transmission: The propagation phenomenon that results in signals reaching the receiving antenna by two or more paths. When two or more signals arrive simultaneously, wave interference results. The received signal fades if the wave interference is time varying or if one of the terminals is in motion.

Pseudo-range: The difference between the ranging signal time of reception (as defined by the receiver's clock) and the time of transmission contained within the satellite's navigation data (as defined by the satellite's clock) multiplied by the speed of light.

Receiver autonomous integrity monitoring (RAIM): A technique whereby a civil GPS receiver/processor determines the integrity of the GPS navigation signals without reference to sensors or non-DoD integrity systems other than the receiver itself. This determination is achieved by a consistency check among redundant pseudo-range measurements.

Selective availability (SA): The denial of full GPS accuracy to civil users by manipulating navigation message orbit data (epsilon) and/or satellite clock frequency (dither).

Further Information

Government Agencies

1. U.S. Coast Guard Navigation Information Service (NIS)

Address: Commanding Officer
 USCG Navigation Center
 7323 Telegraph Road
 Alexandria, VA 22315

Internet: <http://www.navcen.uscg.mil/navcen.htm>
 Phone: (703) 313-5900 (NIS Watchstander)

Formerly the GPS Information Center (GPSIC), NIS has been providing information since March, 1990. The NIS is a public information service. At the present time, there is no charge for the information provided. Hours are continuous: 24 h a day, 7 days a week, including federal holidays.

The mission of the navigation information service (NIS) is to gather, process, and disseminate timely GPS, DGPS, Omega, and LORAN-C status, and other navigation related information to users of these navigation services. Specifically, the functions to be performed by the NIS include the following:

- Provide the Operational Advisory Broadcast Service (OAB).
- Answer questions by telephone or written correspondence.
- Provide information to the public on the NIS services available.
- Provide instruction on the access and use of the information services available.
- Maintain tutorial, instructional, and other relevant handbooks and material for distribution to users.
- Maintain records of GPS, DGPS, and LORAN-C broadcast information, and databases or relevant data for reference purposes.
- Maintain bibliography of GPS, DGPS, and LORAN-C publications.

The NIS provides a watchstander to answer radionavigation user inquiries 24 h a day, seven days a week and disseminates general information on GPS, DGPS, Loran-C, and Radiobeacons through various mediums.

2. NOAA, National Geodetic Survey

Address: 1315 East-West Highway, Station 09202
 Silver Spring, MD 20910

Phone: (301) 713-3242;
 Fax: (301) 713-4172

Monday through Friday, 7:00 a.m.– 4:30 p.m., Eastern Time
 Internet: <http://www.ngs.noaa.gov/>

NOAA is modernizing the Nation's spatial reference system, providing horizontal and vertical positions for navigation and engineering purposes. By implementing a new system called CORS (continuously operating reference stations), NOAA will continuously record carrier phase and pseudo-range measurements for all GPS (global positioning system) satellites at each CORS site. A primary objective of CORS is to monitor a particular site, which is determined to millimeter accuracy and to provide local users a tie to the national spatial reference system. NOAA will also use the CORS sites along with other globally distributed tracking stations in computing precise GPS orbits.

NOAA is also the federal agency responsible for providing accurate and timely global positioning system (GPS) satellite ephemerides ("orbits") to the general public. The GPS precise orbits are derived using 24-h data segments from the global GPS network coordinated by the international geodynamics GPS service (IGS). The reference frame used in the computation is the international earth rotation service terrestrial reference frame (ITRF). In addition, an informational summary file is provided to document the computation and to convey relevant information about the observed satellites, such as maneuvers or maintenance. The orbits generally are available two to six days after the date of observation.

Also available

- Software programs to compute, verify, or adjust field surveying observations; convert coordinates from one geodetic datum to another; or assist in other specialized tasks utilizing geodetic data.
- Listings of publications available on geodesy, mapping, charting, photogrammetry, and related topics, such as plane coordinate systems and numerical analysis.
- Information on NGS programs to assist users of geodetic data, including technical workshops and the geodetic advisor program.
- Information on survey data recently incorporated into NSRS.
- Information on the location of NGS field parties.

3. U.S. Naval Observatory (USNO)

Internet: <http://www.usno.navy.mil/>

USNO is the official source of time used in the U.S. USNO timekeeping is based on an ensemble of cesium beam and hydrogen maser atomic clocks. USNO disseminates information on time offsets of the world's major time services and radionavigation systems.

4. USSPACECOM GPS Support Center

300 O'Malley

Suite 41

Schriever AFB, CO 80912-3041

http://www.peterson.af.mil/usspace/gps_support

The **GPS Support Center** (GSC) is the DoD's focal point for operational issues and questions concerning military use of GPS. The GSC is responsible for

- Receiving reports and coordinating responses to radio frequency interference in the use of GPS in military operations.
- Providing prompt responses to DoD user problems or questions concerning GPS.
- Providing official USSPACECOM monitoring of GPS performance provided to DoD users on a global basis.
- Providing tactical support for planning and assessing military missions involving the use of GPS.

As the DoD's focal point for GPS operational matters, the GSC serves as U.S. Space Command's interface to the civil community, through the U.S. Coast Guard's Navigation Center and Federal Aviation Administration's National Operations Command Center.

5. The Ministry of Defence of the Russian Federation Coordination Scientific Information Center

Internet: http://www.rssi.ru/SFCSIC/SFCSIC_main.html

The mission of the Coordination Scientific Information Center is to plan, manage, and coordinate the activities on

- Use of civil-military space systems (navigation, communications, meteorology etc.)
- Realization of Russian and international scientific and economic space programs
- Realization of programs of international cooperation
- Conversional use of military space facilities, as well as to provide the scientific-informational, contractual and institutional support of these activities.

17.4 Underwater Sonar Systems¹

Sanjay K. Mehta, Clifford G. Carter, and Bernard E. McTaggart

17.4.1 Introduction

A system that uses sound signals (also known as acoustic signals) propagated through the water to detect, classify, and localize underwater objects is referred to as an underwater sound system (sonar). The system generally consists of four major components. The first component is a transmitter that transmits a signal through water. The second is a receiver that receives the transmitted signal, which has been degraded due to underwater propagation effects, ambient noise, or interference from other signal sources, such as surface warships and fishing vessels. A processing unit that processes the received signal to minimize the degradation effects and to maximize the detection and classification capability of the signal is the third component. The fourth consists of the various displays that aid human operators to detect, classify, and localize signals.

Sound, that is, acoustic energy, propagates better underwater than do other types of energy. For example, both light and radio waves (used for satellite or above ground communications) are attenuated to a far greater degree under water than are sound waves. (Note: there has been some limited success propagating blue–green laser energy in clear water.) For this reason sound waves have generally been used to extract information about underwater objects. A typical underwater acoustical signal processing scenario is shown in Fig. 17.38.

Background

In underwater acoustics, the metric system has not been universally applied, and a number of nonmetric units are still used: distances of nautical miles (1852 m), yards (0.9144 m), and kiloyards; speeds of knots (nautical miles per hour); depths of fathoms (6 feet or 1.8288 m); and bearing in degrees (0.01745 rad). In the past two decades, however, there has been a conscious effort to become totally metric, that is, to use meter–kilogram–second (MKS) or Standard International units.

Underwater sound signals that are processed electronically for detection, classification, and localization can be characterized from a statistical point of view. When time averages of each signal are the same as the ensemble average of signals, the signals are ergodic. When the statistics do not change with time, the signals are said to be stationary. The spatial equivalent to stationary is homogeneous. For many introductory problems, only stationary signals and homogeneous noise are considered; more complex problems involve nonstationary, inhomogeneous environments.

Sound signals have a first-order *probability density function* (PDF); for example, the PDF may be Gaussian, or in the case of clicking, sharp noise spikes or crackling ice noise, the PDF may be non-Gaussian.

¹This work is a revised version from Dorf, R., ed. 1993. *Electrical Engineering Handbook*. CRC Press, Boca Raton, FL.

FIGURE 17.38 Active and passive underwater acoustical signal processing.

In addition to being characterized by a PDF, signals can be characterized in the frequency domain by their power spectral density functions, which are Fourier transforms of the autocorrelation functions. White signals, which are uncorrelated from sample to sample, have a delta function autocorrelation or a flat (constant) power spectral density. Ocean signals, in general, are much more colorful and are not limited to being stationary.

Sonar

Sound navigation and ranging, (**SONAR**) (the acronym was adapted in the 1940s similar to the popular acronym for radio detection and ranging (radar)) involves the use of sound to explore the ocean and underwater objects. *Passive sonar* uses sound radiated from the underwater object itself. The duration of the radiated sound may be short or long in time and narrow or broad in frequency. Transmission through the ocean, from the source to a receiving sensor, is one way. *Active sonar* involves echoranging where an acoustical signal is transmitted from a source, and reflected echoes are received back from the object. Here, the transmissions, from a transmitter to an object and back to a receiving sensor are two way. There are three types of active sonar systems

- *Monostatic*: In this most common form, the source and receiver can be identical or distinct, but are located on the same platform (e.g., a surface ship).
- *Bistatic*: In this form, the transmitter and receiver are on different platforms.
- *Multistatic*: Here, one or more transmitters and multiple receivers are located on different receiving platforms or ships.

Passive sonar signals are primarily modeled as random signals. Their first-order PDFs are typically Gaussian; one exception is a stable sinusoidal signal that is non-Gaussian and has a power spectral density function that is a Dirac delta function in the frequency domain. Such sinusoidal signals can be detected by measuring the energy output of narrowband filters. This can be done with fast fourier transform (FFT) electronics and long integration times. In the ocean environment, however, an arbitrarily narrow-frequency width is never observed, and signals have some finite bandwidth. Indeed, the full spectrum of

most underwater signals is quite “colorful.” In fact, the signals of interest are not unlike speech signals, except that the **signal-to-noise ratio (SNR)** is much higher for speech than for sonar.

Received active sonar signals can be viewed as consisting of the results of (1) a deterministic component (known transmit signal) convolved with the medium and reflector transfer functions and (2) a random (noise) component. The **Doppler** imparted (frequency shift) to the reflected signal makes the total system effect nonlinear, thereby complicating analysis and processing of these signals. In addition, in active systems the noise is typically correlated with the signal, making detection of signals more difficult.

17.4.2 Underwater Propagation

Sound speed c in the ocean, in general, lies between 1450–1540 m/s and varies as a function of several physical parameters, such as temperature, salinity, and pressure (depth). Variations in sound speed can significantly affect the propagation (range or quality) of sound in the ocean. Table 17.7 gives approximate expressions for sound speed as a function of these physical parameters.

Sound Velocity Profiles

Sound rays that are normal (perpendicular) to the signal acoustic wavefront can be traced from the source to the receiver by a process called ray tracing. (Ray tracing models are used for high-frequency signals and in deep water. Generally, if the depth-to-wavelength ratio is 100 or more, ray tracing models are accurate. Below that, corrections must be made to these models. In shallow water or low frequencies, that is, when depth-to-wavelength is about 30 or less, mode theory models are used.) In general, the acoustic ray paths are not straight, but bend in a manner analogous to optical rays focused by a lens. In underwater sound, the ray paths are determined by the **sound velocity profile (SVP)** or *sound speed profile (SSP)*: that is, the speed of sound in water as a function of water depth. The sound speed not only varies with depth but also varies in different regions of the ocean and with time as well. In deep water, the SVP fluctuates the most in the upper ocean due to variations of temperature and weather. Just below the sea surface is the *surface layer* where the sound speed is greatly affected by temperature and wind action. Below this layer lies the *seasonal thermocline* where the temperature and speed decrease with depth, and the variations are seasonal. In the next layer, the *main thermocline*, the temperature and speed decrease with depth, and surface conditions or seasons have little effect. Finally, there is the *deep isothermal layer* where the temperature is nearly constant at 39°F, and the sound velocity increases almost linearly with depth. A typical deep water sound velocity profile as a function of depth is shown in Fig. 17.39.

If the sound speed is a minimum at a certain depth below the surface, then this depth is called the *axis* of the *underwater sound channel* (also called the *sound fixing and ranging (SOFAR) channel*.) The sound velocity increases both above and below this axis. When the sound wave travels through a medium with a sound speed gradient, the direction of travel of the sound wave is bent toward the area of lower sound speed.

FIGURE 17.39 A Typical sound velocity profile (SVP). (Source: Urick, R.J. 1983. *Principles of Underwater Sound*, p. 118. McGraw-Hill, New York.)

Although the definition of shallow water can be signal dependent, in terms of depth-to-wavelength ratio, water depth of less than 100 m is generally referred to as shallow water. In shallow water, the SVP is irregular and difficult to predict because of large surface temperature and salinity variations, wind effects, and multiple reflections of sound from the ocean bottom.

Three Propagation Modes

In general, there are three dominant propagation modes that depend on the distance or range between the sound source and the receiver.

- *Direct path:* Sound energy travels in a (nominal) straight line path between the source and receiver, usually at short ranges.
- *Bottom bounce path:* Sound energy is reflected from the ocean bottom (at intermediate ranges, see Fig. 17.40).
- *Convergence zone (CZ) path:* Sound energy converges at longer ranges where multiple acoustic ray paths add or recombine coherently to reinforce the presence of signal energy from the radiating/reflecting source.

FIGURE 17.40 Typical sound paths between source and receiver, in fathom: unit of length or depth generally used for underwater measurements where 1 fathom = 6 ft. (Source: Cox, A.W. 1974. *Sonar and Underwater Sound*, p. 25. Lexington Books, D.C. Heath and Co., Lexington, MA.)

FIGURE 17.41 Multipaths for a first-order bottom bounce propagation model.

Multipaths

The ocean splits signal energy into multiple acoustic paths. When the receiving system can resolve these multiple paths (or multipaths), they should be coherently recombined by optimal signal processing to fully exploit the available signal energy for detection (Chan, 1989). It is also theoretically possible to exploit the geometrical properties of multipaths present in the bottom bounce path by investigation of a virtual aperture that is created by the different path arrivals to localize the energy source. In the case of first-order bottom bounce transmission (i.e., only one bottom interaction), there are four paths (from source to receiver):

- A bottom bounce ray path (B)
- A surface interaction followed by a bottom interaction (SB)
- A bottom bounce followed by a surface interaction (BS)
- A path that first hits the surface, then the bottom, and finally the surface (SBS)

Typical first-order bottom bounce ocean propagation paths are depicted in Fig. 17.41.

Sonar System Performance

The performance of sonar systems can be assessed by the passive and active *sonar equations*. The major parameters in the sonar equation, measured in **decibel**, are as follows:

- L_S = source level
- L_N = noise level
- N_{DI} = directivity index
- N_{TS} = echo level or target strength
- N_{RD} = recognition differential.

Here, L_S is the target-radiated signal strength (for passive) or transmitted signal strength (for active), and L_N is the total background noise level. N_{DI} , or D_I , is the directivity index, which is a measure of the capability of a receiving array to electronically discriminate against unwanted noise. N_{TS} is the received echo level or target strength. Underwater objects with large values of N_{TS} are more easily detectable with active sonar than are those with small values of N_{TS} . In general, N_{TS} varies as a function of object size, aspect angle (i.e., the direction at which impinging acoustic signal energy reaches the underwater object), and reflection angle (the direction at which the impinging acoustic signal energy is reflected off the underwater object). N_{RD} is the recognition differential of the processing system.

The **figure of merit (FOM)**, a basic performance measure involving parameters of the sonar system, ocean, and target, is computed for active and passive sonar systems (in decibel) as follows:

For passive sonar

$$\text{FOM}_P = L_S - (L_N - N_{DI}) - N_{RD}$$

For active sonar

$$\text{FOM}_A = (L_S + N_{TS}) - (L_N - N_{DI}) - N_{RD}$$

Sonar systems are designed so that the FOM exceeds the signal propagation loss for a given set of parameters of the sonar equations. The amount above the FOM is called the *signal excess*. When two sonar systems are compared, the one with the largest signal excess is said to hold the *acoustic advantage*. It should be noted, however, that the set of parameters in the FOM equations given here is simplified. Depending on the design or parameter measurability conditions, parameters can be combined or expanded in terms of such quantities as the frequency dependency of the sonar system in particular ocean conditions, the speed and bearing of the receiving or transmitting platforms, **reverberation** loss, and so forth. Furthermore, due to multipaths, differences in sonar system equipment and operation, and the constantly changing nature of the ocean medium, the FOM parameters fluctuate with time. Thus, the FOM is not an absolute measure of performance but rather an average measure of performance over time.

Sonar System Performance Limitations

In a typical reception of a signal wavefront, noise and interference can degrade the performance of the sonar system and limit the system's capability to detect signals in the underwater environment. The effects of these degradations must be considered when any sonar system is designed. The noise or interference could be from a school of fish, shipping (surface or subsurface), active transmission operations (e.g., jammers), or the use of multiple receivers or sonar systems simultaneously. Also, the ambient noise may have unusual vertical or horizontal directivity, and in some environments, such as the Arctic, the noise due to ice motion may produce unusual interference. Unwanted backscatterers, similar to the headlights of a car driving in fog, can cause a signal-induced and signal-correlated noise that degrades processing gain. Some other performance-limiting factors are

- The loss of signal level and acoustic coherence due to boundary interaction as a function of grazing angle
- The radiated pattern (signal level) of the object and its spatial coherence
- The presence of surface, bottom, and volume reverberation (in active sonar)
- Signal spreading (in time, frequency, or bearing) owing to the modulating effect of surface motion
- Biologic noise as a function of time (both time of day and time of year)
- Statistics of the noise in the medium (e.g., does the noise arrive in the same ray path angles as the signal?).

Imaging and Tomography Systems

Underwater sound and signal processing can be used for bottom imaging and underwater oceanic tomography (Spindel, 1985). Signals are transmitted in succession and the **time delay** measurements between signals and measured multipaths are then used to determine the speed of sound in the ocean. This information along with bathymetry data is used to map depth and temperature variations of the ocean. In addition to mapping ocean bottoms, such information can aid in quantifying global climate and warming trends.

17.4.3 Underwater Sound Systems: Components and Processes

In this section, we describe a generic sonar system and provide a brief summary for some of its components. In Sec. 17.4.4, we describe some of the signal processing functions. A detailed description of the sonar components and various signal processing functions can be found in Knight, Pridham, and Kay (1981), Hueter (1972), and Winder (1975). Figures 17.42 and Figure 17.43 show block diagrams of the major components of a typical active and passive sonar system, respectively. Except for the signal generator, which is present only in active sonar, there are many similarities in the basic components and functions for the active and passive sonar system.

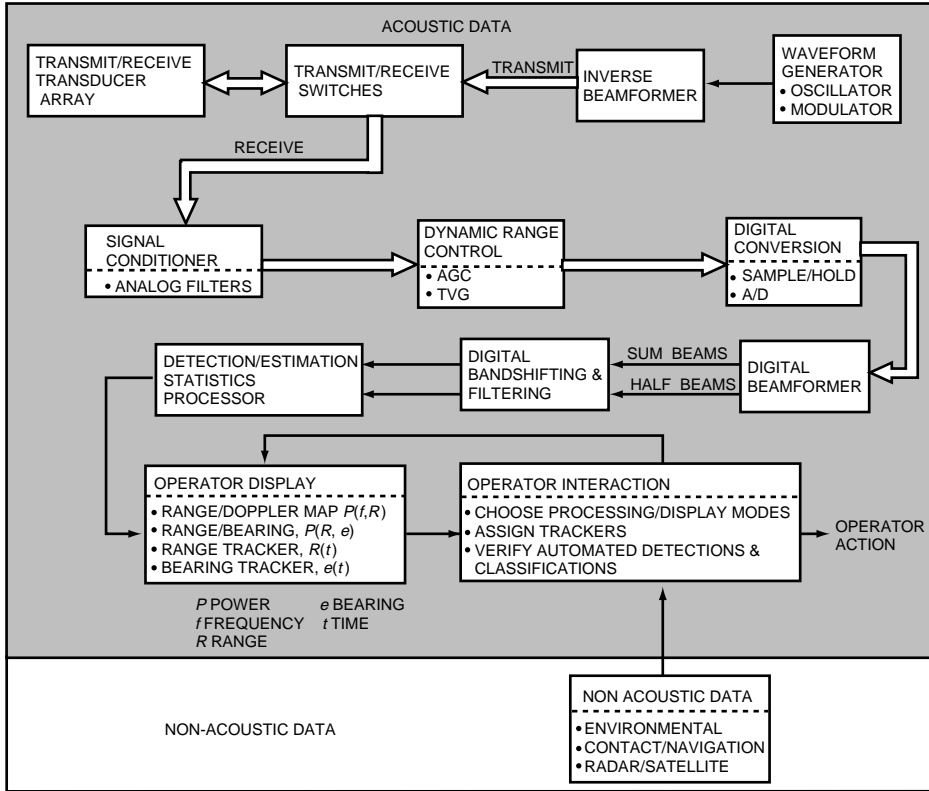

FIGURE 17.42 Generic active sonar system. (Source: Adapted from Knight, W., Pridham, R.G., and Kay, S.M. 1981. Digital signal processing for sonar. *Proceedings of the IEEE* 69(11):1454. © IEEE 1981.)

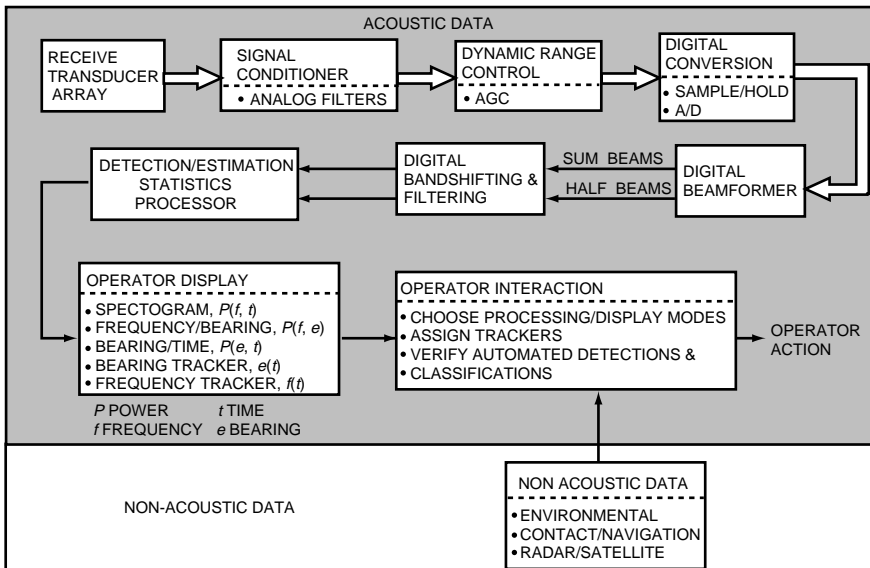

FIGURE 17.43 Generic passive sonar system. (Source: Adapted from Knight, W., Pridham, R.G., and Kay, S.M. 1981. Digital signal processing for sonar. *Proceedings of the IEEE* 69(11):1454. © IEEE 1981.)

In an active sonar system, an electronic signal generator produces a signal. The signal is then inverse beamformed by delaying it in time by various amounts. A separate **projector** is used to transmit each of the delayed signals by transforming the electrical signal into an acoustic pressure wave that propagates through water. Thus, an array of projectors is used to transmit the signal and focus it in the desired direction. Depending on the desired range and Doppler resolution, different signal waveforms can be generated and transmitted.

At the receiver (an array of **hydrophones**), the acoustic or pressure waveform is converted back to an electrical signal. The received signal consists of the source signal (usually the transmitted signal in the active sonar case) embedded in ambient noise and interference from other sources present in water. The signal then goes through a number of signal processing functions. In general, each channel of the analog signal is first filtered in a signal conditioner. It is then amplified or attenuated within a specified dynamic range using an automatic gain control (AGC). For active sonar, we can also use a time varied gain (TVG) to amplify or attenuate the signal. The signal, which is analog until this point, is then sampled and digitized by analog-to-digital (A/D) converters. The individual digital sensor outputs are next combined by a digital **beamformer** to form a set of beams. Each beam represents a different search direction of the sonar. The beam output is further processed (bandshifted, filtered, normalized, down sampled, etc.) to obtain *detection*, *classification*, and *localization* (DCL) estimates, which are displayed to the operator on single or multiple displays. Based on the display output (acoustic data) and other nonacoustic data (environmental, contact, navigation, and radar/satellite), the operators make their final decision.

Signal Waveforms

The transmitted signal is an essential part of an active sonar system. The properties of the transmitted signal will strongly affect the quality of the received signal and the information derived from it. The main objective in active sonar is to detect a target and estimate its range and velocity. The range and velocity information is obtained from the reflected signal. To show how the range and velocity information is contained in the received signal, we consider a simple case where $s(t)$, $0 \leq t \leq T$ is transmitted. Neglecting medium, noise, and other interference effects, we let the transmitted signal be reflected back from a moving target located at range $R = R_0 + vt$, where v is the velocity of the target. The received signal is then given by

$$r(t) = a(R)s[(1 - b)t - \tau]$$

$$\tau = 2R_0/c, \quad b = 2v/c$$

where $a(R)$ is the propagation loss attenuation factor (more generally $a(R)$ is also a function of frequency) and c is the speed of sound. Measuring the delay τ gives the propagation time to and from the target. We can then calculate the range from the time delay. The received signal is also time compressed or expanded by b . The velocity of the target can be estimated by determining the compression or expansion factor of the received signal. Each signal has different range and Doppler (velocity) resolution properties. Some signals are good for range resolution but not for Doppler, some for Doppler but not for range, some for reverberation-limited environments, and some for noise-limited environments (Winder, 1975). Commonly used signals in active sonar are *continuous wave* (CW), *linear frequency modulation* (LFM), *hyperbolic frequency modulation* (HFM), and *pseudo-random noise* (PRN) signals. CW signals have been used in sonar for decades, whereas signals such as *frequency hop codes* (FHC) and Newhall waveforms are recently rediscovered signals (Rihaczek, 1985) that work well in high-reverberation shallow water environments.

Some of the most commonly used signals will be described. So far we have made generalized statements about the effectiveness of signals, which only provide a broad overview. More specifically, the signal has properties that depend on a number of factors not discussed here, such as time duration and frequency bandwidth. Rihaczek (1985) provides a detailed analysis of the properties and effectiveness of signals. The simplest signal is a rectangular CW pulse, which is a single-frequency sinusoid. The CW signal may have high resolution in range (short CW) or Doppler (long CW) but not in both simultaneously. LFM signals are waveforms whose instantaneous frequency varies linearly with time; in HFM signals the instantaneous

frequency sweeps monotonically as a hyperbola. Both these signals are good for detecting low Doppler targets in reverberation-limited conditions. PRN signals, which are generated by superimposing binary data on sinusoid carriers, provide simultaneous resolution in range and Doppler. However, such range resolution may not be as good as LFM alone and Doppler resolution is not as good as CW alone. An FHC signal is a waveform that consists of subpulses of equal duration. Each subpulse has a distinct frequency, and these frequencies jump or hop in a defined manner. Similar to the PRN, FHC also provides simultaneous resolution in range and Doppler. Newhall waveforms (also known as coherent pulse trains or saw-tooth frequency modulation), which are trains of repeated modulated subpulses (typically HFM or LFM), allow reverberation suppression and low Doppler target detection.

Sonar Transducers

A transducer is a fundamental element of both receiving hydrophones and projectors. It is a device that converts one form of energy into another. In the case of a sonar transducer, the two forms of energy are electricity and pressure, the pressure being that associated with a signal wavefront in water. The transducer is a reciprocal device, such that when electricity is applied to the transducer, a pressure wave is generated in the water, and when a pressure wave impinges on the transducer, electricity is developed. The heart of a sonar transducer is its active material, which makes the transducer respond to electrical or pressure excitations. These active materials produce electrical charges when subjected to mechanical stress and conversely produce a stress proportional to the applied electrical field strength when subjected to an electrical field. Most sonar transducers employ piezoelectric materials, such as lead zirconate titanate ceramic, as the active material. Magnetostictive materials, such as nickel, can also be used. Figure 17.44 shows a flextensional transducer. In this configuration, the ceramic stack is mounted on the major axis of a metallic elliptical cylinder. Stress is applied by compressing the ellipse along its minor axis, thereby extending the major axis. The ceramic stacks are then inserted into the cylinder and the stress is released, which places the ceramic stacks in compression. This design allows a small change imparted at the ends of the ceramic stack to be converted into a larger change at the major faces of the ellipse.

FIGURE 17.44 The flextensional transducer. (Source: Burdic, W.S. 1984. *Underwater Acoustic System Analysis*, p. 93. Prentice-Hall, Englewood Cliffs, NJ.)

Figure 17.44 shows a flextensional transducer. In this configuration, the ceramic stack is mounted on the major axis of a metallic elliptical cylinder. Stress is applied by compressing the ellipse along its minor axis, thereby extending the major axis. The ceramic stacks are then inserted into the cylinder and the stress is released, which places the ceramic stacks in compression. This design allows a small change imparted at the ends of the ceramic stack to be converted into a larger change at the major faces of the ellipse.

Hydrophone Receivers

Hydrophone sensors are microphones capable of operating in water under hydrostatic pressure. These sensors receive radiated and reflected sound energy that arrives through the multiple paths of the ocean medium from a variety of sources and reflectors. As with a microphone, hydrophones convert acoustic pressure to electrical voltages or to optical signals. Typical hydrophones are hollow piezoelectric ceramic cylinders with end caps. The cylinders are covered with rubber or polyethylene as water proofing, and an electrical cable exits from one end. These hydrophones are isolation mounted so that they do not pick up stray vibrations from the ship. Most hydrophones are designed to operate below their resonance frequency, thus resulting in a flat or broadband receiving response.

Sonar Projectors (Transmitters)

A sonar projector is a transducer designed principally for transmission, that is, to convert electrical voltage or energy into sound energy. Although sonar projectors are also good receivers (hydrophones), they are too expensive and complicated (it is designed for a specific frequency band of operation) for just receiving signals. Most sonar projectors are of a *tonpizl* (sound mushroom) design with the piezoelectric material sandwiched between a head and tail mass. The head mass is usually very light and stiff (aluminum) and the tail mass very heavy (steel). The combination results in a projector that is basically a half-wavelength

FIGURE 17.45 The tonpiz projector. (Sources: Burdic, W.S. 1984. *Underwater Acoustic System Analysis*, p. 92. Prentice-Hall, Englewood Cliffs, NJ; Hueter, T.F., 1972. Twenty years in underwater acoustics: Generation and reception. *J. of the Acoustical Soc. of America* 51(3):1032.)

long at its resonance frequency. The tonpiz resonator is housed in a watertight case that is designed so that the tonpiz is free to vibrate when excited. A pressure release material such as corprene (cork neoprene) is attached to the tail mass so that the housing does not vibrate and all the sound is transmitted from the front face. The piezoelectric material is a dielectric and, as such, acts as a capacitor. To ensure an efficient electrical match to driver amplifiers, a tuning coil or even a transformer is usually contained in the projector housing. A tonpiz projector is shown in Fig. 17.45.

Active Sources

One type of sonar transducer, primarily used in the surveillance community, is a low-frequency active source. The tonpiz design is commonly used for such projectors at frequencies down to about 2 kHz (a tonpiz at this frequency is almost 0.75-m long). For frequencies below 2 kHz, other types of transducer technology are employed, including mechanical transformers such as flexing shells, moving coil (loud speaker) devices, hydraulic sources, and even impulse sources such as spark gap and air. Explosives are a common source for surveillance, and when used with towed arrays make a very sophisticated system.

Receiving Arrays

Most individual hydrophones have an omnidirectional response; that is, sound emanates almost uniformly in all directions. To focus sound in a particular direction requires an array of hydrophones or projectors. The larger the array, the narrower and more focused is the beam of sound energy, and hence the more the signal is isolated from the interfering noise. An array of hydrophones allows discrimination against unwanted background noise by focusing its main response axis (MRA) on the desired signal direction. Arrays of projectors and hydrophones are usually designed with elements spaced one-half wavelength apart. This provides optimum beam structure at the design frequency. As the frequency of operation increases and exceeds three-quarter wavelength spacing, the beam structure, although narrowing, deteriorates. As the frequency decreases, the beam increases in width to the point that focusing diminishes. Some common array configurations are linear (omnidirectional), planar (fan shaped), cylindrical (searchlight) and spherical (steered beams). Arrays can be less than 3.5 in. in diameter and can have on the order of 100 hydrophones or acoustic channels. Some newer arrays have even more channels. Typically, these channels are nested, subgrouped and combined in different configurations to form the low-frequency (LF), mid-frequency

FIGURE 17.46 (a) Schematic of a towed line array. (Source: Urick, R.J. 1983. *Principles of Underwater Sound*, p. 13. McGraw-Hill, New York.) (b) bow array assembly for the seawolf submarine (SSN-21). (Source: NUWC. 1991. Division Newport, BRAC 1991 presentation. Naval Undersea Warfare Center, New London, CT.)

(MF) and high-frequency (HF) apertures of the array. Depending on the frequency of interest, one can use any one of these three apertures to process the data. The data are then prewhitened, amplified, and low-pass filtered before being routed to A/D converters. The A/D converters typically operate or sample the data at about three times the low-pass cutoff frequency.

A common array, shown in Figure 17.46(a), is a single linear line of hydrophones that makes up a device called a *towed array*, which in the oil exploration business are often called *streamers*. The line is towed behind the ship and is effective for searching for low-level and low-frequency signals without interference from the ship's self-noise. Figure 17.46(b) shows a more sophisticated bow array (sphere) assembly.

Sonobuoys

These small expendable sonar devices contain a transmitter to transmit signals and a single hydrophone to receive the signal. Sonobuoys are generally dropped by fixed-wing or rotary wing aircraft for underwater signal detection.

Dynamic Range Control

Analog signals received by the receiving array are converted into a digital format, while ensuring that the dynamic range of the data is within acceptable limits. The receiving array must have sufficient dynamic range so that it can detect the weakest signal but also not saturate upon receiving the largest signal in the presence of noise and interference. To be able to convert the data into digital form and display it, large fluctuations in the data must be eliminated. Not only do these fluctuations overload the digital range capacity, they will affect the background quality and contrast of the displays as well. It has been shown that the optimum display background, a background with uniform fluctuations as a function of range, time, and bearing, for detection is one that has constant temporal variance at a given bearing and a constant spatial variance at a given range. Since the fluctuations (noise, interference, propagation conditions, etc.) are time varying, it is necessary to have a threshold level that is independent of the fluctuations. The concept is to use techniques that can adapt the high dynamic range of the received signal to the limited dynamic range of the computers and displays. Time-varied gain (TVG) for active sonar and automatic gain control (AGC) are two popular techniques to control the dynamic range. TVG controls the receiver gain so that it follows a prescribed variation with time, independent of the background conditions. The disadvantage of TVG is that the variations of gain with time do not follow the variations in reverberation. TVG is sufficient if the reverberation is uniform in bearing and monotonically decreasing in range (which is not the case in shallow water). AGC on the other hand continuously varies the gain according to the current reverberation or interference conditions. Details of how TVG, AGC, and other gain control techniques such as notch filters, reverberation controlled gain, logarithmic receivers, and hard clippers work are presented in Winder (1975).

Beamforming

Beamforming is a process in which outputs from the hydrophone sensors of an array are coherently combined by delaying and summing the outputs to provide enhanced detection and estimation. In underwater applications, we are trying to detect a directional (single direction) signal in the presence of normalized background noise that is ideally isotropic (nondirectional). By arranging the hydrophone (array) sensors in different physical geometries and electronically steering them in a particular direction, we can increase the signal-to-noise ratio in a given direction by rejecting or canceling the noise in other directions. There are many different kinds of arrays that can be beamformed (e.g., equally spaced line, continuous line, circular, cylindrical, spherical, or random sonobuoy arrays). The beam pattern specifies the response of these arrays to the variation in direction. In the simplest case, the increase in SNR due to the beamformer, called the **array gain** (in decibel), is given by

$$AG = 10 \log \frac{\text{SNR}_{\text{array(output)}}}{\text{SNR}_{\text{single sensor(input)}}$$

Displays

Advancements in processing power and display technologies over the last two decades have made displays an integral and essential part of any sonar system today. Displays have progressed from a single monochrome terminal to very complicated interactive real-time multiterminal color display electronics. The amount of data that can be provided to an operator can be overwhelming; time series, power spectrum, narrowband and broadband lofargrams, time bearing, range bearing, time Doppler, and sector scans are just some of the many available displays. Then add to this a source or contact tracking display for single or multiple sources over multiple (50–100) beams. The most recent displays provide these data in an interactive mode to make it easier for the operator to make a decision.

For passive systems the three main parameters of interest are time, frequency, and bearing. Since three-dimensional data are difficult to visualize and analyze, it is usually displayed in the following formats:

- *Bearing time*: Obtained by integrating over frequency. Useful for targets with significant broadband characteristics; also called bearing time recorder (BTR).
- *Bearing frequency*: Obtained at particular intervals of time or by integrating over time. Effective for targets with strong stable spectral lines; also called *frequency azimuth* (FRAZ).

- *Time frequency*: Usually effective for targets with weak or unstable spectral lines in a particular beam; also called *lofargram* or *sonogram*.

In active systems, two additional parameters, range and Doppler, can be estimated from the received signals, providing additional displays of range bearing and time Doppler where Doppler provides the speed estimate of the target.

In general, all three formats are required for the operator to make an informed decision. The operator must sort the outputs from all of the displays before classifying them into targets. For example, in passive narrow-band sonar, classification is usually performed on the outputs from spectral/tonal contents of the targets. The operator uses the different tonal content and its harmonic relations of each target for classification. In addition to the acoustic data information and displays, nonacoustic data such as environmental, contact and navigation information, and radar/satellite photographs are also available to the operator.

17.4.4 Signal Processing Functions

Detection of signals in the presence of noise, using classical Bayes or Neyman–Pearson decision criteria, is based on hypothesis testing. In the simplest binary hypothesis case, the detection problem is posed as two hypotheses:

H_0 : Signal is not present (referred to as the null hypothesis).

H_1 : Signal is present.

For a received wavefront, H_0 relates to the noise-only case and H_1 to the signal-plus-noise case. Complex hypotheses (M hypotheses) can also be formed if detection of a signal among a variety of sources is required.

Probability is a measure, between zero and unity, of how likely an event is to occur. For a received wavefront, the likelihood ratio L , is the ratio of P_{H_1} (probability that hypothesis H_1 is true) to P_{H_0} (probability that hypothesis H_0 is true). A decision (detection) is made by comparing the likelihood to a predetermined threshold h . (Sometimes the logarithm of the likelihood, ratio called the *log-likelihood ratio*, is used.) That is, if $L = P_{H_1}/P_{H_0} > h$, a decision is made that the signal is present.

Probability of detection P_D measures the likelihood of detecting an event or object when the event does occur. *Probability of false alarm* P_{fa} is a measure of the likelihood of saying something happened when the event did *not* occur. **Receiver operating characteristics (ROC)** curves plot P_D vs. P_{fa} for a particular (sonar signal) processing system. A single plot of P_D vs. P_{fa} for one system must fix the SNR and processing time. The threshold h is varied to sweep out the ROC curve. The curve is often plotted on either log-log scale or probability scale. In comparing a variety of processing systems, we would like to select the system (or develop one) that maximizes the P_D for every given P_{fa} . Processing systems must operate on their ROC curves, but most processing systems allow the operator to select where on the ROC curve the system is operated by adjusting a threshold; low thresholds ensure a high probability of detection at the expense of high false alarm rate. A sketch of two monotonically increasing ROC curves is given in Fig. 17.47. By proper adjustment of the decision threshold, we can tradeoff detection performance for false alarm performance. Since the points (0, 0) and (1, 1) are on all ROC curves, we can always guarantee 100% probability of detection with an arbitrarily low threshold (albeit at the expense of 100% probability of false alarm) or 0% probability of false alarm with an arbitrarily high threshold (albeit at the expense of 0% probability of detection). The (log) *likelihood detector* is a detector that

FIGURE 17.47 Typical ROC curves. Note that points (0, 0) and (1, 1) are on all ROC curves; upper curve represents higher P_D for fixed P_{fa} and, hence, better performance by having higher SNR or processing time.

achieves the maximum probability of detection for fixed probability of false alarm; it is shown in Fig. 17.48 for detecting Gaussian signals reflected or radiated from a stationary object. For spiky non-Gaussian noise, clipping prior to filtering improves detection performance.

In active sonar, the filters are matched to the known transmitted signals. If the object (acoustic reflector) has motion, it will induce Doppler on the reflected signal, and the receiver will be complicated by the addition of a bank of Doppler compensators. Returns from a moving object are shifted in frequency by $\Delta f = (2v/c)f$, where v is the relative velocity (range rate) between the source and object, c is the speed of sound in water, and f is the operating frequency of the source transmitter.

In passive sonar, at low SNR, the optimal filters in Fig. 17.48 (so-called Eckart filters) are functions of $G_{ss}^{1/2}(f)/G_{nn}(f)$, where f is frequency in hertz, $G_{ss}(f)$ is the signal power spectrum, and $G_{nn}(f)$ is the noise power spectrum.

Estimation/Localization

The second function of underwater signal processing estimates the parameters that localize the position of the detected object. The source position is estimated in range, bearing, and depth, typically from the underlying parameter of time delay associated with the acoustic signal wave front. The statistical uncertainty of the positional estimates is important. Knowledge of the first-order probability density function or its first- and second-order moments, the mean (expected value), and the variance are vital to understanding the expected performance of the processing system. In the passive case, the ability to estimate range is extremely limited by the geometry of the measurements; indeed, the variance of passive range estimates can be extremely large, especially when the true range to the signal source is long when compared with the aperture length of the receiving array. Figure 17.49 depicts direct path passive ranging uncertainty from a collinear array with sensors clustered so as to minimize the bearing and uncertainty region. Beyond the direct path, multipath signals can be processed to estimate source depth passively. Range estimation accuracy is not difficult with the active sonar, but active sonar is not covert, which for some applications can be important.

Classification

The third function of sonar signal processing is classification. This function determines the type of object that has radiated or reflected signal energy. For example, was the sonar signal return from a school of fish or a reflection from the ocean bottom? The action taken by the operator is highly dependent on this important function. The amount of radiated or reflected signal power relative to the background noise (that is, SNR) necessary to achieve good classification may be many decibels higher than for detection. Also, the type of signal processing required for classification may be different than the type of processing for detection. Processing methods that are developed on the basis of detection might not have the requisite SNR to adequately perform the classification function. Classifiers are, in general, divided into feature (or

FIGURE 17.48 Log likelihood detector structure for uncorrelated Gaussian noise in the received signal $r_j(t)$, $j = 1, \dots, M$.

FIGURE 17.49 Array Geometry used to estimate source position. (Source: Carter, G.C., 1987. Coherence and time delay estimation. *Proceedings of the IEEE* 75(2):251. © IEEE 1987.)

clue) extractors followed by a classifier decision box. A key to successful classification is feature extraction. Performance of classifiers is plotted (as in ROC detection curves) as the probability of deciding on class A , given A was actually present, or $P(A|A)$, vs. the probability of deciding on class B , given that A was present, or $P(B|A)$, for two different classes of objects, A and B . Of course, for the same class of objects, the operator could also plot $P(B|B)$ vs. $P(A|B)$.

Target Motion Analysis

The fourth function of underwater signal processing is to perform contact or target motion analysis (TMA), that is, to estimate parameters of bearing and speed. Generally, nonlinear filtering methods, including Kalman–Bucy filters, are applied; typically these methods rely on a state-space model for the motion of the contact. For example, the underlying model of motion could assume a straight line course and a constant speed for the contact of interest. When the signal source of interest behaves like the model, then results consistent with the basic theory can be expected. It is also possible to incorporate motion compensation into the signal processing detection function. For example, in the active sonar case, proper signal selection and processing can reduce the degradation of detector performance caused by uncompensated Doppler. Moreover, joint detection and estimation can provide clues to the TMA and classification processes. For example, if the processor simultaneously estimates depth in the process of performing detection, then a submerged object would not be classified as a surface object. Also joint detection and estimation using Doppler for detection can directly improve contact motion estimates.

Normalization

Another important signal processing function for the detection of weak signals in the presence of unknown and (temporal and spatial) varying noise is normalization. The statistics of noise or reverberation for oceans typically varies in time, frequency, and/or bearing from measurement-to-measurement and location-to-location. To detect a weak signal in a broadband, nonstationary, inhomogeneous background, it is usually desirable to make the noise background statistics as uniform as possible for the variations in time, frequency, and/or bearing. The noise background estimates are first obtained from a window of resolution cells (which usually surrounds the test data cell). These estimates are then used to normalize the test cell, thus reducing the effects of the background noise on detection. Window length and distance from the test cell are two of the parameters that can be adjusted to obtain accurate estimates of the different types of stationary or nonstationary noise.

17.4.5 Advanced Signal Processing

Adaptive Beamforming

Beamforming was discussed earlier in Sec. 17.4.3. The cancellation of noise through beamforming can also be done adaptively, which can improve array gain further. Some of the various adaptive beamforming techniques (Knight, Pridham, and Kay, 1981) use Dicanne, sidelobe cancellers, maximum entropy array processing, and maximum-likelihood (ML) array processing.

Coherence Processing

Coherence is a normalized (so that it lies between zero and unity), cross-spectral density function that is a measure of the similarity of received signals and noise between any sensors of the array. The complex coherence functions between two wide-sense-stationary processes x and y are defined by

$$\gamma_{xy}(f) = \frac{G_{xy}(f)}{\sqrt{G_{xx}(f)G_{yy}(f)}}$$

where, as before, f is the frequency in hertz and G is the power spectrum function. Array gain depends on the coherence of the signal and noise between the sensors of the array. To increase the array gain, it is necessary to have high signal coherence but low noise coherence. Coherence of the signal between sensors

improves with decreasing separation between the sensors, frequency of the received signal, total bandwidth, and integration time. Loss of coherence of the signal could be due to ocean motion, object motion, multipaths, reverberation, or scattering. The coherence function has many uses, including measurement of SNR or array gain, system identification, and determination of time delays (Carter, 1987, 1993).

Acoustic Data Fusion

Acoustic data fusion is a technique that combines information from multiple receivers or receiving platforms about a common object or channel. Instead of each receiver making a decision, relevant information from the different receivers is sent to a common control unit where the acoustic data is combined and processed (hence the name *data fusion*). After fusion, a decision can be relayed or fed back to each of the receivers. If data transmission is a concern, due to time constraints, cost, or security, other techniques can be used in which each receiver makes a decision and transmits only the decision. The control unit makes a global decision based on the decisions of all of the receivers and relays this global decision back to the receivers. This is called distributed detection. The receivers can then be asked to re-evaluate their individual decisions based on the new global decision. This process could continue until all of the receivers are in agreement or could be terminated whenever an acceptable level of consensus is attained.

An advantage of data fusion is that the receivers can be located at different ranges (e.g., on two different ships), in different mediums (shallow or deep water, or even at the surface), and at different bearings from the object, thus giving comprehensive information about the object or the underwater acoustic channel.

17.4.6 Application

Since World War II, in addition to military applications, there has been an expansion in commercial and industrial underwater acoustic applications. Table 17.8 lists the military and nonmilitary functions of

TABLE 17.8 Underwater Acoustic Applications

Function	Description
<i>Military:</i>	
Detection	Deciding if a target is present or not.
Classification	Deciding if a detected target does or does not belong to a specific class.
Localization	Measuring at least one of the instantaneous positions and velocity components of a target (either relative or absolute), such as range, bearing, range rate, or bearing rate.
Navigation	Determining, controlling, and/or steering a course through a medium (includes avoidance of obstacles and the boundaries of the medium).
Communications	Instead of a wire link, transmitting and receiving acoustic power and information.
Control	Using a sound-activated release mechanism.
Position marking	Transmitting a sound signal continuously (Beacons) or transmitting only when suitably interrogated (Transponders).
Depth sounding	Sending short pulses downward and timing the bottom return.
Acoustic-Speedometers	Using pairs of transducers pointing obliquely downward to obtain speed over the bottom from the Doppler shift of the bottom return.
<i>Commercial Applications:</i>	
Industrial	Oceanographic
Fish finders/fish herding	Subbottom geological mapping
Fish population estimation	Environmental monitoring
Oil and mineral explorations	Ocean topography
River flow meter	Bathyvelocimeter
Acoustic holography	Emergency telephone
Viscosimeter	Seismic simulation and measurement
Acoustic ship docking system	Biological signal and noise measurement
Ultrasonic grinding/drilling	Sonar calibration
Biomedical ultrasound

Defining Terms

Array gain: A measure of how well an array discriminates signals in the presence of noise as a result of beamforming. It is represented as a ratio of the array SNR divided by the SNR of an individual omnidirectional hydrophone. For complex noise environments array gain is also given by the overall signal gain divided by noise gain.

Beamformer: A process in which outputs from individual hydrophone sensors of an array are coherently combined by delaying and summing the outputs to provide enhanced SNR.

Coherence: A normalized cross-spectral density function that is a measure of the similarity of received signals and noise between any sensors of an array.

- Decibel (dB):** Logarithmic scale representing the ratio of two quantities given as $10 \log_{10}(P_1/P_0)$ for power level ratios and $20 \log_{10}(V_1/V_0)$ for acoustic pressure or voltage ratios. A standard reference pressure or intensity level in SI units is equal to 1 micropascal (1 pascal = 1 newton per square meter = 10 dyne per square centimeter).
- Doppler shift:** Shift in frequency of transmitted signal due to the relative motion between the source and object.
- Figure of merit/sonar equation:** Performance evaluation measure for the various target and equipment parameters of a sonar system. It is a subset, which includes reverberation effects, of the broader sonar performance given by the *sonar equations*.
- Receiver operating characteristics (ROC) curves:** Plots of the probability of detection (likelihood of detecting the object when the object is present) vs. the probability of false alarm (likelihood of detecting the object when the object is not present) for a particular processing system.
- Reverberation/clutter:** Inhomogeneities, such as dust, sea organisms, schools of fish, and sea mounds on the bottom of the sea, which form mass density discontinuities in the ocean medium. When an acoustic wave strikes these inhomogeneities, some of the acoustic energy is reflected and reradiated. The sum total of all such reradiations is called reverberation. Reverberation is present only in active sonar, and in the case where the object echoes are completely masked by reverberation, the sonar system is said to be reverberation limited.
- SONAR:** Acronym for sound navigation and ranging, adapted in the 1940s, involves the use of sound to explore the ocean and underwater objects.
- Sonar hydrophone:** Receiving sensors that convert sound energy into electrical or optical energy (analogous to underwater microphones).
- Sonar projector:** A transmitting source that converts electrical energy into sound energy.
- Sound velocity profile (SVP):** Description of the speed of sound in water as a function of water depth.
- SNR:** The signal-to-noise (power) ratios, usually measured in decibel.
- Time Delay:** The time (delay) difference in seconds from when an acoustic wavefront impinges on one hydrophone or receiver until it strikes another.

Further Information

Journal of Acoustical Society of America (JASA), *IEEE Transactions on Signal Processing* (formerly the *IEEE Transactions on Acoustics, Speech and Signal Processing*), and *IEEE Journal of Oceanic Engineering* are professional journals providing current information on underwater acoustical signal processing.

The annual meetings of the *International Conference on Acoustics, Speech and Signal Processing*, sponsored by the IEEE, and the biannual meetings of the *Acoustical Society of America* are good sources for current trends and technologies.

Digital Signal Processing for Sonar, (Knight, Pridham, and Kay, 1981) and *Sonar System Technology* (Winder, 1975) are informative and detailed tutorials on underwater sound systems. Also the March 1972 issue of *The Journal of Acoustical Society of America*, Vol. 51, No. 3 (Part 2), has historical and review papers on underwater acoustics related topics.

17.5 Electronic Warfare and Countermeasures

Robert D. Hayes

17.5.1 Introduction

Electronic warfare (EW) generally applies to military actions. Specifically, it involves the use of electromagnetic energy to create an advantage for the friendly side of engaged forces while reducing the effectiveness of the opposing hostile armed forces.

Electronic warfare support measures (ESM) or electronic warfare support (ES) are the actions and efforts taken to listen, to search space and time, to intercept and locate the source of radiated energy, and to analyze, identify, and characterize the electromagnetic energy. Tactical employment of forces is established and plans are executed for electronic countermeasures.

Electronic countermeasures (ECM) or electronic attack (EA) are those actions taken to reduce the enemy’s effective use of the electromagnetic spectrum. These actions may include jamming, electronic deception, false targets, chaff, flares, transmission disruption, and changing tactics.

Electronic counter-countermeasures (ECCM) or electronic protection (EP) are actions taken to reduce the effectiveness of enemy used ECM to enhance the use of the electromagnetic spectrum for friendly forces (Fig. 17.51). These actions are of a protective nature and are applied to tactical and strategic operations across the equipment used for sonar, radar, command, control, communications, and intelligence.

17.5.2 Radar and Radar Jamming Signal Equations

Electronic jamming is a technique where a false signal of sufficient magnitude and bandwidth is introduced into a receiving device so as to cause confusion with the expected received signal and to create a loss of

GHz	0.1	0.3	0.5	1.0	2	3	4	6	8	10	20	40	60	100

information. For a communication receiver, it simply overpowers the radio transmission; for radar, the jamming signal overrides the radar echo return from an object under surveillance or track. The jamming equation is the same for both communications and radar systems. In the case of a radar jammer, there are several operational scenarios to consider.

The radar jammer signal level must be determined for the various applications and jammer location. When the jammer is located on the target (self-protection), the jammer signal level must exceed the effective radar cross section of the target to form an adequate screen; when the jammer is located away from the vehicle under protection (stand-off jammer), the jammer should simulate the expected radar cross section observed at a different range and different aspect.

The monostatic radar received signal power equation representing the signal received at an enemy detection radar, and the received jamming power transmitted toward the same enemy detection radar, are presented in the equations given in Table 17.9. Each quantity in the equations is defined in the table. These

TABLE 17.9 Fundamental Radar Equations

Monostatic Radar Equation	Jamming Radar Equation	Quantity	Dependent Function

quantities are dependent on electrical, polarization, material, shape, roughness, density, and atmospheric parameters.

Background interference is encountered in every branch of engineering. The received radar/communication signal power will compete with interfering signals that will impose limitations on performance of the detecting electronic system. There are many types of interference. A few are channel crosstalk, nonlinear harmonic distortion, AM and FM interference, phase interference, polarization cross talk, and noise. The common limiting interference in electronic systems is noise.

There are many types of noise. Every physical body not at absolute zero temperature emits electromagnetic energy at all frequencies, by virtue of the thermal energy the body possesses. This type of radiation is called thermal noise radiation. Johnson noise is a result of random motion of electrons within a resistor; semiconductor noise occurs in transistors; shot noise occurs in both transmitter and receiver vacuum tubes as a result of random fluctuations in electron flow. These fluctuations are controlled by a random mechanism and, thus, in time are random processes described by the Gaussian distribution. The signal is random in phase and polarization, and usually are broad in frequency bandwidth. The average noise power is given by

$$P_N = kTB$$

where

P_N = power, watts

k = Boltzman's constant

T = temperature, absolute degrees.

Noise jamming has been introduced into EW from several modes of operation. *Spot noise jamming* requires the entire output power of the jammer to be concentrated in a narrow bandwidth ideally identical to the bandwidth of the victim radar/communication receiver. It is used to deny range, conversation, and sometimes angle information. *Barrage noise jamming* is a technique applied to wide frequency spectrum to deny the use of multiple channel frequencies to effectively deny range information, or to cover a single wide-band system using pulse compression or spread-spectrum processing. *Blinking* is a technique using two spot noise jammers located in the same cell of angular resolution of the victim system. The jamming transmission is alternated between the two sources causing the radar antenna to oscillate back and forth. Too high a blinking frequency will let the tracker average the data and not oscillate, whereas too low a frequency will allow the tracker to lock on one of the jammers.

In free space the radar echo power returned from the target varies inversely as the fourth power of the range, whereas the power received from a jammer varies as the square of the range from the jammer to the victim radar. There will be some range where the energy for the noise jammer is no longer great enough to hide the friendly vehicle. This range of lost protection is called the burn-through range.

In both EW technology and target identification technology, the received energy, as compared to the received power, better defines the process of signal separation from interference. The received radar energy will be given by

$$S = P\tau$$

where τ is the transmitted pulse length. When the radar receiver bandwidth is matched to the transmitter pulse length, then

$$S = \frac{P_r}{B_r}$$

where B_r is the bandwidth of radar receiver. The transmitted jamming energy will be given by

$$J = \frac{P_j}{B_j}$$

where B_j is the bandwidth of jamming signal.

If for a moment, the system losses are neglected, the system efficiency is 100%, and there are negligible atmospheric losses, then the ratio of jamming energy received to radar energy

$$\frac{J}{S} = \frac{4\pi P_j G_j G_r \lambda^2 F_j^2 R_r^4 B_r}{P_r G_r^2 \sigma \lambda^2 F_r^4 R_j^2 B_j}$$

for the standoff jammer, and

$$\frac{J}{S} = \frac{4\pi P_j G_j B_r R^2}{P_r G_r \sigma F^2 B_j}$$

for the self-protect jammer. For whatever camouflage factor is deemed sufficient (example, $J/S = 10$), the burnthrough range can be determined from this self-protect jamming equation.

Radar Receiver Vulnerable Elements

Range gate pulloff (RGPO) is a deception technique used against pulse tracking radars using range gates for location. The jammer initially repeats the skin echo signal with minimum time delay at a high power to capture the receiver automatic gain control circuitry. The delay is progressively changed, forcing the tracking gates to be pulled away from (walked off) the skin echo. Frequency memory loops (FMLs) or transponders provide the variable delay. The deceptive pulse can be transmitted before the radar pulse is received if the pulse repetition rate is stored and repeated at the proper time. In this technique the range gate can be either pulled off or pulled in.

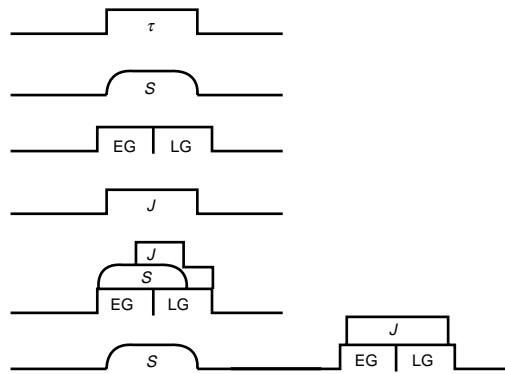

FIGURE 17.52 Range gate pulloff concept.

One implementation is shown in Fig. 17.52. A split gate (early/late gates) range tracking scheme has two gates, which are positioned by an automatic tracking loop so that equal energy appears in each gate. The track point is positioned on the target centroid. First, there is an initial dwell at the target range long enough for the tracker to capture the radar receiver. The received echo has S energy.

Then, a jamming signal is introduced which contains J amount of energy. The energy in the early and late gates are compared and the difference is used to reposition the gates so as to keep equal energy in each gate. In this manner, the range gate is continually moved to the desired location. When RGPO is successful, the jamming signal does not compete with the target’s skin return, resulting with an almost infinite J/S ratio.

Velocity gate pulloff (VGPO) is used against the radar’s received echo modulation frequency tracking gates in a manner analogous to the RGPO used against the received echo signal amplitude tracking gates. Typically in a Doppler or moving target indicator (MTI) system there are a series of fixed filters or a group of frequency tracking filters used to determine the velocity of a detected moving target. By restricting the bandwidth of the tracking filters, the radar can report very accurate speeds, distinguish between approaching and receding targets, and reduce echos from wide-band clutter. Typically, the tracking filters are produced by linearly sweeping across the frequency domain of interest to the detecting radar. The ECM approach to confuse this linear sweep is to transmit a nonlinear frequency modulated sweep which could be parabolic or cubic. The jamming signal will cause the Doppler detector to be walked off of the true frequency as shown in Fig. 17.53.

FIGURE 17.53 Frequency gate pulloff concept.

Another technique used to generate a frequency shift is to modulate the phase of the transmitted jamming signal. The instantaneous frequency of any modulated signal is directly related to the change in phase.

$$2\pi f = \frac{d\theta}{dt}$$

When the phase is given by $\theta = 2\pi f_c t + kt$ where f_c is the carrier frequency and k the change of phase with time, then

$$\frac{d\theta}{dt} = 2\pi f_c + k$$

and

$$f = f_c + \frac{k}{2\pi}$$

This type of modulation has been referred to as serrrodyne modulation and used with control voltage modulation of an oscillator or traveling wave tube (TWT).

An inverse-gain jammer is a repeater in which a signal is directed back toward the enemy radar to create false targets by varying the jammer transmitted signal level inversely with the magnitude of the received radar signal. To defeat conical scan trackers, the transponder signals have been modulated at the nutation of the scan rate to deceive angle tracking (Fig. 17.54).

FIGURE 17.54 Surgical countermeasure block diagram.

Most ECM techniques are open-loop control functions, which add signals to the enemy radar return signal so as to confuse or deceive the weapon's ability to track.

17.5.3 Radar Antenna Vulnerable Elements

Radar backscatter from a variety of antennas was measured by Hayes at Georgia Institute of Technology for the U.S. Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio (Hayes and Eaves, 1966).

Typical measured data are presented in Fig. 17.55 and Fig. 17.56 for an AN/APS-3 antenna. This antenna is an 18-in. parabolic dish with a horizontally polarized double-dipole feed built upon a waveguide termination for use at a wavelength of 3.2 cm with an airborne radar. The instrument measured radar operated at a wavelength of 3.2 cm and transmitted either horizontally or vertically polarized signals, while simultaneously receiving both horizontally and vertically polarized signals.

First, the APS-3 antenna was terminated with a matched waveguide load and the backscatter patterns for horizontally polarized and vertically polarized echos obtained for both horizontal polarized transmissions and, second, for vertical polarized transmissions. Then an adjustable short-circuit termination was placed at the end of the waveguide output port. The position of the waveguide termination greatly influenced the backscatter signal from the APS-3 antenna when the polarization of the interrogating measurement radar matched the operational horizontal polarization of the antenna. Tuning of the adjustable short circuit produced returns both larger and smaller than those returns recorded when the matched load was connected to the output port. The waveguide termination had very little effect on the backscatter when the interrogating transmission was vertical polarization (cross pol). In addition to the APS-3, there were several other antennas and pyramidal horns (both in-band and out-of-band) investigated. The W shape in the center of the main beam is typical of backscatter patterns when the waveguide is terminated in

FIGURE 17.55 Backscatter from AN/APS-3 antenna, parallel polarization.

FIGURE 17.56 Backscatter from AN/APS-3 antenna, cross polarization.

a matched load and when the interrogating measurement radar matched the operational frequency and polarization of the antenna under test.

Butler (1981) of Hughes Radar Systems has presented an analytical model of an antenna consisting of two scattering mechanisms. One component is the backscatter from the antenna surfaces (one-way scattering), and the second component is scattering from the feed system, which is coupled to the waveguide input/output port (round trip scattering). It has been shown that the amplitude and phase relationships of the two scattering mechanisms will interact and can create this W shape in the equivalent main beam of an impedance-matched antenna when interrogated at the designed operating frequency and polarization.

A reflector antenna having a curved surface will generate a polarized signal, which is orthogonal to the polarization of the signal impinging upon the curved surface, when the impinging signal is not parallel to the surface. This new (cross-polarized) signal is a result of the boundary value requirement to satisfy a zero electrical field at the surface of a conductor. For a parabolic reflector antenna designed for operation with a horizontal polarization, there will be a vertically polarized component in the transmitted signal, the received signal, and the reflected signal. Curved surfaces produce cross-polarized components regardless of frequency and polarization. Thus, if horizontal polarized signals impinge upon a curved surface, vertical polarized signals as well as horizontal polarization are produced; vertical polarized impinging signals produce horizontal signals; right-circular polarized impinging signals produce a cross-polarized left-circular polarized signal, etc.

An example of parallel- and cross-polarized signals from a parabolic reflector antenna is shown in Fig. 17.57. These data are provided by the courtesy of Millitech Corp. Please note that the antenna is designed to operate at 94 GHz, showing that the effect of cross polarization will occur even at millimeter waves. The orthogonally polarized signals have four peaks (one in each quadrant), which are on the 45° lines to the principal axis and are within the main beam of the principal polarized signal. The magnitude of these peaks is typically 13–20 dB below the peak of the principal polarized signal. The cross-polarized signal is

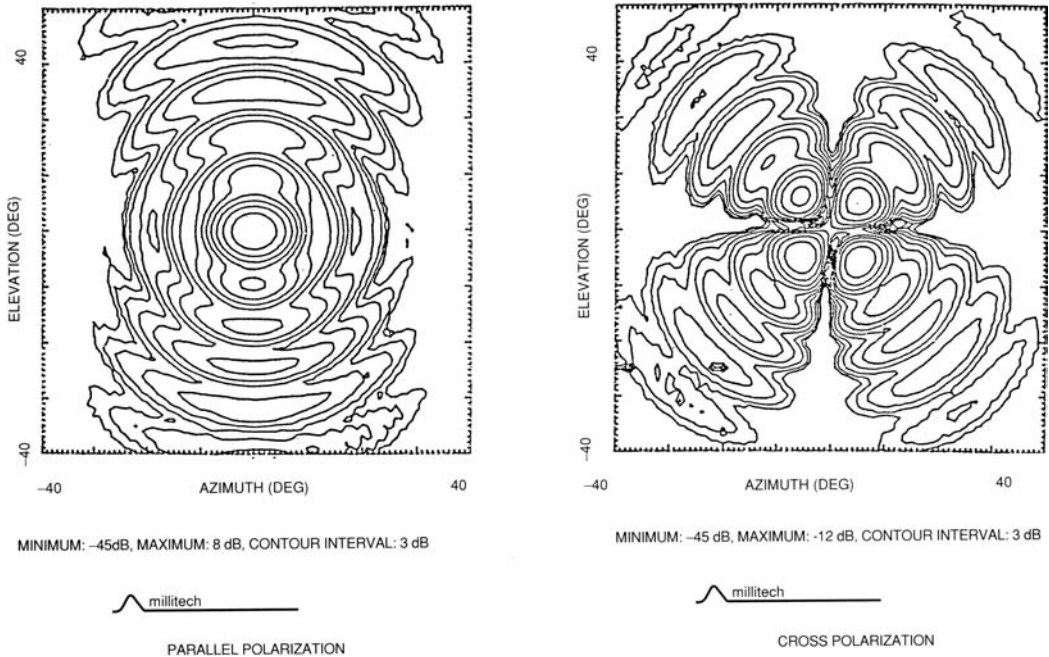

FIGURE 17.57 Antenna radiation patterns for parabola, conical feed, 94 GHz.

theoretically zero on the two principal plane axes, so when perfect track lockup is made, cross polarization will have no effect.

Injecting a cross-polarized signal into a system will have the same effect as entering a monopulse tracker. That is to say, the receiving system cannot detect the difference between parallel and cross-polarized signals and yet the cross-polarized pattern has nulls on the major axes and peaks off the boresight. When the cross-polarized signal dominates, the track should go to an angle at about the 10-dB level of the normal sum main beam.

Cross-eye is a countermeasure technique employed against conical scan and monopulse type angle tracking radars. The basic idea is to intercept the enemy propagated signal, phase shift the signal, and then retransmit the signal to make it appear that the signal represents a reflected return emanating from an object located at an angular position different from the true location. In generating the retransmitted signal, there are two basic approaches to signal level configuration: saturated levels and linear signal levels. A typical implementation of a four antenna cross-eye system is shown in Fig. 17.58. Let us assume that

FIGURE 17.58 Cross-eye system block diagram.

the two transmit antennas radiate about the same amount of power (a slight difference could occur due to line loss, different amplifier gain, etc.). The signal received by antenna 2 is simply amplified with no phase shift and retransmitted out antenna 3, whereas the signal received by antenna 4 is amplified and phase shifted 180° before it is retransmitted out of antenna 1.

The two wavefronts (generated by antennas 1 and 3) are of equal amplitude and 180° out of phase, thus their sum will be zero on boresight, while their differences will be finite. Radars, such as a monopulse tracker, which generate sum and difference signals, will interpret the results of the two wave fronts as a tracking error. The track point will drift, moving the target off boresight in such a manner as to cause the radar lockup point to be off target, where the difference signal becomes zero.

The maximum tracking error for a saturated cross-eye is about $0.5\theta_{3\text{dB}}$ where $\theta_{3\text{dB}}$ is the antenna half-power beamwidth of the sum pattern of the radar. This is the angular position where the difference pattern has peaks and zero slope.

The addition of sawtooth modulation to the cross-eye signal can produce multiple beamwidth tracking errors in excess of the $0.5\theta_{3\text{dB}}$. Figure 17.59 shows two sawtooth waveforms. The RF power from one antenna is linearly increased as a function of time, while the RF power from the other antenna is linearly decreased with time. At the end of the ramp, the process is repeated, creating the sawtooth. When the antenna is given sufficient momentum during the first half of the modulation cycle to enable the antenna to traverse the singularity at $0.5\theta_{3\text{dB}}$, tracking pulloff will occur. Successive periods of modulation can cause the monopulse tracker to lock onto successive lobes of the sum pattern.

FIGURE 17.59 Saw-tooth modulation diagram for cross-eye.

In linear cross-eye, the amplifiers are never allowed to go into saturation. Linear cross-eye differs from saturated cross-eye in that the sum pattern is zero for all pointing angles, and the difference pattern is never zero. No stable track points exist with linear cross-eye and large tracking errors can occur, resulting in large angular breaklocks.

The two most common types of angle tracking used today are sequential lobing and simultaneous lobing.

A common implementation of sequential lobing is to rotate a single antenna lobe about the boresight axis in a cone; the signal amplitude will be modulated at the conical scan frequency. The direction off the boresight is determined by comparing the phase of the scan modulation with an internal reference signal.

As the source is brought on to axis, the modulation will go to zero. The source of the RF signal can be either an active source such as a beacon or a communication transmitter, or the target scattering, as in a radar application.

In a typical radar, the conical scan rate is chosen early in the system design. The rate should be slow relative to the radar pulse repetition frequency (PRF), so as to have ample samples to determine the error amplitude. However, the scan rate must be high enough to track source motions in the expected dynamic engagement. The list on tradeoffs puts the scan rates typically in the range of 10–1000 Hz, where the weight and size of the antenna play an important role.

The most effective countermeasure is to introduce an interference signal into the tracker that has the same frequency as the tracker's scan rate, but is 180° out of phase. This is simple to accomplish when the victim's scan rate is known to the ECM system. When the exact scan frequency is not known, then the ECM system must vary the jamming modulation over the expected range of the victim's operation with enough power and phase difference to cause mistracking. A technique known as swept square wave (SSW) has been successful in pulling radar conical scanners off track. The critical item is to keep within the audio bandwidth of the tracker control loop. There can be several variables in attempting to penetrate the tracking loop controls (Fig. 17.60). The sweep frequency may be linear, nonlinear, or triangular, and the sweep time may have a varying time base and dwell times.

FIGURE 17.60 Swept square wave for conical scan pulloff.

For radar trackers that do not scan the transmitted beam, but instead scan a receiving antenna, the scanning rate is not usually known. It can be assumed with reasonable accurate results that the transmitted beam will be close to boresight of the COSRO tracker, so that a repeated RF signal directed back toward the illuminating beam will intercept the COSRO beam. This energy transmitted toward the victim radar should be at the same RF carrier frequency and amplitude modulated with sufficient noise spectrum so as to cover the audio bandwidth of the tracking control system. The use of pulsed and CW TWTs as jamming noise power sources is common.

In a radar system employing track while scan (TWS), the tracking function is performed in a signal processor/computer by keeping track of the reported position in range, azimuth, and elevation on a scan-to-scan basis. The antenna must move reasonably fast over the field-of-view in order to report target locations in a sufficiently timely basis. The antenna does not produce continuous tracking, and thus does not remain fixed in azimuth or elevation for any long period of time. The countermeasure to a TWS radar is to move fast, turn fast, dispense chaff, noise jam, or some cover technique.

Simultaneous lobing, or monopulse techniques, reduce the number of pulses required to measure the angular error of a target in two dimensions, elevation and azimuth. A minimum of three pulses is required in monopulse tracking, whereas more than four pulses are required for conical scan trackers. In the amplitude comparison monopulse, each pulse is measured in a sum and difference channel to determine the magnitude of the error off boresight, and then the signals are combined in a phase sensitive detector to determine direction. In a four horn antenna system, a sum pattern is generated for transmission and reception to determine range and direction. Two difference patterns, elevation and azimuth, are generated on reception for refining the error off the boresight. The receiving difference patterns produce a passive

FIGURE 17.61 Squint angle monopulse $(\sin u)/u$ patterns.

receiving tracking system, and there is no scanning. Difference patterns are generated by two patterns (for each plane of tracking) offset in angle by the quantity squint angle, $u_s = \frac{\pi d}{\lambda} \sin \theta_s$, and 180° phase difference, such that on boresight ($u = 0$) the difference pattern has a null, and this null is in the center of the sum pattern. The use of the function u instead of the angle θ keeps the offset functions mirror images. There is no absolute optimum value of squint angle since the desire may be to have the best linearity of the track angle output, or to have the maximum sensitivity, with all of the possible illumination functions on the reflecting surface (Rhodes, 1980).

The monopulse tracker is almost completely immune to amplitude modulations.

The two beams, which form the difference pattern (one beam $+$, and one beam $-$), cross each other at less than 3 dB below their peaks for maximum error slope-sum pattern product and to give increased angle tracking accuracy. This can be seen in Fig. 17.61 in Skolnik (1962) and in Fig. 17.62 in Rhodes (1980), where a comparison is shown between squint angle and the two difference beam magnitude crossover.

The difference pattern has a minimum on boresight, which coincides with the peak of the sum pattern on boresight. The difference pattern is typically 35–40 dB below the sum pattern. These pattern values will typically improve the identity of the target location by 25:1 over a simple track-the-target in the main beam technique. Some ECM techniques are to fill the null of the difference channel so that the tracking accuracy is reduced from the 25:1 expected. If two transmitters are separated by the 3 dB width of the sum pattern (about the same as the peak of the two difference patterns), then a standard ECM technique of blinking of the two transmitters works very well.

Squint angle is a parameter within the control of the victim antenna designer; it may be chosen so as to optimize some desired function such as the best tracking linearity angle output, or maximum sensitivity on boresight. With the many options available to the antenna designer of the victim radar, the ECM designer will have to make some general assumptions. The assumption is that the squint angle off boresight is 0.4

FIGURE 17.62 Two targets under track by monopulse antenna.

of the half-power antenna beamwidth, given by setting the two difference patterns at a crossover of 2 dB, as shown in Fig. 17.61. (A squint of 0.5 the half-power angle is given by a 3 dB crossover). Two signals of equal amplitude (these may be radar backscatters or electronic sources, it makes no difference) and separated by 0.6 of the sum half-power beamwidth are introduced into the monopulse tracker. A typical monopulse tracker victim radar will seek the positive-going zero crossing of the error signal as a track point. In an example considering these system parameters, when the phase difference of these two signals is 90° or less, the track center position is between the two signals. When the phase difference between the two signals is between 90 and 180° the positive going error signal is both to the left and the right outside the signal sources and the radar track will be outside of the sources. This can be seen in Fig. 17.62. (Dr. E. Rhodes, private communication, Georgia Institute of Technology). Neither target is sought, and wandering of the boresight center is expected. Complex targets, such as multiscattering facet aircraft, can produce 180° differences by slight changes in angle of attack. At X-band, 180° is only 1.5 cm. Thus it is shown that in a buddy system, a monopulse radar tracker can be made to track off of the two sources by slight changes in flight course.

17.5.4 Radar Counter-Countermeasures

The concept of counter-countermeasures is to prevent, or at least decrease, the detection, location, and tracking processes so that the mission can be accomplished before the victim group can defeat the attackers. Reducing the radar scattering cross section has produced real time advantages in combat. This technique, commonly referred to as stealth, has become a part of all advanced systems. The concept is to reduce the cross section of the weapon's delivery system to such a low value that the detection range is so short that the defense system does not have time to react before the mission is completed.

The basic concepts of stealth is to make the object to appear to have a characteristic impedance that is the same as free space, or to absorb all energy that impinges upon our platform, or to reflect the energy in some obscure direction. This is not a new concept. The Germans were using paints and shaping techniques on their U-boats during WW II to reduce 3-GHz radar reflections. A semiflexible material was developed at the Massachusetts Institute of Technology Radiation Laboratories in the U.S. during WW II and it was called HARP. The material consisted of copper, aluminum, and ferromagnetic material in a nonconduction rubber binder and made into cloth, sometimes with conductive backing. HARP-X was used at the X-band. Several techniques are appropriate in this process. First, the impinging signal can be reflected off axis so that no signals are returned in the direction of the transmitter/receiver, or multisignals are generated from multisurfaces, which will be out of phase and appear to cancel in the direction of the transmitter/receiver. These techniques are accomplished by physical configuration and shaping of our platform. The second approach is to bend, absorb, or alter the propagation of the impinging wave in the material covering our platform. Radar absorbing material (RAM) techniques are accomplished by material changes: typically, changing the complex dielectric constant, the dielectric-loss tangent, the magnetic permeability, and/or the magnetic-loss tangent. The Salisbury screen (Salisbury, 1952), single layer of dielectric material backed by a reflecting surface, is often used as a model.

These devices create a resonant impedance to reduce reflections at multiple frequencies corresponding to multiple quarter-wavelengths of the dielectric material. Multilayers, or Jaumann absorbers, are generally more frequency broadband absorbers and may even be graded multielectric or multimagnetic materials and thus increase the effectiveness at angles off of normal. Knott has shown that the thickness of the absorber can be reduced and the bandwidth considerably expanded if the sheets are allowed to have capacitive reactance in addition to pure resistance (Knott and Lunden, 1995).

The physics of RAM is well described by the Fresnel reflection and transmission equations. The material composite is driven by application, and includes concerns such as weight, weather durability, flexibility, stability, life cycle, heat resistance, and cost.

The application of electronic coding of the transmitter signal and new techniques in processing the received signals have lead to a system concept referred to as low probability of intercept (LPI). There are many subtechnologies under this great umbrella, such as spread spectrum and cover pulses on transmission,

pulse compression, frequency-coded and phase-coded chirp, frequency hopping, and variable pulse repetition frequencies. Dave Barton (1975, 1977) has collected a number of papers describing the state of unclassified technology before 1977 in two ready references. A number of publications, primarily U.S. Naval Research Laboratory reports and IEEE papers on coding techniques and codes themselves have been collected by Lewis, Kretschmer, and Shelton (1986).

In developing an LPI system concept, the first item will be to reduce the peak power on transmission so that the standoff detection range is greatly reduced. To have the same amount of energy on target, the transmitter pulse length must be increased. To have the same resolution for target detection, identification, and tracking, the new long pulse can be subdivided on transmission and coherently compressed to construct a much shorter pulse on reception. The compressed pulse produces an effective short pulse for greater range resolution and a greater peak signal, which can exceed noise, clutter, or other interference for improved target detection.

One of the earliest pulse compression techniques was developed at the Bell Telephone Laboratories (Klauder et al., 1960; Rhodes, 1980). The technique was called CHIRP and employs frequency modulation. In a stepped modulation, each separate frequency would be transmitted for a time, which would correspond to a pulse length in a pulsed radar system. Upon reception, the separate frequencies are folded together to effectively form one pulse width containing the total energy transmitted. In a linear modulation, the frequency is continuous swept over a bandwidth in a linear manner during the transmitted pulse length. The received signal can be passed through a matched filter, a delay line inversely related to frequency, an autocorrelator, or any technique to produce an equivalent pulse length equal to the reciprocal of the total bandwidth transmitted. The amplitude of this compressed signal is equal to the square root of the time-frequency-bandwidth product of the transmitted signal. The errors are limited to system component phase and frequency stabilities and linearities over the times to transmit and to receive. When using the Fourier transforms to transform from the frequency domain to the time and thus range domain, sidelobes are generated, and these sidelobes appear as false targets in range. Sidelobe suppression techniques are the same as employed in antenna sidelobe suppression design (Fig. 17.63).

FIGURE 17.63 Sidelobe interference reduction concept.

One of the first biphase coded waveforms proposed for radar pulse compression was the Barker code. See for example, Farnett, Howard, and Stevens (1970). This code changes the phase of the transmitted signal 180° at a time span corresponding to a pulse length of a standard pulse-transmitter radar. The Barker codes are optimum in the sense that the peak magnitude of the autocorrelation function is equal to the length of the coded pulse (or the number of subpulses), and the sidelobes are less than one. When the received signal is reconstructed from the phase domain, the range resolution is the same as the pulse length (or the length of a Barker subpulse) of the standard pulse-transmitter radar.

The maximum length of a Barker code is 13, and this code has sidelobes of -22.3 dB. The phase will look like $+++ + -- + + - + - +$, or $----- + + -- + - + -$.

There are many phase codes discussed by Lewis, Kretschmer, and Shelton (1986), which are unique and thus have unique autocorrelation functions. The compression ratios can be very large and the side lobes very low. The price to be paid is equipment phase stability in polyphase code implementation, length of time to transmit, minimum range due to the long transmitted pulse, and equipment for reception signal processing. The advantages gained are high range resolution, low peak power, forcing the observer to use

more power in a noise mode because your radar uses wider bandwidth spread over segments of narrow bandwidths.

Another technique found helpful in reducing interference is to change the transmitted frequency on a pulse-by-pulse basis. This frequency hopping is effective, but does require that the receiver and local oscillator be properly tuned so that the receiver is matched to the return signal for efficient operation. When Doppler or moving target indicators are employed, then the frequency hopping is done in batches. There must be enough pulses at any one frequency to permit enough resolution in the Fourier transform (FT) or the proper number of filter banks to resolve the Doppler components. If the transmitter can handle the total bandwidth and keep each frequency separate so there is no crosstalk in the FTs or in the filters, then this is very effective jamming reduction. Today's digital systems are set up for frequency groups like 32, 64, or 128 and then repeat the frequency hopping in the same frequency direction, or the reverse direction. This reduces velocity gate pulloff.

If the counter measure system has identified your PRF and thus can lock on the your radar's range gate, then there are several techniques to reduce the EW range-gate pulloff. One technique is to place a noise pulse over the standard pulse. This noise pulse is longer than the system range resolution pulse and is not symmetrical around the range pulse. Only your system should know where your own target identification pulse is in the chain of PRF pulses. Another technique is to change the PRF after a batch of pulses have been transmitted. Typically the batch length is controlled in a digital manner. Again, as in the case of frequency hopping, PRF hopping still must permit processing in range for resolution, in frequency for Doppler, and in polarization (or other identifiers) for target identification.

So far as our system is concerned, there is no difference if a jamming or interference signal enters the main beam of our system antenna or a sidelobe of our system antenna. From the jammer's point of view, there needs to be 20–30 dB more power, or 20–30 dB closer in range if the jammer is directed at a sidelobe instead of the main antenna lobe.

Suppression of sidelobe jamming can be accomplished by employing omnidirectional auxiliary antennas having gains greater than the highest sidelobe to be suppressed, and yet lower than the main beam of the antenna. The auxiliary antenna feeds a receiver identical to the receiver used by the radar. The detected output of the auxiliary receiver and the radar receiver are compared, and when the auxiliary receiver output is larger than the radar then the radar is blanked in all range cells where this occurs. The auxiliary antenna should be placed as close as possible to the phase center of the radar antenna to insure that the samples of the interference in the auxiliary antenna can be correlated with interference in the main radar antenna. This requires that the time of arrival of the signals to be compared must be less than the reciprocal of the smaller of the two bandwidths, in the radar receiver or the interference signal.

17.5.5 Chaff

Cylindrical metal rods scatter energy in the same manner as a dipole radiates energy. The same parameters affect the efficiency, beamwidth, loss, and spatial patterns. Thus, in this discussion of chaff as a scattering element, consideration will be given to rod length in terms of excitation frequency, length-to-diameter ratio, impedance or loss scattering pattern as a function of polarization, and interaction (or shielding) between adjacent elements.

The aerodynamic characteristics are determined by material, density, shape, drag coefficient, and atmospheric parameters such as temperature, pressure, and relative humidity. In addition to these parameters, the movement of a rod is strongly influenced by local winds, both horizontal and vertical components, and by wind turbulence and shear.

When all of these variable parameters are defined, the radar scattering characteristic of a collection of rods forming a cloud of chaff can be calculated. The radar parameters of interest in this presentation are the scattering cross section from the cloud, the power spectral density to define the frequency spread, Doppler frequency components, polarization preference, signal attenuation through the cloud, bandwidth, and length of time that these clouds can be expected to exist.

From antenna theory, the tuned half-wave dipole produces the maximum scattering coefficient. There are sources for reference reading; examples are Terman (1943); Kraus (1950); Thourel (1960); Jasik (1961); Eustace (1975–1991); and Van Vleck, Bloch, and Hamermesh (1947).

When the dipole is observed broadside, and with a polarization parallel to the rod, then the maximum radar cross-section is observed and has a value of

$$\sigma = 0.86\lambda^2$$

As the dipole tumbles and is observed over all possible orientations, then the average radar cross section has been calculated and found to be

$$\sigma = 0.18\lambda^2$$

Since the rod has a finite diameter, the maximum scattering cross section occurs for lengths slightly less than $\lambda/2$. A reasonable value of 0.48λ for the length will be assumed to compensate for the end effects of the rod. The first resonance is plotted as a function of the length-to-diameter ratio in the June, 1976 edition of ICH (Eustace, 1975–1991). The equations relating radar cross section to the rod length and diameter in terms of wave length are complicated. The radar cross section has been shown to be directly related to the ratio of physical length-to-radar wave length, and inversely related to the logarithm of the physical length-to-radius ratio in Van Vleck, Bloch, and Hamermesh (1947). Their article is a classic and, along with their references, is the place to begin.

The polarization of the observing radar and the alignment of the chaff material is important since horizontally aligned rods fall more slowly than vertically aligned rods. Under many applications, one end of the chaff filaments is weighted causing these rods to be vertically aligned shortly after release, thus enlarging the chaff cloud rapidly in the vertical elevation plane as well as making the radar cross section of the lower elevation portion of the cloud more susceptible to vertically polarized waves and the upper elevation section of the chaff cloud having a higher cross section to horizontally polarized waves.

Chaff elements have been constructed in all sizes and shapes. Early manufactured elements were cut from sheets of metal, were rectangular in cross section and cut to half-wave dipoles in length; some were bent in V shape, some were long to form ribbons, some were made as ropes; some were cut from copper wire and some from aluminum. In the past decade or two, glass rods coated with aluminum have become very popular, and this configuration will be assumed typical for this discussion. There has been a reasonable amount of experimental work and calculations made for dipoles constructed of both 1-mil- and 1/2-mil-diam glass rods for use as chaff. The metal coating should be at least 3 skin depths at the designed frequency. One skin depth is defined as the thickness where the signal has decreased to $1/e$ of the original value.

There have been limited amounts of work done at 35 and 95 GHz as compared to much work done at lower frequencies. Consider that the wave length at 35 GHz is only 0.857 cm and a half-wave length is only 0.1687 in. Thus, a cloud of dipoles will be a lot of very short elements of material. To have a reasonable length-to-diameter ratio and reduce end effects, as well as to provide good electrical bandwidth, it will be assumed that 1/2-mil-diam dipoles would be acceptable. From these dimensions, manufacturing of large bundles of these dipoles is not a trivial matter. Some areas of concern are: (1) the plating of the small diameter glass will not be simple and most likely will produce considerable variations in weight and L/D , with results in varying fall rates and changes in bandwidth of the scattering signal; (2) to consistently cut bundles of pieces of elements this short in length requires considerable ability; and (3) it is required that each dipole be independent and not mashed with several other dipoles or the result is reduction in radar cross section and bird nesting. These effects result in lost efficiency.

There are two types of antennas, which are discussed in the literature on antennas: the thin-wire antenna and the cylindrical antenna. The thin-wire antenna model, where assumed length-to-diameter is greater than 5000, is used to predict general scattering patterns and characteristic impedance as a function of rod length and frequency. The cylindrical antenna will show the effect of wire diameter, which in turn reveals changes in the reactive portion of the terminal impedance and, thus, changes in gain, propagation and scattering diagrams, filling in of pattern nulls, reduction of sidelobes, and wider frequency bandwidth.

It has been shown that a thin-wire half-wave dipole, excited at the center, and at resonance, has an impedance in ohms of

$$Z = 73.2 + j42.5$$

When the length is not half-wave, and the diameter is not negligible, then to a first-order approximation

$$Z = 73.2 + j42.5 \pm j120 \left[\ln \frac{L}{D} - 0.65 \right] \cot \frac{2\pi L}{\lambda}$$

As is the response in all tuned circuits, the bandpass characteristics are primarily determined by the reactive elements as the frequency moves away from the resonant frequency. In low Q circuits, the real part of the impedance also has a notable effect on the total impedance and, thus, also on the bandpass characteristics. To a first-order effect, the real part of the half-wave dipole does not change drastically (less than 10%) from 73.2 Ω; however, the reactive part varies as (ln L/D). As shown by Van Vleck, Bloch, and Hamermash (1947), the radar cross section off of resonance is expressed in reciprocal terms of ln(rod length/rod radius). The effective half-power bandwidth of dipole scatters is, thus, usually referenced to the ratio of dipole length to dipole diameter as shown in Fig. 17.64. As it is desirable to have some bandwidth in television antennas, it is also desirable to have some bandwidth in the radar scattering from chaff, which leads to a measurable diameter of the rods or width of the ribbon strips used for chaff.

FIGURE 17.64 Backscatter bandwidth response for chaff.

Consider an application at X-band in which it is desirable to screen against a wide-band pulse compression radar having a bandwidth of 1.5 GHz. The rods will be cut to 0.48λ. From Fig. 17.64, the value of L/D = 750,

$$L/D = 750 = 0.48\lambda/D,$$

where D = 0.48 × 3 cm/750 = 0.00192 cm = 0.000756 in = 0.756 mil.

Consider now the generation of a chaff cloud having a radar backscatter cross section per unit volume of -60-dB m²/m³. This value cross section is comparable to the radar return from 10 mm/h of rain observed at X-band (Currie, Hayes, and Trebits, 1992). These small aluminum-coated glass cylinders fall very slowly in still air and have been known to stay aloft for hours. The movement is so strongly influenced by local wind conditions that meteorologists in several countries (including the former U.S.S.R., Germany, and the U.S.) have used chaff clouds to determine wind profiles (Nathenson, 1969). Local conditions give extreme wind variations even when the local wind structure is free from perturbations such as squalls, fronts, thunderstorms, etc. Some wind profile models include terrain surface material such as water, grass, dirt, and surface roughness, time of day, time of year, northern hemisphere, and other parameters shown to affect a particular area. At altitudes above 500 ft, the profile of wind has been shown to vary mostly in a horizontal manner, with little vertical constantly defined variations (AFCRC, 1960). The strong jet streams at around 35,000–40,000 ft define the topmost layer typical of zero water vapor levels, zero oxygen levels, definable temperature profiles, wind stability, and pressure profiles. This being the case, it behooves the EW engineer to apply local meteorological records whenever possible.

One-mil-diam aluminum-coated, glass-filament chaff, for example, will adjust to sharp wind gust of up to 50 ft/s within 15 ms (Coleman, 1976–1977). The vertical fall rate of chaff is proportional to the weight and air resistance; thus, the important chaff parameters are diameter, length, and coating. A typical approach is to use a mixture of dipole diameter sizes so that a vertical cloud is generated from different fall rates. For the example above, the diameter mixture could be between 0.5- and 1.0-mil coated glass.

Consider a typical wind condition of a 5-kn horizontal wind, and a wind profile of 1/5 power relationship at a height below 500 ft. Coleman (1976–1977) has shown that a cloud mixture of 0.5–1.0 mil chaff would stay aloft for about 20 min when dispensed at 500 ft. The chaff cloud will smear in both elevation and in horizontal dimensions. The volume of the ellipsoid generated by the horizontal winds and the vertical fall rate is given by

$$\text{volume} = V = \frac{4}{3}\pi abc$$

In this example $a = 100$ ft and $b = c = 300$ ft. The resulting volume is 1,068,340 m³.

The radar cross section of such a cloud is given by

$$\begin{aligned}\sigma_T &= V\sigma_V \\ &= (1.068 \times 10^6)(10^{-6}) \\ &= 1.068 \text{ m}^2\end{aligned}$$

This is not a strong target. But we know that 10 mm/h of rain is not a strong target at X-band. The big problem with rain is a deep volume producing a large amount of attenuation. You notice here that the chaff cloud is only 600 ft across; this would not be a typical rain cloud. Perhaps the comparison should be for the chaff cloud to cover (hide) a 30-dB cross section vehicle.

The number of dipoles in a cloud of chaff is given by

$$N = \frac{\sigma_T}{\sigma_d}$$

where σ_T is the total cross section, and σ_d the cross section of each dipole, by substitution

$$\begin{aligned}N &= \frac{1000}{0.18(3/100)^2}, \frac{\text{m}^2}{\text{m}^2} \\ &= 6.17 \times 10^6\end{aligned}$$

The density of dipoles is given by

$$\begin{aligned}\frac{N}{V} &= \frac{6.17 \times 10^6}{1.068 \times 10^6} \\ &= 5.78 \text{ dipoles/m}^3\end{aligned}$$

This is not a dense chaff cloud, and thus you can see the value of such a cloud to hide a good size target. Of course, there is short fall; the cloud may last only 20 min and will drift several thousand feet in this time. This requires that there be proper area and time planning for chaff use. If the volume to be covered is larger than the 100 × 300 × 300 ft, then, several clouds need to be dispersed.

In the International Countermeasures Handbook (EW Comm., 1975), the author has presented a graph to be used to determine the signal attenuation produced by a chaff cloud. The graph relates normalized two-way attenuation per wave length squared to the number of half-way dipoles per cubic meter, as a function of the dipole orientation K relative to the radar polarization. When the dipoles are uniformly distributed and randomly oriented, K can be as low as 0.115; when the dipoles are aligned with the E -field, $K = 1.0$ and the loss is 10 dB higher; when the dipoles are almost crosspolarized to the radar, $K = 0.0115$, the attenuation will be 10 dB less than the random orientation. For $K = 0.115$, the attenuation relationship is given by

$$L/\lambda^2 = N/\text{m}^3$$

in units of decibel per cubic meter = number/cubic meter. Typical ranges of cloud density range from 10⁻⁷ to 10⁺² dipoles per cubic meter. For the example given, a cloud density of 5.78 dipoles/m³ cube will

give a value of $L/\lambda^2 = 5.78$. For a two way loss per meter of chaff cloud, $L = 0.0052$ dB/m at $\lambda = 0.03$ m, giving 0.5 dB of attenuation in a 100-m cloud.

Expendable Jammers

Expendable jammers are a class of electronic devices that are designed to be used only once. These devices are typically released from chaff/flare dispensers much as chaff is deployed. The electronic package can be deployed as a free-falling object, or released with a parachute for slow fall rates. Such packages have been used as screening devices and as simulated false targets. The RF energy can be continuous, pulsed, or modulated to respond as a repeater or a false radar. Expendable jammers have been configured as spot noise jammers and have been deployed as barrage noise jammers, depending upon the mission and victim radars.

Defining Terms

P = power, watts

k = Boltzman constant = 1.38×10^{-23} joules/K

T = temperature = absolute temperature, K

S = energy = power \times transmitted pulse length, joules

B = bandwidth, Hz

f = frequency, Hz

Hz = 1 cycle per second

dB = 10 times logarithm of power ratio

Z = impedance, ohms

18.1 Measurement Techniques: Sensors and Transducers

Cecil Harrison

18.1.1 Introduction

An automatic control system is said to be *error actuated* because the **forward path** components (*comparator, controller, actuator, and plant or process*) respond to the error signal (Fig. 18.1). The error signal is developed by comparing the measured value of the **controlled output** to some **reference input**, and so the accuracy and precision of the controlled output are largely dependent on the accuracy and precision with which the controlled output is measured. It follows then that measurement of the controlled output, accomplished by a system component called the **transducer**, is arguably the single most important function in an automatic control system.

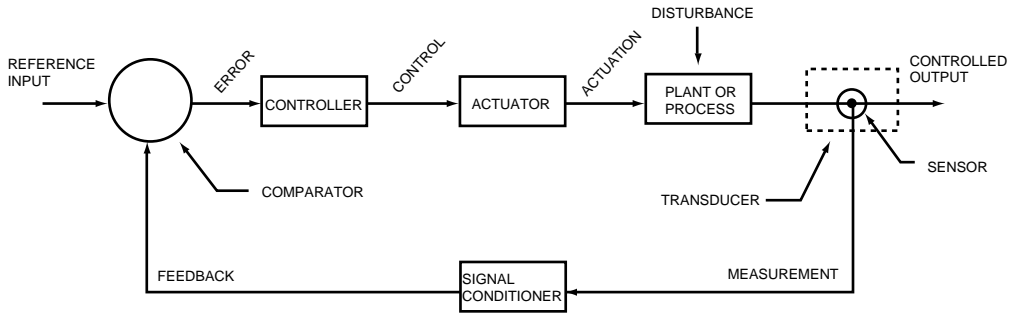

FIGURE 18.1 Functional block diagram of a canonical (standard) automatic control system.

A transducer senses the magnitude or intensity of the controlled output and produces a proportional signal in an energy form suitable for transmission along the feedback path to the comparator. (The term proportional is used loosely here because the output of the transducer may not always be directly proportional to the controlled output; that is, the transducer may not be a linear component. In linear systems, if the output of the transducer (the measurement) is not linear, it is linearized by the signal conditioner.) The element of the transducer which senses the controlled output is called the *sensor*; the remaining elements of a transducer serve to convert the sensor output to the energy form required by the **feedback path**. Possible configurations of the feedback path include

- Mechanical linkage
- Fluid power (pneumatic or hydraulic)
- Electrical, including optical coupling, RF propagation, magnetic coupling, or acoustic propagation

Electrical signals suitable for representing measurement results include

- DC voltage or current amplitude
- AC voltage or current amplitude, frequency, or phase (CW modulated)
- Voltage or current pulses (digital)

In some cases, representation may change (e.g., from a DC amplitude to digital pulses) along the feedback path.

The remainder of this discussion pertains to a large number of automatic control systems in which the feedback signal is electrical and the feedback path consists of wire or cable connections between the feedback path components. The transducers considered hereafter sense the controlled output and produce an electrical signal representative of the magnitude, intensity, or direction of the controlled output.

The **signal conditioner** accepts the electrical output of the transducer and transmits the signal to the comparator in a form compatible with the reference input. The functions of the signal conditioner include

- Amplification/attenuation (scaling)
- Isolation
- Sampling
- Noise elimination
- Linearization
- Span and reference shifting
- Mathematical manipulation (e.g., differentiation, division, integration, multiplication, root finding, squaring, subtraction, or summation)
- Signal conversion (e.g., DC–AC, AC–DC, frequency–voltage, voltage–frequency, digital–analog, analog–digital, etc.)
- Buffering
- Digitizing
- Filtering
- Impedance matching
- Wave shaping
- Phase shifting

In cases in which part or all of the required signal conditioning is accomplished within the transducer, the transducer output may be connected directly to the comparator. (Connection of the transducer output

directly to the comparator should not be confused with unity feedback. Unity feedback occurs when the cascaded components of the feedback path (transducer and signal conditioner) have a combined transfer function equal to 1 (unity.) In a digital control system, many of the signal conditioning functions listed here can also be accomplished by software.

Transducers are usually considered in two groups:

- **Motion and force transducers**, which are mainly associated with **servomechanisms**
- **Process transducers**, which are mainly associated with **process control** systems

As will be seen, most process transducers incorporate some sort of motion transducer.

18.1.2 Motion and Force Transducers

This section discusses those transducers used in systems that control motion (i.e., *displacement, velocity, and acceleration*). Force is closely associated with motion, because motion is the result of unbalanced forces, and so force transducers are discussed concurrently. The discussion is limited to those transducers that measure *rectilinear* motion (straight-line motion within a stationary frame of reference) or *angular* motion (circular motion about a fixed axis). Rectilinear motion is sometimes called *linear* motion, but this leads to confusion in situations where the motion, though along a straight line, really represents a mathematically nonlinear response to input forces. Angular motion is also called *rotation* or *rotary motion* without ambiguity.

The primary theoretical basis for motion transducers is found in rigid-body mechanics. From the equations of motion for rigid-bodies (Table 18.1), it is clear that if any one of displacement, velocity, or

TABLE 18.1 Equations of Motion

Continuous	Discrete $\Delta t = t_i - t_{i-1}$
Rectilinear displacement:	
$x(t) = \int v(t)dt$	$x_i = x_{i-1} + \frac{v_i + v_{i-1}}{2} \cdot (\Delta t)$
$= \int \int a(t)dt$	$= 2x_{i-1} - x_{i-2} + \frac{a_i + 2a_{i-1} + a_{i-2}}{2} \cdot \frac{(\Delta t)^2}{2}$
Angular displacement:	
$\theta(t) = \int \omega(t)dt$	$\theta_i = \theta_{i-1} + \frac{\omega_i + \omega_{i-1}}{2} \cdot (\Delta t)$
$= \int \int \alpha(t)dt$	$= 2\theta_{i-1} - \theta_{i-2} + \frac{\alpha_i + 2\alpha_{i-1} + \alpha_{i-2}}{2} \cdot \frac{(\Delta t)^2}{2}$
Rectilinear velocity:	
$v(t) = \frac{d}{dt}x(t)$	$v_i = \frac{x_i - x_{i-1}}{\Delta t}$
$= \int a(t)dt$	$= v_{i-1} + \frac{a_i + a_{i-1}}{2} \cdot (\Delta t)$
Angular velocity:	
$\omega(t) = \frac{d}{dt}\theta(t)$	$\omega_i = \frac{\theta_i - \theta_{i-1}}{\Delta t}$
$= \int \alpha(t)dt$	$= \omega_{i-1} + \frac{\alpha_i + \alpha_{i-1}}{2} \cdot (\Delta t)$
Rectilinear acceleration:	
$a(t) = \frac{d}{dt}v(t)$	$a_i = \frac{v_i - v_{i-1}}{\Delta t}$
$= \frac{d^2}{dt^2}x(t)$	$= \frac{x_i - 2x_{i-1} + x_{i-2}}{(\Delta t)^2}$
Angular acceleration:	
$\alpha(t) = \frac{d}{dt}\omega(t)$	$\alpha_i = \frac{\omega_i - \omega_{i-1}}{\Delta t}$
$= \frac{d^2}{dt^2}\theta(t)$	$= \frac{\theta_i - 2\theta_{i-1} + \theta_{i-2}}{(\Delta t)^2}$

acceleration is measured, the other two can be derived by mathematical manipulation of the signal within an analog signal conditioner or within the controller software of a digital control system.

Position is simply a location within a frame of reference; thus, any measurement of displacement relative to the frame is a measurement of position, and any displacement transducer whose input is referenced to the frame can be used as a position transducer.

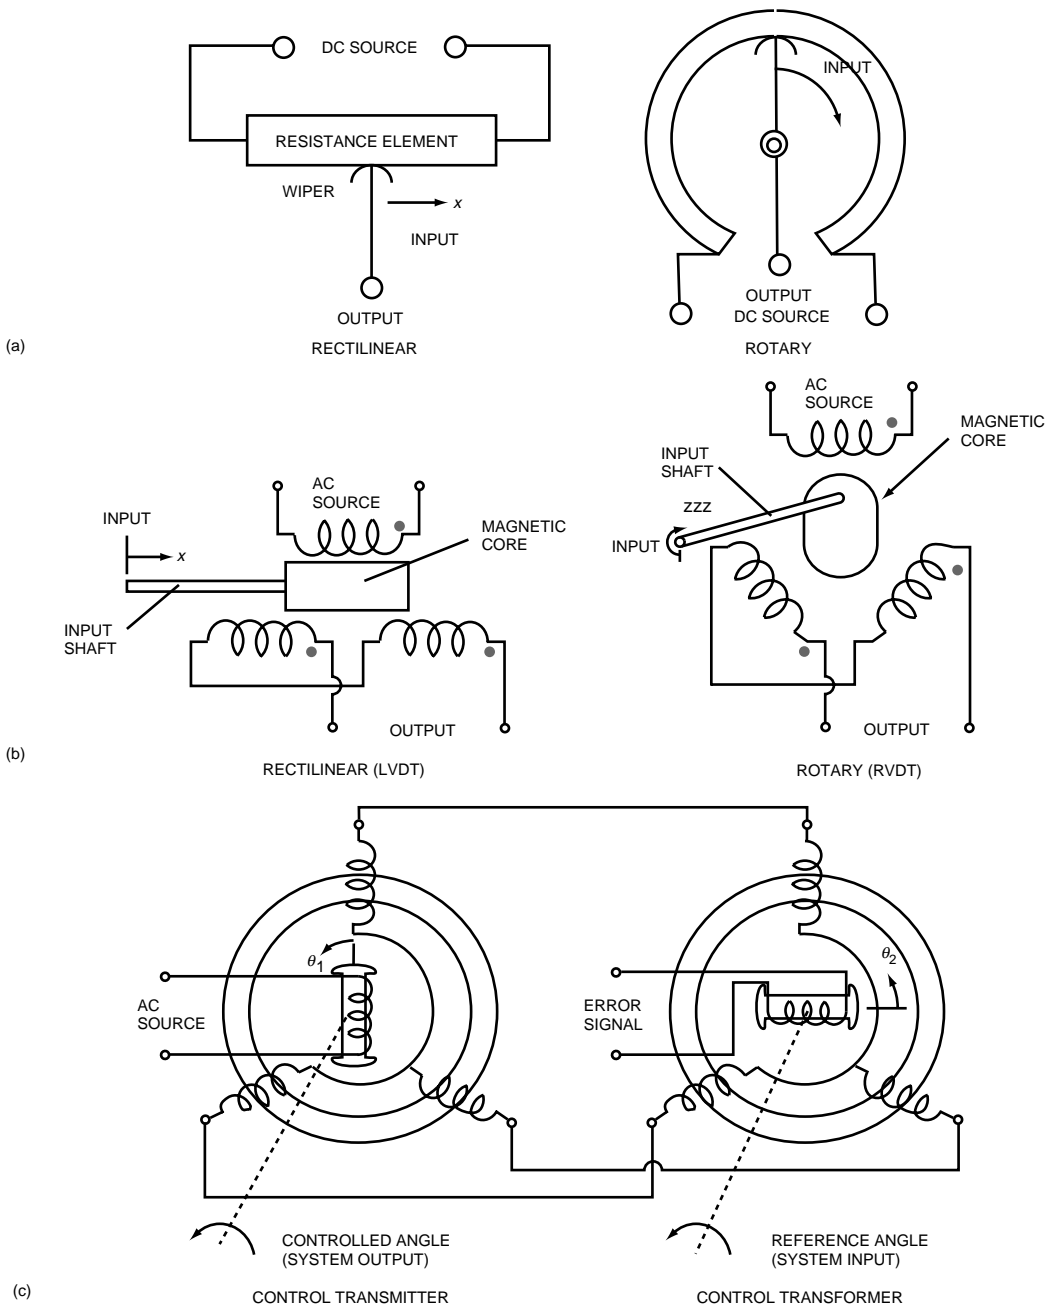

FIGURE 18.2 Gross displacement transducers: (a) potentiometers, (b) variable differential transformers (VDT), (c) synchros (typical connection), (d) resolvers (typical connection), (e) absolute position encoders, (f) code track for incremental position encoder.

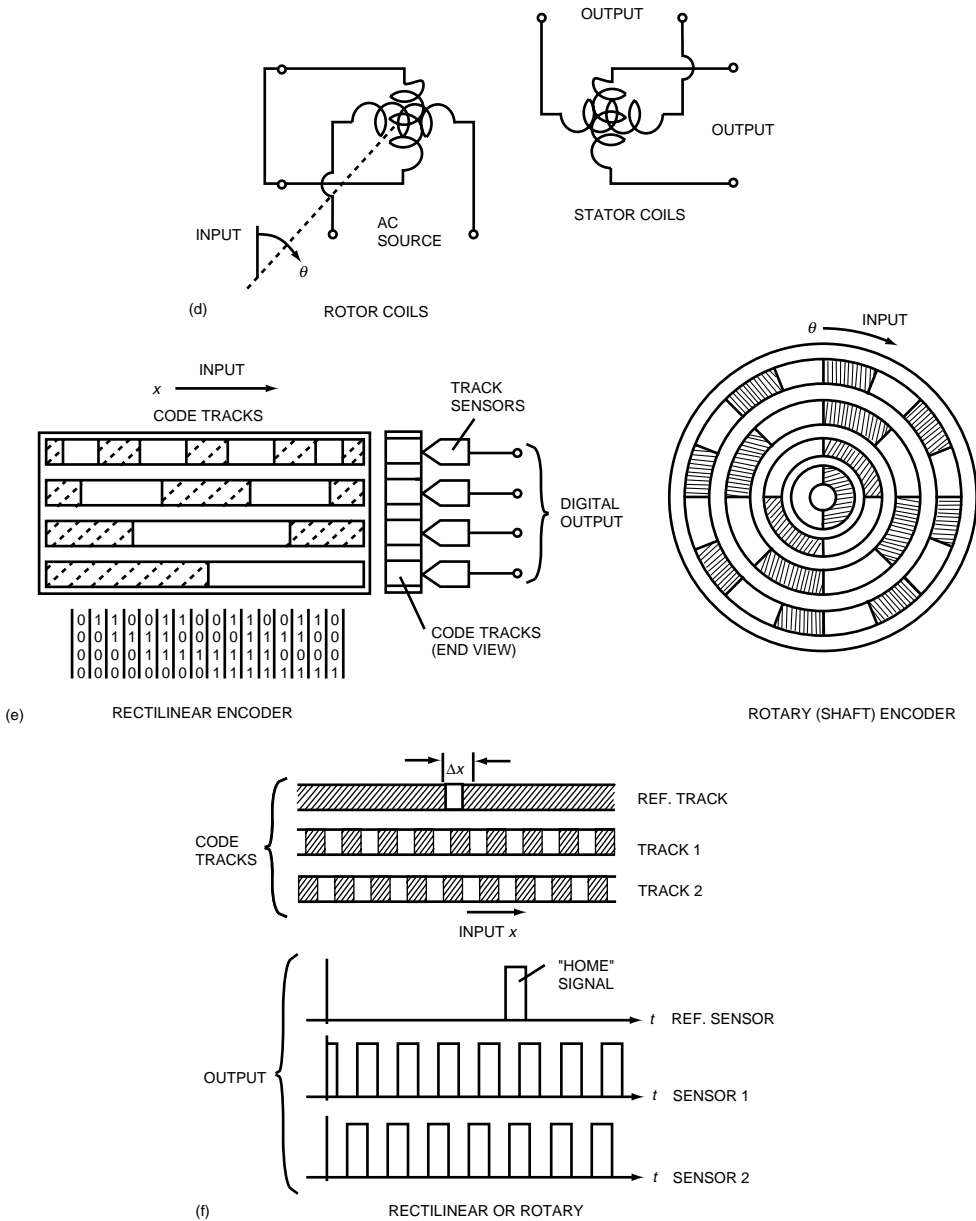

FIGURE 18.2 (Continued).

Displacement (Position) Transducers

Displacement transducers may be considered according to application as *gross* (large) displacement transducers or *sensitive* (small) displacement transducers. The demarcation between gross and sensitive displacement is somewhat arbitrary, but may be conveniently taken as approximately 1 mm for rectilinear displacement and approximately $10'$ arc ($1/6^\circ$) for angular displacement. The predominant types of gross displacement transducers (Fig. 18.2) are

- *Potentiometers* (Fig. 18.2(a))
- *Variable differential transformers (VDT)* (Fig. 18.2(b))

- *Synchros* (Fig. 18.2(c))
- *Resolvers* (Fig. 18.2(d))
- *Position encoders* (Fig. 18.2(e))

Potentiometer-based transducers are simple to implement and require the least signal conditioning, but potentiometers are subject to wear due to sliding contact between the wiper and the resistance element and may produce noise due to wiper bounce (Fig. 18.2(a)). Potentiometers are available with strokes ranging from less than 1 cm to more than 50 cm (rectilinear) and from a few degrees to more 50 turns (rotary).

VDTs are not as subject to wear as potentiometers, but the maximum length of the stroke is small, approximately 25 cm or less for a linear VDT (LVDT) and approximately 60° or less for a rotary VDT (RVDT). VDTs require extensive signal conditioning in the form of phase-sensitive demodulation of the AC signal; however, the availability of dedicated VDT demodulators in integrated circuit (IC) packages mitigates this disadvantage of the VDT.

Synchros are rather complex and expensive three-phase AC machines, which are constructed to be precise and rugged. Synchros are capable of measuring angular differences in the positions (up to $\pm 180^\circ$) of two continuously rotating shafts. In addition, synchros may function simultaneously as reference input, output measurement device, feedback path, and comparator (Fig. 18.2(c)).

Resolvers are simpler and less expensive than synchros, and they have an advantage over RVDTs in their ability to measure angular displacement throughout 360° of rotation. In Fig. 18.2(d), which represents one of several possibilities for utilizing a resolver, the signal amplitude is proportional to the cosine of the measured angle at one output coil and the sine of the measured angle at the other. Dedicated ICs are available for signal conditioning and for conversion of resolver output to digital format. The same IC, when used with a *Scott-T transformer* can be used to convert synchro output to digital format.

Position encoders are highly adaptable to digital control schemes because they eliminate the requirement for digital-to-analog conversion (DAC) of the feedback signal. The code tracks are read by track sensors, usually wipers or electro-optical devices (typically infrared or laser). Position encoders are available for both rectilinear and rotary applications, but are probably more commonly found as shaft encoders in rotary applications. Signal conditioning is straightforward for *absolute* encoders (Fig. 18.2(e)), requiring only a decoder, but position resolution depends on the number of tracks, and increasing the number of tracks increases the complexity of the decoder. *Incremental* encoders require more complex signal conditioning, in the form of counters and a processor for computing position. The number of tracks, however, is fixed at three (Fig. 18.2(f)). Position resolution is limited only by the ability to render finer divisions of the code track on the moving surface.

Although gross displacement transducers are designed specifically for either rectilinear or rotary motion, a *rack and pinion*, or a similar motion converter, is often used to adapt transducers designed for rectilinear motion to the measurement of rotary motion, and vice versa.

The predominant types of *sensitive* (small) displacement transducers (Fig. 18.3) are

- *Differential capacitors*
- *Strain gauge resistors*
- *Piezoelectric crystals*

Figure 18.3(a) provides a simplified depiction of a differential capacitor used for sensitive displacement measurements. The motion of the input rod flexes the common plate, which increases the capacitance of one capacitor and decreases the capacitance of the other. In one measurement technique, the two capacitors are made part of an impedance bridge (such as a Schering bridge), and the change in the bridge output is an indication of displacement of the common plate. In another technique, each capacitor is allowed to serve as tuning capacitor for an oscillator, and the difference in frequency between the two oscillators is an indication of displacement.

A strain gauge resistor is used to measure elastic deformation (strain) of materials by bonding the resistor to the material (Fig. 18.3(b)) so that it undergoes the same strain as the material. The resistor is usually incorporated into one of several bridge circuits, and the output of the bridge is taken as an indication of strain.

FIGURE 18.3 Sensitive displacement transducers: (a) differential capacitor, (b) strain gauge resistor, (c) piezoelectric crystals.

The piezoelectric effect is used in several techniques for sensitive displacement measurements (Fig. 18.3(c)). In one technique, the input motion deforms the crystal by acting directly on one electrode. In another technique, the crystal is fabricated as part of a larger structure, which is oriented so that input motion bends the structure and deforms the crystal. Deformation of the crystal produces a small output voltage and also alters the resonant frequency of the crystal. In a few situations, the output voltage is taken directly as an indication of motion, but more frequently the crystal is used to control an oscillator, and the oscillator frequency is taken as the indication of strain.

FIGURE 18.4 Velocity transducers: (a) magnet and coil, (b) proximity sensors.

Velocity Transducers

As stated previously, signal conditioning techniques make it possible to derive all motion measurements—displacement, velocity, or acceleration—from a measurement of any one of the three. Nevertheless, it is sometimes advantageous to measure velocity directly, particularly in the cases of short-stroke rectilinear motion or high-speed shaft rotation. The analog transducers frequently used to meet these two requirements are

- *Magnet-and-coil velocity transducers* (Fig. 18.4(a))
- *Tachometer generators*

A third category of velocity transducers, *Counter-type velocity transducers* (Fig. 18.4(b)), is simple to implement and is directly compatible with digital controllers.

The operation of magnet-and-coil velocity transducers is based on Faraday's law of induction. For a solenoidal coil with a high length-to-diameter ratio made of closely spaced turns of fine wire, the voltage induced into the coil is proportional to the velocity of the magnet. Magnet-and-coil velocity transducers are available with strokes ranging from less than 10 mm to approximately 0.5 m.

A tachometer generator is, as the name implies, a small AC or DC generator whose output voltage is directly proportional to the angular velocity of its rotor, which is driven by the controlled output shaft. Tachometer generators are available for shaft speeds of 5000 r/min, or greater, but the output may be nonlinear and there may be an unacceptable output voltage ripple at low speeds.

AC tachometer generators are less expensive and easier to maintain than DC tachometer generators, but DC tachometer generators are directly compatible with analog controllers and the polarity of the output is a direct indication of the direction of rotation. The output of an AC tachometer generator must be demodulated (i.e., rectified and filtered), and the demodulator must be phase sensitive in order to indicate direction of rotation.

Counter-type velocity transducers operate on the principle of counting electrical pulses for a fixed amount of time, then converting the count per unit time to velocity. Counter-type velocity transducers

rely on the use of a proximity sensor (*pickup*) or an incremental encoder (Fig. 18.2(f)). Proximity sensors may be one of the following types:

- *Electro-optic*
- *Variable reluctance*
- *Hall effect*
- *Inductance*
- *Capacitance*

Two typical applications of counter-type velocity transducers are shown in Fig. 18.4(b).

Since a digital controller necessarily includes a very accurate electronic clock, both pulse counting and conversion to velocity can be implemented in software (i.e., made a part of the controller program). Hardware implementation of pulse counting may be necessary if time-intensive counting would divert the controller from other necessary control functions. A special-purpose IC, known as a *quadrature decoder/counter interface*, can perform the decoding and counting functions and transmit the count to the controller as a data word.

Acceleration Transducers

As with velocity measurements, it is sometimes preferable to measure acceleration directly, rather than derive acceleration from a displacement or velocity measurement. The majority of acceleration transducers may be categorized as *seismic* accelerometers because the measurement of acceleration is based on measuring the displacement of a mass called the *seismic element* (Fig. 18.5). The configurations shown in Fig. 18.5(a) and Fig. 18.5(b) require a rather precise arrangement of springs for suspension and centering of the seismic mass. One of the disadvantages of a seismic accelerometer is that the seismic mass is displaced during acceleration, and this displacement introduces nonlinearity and bias into the measurement. The force-balance configuration shown in Fig. 18.5(c) uses the core of an electromagnet as the seismic element. A sensitive displacement sensor detects displacement of the core and uses the displacement signal in a negative feedback arrangement to drive the coil, which returns the core to its center position. The output of the force-balance accelerometer is the feedback required to prevent displacement rather than displacement *per se*.

A simpler seismic accelerometer utilizes one electrode of a piezoelectric crystal as the seismic element (Fig. 18.5(d)). Similarly, another simple accelerometer utilizes the common plate of a differential capacitor (Fig. 18.3(a)) as the seismic element.

Force Transducers

Force measurements are usually based on a measurement of the motion which results from the applied force. If the applied force results in gross motion of the controlled output, and the mass of the output element is known, then any appropriate accelerometer attached to the controlled output produces an output proportional to the applied force ($F = Ma$). A simple spring-balance scale (Fig. 18.6(a)) relies on measurement of displacement, which results from the applied force (weight) extending the spring.

Highly precise force measurements in high-value servomechanisms, such as those used in pointing and tracking devices, frequently rely on gyroscope precession as an indication of the applied force. The scheme is shown in Fig. 18.6(b) for a gyroscope with gimbals and a spin element. A motion transducer (either displacement or velocity) on the precession axis provides an output proportional to the applied force. Other types of gyroscopes and precession sensors are also used to implement this force measurement technique.

Static force measurements (in which there is no apparent motion) usually rely on measurement of strain due to the applied force. Figure 18.6(c) illustrates the typical construction of a common force transducer called a *load cell*. The applied force produces a proportional strain in the S-shaped structural member, which is measured with a sensitive displacement transducer, usually a strain gauge resistor or a piezoelectric crystal.

FIGURE 18.6 Force transducers: (a) spring scale, (b) gyroscope, (c) load cell.

18.1.3 Process Transducers

This section discusses transducers used in measuring and controlling the *process variables* most frequently encountered in industrial processes, namely

- Fluid pressure
- Fluid flow
- Liquid level
- Temperature

Fluid Pressure Transducers

Most fluid pressure transducers are of the *elastic* type, in which the fluid is confined in a chamber with at least one elastic wall, and the deflection of the elastic wall is taken as an indication of the pressure. The *Bourdon tube* and the *bellows* are examples of elastic pressure transducers, which are used in laboratory-grade transducers and in some industrial process control applications. The fluid pressure transducer depicted in Fig. 18.7, which uses an elastic *diaphragm* to separate two chambers, is the type most frequently encountered in industrial process control. Diaphragms are constructed from one of a variety of elastic materials ranging from thin metal to polymerized fabric.

FIGURE 18.7 Diaphragm pressure transducer.

For gross pressure measurements, the displacement of the diaphragm is sensed by a potentiometer or LVDT; for more sensitive pressure measurements, any one of the three sensitive displacement sensors described earlier is used. In the most common configuration for sensitive pressure transducers, a strain gauge resistor with a rosette pattern is bonded to the diaphragm. In another configuration, the outer walls of the pressure sensor serve as capacitor plates and the diaphragm serves as the common plate of a differential capacitor. In a very sensitive and highly integrated configuration, the diaphragm is a silicon wafer with a piezoresistive strain gauge and signal conditioning circuits integrated into the silicon.

High-vacuum (very low pressure) measurements, usually based on observations of viscosity, thermal conductivity, acoustic properties, or ionization potential of the fluid, will not be included in this discussion. Transducers used in high-pressure hydraulic systems (70 MPa (10,000 psi) or greater) are usually of the *piston and spring* type (Fig. 18.8).

FIGURE 18.8 Piston-and-spring transducer.

In either of the pressure transducers, the output is actually a measure of the *difference* in pressure between the working chamber and the reference chamber of the transducer (i.e., $p_{OUT} = p - p_{REF}$). The measurement is called

- An *absolute pressure* if the reference chamber is sealed and evacuated (i.e., $p_{REF} = 0$ and $p_{OUT} = p$)
- A *gauge pressure* if the reference chamber is vented to the atmosphere (i.e., $p_{OUT} = p - p_{ATM}$)
- A *differential pressure* if any other pressure is applied to the reference chamber

Fluid Flow Transducers (Flowmeters)

Flowmetering, because of the number of variables involved, encompasses a wide range of measurement technology and applications. In industrial processes, the term *fluid* is applied not only to gases and liquids, but also to flowable mixtures (often called *slurries* or *sludges*) such as concrete, sewage, or wood pulp. Control of a fluid flow, and hence the type of measurement required, may involve *volumetric* flow rate, *mass* flow rate, or flow direction. Gas flows may be *compressible*, which also influences the measurement technique. In addition, the condition of the flow—whether or not it is homogenous and clean (free of suspended particles)—has a bearing on flowmeter technology. Another factor to be considered is flow velocity; slow moving laminar flows of viscous material require different measurement techniques than

those used for high-velocity turbulent flows. Still another consideration is confinement of the flow. Whereas most fluid flow measurements are concerned with *full flow* through *closed channels* such as ducts and pipes, some applications require measurements of *partial flow* through *open channels* such as troughs and flumes. Only the most widely used flowmeters are considered here.

The major categories of flowmeters are

- *Differential pressure, constriction-type (venturi, orifice, flow nozzle, elbow (or pipe bend), and pitot static) (Fig. 18.9)*
- *Fluid-power (gear motors, turbines and paddle wheels) (Fig. 18.10)*
- *Ultrasound (Fig. 18.11)*
- *Vortex shedding (Fig. 18.12)*
- *Thermal anemometer (Fig. 18.13)*
- *Electromagnetic (Fig. 18.14)*
- *Rotameter (variable-area in-line flowmeter) (Fig. 18.15)*

Differential pressure flowmeters are suited to high- and moderate-velocity flow of gas and clean, low-viscosity liquids. Venturi flowmeters (Fig. 18.9(a)) are the most accurate, but they are large and expensive. Orifice flowmeters (Fig. 18.9(b)) are smaller, less expensive, and much less accurate than venturi flowmeters. Nozzle flowmeters (Fig. 18.9(c)) are a compromise between venturi and orifice flowmeters. Pipe-bend flowmeters (Fig. 18.9(d)), which can essentially be installed in any bend in an existing piping system, are used primarily for gross flow rate measurements. Pitot-static flowmeters (Fig. 18.9(e)) are used in flows which have a large cross-sectional area, such as in wind tunnels. Pitot-static flowmeters are also used in freestream applications such as airspeed indicators for aircraft.

Fluid-power flowmeters are used in low-velocity, moderately viscous flows. In addition to industrial control applications, turbine flowmeters (Fig. 18.10(a)) are sometime used as speed indicators for ships or boats. Paddle wheel flowmeters (Fig. 18.10(b)) are used both in closed- and open-flow applications such as liquid flow in flumes. Since a fluid-power gear motor (Fig. 18.10(c)) is a constant volume device, motor shaft speed is always a direct indication of fluid flow rate.

Ultrasound flowmeters of the transmission type (Fig. 18.11(a)), which are based on the principle that the sound transmission speed will be increased by the flow rate of the fluid, are used in all types of clean, subsonic flows. Doppler flowmeters (Fig. 18.11(b)) rely on echoes from within the fluid, and are thus only useful in dirty flows that carry suspended particles or turbulent flows that produce bubbles. Ultrasound flowmeters are nonintrusive devices, which can often be retrofitted to existing duct or pipe systems.

Vortex shedding flowmeters (Fig. 18.12) introduce a *shedding body* into the flow to cause production (*shedding*) of *vortices*. The sound accompanying the production and collapse of the vortices is monitored and analyzed. The dominant frequency of the sound is indicative of the rate of vortex production and collapse, and hence an indication of flow rate. Vortex shedding flowmeters are useful in low-velocity, nonturbulent flows.

Thermal anemometers (Fig. 18.13) are used in low-velocity gas flows with large cross-sectional area, such as in heating, ventilation, and air conditioning (HVAC) ducts. Convection cooling of the heating element is related to flow rate. The flow rate measurement is based either on the current required to maintain a constant temperature in the heating element, or alternatively on the change in temperature when the current is held constant.

Electromagnetic flowmeters (Fig. 18.14) are useful for slow moving flows of liquids, sludges, or slurries. The flow material must support electrical conduction between the electrodes, and so in some cases it is necessary to ionize the flow upstream from the measurement point in order to use an electromagnetic flowmeter.

Variable-area in-line flowmeters (Fig. 18.15), or *rotameters*, are sometimes referred to as sight gauges because they provide a visible indication of flow rate. These devices, when fitted with proximity sensors (such as capacitive pickups), which sense the presence of the float, can be used in on-off control applications.

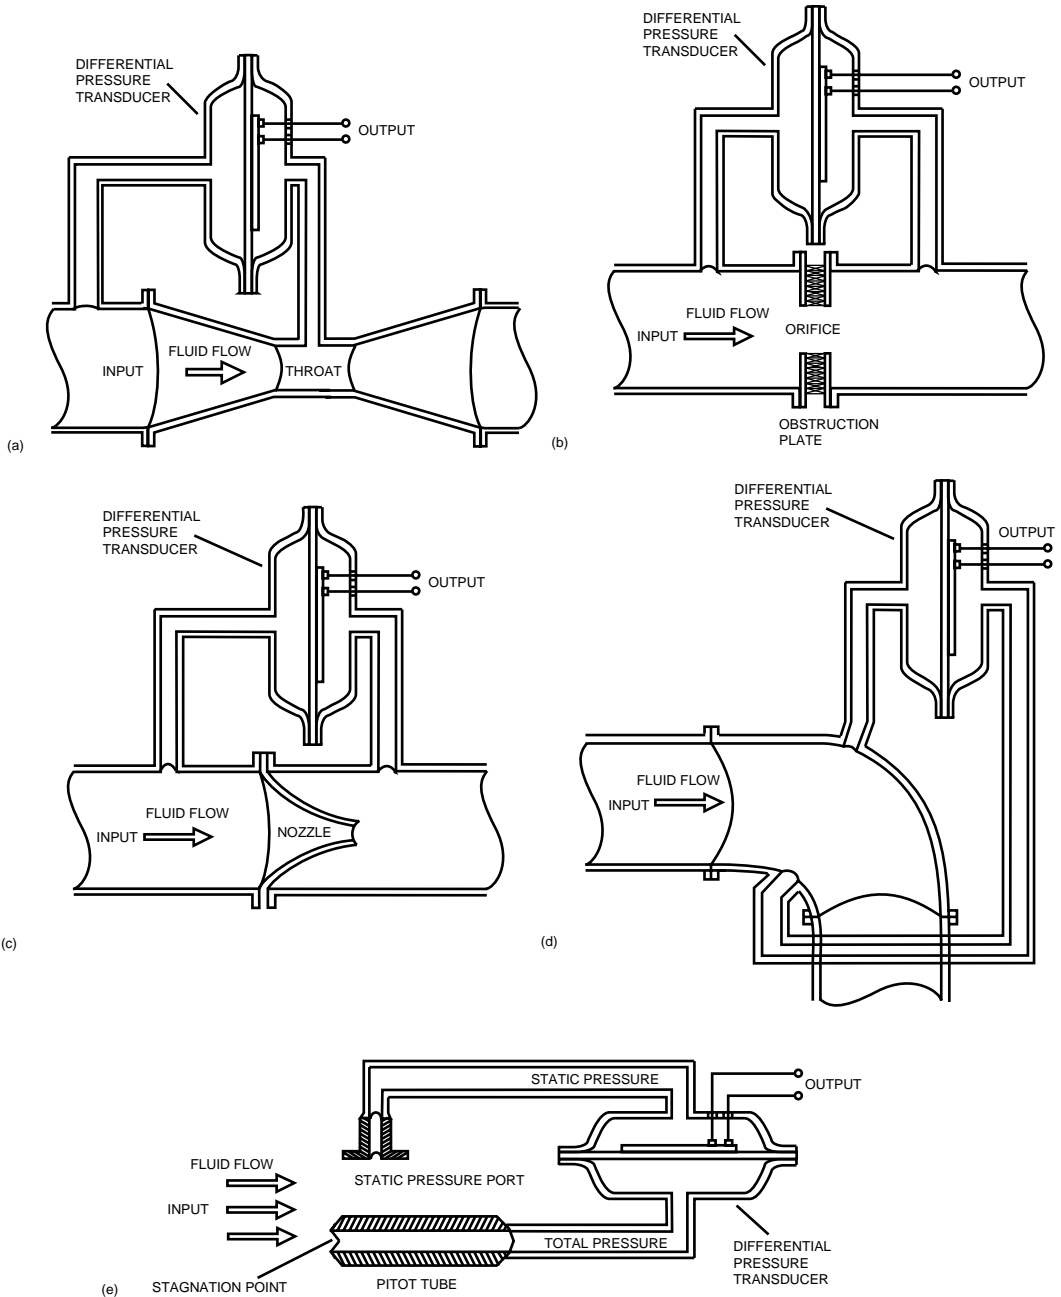

FIGURE 18.9 Differential pressure flowmeters: (a) Venturi flowmeter, (b) orifice flowmeter, (c) nozzle flowmeter, (d) pipebend (elbow) flowmeter, (e) pitot-static-flowmeter.

Liquid Level Transducers

Liquid-level measurements are relatively straightforward, and the transducers fall into the categories of *contact* or *noncontact*. Measurements may be *continuous*, in which the liquid level is monitored continuously throughout its operating range, or *point*, in which the liquid level is determined to be above or below some predetermined level.

FIGURE 18.10 Fluid power flowmeters: (a) turbine flowmeter, (b) paddle wheel flowmeter, (c) gear motor flowmeter.

FIGURE 18.14 Electromagnetic flowmeter.

FIGURE 18.15 Variable-area in-line flowmeter (rotameter).

FIGURE 18.16 Float-type liquid level transducers.

The contact transducers encountered most frequently are

- *Float*
- *Hydrostatic pressure*
- *Electrical capacitance*
- *Ultrasound*

The noncontact transducers encountered most frequently are

- *Capacitive proximity sensors*
- *Ultrasound*
- *Radio frequency*
- *Electro-optical*

Float-type liquid level transducers are available in a wide variety of configurations for both continuous and point measurements. One possible configuration is depicted in Fig. 18.16 for continuous measurement and for both single- and dual-point measurements.

Hydrostatic pressure liquid level transducers may be used in either vented or pressurized applications (Fig. 18.17). In either case the differential pressure is directly proportional to the weight of the liquid column, since the differential pressure transducer accounts for surface pressure.

Capacitance probes (Fig. 18.18(a)) are widely used in liquid level measurements. It is possible, when the tank walls are metal, to use a single bare or insulated metal rod as one capacitor plate and the tank walls as the other. More frequently, capacitance probes consist of a metal rod within a concentric cylinder open at the ends, which makes the transducer independent of the tank construction. An interesting application of this type of capacitance probe is in aircraft fuel quantity indicators. Capacitance switches can be utilized as depicted in Fig. 18.18(b) to provide noncontact point measurements of liquid level.

Ultrasound echo ranging transducers can be used in either *wetted* (contact) or *nonwetted* (noncontact) configurations for continuous measurement of liquid level (Fig. 18.19(a)). An interesting application of wetted transducers is as depth finders and fish finders for ships and boats. Nonwetted transducers can also be used with bulk materials such as grains and powders. Radio-frequency and electro-optic liquid level transducers are usually noncontact, echo ranging devices, which are similar in principle and application to the nonwetted ultrasound transducer.

Ultrasonic transducers can also be adapted to point measurements by locating the transmitter and the receiver opposite one another across a gap (Fig. 18.19(b)). When liquid fills the gap, attenuation of the

FIGURE 18.17 Hydrostatic pressure liquid level transducers.

FIGURE 18.18 Capacitive-type liquid level transducers: (a) capacitive probes, (b) capacitive switches.

FIGURE 18.19 Ultrasound liquid level transducers: (a) echo-ranging liquid level transducer, (b) ultrasound switch.

FIGURE 18.20 Bimetallic thermal switch.

ultrasound energy is markedly less than when air fills the gap. The signal conditioning circuits utilize this sharp increase in the level of ultrasound energy detected by the receiver to activate a switch.

Temperature Transducers

Temperature measurement is generally based on one of the following physical principles:

- *Thermal expansion*
- *Thermoelectric phenomena*
- *Thermal effect on electrical resistance*
- *Thermal effect on conductance of semiconductor junctions*
- *Thermal radiation*

(Strictly speaking, any device used to measure temperature may be called a thermometer, but more descriptive terms are applied to devices used in temperature control.)

Bimetallic switches (Fig. 18.20) are widely used in on-off temperature control systems. If two metal strips with different *coefficients of thermal expansion* are bonded together while both strips are at the same temperature, the bimetallic structure will bend when the temperature is changed. Although these devices are often called *thermal cutouts*, implying that they are used in normally closed switches, they can be fabricated in either normally closed or normally open configurations. The bimetallic elements can also be fabricated in coil or helical configurations to extend the range of motion due to thermal expansion.

Thermocouples are rugged and versatile temperature sensors frequently found in industrial control systems. A thermocouple consists of a pair of dissimilar metal wires twisted or otherwise bonded at one end. The *Seebeck effect* is the physical phenomena which accounts for thermocouple operation, so thermocouples are known alternatively as *Seebeck junctions*. The potential difference (*Seebeck voltage*) between the free ends of the wire is proportional to the difference between the temperature at the junction and the temperature at the free ends. Thermocouples are available for measurement of temperature as low as -270°C and as high as 2300°C , although no single thermocouple covers this entire range. Thermocouples are identified as type B, C, D, E, G, J, K, N, R, S, or T, according to the metals used in the wire.

Signal conditioning and amplification of the relatively small Seebeck voltage dictates that the thermocouple wires must be connected to the terminals of a signal conditioning circuit. These connections create two additional Seebeck junctions, each of which generates its own Seebeck voltage, which must be canceled in the signal conditioning circuit. To implement cancellation to the corrections the following are necessary (Fig. 18.21(a)):

- The input terminals of the signal conditioning circuit must be made of the same metal.
- The two terminals must be on an *isothermal terminal block* so that each Seebeck junction created by the connection is at the same temperature.
- The temperature of the terminal block must be known.

FIGURE 18.21 Thermocouples: (a) typical thermocouple connection, (b) some thermocouple accessories and configurations.

The first two requirements are met by appropriate construction of the signal conditioning circuit. The third requirement is met by using a reference temperature sensor, probably an IC temperature transducer of the type described later.

Thermocouple and thermocouple accessories are fabricated for a variety of applications (Fig. 18.21(b)). Protective shields are used to protect thermocouple junctions in corrosive environments or where conducting liquids can short circuit the thermocouple voltage; however, exposed (bare) junctions are used wherever possible, particularly when fast response is essential.

Resistance temperature detectors (RTDs) are based on the principle that the electrical *resistivity* of most metals increases predictably with temperature. Platinum is the preferred metal for RTDs, although other less expensive metals are used in some applications. The resistivity of platinum is one of the standards by which temperature is measured. The relatively good linearity of the resistivity of platinum over a wide temperature range (-200 – 800°C) makes platinum RTDs suitable for stable, accurate temperature transducers, which are easily adapted to control systems applications.

The disadvantage of the RTD is that the temperature-sensitive element is a rather fragile metal filament wound on a ceramic bobbin or a thin metal film deposited on a ceramic substrate. RTD elements are usually encapsulated and are rarely used as bare elements. The accessories and application packages used with RTDs are similar to those used with thermocouples (Fig. 18.21(b)).

Most platinum RTDs are fabricated to have a nominal resistance of $100\ \Omega$ at 0°C . The *resistance temperature coefficient* of platinum is approximately 3 – $4\ \text{m}\Omega/\Omega/^{\circ}\text{C}$, so resolution of temperature to within 1°C for a nominal 100 - Ω RTD element requires resolution of the absolute resistance within 0.3 – $0.4\ \Omega$. These resistance resolution requirements dictate use of special signal conditioning techniques to cancel the lead and contact resistance of the RTD element (Fig. 18.22). The circuit depicted in Fig. 18.22 is a variation of a *4-wire ohmmeter*. Most RTDs are manufactured with four leads to be compatible with such circuits.

Thermistors are specially prepared metal oxide semiconductors that exhibit a strong *negative* temperature coefficient, in sharp contrast to the weak positive temperature coefficient of RTDs. Nominal thermistor resistance, usually specified for 25°C , ranges from less than $1000\ \Omega$ to more than $1\ \text{M}\Omega$, with

sensitivities greater than $100 \Omega/^{\circ}\text{C}$. Thus, the thermistor is the basis for temperature sensors that are much more sensitive and require less special signal conditioning than either thermocouples or RTDs. The tradeoff is the marked nonlinearity of the resistance-temperature characteristic. To minimize this problem, manufacturers provide packages in which the thermistor has been connected into a resistor network chosen to provide a relatively linear resistance-temperature characteristic over a nominal temperature range.

The development of thermistor technology has led to the IC temperature sensor in which the temperature-sensitive junction(s) and the required signal conditioning circuits are provided in a monolithic package. The user is only required to provide a supply voltage (typically 5 V DC) to the IC in order to obtain an analog output voltage proportional to temperature. Thermistors and IC temperature sensors can be produced in very small packages, which permit highly localized temperature measurements. Some thermistors designed for biological research are mounted in the tip of a hypodermic needle. The shortcomings of both thermistor and IC temperature sensors are that they are not rugged, cannot be used in caustic environments, and are limited to temperatures below approximately 200°C .

Radiation thermometers are used for remote (non-contact) sensing of temperature in situations where the contact sensors cannot be used. Operation is based on the principles of heat transfer through thermal radiation. Radiation thermometers focus the *infrared* energy from a heat source onto a *black body* (target) within the radiation thermometer enclosure (Fig. 18.23). One of the contact temperature sensors described previously is incorporated into the target to measure the target temperature. The rise in temperature at the target is related to the source temperature. Typical radiation thermometers have standoff ranges (focal lengths) of 0.5–1.5 m, but instruments with focal length as short as 1 cm or as long as 10 m are available. Radiation thermometers are available for broadband, monochromatic, or two-color thermometry.

FIGURE 18.22 Typical resistance temperature detector (RTD) application.

FIGURE 18.23 Schematic of the radiation thermometry scheme.

18.1.4 Transducer Performance

The operation of a transducer within a control system can be described in terms of its *static performance* and its *dynamic performance*. The static characteristics of greatest interest are

- *Scale factor* (or *sensitivity*)
- *Accuracy, uncertainty, precision, and system error* (or *bias*)
- *Threshold, resolution, dead band, and hysteresis*
- *Linearity*
- *Analog drift*

The dynamic characteristics of greatest interest are

- *Time constant, response time, and rise time*
- *Overshoot, settling time, and damped frequency*
- *Frequency response*

Static performance is documented through *calibration*, which consists of applying a known input (quantity or phenomenon to be measured) and observing and recording the transducer output. In a typical calibration procedure, the input is increased in increments from the lower range limit to the upper range limit of the transducer, then decreased to the lower range limit. The range of a component consists of all allowable input values. The difference between the upper and lower range limits is the *input span* of the component; the difference between the output at the upper range limit and the output at the lower range limit is the *output span*.

Dynamic performance is documented by applying a known change, usually a step, in the input and observing and recording the transducer output.

18.1.5 Loading and Transducer Compliance

A prime requirement for an appropriate transducer is that it be *compliant* at its input. Compliance in this sense means that the input energy required for proper operation of the transducer, and hence a correct measurement of the controlled output, does not significantly alter the controlled output. A transducer that does not have this compliance is said to *load* the controlled output. For example, a voltmeter must have a high-impedance input in order that the voltage measurement does not significantly alter circuit current and, hence, alter the voltage being measured.

Defining Terms

Controlled output: The principal product of an automatic control system; the quantity or physical activity to be measured for automatic control.

Feedback path: The cascaded connection of transducer and signal conditioning components in an automatic control system.

Forward path: The cascaded connection of controller, actuator, and plant or process in an automatic control system.

Motion transducer: A transducer used to measure the controlled output of a servomechanism; usually understood to include transducers for static force measurements.

Plant or process: The controlled device that produces the principal output in an automatic control system.

Process control: The term used to refer to the control of industrial processes; most frequently used in reference to control of temperature, fluid pressure, fluid flow, and liquid level.

Process transducer: A transducer used to measure the controlled output of an automatic control system used in process control.

Reference input: The signal provided to an automatic control system to establish the required controlled output; also called *setpoint*.

Servomechanism: A system in which some form of motion is the controlled output.

Signal conditioning: In this context, the term used to refer to the modification of the signal in the feedback path of an automatic control system; signal conditioning converts the sensor output to an electrical signal suitable for comparison to the reference input (setpoint); the term can also be applied to modification of forward path signals.

Transducer: The device used to measure the controlled output in an automatic control system; usually consists of a sensor or pickup and signal conditioning components.

18.2 Data Acquisition

Edward McConnell and David Jernigan

18.2.1 Fundamentals of Data Acquisition

The fundamental task of a data acquisition system is the measurement or generation of real-world physical signals. Before a physical signal can be measured by a computer-based system, you must use a sensor or transducer to convert the physical signal into an electrical signal, such as voltage or current. Often only the plug-in **data acquisition (DAQ)** board is considered the data acquisition system; however, it is only one of the components in the system. Unlike stand-alone instruments, signals often cannot be directly connected to the DAQ board. The signals may need to be conditioned by some signal conditioning accessory before they are converted to digital information by the plug-in DAQ board. Finally, software controls the data acquisition system—acquiring the raw data, analyzing the data, and presenting the results. The components are shown in Fig. 18.24.

FIGURE 18.24 Components of data acquisition system.

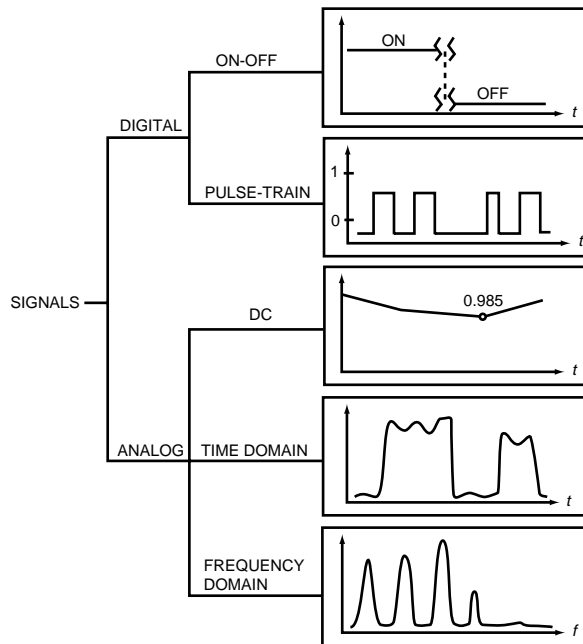

FIGURE 18.25 Classes of signals.

Signals

Signals are defined as any physical variable whose magnitude or variation with time contains information. Signals are measured because they contain some types of useful information. Therefore, the first question you should ask about your signal is: What information does the signal contain, and how is it conveyed? The functionality of the system is determined by the physical characteristics of the signals and the type of information conveyed by the signals. Generally, information is conveyed by a signal through one or more of the following signal parameters: state, rate, level, shape, or frequency content.

All signals are, fundamentally, analog, time-varying signals. For the purpose of discussing the methods of signal measurement using a plug-in DAQ board, a given signal should be classified as one of five signals types. Because the method of signal measurement is determined by the way the signal conveys the needed information, a classification based on these criteria is useful in understanding the fundamental building blocks of a data acquisition system.

As shown in the Fig. 18.25, any signal can generally be classified as analog or digital. A digital, or binary, signal has only two possible discrete levels of interest, a high (on) level and a low (off) level. An analog signal, on the other hand, contains information in the continuous variation of the signal with time. The two digital signal types are the on-off signals and the pulse train signal. The three analog signal types are the DC signal, the time-domain signal, and the frequency-domain signal. The two digital types and three analog types of signals are unique in the information conveyed by each. The category to which a signal belongs depends on the characteristic of the signal to be measured. You can closely parallel the five types of signals with the five basic types of signal information: state, rate, level, shape, and frequency content.

Plug-In DAQ Boards

The fundamental component of a data acquisition system is the plug-in DAQ board. These boards plug directly into a slot in a PC and are available with analog, digital, and timing inputs and outputs. The most versatile of the plug-in DAQ boards is the multifunction input/output (I/O) board. As the name implies, this board typically contains various combinations of analog-to-digital convertors (ADCs), digital-to-analog convertors (DACs), digital I/O lines, and counters/timers. ADCs and DACs measure and generate analog

FIGURE 18.26 Analog input section of a plug-in DAQ board.

voltage signals, respectively. The digital I/O lines sense and control digital signals. Counters/timers measure pulse rates, widths, delays, and generate timing signals. These many features make the multifunction DAQ board useful for a wide range of applications.

Multifunction boards are commonly used to measure analog signals. It is done by the ADC, which converts the analog voltage level into a digital number that the computer can interpret. The analog multiplexer (MUX), the instrumentation amplifier, the sample-and-hold (S/H) circuitry, and the ADC comprise the analog input section of a multifunction board (see Fig. 18.26).

Typically, multifunction DAQ boards have one ADC. Multiplexing is a common technique for measuring multiple channels (generally 16 single ended or 8 differential) with a single ADC. The analog mux switches between channels and passes the signal to the instrumentation amplifier and the sample-and-hold circuitry. The multiplexer architecture is the most common approach taken with plug-in DAQ boards. Although plug-in boards typically include up to only 16 single-ended or 8 differential inputs, you can further expanded the number of analog input channels with external multiplexer accessories.

Instrumentation amplifiers typically provide a differential input and selectable gain by jumper or software. The differential input rejects small common-mode voltages. The gain is often software programmable. In addition, many DAQ boards also include the capability to change the amplifier gain while scanning channels at high rates. Therefore, you can easily monitor signals with different ranges of amplitudes. The output of the amplifier is sampled, or held at a constant voltage, by the sample-and-hold device at measurement time so that voltage does not change during digitization.

The ADC digitizes the analog signal into a digital value, which is ultimately sent to computer memory. There are several important parameters of A/D conversion. The fundamental parameter of an ADC is the number of bits. The number of bits of an ADC determines the range of values for the binary output of the ADC conversion. For example, many ADCs are 12 b, so a voltage within the input range of the ADC will produce a binary value that has one of $2^{12} = 4096$ different values. The more bits that an ADC has, the higher the resolution of the measurement. The resolution determines the smallest amount of change that can be detected by the ADC. Depending on your background, you may be more familiar with resolution expressed as number of digits of a voltmeter or dynamic range in decibels, than with bits. Table 18.2 shows the relation between bits, number of digits, and dynamic range in decibels.

The resolution of the A/D conversion is also determined by the input range of the ADC and the gain. DAQ boards usually include an instrumentation amplifier that amplifies the analog signal by a gain factor

TABLE 18.2 Relation Between Bits, Number of Digits, and Dynamic Range

Bits	Digits	dB
20	6.0	120
16	4.5	96
12	3.5	72
8	2.5	48

prior to the conversion. You use this gain to amplify low-level signals so that you can make more accurate measurements.

Together, the input range of the ADC, the gain, and the number of bits of the board determine the maximum accuracy of the measurement. For example, suppose you are measuring a low-level ± 30 mV signal with a 12-b A/D convertor that has a ± 5 V input range. If the system includes an amplifier with a gain of 100, the resulting resolution of the measurement will be $\text{range}/(\text{gain} \times 2^{\text{bits}}) = \text{resolution}$, or $10 \text{ V}/(100 \times 2^{12}) = 0.0244 \text{ mV}$.

Finally, an important parameter of digitization is the rate at which A/D conversions are made, referred to as the *sampling rate*. The A/D system must be able to sample the input signal fast enough to accurately measure the important waveform attributes. To meet this criterion, the ADC must be able to convert the analog signal to digital form quickly enough.

When scanning multiple channels with a multiplexing data acquisition system, other factors can affect the throughput of the system. Specifically, the instrumentation amplifier must be able to settle to the needed accuracy before the A/D conversion occurs. With the multiplexed signals, multiple signals are being switched into one instrumentation amplifier. Most amplifiers, especially when amplifying the signals with larger gains, will not be able to settle to the full accuracy of the ADC when scanning channels at high rates. To avoid this situation, consult the specified settling times of the DAQ board for the gains and sampling rates required by your application.

Types of ADCs

Different DAQ boards use different types of ADCs to digitize the signal. The most popular type of ADC on plug-in DAQ boards is the successive approximation ADC, because it offers high speed and high resolution at a modest cost. *Subranging* (also called *half-flash*) ADCs offer very high-speed conversion with sampling speeds up to several million samples per second. *Delta-sigma modulating* ADCs sample at high rates, are able to achieve high resolution, and offer the best linearity of all ADCs. *Integrating and flash* ADCs are mature technologies still used on DAQ boards. Integrating ADCs are able to digitize with high resolution but must sacrifice sampling speed to obtain it. Flash ADCs are able to achieve the highest sampling rate (GHz) but typically with low resolution. The different types of ADCs are summarized in Table 18.3.

Analog Input Architecture

With the typical DAQ board, the multiplexer switches among analog input channels. The analog signal on the channel selected by the multiplexer then passes to the programmable gain instrumentation amplifier (PGIA), which amplifies the signal. After the signal is amplified, the sample and hold keeps the analog signal constant so that the A/D converter can determine the digital representation of the analog signal. A good DAQ board will then place the digital signal in a first-in first-out (FIFO) buffer, so that no data

TABLE 18.3 Types of ADCs

Type of ADC	Advantages
Successive Approximation	High resolution High speed Easily multiplexed
Subranging	Higher speed
Delta-Sigma	High resolution Excellent linearity Built-in antialiasing
Integrated	High resolution Good noise rejection Mature technology
Flash	Highest speed Mature technology

will be lost if the sample cannot transfer immediately over the PC I/O channel to computer memory. Having a FIFO becomes especially important when the board is run under operating systems that have large interrupt latencies.

Basic Analog Specifications

Almost every DAQ board data sheet specifies the number of channels, the maximum sampling rate, the resolution, and the input range and gain.

The number of channels, which is determined by the multiplexer, is usually specified in two forms, differential and single ended. Differential inputs are inputs that have different reference points for each channel, none of which is grounded by the board. Differential inputs are the best way to connect signals to the DAQ board because they provide the best noise immunity.

Single-ended inputs are inputs that are referenced to a common ground point. Because single-ended inputs are referenced to a common ground, they are not as good as differential inputs for rejecting noise. They do have a larger number of channels, however. You can use the single-ended inputs when the input signals are high level (greater than 1 V), the leads from the signal source to the analog input hardware are short (less than 15 ft), and all input signals share a common reference.

Some boards have pseudodifferential inputs, which have all inputs referenced to the same common—like single-ended inputs—but the common is not referenced to ground. Using these boards, you have the benefit of a large number of input channels, like single-ended inputs, and the ability to remove some common mode noise, especially if the common mode noise is consistent across all channels. Differential inputs are still preferable to pseudodifferential, however, because differential is more immune to magnetic noise.

Sampling rate determines how fast the analog signal is converted to a digital signal. If you are measuring AC signals, you will want to sample at least two times faster than the highest frequency of your input signal. Even if you are measuring DC signals, you can sample faster than you need to and then average the samples to increase the accuracy of the signal by reducing the effects of noise.

If you have multiple DC-class signals, you will want to select a board with *interval scanning*. With interval scanning, all channels are scanned at one sample interval (usually the fastest rate of the board), with a second interval (usually slow) determining the time before repeating the scan. Interval scanning gives the effects of simultaneously sampling for slowly varying signals without requiring the addition cost of input circuitry for true simultaneous sampling.

Resolution is the number of bits that are used to represent the analog signal. The higher the resolution, the higher the number of divisions the input range is broken into and, therefore, the smaller the possible detectable voltage. Unfortunately, some data acquisition specifications are misleading when they specify the resolution associated with the DAQ board. Many DAQ boards specifications state the resolution of the ADC without stating the linearity's and noise and, therefore, do not give you the information you need to determine the resolution of the entire board. Resolution of the ADC, combined with the settling time, integral non-linearity, differential non linearity, and noise will give you an understanding of the accuracy of the board.

Input range and gain tell you what level of signal you can connect to the board. Usually, the range and gain are specified separately, so you must combine the two to determine the actual signal input range as

$$\text{signal input range} = \text{range/gain}$$

For example, a board using an input range of ± 10 V with a gain of 2 will have a signal input range of ± 5 V. The closer the signal input range is to the range of your signal, the more accurate your readings from the DAQ board will be. If your signals have different input ranges, you will want to look for a DAQ board that has the capability of different gains per channel.

18.2.2 Data Acquisition Software

The software is often the most critical component of the data acquisition system. Properly chosen software can save you a great deal of time and money. Likewise, poorly chosen software can cost you time and money. A whole spectrum of software options exists, with important tradeoffs and advantages.

Board Register-Level Programming

The first option is not to use vendor-supplied software and program the DAQ board yourself at the hardware level. DAQ boards are typically register based, that is, they include a number of digital registers that control the operation of the board. The developer may use any standard programming language to write series of binary codes to the DAQ board to control its operation.

Driver Software

Driver software typically consists of a library of function calls usable from a standard programming language. These function calls provide a high-level interface to control the standard functions of the plug-in board. For example, a function called SCAN_OP may configure, initiate, and complete a multiple channel scanning data acquisition operation of a predetermined number of points. The function call would include parameters to indicate the channels to be scanned, the amplifier gains to be used, the sampling rate, and the total number of data points to collect. The driver responds to this one function call by programming the plug-in board, the DMA controller, the interrupt controller, and CPU to scan the channels as requested.

18.2.3 Digital Sampling

Every DAQ system has the task of gathering information about analog signals. To do this, the system captures a series of instantaneous snapshots or samples of the signal at definite time intervals. Each sample contains information about the signal at a specific instant. Knowing the exact **conversion time** and the value of the sample, you can reconstruct, analyze, and display the digitized waveform.

Two classifications of sample timing techniques are used to control the ADC conversions, real-time sampling and equivalent-time sampling (ETS). Depending on the type of signal you acquire and the rate of acquisition, one sampling technique may be better than the other.

Real-Time Sampling Techniques

In real-time sampling, you immediately see the changes, as the signal changes (Fig. 18.27). According to the **Nyquist theorem**, you must sample at least twice the rate of the maximum frequency component in that signal to prevent **aliasing**. The frequency at one-half the sampling frequency is referred to as the Nyquist frequency. Theoretically, it is possible to recover information about those signals with frequencies at or below the Nyquist frequency. Frequencies above the Nyquist frequency will alias to appear between DC and the Nyquist frequency.

FIGURE 18.27 Consecutive discrete samples recreate the input signal.

For example, assume the sampling frequency f_s , is 100 Hz. Also assume the input signal to be sampled contains the following frequencies: 25, 70, 160, and 510 Hz. Figure 18.28 shows a spectral representation of the input signal. The mathematics of sampling theory show us that a sampled signal is shifted in the frequency domain by an amount equal to integer multiples of the sampling frequency, f_s . Figure 18.29 shows the spectral content of the input signal after sampling. Frequencies below 50 Hz, the Nyquist frequency ($f_s/2$), appear correctly. However, frequencies above the Nyquist appear as aliases below the Nyquist frequency. For example, F1 appears correctly; however, both F2, F3, and F4 have aliases at 30, 40, and 10 Hz, respectively.

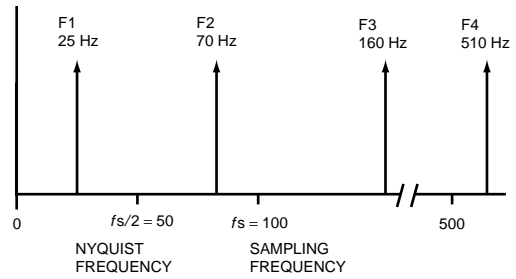

FIGURE 18.28 Spectral of signal with multiple frequencies.

The resulting frequency of aliased signals can be calculated with the following formula:

$$\text{Apparent (Alias) Freq.} = \text{ABS (Closest Integer Multiple of Sampling Freq.-Input Freq.)}$$

For the example of Fig. 18.28 and Fig. 18.29 or 10 Hz

$$\text{alias F2} = |100 - 70| = 30 \text{ Hz}$$

$$\text{alias F3} = |(2)100 - 160| = 40 \text{ Hz}$$

$$\text{alias F4} = |(5)100 - 510| = 10 \text{ Hz}$$

Preventing Aliasing

You can prevent aliasing by using filters on the front end of your DAQ system. These antialiasing filters are set to cut off any frequencies above the Nyquist frequency (half the sampling rate). The perfect filter would reject all frequencies above the Nyquist; however, because perfect filters exist only in textbooks, you must compromise between sampling rate and selecting filters. In many applications, one- or two-pole passive filters are satisfactory. By oversampling (5–10 times) and using these filters, you can sample adequately in most cases.

Alternatively, you can use active antialiasing filters with programmable cutoff frequencies and very sharp attenuation of frequencies above the cutoff. Because these filters exhibit a very steep rolloff, you can sample at two to three times the filter cutoff frequency. Figure 18.30 shows a transfer function of a high-quality antialiasing filter.

The computer uses digital values to recreate or to analyze the waveform. Because the signal could be anything between each sample, the DAQ board may be unaware of any changes in the signal between samples. There are several sampling methods optimized for the different classes of data; they include software polling, external sampling, continuous scanning, multirate scanning, simultaneous sampling, interval scanning, and seamless changing of the sample rate.

Software Polling

A software loop polls a timing signal and starts the ADC conversion via a software command when the edge of the timing signal is detected. The timing signal may originate from the computer’s internal clock or from a clock on the DAQ board. Software polling is useful in simple, low-speed applications, such as temperature measurements.

FIGURE 18.29 Spectral of signal with multiple frequencies after sampled at $f_s = 100$ Hz.

FIGURE 18.30 Transfer function of an antialiasing filter.

The software loop must be fast enough to detect the timing signal and trigger a conversion. Otherwise, a window of uncertainty, also known as *jitter*, will exist between two successive samples. Within the window of uncertainty, the input waveform could change enough to drastically reduce the accuracy of the ADC.

Suppose a 100-Hz, 10-V full-scale sine wave is digitized (Fig. 18.31). If the polling loop takes 5 ms to detect the timing signal and to trigger a conversion, then the voltage of the input sine wave will change as much as 31 mV ($\Delta V = 10 \sin(2\pi \times 100 \times 5 \times 10^{-6})$). For a 12-b ADC operating over an input range of 10 V and a gain of 1, 1 least significant bit (LSB) of error represents 2.44 mV

$$\left(\frac{\text{input range}}{\text{gain} \times 2^n} \right) = \left(\frac{10 \text{ V}}{1 \times 2^{12}} \right) = 2.44 \text{ mV}$$

But because the voltage error due to jitter is 31 mV, the accuracy error is 13 LSB

$$\left(\frac{31 \text{ mV}}{2.44 \text{ mV}} \right)$$

This represents uncertainty in the last 4 b of a 12-b ADC. Thus, the effective accuracy of the system is no longer 12 b, but rather 8 b.

External Sampling

Some DAQ applications must perform a conversion based on another physical event that triggers the data conversion. The event could be a pulse from an optical encoder measuring the rotation of a cylinder. A sample would be taken every time the encoder generates a pulse corresponding to *n* degrees of rotation. External triggering is advantageous when trying to measure signals whose occurrence is relative to another physical phenomena.

FIGURE 18.31 Jitter reduces the effective accuracy of the DAQ board.

FIGURE 18.32 If the channel skew is large compared to the signal, then erroneous conclusions may result.

Continuous Scanning

When a DAQ board acquires data, several components on the board convert the analog signal to a digital value. These components include the analog multiplexer (mux), the instrumentation amplifier, the sample-and-hold circuitry, and the ADC. When acquiring data from several input channels, the analog mux connects each signal to the ADC at a constant rate. This method, known as *continuous scanning*, is significantly less expensive than having a separate amplifier and ADC for each input channel.

Continuous scanning is advantageous because it eliminates jitter and is easy to implement. However, it is not possible to simultaneously sample multiple channels. Because the mux switches between channels, a time skew occurs between any two successive channel samples. Continuous scanning is appropriate for applications where the time relationship between each sampled point is unimportant or where the skew is relatively negligible compared to the speed of the channel scan.

If you are using samples from two signals to generate a third value, then continuous scanning can lead to significant errors if the time skew is large. In Fig. 18.32, two channels are continuously sampled and added together to produce a third value. Because the two sine waves are 90° out of phase, the sum of the signals should always be zero. But because the skew time between the samples, an erroneous sawtooth signal results.

Multirate Scanning

Multirate scanning, a method that scans multiple channels at different scan rates, is a special case of continuous scanning. Applications that digitize multiple signals with a variety of frequencies use multirate scanning to minimize the amount of buffer space needed to store the sampled signals. You can use channel-independent ADCs to implement hardware multirate scanning; however, this method is extremely expensive. Instead of multiple ADCs, only one ADC is used. A channel/gain configuration register stores the scan rate per channel and software divides down the scan clock based on the per-channel scan rate. Software-controlled multirate scanning works by sampling each input channel at a rate that is a fraction of the specified scan rate.

Suppose you want to scan channels 0–3 at 10 kilosamples/sec, channel 4 at 5 kilosamples/sec, and channels 5–7 at 1 kilosamples/sec. You should choose a base scan rate of 10 kilosamples/sec. Channels 0–3 are acquired at the base scan rate. Software and hardware divide the base scan rate by 2 to sample channel 4 at 5 kilosamples/sec, and by 10 to sample channels 5–7 at 1 kilosamples/sec.

Simultaneous Sampling

For applications where the time relationship between the input signals is important, such as phase analysis of AC signals, you must use simultaneous sampling. DAQ boards capable of simultaneous sampling

typically use independent instrumentation amplifiers and sample-and-hold circuitry for each input channel, along with an analog mux, which routes the input signals to the ADC for conversion (as shown in Fig. 18.33).

To demonstrate the need for a simultaneous-sampling DAQ board, consider a system consisting of four 50-kHz input signals sampled at 200 kilosamples/sec. If the DAQ board uses continuous scanning, the skew between each channel is $5 \mu\text{s}$ ($1 \text{ S}/200 \text{ kilosamples/sec}$) which represents a 270° ($15 \mu\text{s}/20 \mu\text{s} \times 360^\circ$) shift in phase between the first channel and fourth channel. Alternately, with a simultaneous-sampling board with a maximum 5 ns interchannel time offset, the phase shift is only 0.09° ($5 \text{ ns}/20 \mu\text{s} \times 360^\circ$). This phenomenon is illustrated in Fig. 18.34.

FIGURE 18.33 Block diagram of DAQ components used to simultaneously sample multiple channels.

Interval Scanning

For low-frequency signals, interval scanning creates the effect of simultaneous sampling, yet maintains the cost benefits of a continuous scanning system. This method scans the input channels at one rate and uses a second rate to control when the next scan begins. You can scan the input channels at the fastest rate of the ADC, creating the effect of simultaneous sampling. Interval scanning is appropriate for slow moving signals, such as temperature and pressure. Interval scanning results in a jitter-free sample rate and minimal skew time between channel samples. For example, consider a DAQ system with 10 temperature signals. Using interval scanning, you can set up the DAQ board to scan all channels with an interchannel delay of $5 \mu\text{s}$, then repeat the scan every second. This method creates the effect of simultaneously sampling 10 channels at 1 S/s, as shown in Fig. 18.35.

FIGURE 18.34 Comparison of continuous scanning and simultaneous sampling.

FIGURE 18.35 Interval scanning: all 10 channels are scanned within $45 \mu\text{s}$; this is insignificant relative to the overall acquisition rate of 1 S/s.

To illustrate the difference between continuous and interval scanning, consider an application that monitors the torque and revolutions per minute (RPMs) of an automobile engine and computes the engine horsepower. Two signals, proportional to torque and RPM, are easily sampled by a DAQ board at a rate of 1000 S/s. The values are multiplied together to determine the horsepower as a function of time. A continuously scanning DAQ board must sample at an aggregate rate of 2000 S/s. The time between which the torque signal is sampled and the RPM signal is sampled will always be 0.5 ms (1/2000). If either signal changes within 0.5 ms, then the calculated horsepower is incorrect. But using interval scanning at a rate of 1000 S/s, the DAQ board samples the torque signal every 1 ms, and the RPM signal is sampled as quickly as possible after the torque is sampled. If a 5- μ s interchannel delay exists between the torque and RPM samples, then the time skew is reduced by 99% $((0.5 \text{ ms} - 5 \mu\text{s})/0.5 \text{ ms})$, and the chance of an incorrect calculation is reduced.

Seamless Changing of the Sampling Rate

This technique, a variation of real-time sampling, is used to vary the sampling rate of the ADC without having to stop and reprogram the counter/timer for different conversion rates. For example, you may want to start sampling slowly, and then, following a trigger, begin sampling quickly; this is particularly useful when performing transient analysis. The ADC samples slowly until the input crosses a voltage level, and then the ADC samples quickly to capture the transient.

Four complex timing and triggering mechanisms are necessary to seamlessly change the sampling rate. They include hardware analog triggering, frequency shift keying (FSK), flexible data acquisition signal routing, and buffered relative-time stamping.

Hardware Analog Triggering

A trigger level serves as the reference point at which the sampling rate changes. Analog trigger circuitry monitors the input voltage of the waveform and generates a transistor-transmitter logic (TTL) high level whenever the voltage input is greater than the trigger voltage V_{set} ; and a TTL low level when the voltage input is less than the trigger voltage. Therefore, as the waveform crosses the trigger level, the analog trigger circuitry signals the counter to count at a different frequency.

Frequency Shift Keying

Frequency shift keying (FSK) occurs when the frequency of a digital pulse varies over time. Frequency modulation (FM) in the analog domain is analogous to FSK in the digital domain. FSK determines the frequency of a generated pulse train relative to the level present at the gate of a counter. For example, when the gate signal is a TTL high level, the pulse train frequency is three times greater than the pulse train frequency when the gate signal is a TTL low level.

Flexible Data Acquisition Signal Routing

For continuous or interval scanning, a simple, dedicated sample timer directly controls ADC conversions. But for more complex sampling techniques, such as seamlessly changing the sampling rate, signals from other parts of the DAQ board control ADC conversions. The DAQ-STC ASIC provides 20 possible signal sources to time each ADC conversion. One of the sources is the output of the general-purpose counter 0, which is more flexible than a dedicated timer. In particular, the general-purpose counter generates the FSK signal that is routed to the ADC to control the sampling rate.

Buffered Relative-Time Stamping

Because different sample rates are used to acquire the signal, keeping track of the various acquisition rates is a challenge for the board and software. The sampled values must have an acquisition time associated with them in order for the signal to be correctly displayed. While values are sampled by the ADC, the DAQ-STC counter/timers measure the relative time between each sample using a technique called *buffered relative-time stamping*. The measured time is then transferred from the counter/timer registers to PC memory via direct memory access.

The counter continuously measures the time interval between successive, same-polarity transitions of the FSK pulse with a measurement resolution of 50 ns. Countings begin at 0. The counter contents are

FIGURE 18.36 The number of counts is stored in a buffer. These counts are used to determine the time between conversions.

stored in a buffer after an edge of the appropriate polarity is detected. Then, the counting begins again at 0. Software routines use DMA to transfer data from the counter to a buffer until the buffer is filled.

For example, in Fig. 18.36, the period of an FSK signal is measured. The first period is 150 ns (3 clock cycles \times 50-ns resolution); the second, third, and fourth periods are 100 ns (2 clock cycles \times 50 ns); the fifth period is 150 ns. For a 10-MHz board that can change its sampling rate seamlessly, the FSK signal determines the ADC conversions; the effective sampling rate is 6.7 MHz for the first part of the signal and 10 MHz for the second part of the signal.

Figure 18.37 details the timing signals necessary to change the sampling rate of the ADC without missing data. As the input waveform crosses the trigger voltage 1 the analog trigger circuitry generates a low on its output. The output signal is routed to a general-purpose counter, which generates pulses at a predetermined frequency 2. Each high-to-low transition of the FSK signal causes the ADC to sample the waveform 3. When the input waveform crosses the trigger level again, the analog trigger circuit generates a high, which causes the general-purpose counter to generate pulses at a second frequency. This timing process continues until a predetermined number of samples has been acquired.

Considerations When Seamlessly Changing the Sampling Rate

The intention of seamlessly changing the sampling rate is to switch between rates, yet not miss significant changes in the signal. Selecting the various rates and the instance at which the rate changes requires some

FIGURE 18.37 Complex triggering, counting, and timing are combined to seamlessly change the sampling rate.

thought. For instance, when switching between a sampling rate of 10 S/s and 20 kilosamples/sec, the analog trigger circuitry checks for a trigger condition every 1/10 of a second. This means that, at most, 0.1 s will pass before the DAQ board is aware of the trigger and increases the sampling rate to 20 kilosamples/sec. If the ADC is switching between a rate of 20 kilosamples/sec and 10 S/s, the trigger condition is checked every 50 ms, and the board will take, at most, 50 ms to switch to the 10 S/s rate. Thus, you should set the trigger condition so that you can detect the trigger and start the faster rate before the signal changes significantly.

Suppose automatic braking systems (ABS) are tested by monitoring signal transients. The test requires a few samples to be recorded before and after the transient, as well as the transient signal. The test specifies a sample rate of 400 kilosamples/sec. If the DAQ board continuously samples the system, you must sample the entire signal at 400 kilosamples/sec. For a signal that is stable for 1 min before the transient, then 24×10^6 samples are acquired before the transient even occurs. If the data are stored on disk, a large hard disk is needed. But if the stable portion of the signal is sampled more slowly, such as 40 S/s, the amount of unnecessary data acquired is reduced. If the sampling rate is changed on the fly, then the board can sample at 40 S/s before and after the transient and at 400 kilosamples/sec during the transient. In the 1 min before the transient, only 2400 samples are logged. Once the transient occurs, the board samples at 400 kilosamples/sec. Once the transient passes, the ADC begins to sample at 40 S/s again. Using this method, exactly the number of samples needed relative to the signal are logged to disk.

18.2.4 Equivalent-Time Sampling

If real-time sampling techniques are not fast enough to digitize the signal, then consider ETS as an approach. Unlike continuous, interval, or multirate scanning, complex counter/timers control ETS conversions, and ETS strictly requires that the input waveform be repetitive throughout the entire sampling period.

In ETS mode, an analog trigger arms a counter, which triggers an ADC conversion at progressively increasing time intervals beyond the occurrence of the analog trigger (as shown in Fig. 18.38). Instead of acquiring samples in rapid succession, the ADC digitizes only one sample per cycle. Samples from several cycles of the input waveform are then used to recreate the shape of the signal.

ETS Counter/Timer Operations

Four complex timing and triggering mechanisms are necessary for ETS. They include hardware analog triggering, retriggerable pulse generation, autoincrementing, and flexible data acquisition signal routing.

Hardware Analog Triggering

Analog trigger circuitry monitors the input voltage of the waveform and generates a pulse whenever the trigger conditions are met. Each time the repetitive waveform crosses the trigger level, the analog trigger circuitry arms the board for another acquisition.

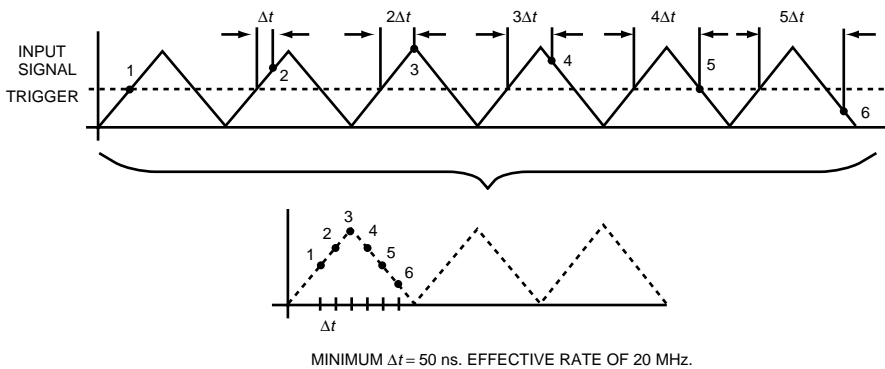

FIGURE 18.38 In ETS mode, a waveform is recreated from samples taken from several cycles of the input waveform.

Retriggerable Pulse Generation

The ADC samples when it receives a pulse for the conversion counter. In real-time sampling, the conversion counter generates a series of continuous pulses that cause the ADC to successively digitize multiple values. In ETS, however, the conversion counter generates only one pulse, which corresponds to one sample from one cycle of the waveform. This pulse is regenerated in response to a signal from the analog trigger circuitry, which occurs after each new cycle of the waveform.

Autoincrementing

If the ADC sampled every occurrence of the waveform using only retriggerable pulse generation, the same point along the repetitive signal would be digitized, namely, the point corresponding to the analog trigger. A method is needed to make the ADC sample different points along different cycles of the waveform. This method, known as *autoincrementing*, is the most important counter/timer functional for controlling ETS. An autoincrementing counter produces a series of delayed pulses.

Flexible Data Acquisition Signal Routing

As with seamlessly changing the sample rate, ETS uses signals from other parts of the board to control ADC conversions. The DAQ-STC generates autoincrementing retriggerable pulses.

Figure 18.39 details the timing signals used for ETS. As the input waveform crosses the trigger voltage 1, the analog trigger circuitry generates a pulse at the gate input of the autoincrementing counter. This counter generates a conversion pulse 2, which is used to trigger the ADC to take a sample 3. The timing process continues until a predetermined number of samples has been acquired. The delay time Dt is directly related to the relative sampling rate set. For example, for an effective sampling rate of 20 MS/s, Dt is equal to 50 ns. Because the waveform is repetitive over the complete acquisition, the points in the recreated waveform appear as if they were taken every 50 ns.

Considerations When Using ETS

Although ETS is useful in a number of applications, ETS users need to be aware of a few issues. First, the input waveform must be repetitive. ETS will not correctly reproduce a waveform that is nonrepetitive because the analog trigger will never occur at the same place along the waveform. One-shot acquisitions are not possible, because ETS digitizes a sample from several cycles of a repetitive waveform.

The accuracy of the conversion is limited to the accuracy of the counter/timer. Jitter in the counter/timer causes the sample to be taken within a multiple of 50 ns from the trigger. The sample may occur along a

FIGURE 18.39 Complex triggering, counting, and timing are combined to control the ADC in ETS.

slightly different portion of the input waveform than expected. For example, using a 12-b board to sample the 100-Hz, 10-V peak-to-peak sine wave in Fig. 18.31, the accuracy error is 0.13 LSB.

$$\frac{\Delta V}{2.44 \text{ mV}} = \frac{10 \sin(72\pi \times 100 \times 50 \times 10^{-9})}{2.44 \text{ mV}}$$

ETS Application Examples

ETS techniques are useful in measuring the rise and fall times of TTL signals. ETS is also used to measure the impulse response of a 1-MHz, low-pass filter subject to a 2-ms repetitive impulse. The impulse response is a repetitive signal of pulses that also have a duration of 2 ms. Using a 20-MHz ETS conversion rate results in 40 digitized samples per input impulse. This is enough samples to display the impulse response in the time domain. Other applications for ETS include disk drive testing, nondestructive testing, ultrasonic testing, vibration analysis, laser diode characterization, and impact testing.

18.2.5 Factors Influencing the Accuracy of Your Measurements

How do you tell if the plug-in data acquisition board that you already have or the board that you are considering integrating into your system will give you the results you want? With a sophisticated measuring device like a plug-in DAQ board, you can obtain significantly different accuracies depending on which board you are using. For example, you can purchase DAQ products on the market today with 16-b analog to digital converters and get less than 12 b of useful data, or you can purchase a product with a 16-b ADC and actually get 16 b of useful data. This difference in accuracies causes confusion in the PC industry where everyone is used to switching out PCs, video cards, printers, and so on, and experiencing similar results between equipment.

The most important thing to do is to scrutinize more specifications than the resolution of the A/D converter that is used on the DAQ board. For DC-class measurements, you should at least consider the settling time of the instrumentation amplifier, **differential non-linearity (DNL)**, **relative accuracy**, **integral nonlinearity (INL)**, and noise. If the manufacturer of the board you are considering does not supply you with each of these specifications in the data sheets, you can ask the vendor to provide them or you can run tests yourself to determine these specifications of your DAQ board.

Linearity

Ideally, as you increase the level of voltage applied to a DAQ board, the digital codes from the ADC should also increase linearly. If you were to plot the voltage vs. the output code from an ideal ADC, the plot would be a straight line. Deviations from this ideal straight line are specified as the nonlinearity. Three specifications indicate how linear a DAQ boards transfer function is: differential nonlinearity, relative accuracy, and integral nonlinearity.

Differential Nonlinearity

For each digital output code, there is a continuous range of analog input values that produce it. This range is bounded on either side by transitions. The size of this range is known as the *code width*. Ideally, the width of all binary code values is identical and is equal to the smallest detectable voltage change,

$$\text{ideal code width} = \frac{\text{input voltage range}}{2^n}$$

where n is the resolution of the ADC. For example, a board that has a 12-b ADC, input range of 0–10, and a gain of 100 will have an ideal code width of

$$\frac{10 \text{ V}/100}{2^{12}} = 24 \mu\text{V}$$

This ideal analog code width defines the analog unit called the least significant bit. DNL is a measure in LSB of the worst-case deviation of code widths from their ideal value of 1 LSB. An ideal DAQ board has a DNL of 0 LSB. Practically, a good DAQ board will have a DNL within ± 0.5 LSB.

FIGURE 18.40 Demonstration of a missing code: (a) an ideal transfer curve with DNL of 0 and no missing codes, (b) a poor transfer curve with a missing code at 120 μV .

There is no upper limit on how wide a code can be. Codes do not have widths of less than 0 LSB, so the DNL is never worse than -1 LSB. A poorly performing DAQ board may have a code width equal to or very near zero, which indicates a *missing code*. No matter what voltage you input to the DAQ board with a missing code, the board will never quantize the voltage to the value represented by this code. Sometimes DNL is specified by stating that a DAQ board has no missing codes, which means that the DNL is bounded below by -1 LSB but does not make any specifications about the upper bound.

If the DAQ board in the previous example had a missing code at 120 μV , then increasing the voltage from 96 to 120 μV would not be detectable. Only when the voltage is increased another LSB, or in this example, 24 μV , will the voltage change be detectable (Fig. 18.40). As you can see, poor DNL reduces the resolution of the board.

To run your own DNL test:

1. Input a high-resolution, highly linear triangle wave into one channel of the DAQ board. The frequency of the triangle should be low and the amplitude should swing from minus full scale to plus full scale of the input to the DAQ board.
2. Start an acquisition on the plug-in board so that you acquire a large number of points. Recommended values are 1×10^6 samples for a 12-b board and 20×10^6 million samples for a 16-b board.
3. Make a histogram of all the acquired binary codes. This will give you the relative frequency of each code occurrence.
4. Normalize the histogram by dividing by the averaged value of the histogram.
5. The DNL is the greatest deviation from the value of 1 LSB. Because the input was a triangle wave, it had a uniform distribution over the DAQ board codes. The probability of a code occurring is directly proportional to the code width, and therefore shows the DNL.

Figure 18.41 shows a section of the DNL plot of two products with the same 16-b ADC yet significantly different DNL. Ideally, the codewidth plot will be a straight line at 1 LSB. Figure 18.41(a) shows the codewidth plot of a product that has DNL of less than ± 0.5 LSB. Because the codewidth is never 0, the product also has no missing codes. Figure 18.41(b) shows the codewidth plot of a product that has poor DNL. This product has many missing codes, a code width that is as much as 4.2 LSB at the code value 0, and is clearly not 16-b linear.

Relative Accuracy

Relative accuracy is a measure in LSBs of the worst-case deviation from the ideal DAQ board transfer function, a straight line. To run your own relative accuracy test:

1. Connect a high-accuracy analog voltage-generation source to one channel of the DAQ board. The source should be very linear and have a higher resolution than the DAQ board that you wish to test.

FIGURE 18.41 Section of DNL plots at the critical point (zero crossing) of two products that have the same ADC: (a) the product is the National Instruments AT-MIO-16X, which has a DNL of less than ± 0.5 and has no missing codes, (b) the product has very poor DNL and many missing codes.

2. Generate a voltage that is near minus full scale.
3. Acquire at least 100 samples from the DAQ board and average them. The reason for averaging is to reduce the effects of any noise that is present.
4. Increase the voltage slightly and repeat step 3. Continue steps 3 and 4 until you have swept through the input range of the DAQ board.
5. Plot the averaged points on the computer. You will have a straight line, as shown in Fig. 18.42(a), unless the relative accuracy of your DAQ board is astonishingly bad.
6. To see the deviation from a straight line, you must first generate an actual straight line in software that starts at the minus full-scale reading and ends at the plus full-scale reading using a straight-line endpoint fit analysis routine.
7. Subtract the actual straight line from the waveform that you acquired. If you plot the resulting array, you should see a plot similar to Fig. 18.42(b).
8. The maximum deviation from zero is the relative accuracy of the DAQ board.

FIGURE 18.42 Determining the relative accuracy of a DAQ board: (a) the plot generated by sweeping the input and how it appears as a straight line, (b) how the straight line of Fig. 18.42(a) is not actually straight by subtracting an actual straight line.

The driver software for a DAQ board will translate the binary code value of the ADC to voltage by multiplying by a constant. Good relative accuracy is important for a DAQ board because it ensures that the translation from the binary code of the ADC to the voltage value is accurate. Obtaining good relative accuracy requires that both the ADC and the surrounding analog support circuitry be designed properly.

Integral Nonlinearity

INL is a measure in LSB of the straightness of a DAQ board's transfer function. Specifically, it indicates how far a plot of the DAQ boards *transitions* deviates from a straight line. Factors that contribute to poor INL on a DAQ board are the ADC, multiplexer, and instrumentation amplifier. The INL test is the most difficult to make:

1. Input a signal from a digital to analog converter that has higher resolution and linearity than the DAQ board that you are testing.
2. Starting at minus full scale, increase the codes to the DAC until the binary reading from the ADC flickers between two consecutive values. When the binary reading flickers evenly between codes, you have found the LSB transition for the DAQ board.
3. Record the DAC codes of all transitions.
4. Using an analysis routine, make an endpoint fit on the recorded DAC codes.
5. Subtract the endpoint fit line from the recorded DAC values.
6. The farthest deviation from zero is the INL.

Even though highly specified, the INL specification does not have as much value as the relative accuracy specification and is much more difficult to make. The relative accuracy specification is showing the deviation from the ideal straight line whereas the INL is showing the deviation of the transitions from an ideal straight line. Therefore, relative accuracy takes the quantization error, INL, and DNL into consideration.

Settling Time

On a typical plug-in DAQ board, an analog signal is first selected by a multiplexer, and then amplified by an instrumentation amplifier before it is converted to a digital signal by the ADC. This instrumentation amplifier must be able to track the output of the multiplexer as the multiplexer switches channels, and the instrumentation amplifier must be able to settle to the accuracy of the ADC. Otherwise, the ADC will convert an analog signal that has not settled to the value that you are trying to measure with your DAQ board. The time required for the instrumentation amplifier to settle to a specified accuracy is called the *settling time*. Poor settling time is a major problem because the amount of inaccuracy usually varies with gain and sampling rate. Because the errors occur in the analog stages of the DAQ board, the board cannot return an error message to the computer when the instrumentation amplifier does not settle.

The instrumentation amplifier is most likely not to settle when you are sampling multiple channels at high gains and high rates. When the application is sampling multiple channels, the multiplexer is switching among different channels that can have significant differences in voltage levels (Fig. 18.43). Instrumentation amplifiers can have difficulty tracking this significant difference in voltage. Typically, the higher the gain and the faster the channel switching time, the less likely it is that the instrumentation amplifier will settle.

It is important to be aware of settling time problems so you know at what multichannel rates and gains you can run your DAQ board and maintain accurate readings. Running your own settling time test is relatively easy:

1. Apply a signal to one channel of your DAQ board that is nearly full scale. Be sure to take the range and gain into account when you select the levels of the signal you will apply. For example, if you are using a gain of 100 on a ± 10 V input range on the DAQ board, apply a signal slightly less than 10 V/100 or ± 0.1 -V signal to the channel.
2. Acquire at least 1000 samples from one channel only and average them. The averaged value will be the expected value of the DAQ board when the instrumentation amplifier settles properly.
3. Apply a minus full-scale signal to a second channel. Be sure to take range and gain into account, as described earlier.

FIGURE 18.43 The input to an instrumentation amplifier that is multiplexing 40 DC signals appears to be a high-frequency AC signal.

4. Acquire at least 1000 samples from the second channel only and average them. This will give you the expected value for the second channel when the instrumentation amplifier settles properly.
5. Have the DAQ board sample both channels at the highest possible sampling rate so that the multiplexer is switching between the first and the second channels.
6. Average at least 100 samples from each channel.
7. The deviation between the values returned from the board when you sampled the channels using a single channel acquisition and the values returned when you sampled the channels using a multichannel acquisition will be the settling time error.

To plot the settling time error, repeat steps 5 and 6, but reduce the sampling rate each time. Then plot the greatest deviation at each sampling rate. A DAQ board settles to the accuracy of the ADC only when the settling time error is less than ± 0.5 LSB. By plotting the settling time error, you can determine at what rate you can sample with your DAQ board and settle to the accuracy that your application requires. The settling-time plot will usually vary with gain and so you will want to repeat the test at different gains.

Figure 18.44 shows an example of two DAQ boards that have a 12-b resolution ADC, yet have significantly different settling times. For the tests, both boards were sampling two channels with a gain of 100. The settling-time plot for the first board, shown in Fig. 18.44(a), uses an off-the-shelf instrumentation amplifier, which has 34 LSBs of settling-time error when sampling at 100 kHz. Because the board was using an input range of 20 V at a gain of 100, 1 LSB = $48.8 \mu\text{V}$. Therefore, data are inaccurate by as much as 1.7 mV due

FIGURE 18.44 Settling plots for two DAQ boards that have the same resolution ADC yet significantly different settling times. Both boards were using a gain of 100 (a) settling time of off-the-shelf instrumentation amplifier, (b) settling time of NI-PGIA instrumentation amplifier.

to settling-time when the board is sampling at 100 kHz at a gain of 100. If you use this board you must either increase the sampling period to greater than $20 \mu\text{s}$ so that the board can settle, or be able to accept the settling-time inaccuracy. The settling-time plot for the second board, shown in Fig. 18.44(b), settles properly because it uses a custom instrumentation amplifier designed specifically to settle in DAQ board applications. Because the board settles to within ± 0.5 LSB at the maximum sampling rate, you can run the board at all sampling rates and not have any detectable settling-time error.

Applications that are sampling only one channel, applications that are sampling multiple channels at very slow rates, or applications that are sampling multiple channels at low gains usually do not have a problem with settling time. For the other applications, your best solution is to purchase a DAQ board that will settle at all rates and all gains. Otherwise, you will have to either reduce your sampling rate or realize that your readings are not accurate to the specified value of the ADC.

Noise

Noise is any unwanted signal that appears in the digitized signal of the DAQ board. Because the PC is a noisy digital environment, acquiring data on a plug-in board takes a very careful layout on multilayer DAQ boards by skilled analog designers. Designers can use metal shielding on a DAQ board to help reduce noise. Proper shielding should not only be added around sensitive analog sections on a DAQ board, but must also be built into the DAQ board with ground planes.

Of all of the tests to run, a DC-class signal noise test is the easiest to run:

1. Connect the + and – inputs of the DAQ board directly to ground. If possible, make the connection directly on the I/O connector of the board. By doing this, you can measure only the noise introduced by the DAQ board instead of noise introduced by your cabling.
2. Acquire a large number of points (1×10^6) with the DAQ board at the gain you choose in your application.
3. Make a histogram of the data and normalize the array of samples by dividing by the total number of points acquired.
4. Plot the normalized array.
5. The deviation, in LSB, from the highest probability of occurrence is the noise.

Figure 18.45 shows the DC-noise plot of two DAQ products, both of which use the same ADC. You can determine two qualities of the DAQ board from the noise plots—range of noise and the distribution.

FIGURE 18.45 Noise plots of two DAQ products, which have significantly different noise performance even though they use the same 16-b ADC: (a) The National Instruments AT-MIO-16X, which has codes ranging from -3 LSB to $+3$ LSB. The codes at ± 3 LSB have less than a 10^4 and a 10^{-7} probability of occurrence. (b) The DAQ product has noise as high as ± 20 LSB and has a high probability (10^{-4}) of codes occurring as much as 15 LSB from the expected value.

The plot in Fig. 18.45(a) has a high distribution of samples at 0 and a very small number of points occurring at other codes. The distribution is Gaussian, which is what is expected from random noise. From the plot, the noise level is within ± 3 LSB. The plot in Fig. 18.45(b) is a very noisy DAQ product, which does not have the expected distribution and has a noise greater than ± 20 LSB, with many samples occurring at points other than the expected value. For the DAQ product in Fig. 18.45(b), the tests were run with an input range of ± 10 V and a gain of 10. Therefore, $1 \text{ LSB} = 31 \mu\text{V}$, thus a noise level of 20 LSB is equivalent to $620 \mu\text{V}$ of noise.

18.2.6 Common Issues with PC-based Data Acquisition

Aside from software and programming, the most common problem users run into when putting together DAQ systems is a noisy measurement. Unfortunately, noise in DAQ systems is a complicated issue and difficult to avoid. However, it is useful to understand where noise typically comes from, how much noise is to be expected, and some general techniques to reduce or avoid noise corruption.

The Low-Noise Voltmeter Standard

One of the most common questions asked of technical support personnel of DAQ vendors concerns the voltmeter. Users connect their signal leads to a handy voltmeter or digital multimeter (DMM), without worrying too much about cabling and grounding, and obtain a rock solid reading with little jitter. The user then duplicates the experiment with a DAQ board and is disappointed to find that the readings returned by the DAQ board look very noisy and very unstable.

The user decides there is a problem with the DAQ board and calls the technical support line for help. In fact, the user has just demonstrated the effects of two different measurement techniques, each with advantages and disadvantages. DAQ boards are designed as flexible, general-purpose measurement devices. The DAQ board front end typically consists of a gain amplifier and a *sampling* analog-to-digital converter. A sampling ADC takes an instantaneous measurement of the input signal. If the signal is noisy, the sampling ADC will digitize the signal as well as a noise. The digital voltmeter, on the other hand, will use an *integrating* ADC that integrates the signal over a given time period. This integration effectively filters out any high-frequency noise that is present in the signal.

Although the integrating input of the voltmeter is useful for measuring static, or DC signals, it is not very useful for measuring changing signals or digitizing waveforms, or for capturing transient signals. The plug-in DAQ for board, with its sampling ADC, has the flexibility to perform all of these types of measurements. With a little software, the DAQ board can also emulate the operation of the integrating voltmeter by digitizing the static signal at a higher rate and performing the integration, or averaging, of the signal in software.

Where Does Noise Come from?

There are basically four possible sources of noise in a DAQ system:

- Signal source, or transducer
- Environment (noise induced onto signal leads)
- PC environment
- DAQ board

Although the signal source is commonly a significant source of noise, that topic is beyond the scope of this chapter. Most measurement noise problems are the result of noise that is radiated, conducted, or coupled onto signal wires attaching the sensor or transducer to the DAQ equipment. Signal wires basically act as antennas for noise.

Placing a sensitive analog measurement device, like a plug-in DAQ board, inside a PC chassis might seem like asking for trouble. The high-speed digital traffic and power supplies inside a PC are prime candidates for noise radiation. For example, it is a good idea to not install your DAQ board directly next to your video card.

Probably the most dangerous area for your analog signals is not inside the PC, but on top of it. Keep your signal wires clear of your video monitor, which can radiate large high-frequency noise levels onto your signal.

The DAQ board itself can be a source of measurement noise. Poorly designed boards, for example, may not properly shield the analog sections from the digital logic sections that radiate high-frequency switching noise. Properly designed boards, with well-designed shielding and grounding, can provide very low-noise measurements in the relatively noisy environment of the PC.

Proper Wiring and Signal Connections

In most cases, the major source of noise is the environment through which the signal wires must travel. If your signal leads are relatively long, you will definitely want to pay careful attention to your cabling scheme. A variety of cable types are available for connecting sensors to DAQ systems. Unshielded wires or ribbon cables are inexpensive and work fine for high-level signals and short to moderate cable lengths. For low-level signals or longer signal paths, you will want to consider shielded or twisted-pair wiring. Tie the shield for each signal pair to ground reference at the source. Practically speaking, consider shielded, twisted-pair wiring if the signal is less than 1 V or must travel farther than approximately 1 m. If the signal has a bandwidth greater than 100 kHz, however, you will want to use coaxial cables.

Another useful tip for reducing noise corruption is to use a *differential* measurement. Differential inputs are available on most signal conditioning modules and DAQ boards. Because both the (+) and (–) signal lines travel from signal source to the measurement system, they pick up the same noise. A differential input will reject the voltages that are common to both signal lines. Differential inputs are also best when measuring signals that are referenced to ground. Differential inputs will avoid ground loops and reject any difference in ground potentials. On the other hand, single-ended measurements reference the input to ground, causing ground loops and measurement errors.

Other wiring tips:

- If possible, route your analog signals separately from any digital I/O lines. Separate cables for analog and digital signals are preferred.
- Keep signal cables as far as possible from AC and other power lines.
- Take caution when shielding analog and digital signals together. With a single-ended (not differential) DAQ board, noise coupled from the digital signals to the analog signals via the shield will appear as noise. If using a differential input DAQ board, the coupled noise will be rejected as common-mode noise (assuming the shield is tied to ground at one end only).

Source Impedance Considerations

When time-varying electric fields, such as AC power lines, are in the vicinity of your signal leads, noise is introduced onto the signal leads via capacitive coupling. The capacitive coupling increases in direct proportion to the frequency and amplitude of the noise source and to the impedance of the measurement circuit. Therefore, the source impedance of your sensor or transducer has a direct effect on the susceptibility of your measurement circuit to noise pickup. The higher the source impedance of your sensor or signal source, the larger the amount of capacitive coupling. The best defense against capacitive noise coupling is the shield that is grounded at the source end. [Table 18.4](#) lists some common transducers and their impedance characteristic.

Pinpointing Your Noise Problems

If your system is resulting in noisy measurements, follow these steps to determine the source of the noise and how best to reduce it. The first step can also give you an idea of the noise performance of your DAQ board itself. The steps are

1. Short one of the analog input channels of the DAQ board to ground directly at the I/O connector of the board. Then, take a number of readings and plot the results. The amount of noise present is the amount of noise introduced by the PC and the DAQ board itself with a very low-impedance

TABLE 18.4 Impedance Characteristics of Transducers

Transducer	Impedance Characteristic
Thermocouples	Low ($<20 \Omega$)
RTDs	Low ($<1 \text{ k}\Omega$)
Strain gauges	Low ($<1 \text{ k}\Omega$)
Thermistors	Moderate to high ($>1 \text{ k}\Omega$)
Solid-state pressure transducer	High ($<1 \text{ k}\Omega$)
Potentiometer	High (500 to $100 \text{ k}\Omega$)
Glass pH electrode	Very high ($10^9 \Omega$)

input. Typical results are shown in Fig. 18.46. This plot shows a reading that jumps between 0.00 and 2.44 mV. Because this particular board uses a 12-b ADC and the amplifier was set to a gain of 1, this deviation corresponds to only 1 b, or LSB. In other words, the 12-b ADC toggled between binary values 0 and 1. If this test yields large amount of noise, your DAQ board is not operating properly, or another plug-in board in the PC may be radiating noise onto the DAQ board. Try removing other PC boards to see if the noise level decreases.

2. Attach your signal wires to the DAQ board. At your signal source or signal conditioning unit, ground or short the input leads. Acquire and plot a number of readings as in step 1. If the observed noise levels are roughly the same as those with the actual signal source instead of the short in place, the cabling and/or the environment in which the cabling is run is the culprit. You may need to try relocating your cabling farther from potential noise sources. If the noise source is not known, spectral analysis can help identify the source of the noise.
3. If the noise level in step 2 is less than with the actual signal source, replace the short with a resistor approximately equal to the output impedance of the signal source. This setup will show whether capacitive coupling in the cable due to high impedance is the problem. If the observed noise level is still less than with the actual signal source, then cabling and the environment can be dismissed as the problem. In this case, the culprit is either the signal source itself, or improper grounding configuration.

Noise Removal Strategies

After you have optimized your cabling and hardware setup, you may still need additional techniques to reduce noise that is unavoidable with proper cabling and grounding.

Signal Amplification

If you must pass very low-level signals through long signal leads, you will want to consider amplifying the signals near the source. An amplifying signal conditioner could boost the signal level before it is subject to the noise corruption of the environment. The same amount of noise will be radiated onto the signal, but will have a much smaller effect on the high-level signal.

**FIGURE 18.46** Measured noise with shorted inputs to DAQ board.

FIGURE 18.47 Simple low-pass RC filter.

Averaging

A very powerful technique for making low-noise measurements of static, or DC, signals is data averaging. For example, suppose you were monitoring the output of a thermocouple in an environment known to contain high amounts of 60-Hz power line noise. For each required temperature reading, therefore, you collect 100 readings over a time period of $i/60$ s, where i is some integer, and average the 100 data readings. Because the data were collected over an integer number of 60-Hz power cycles, the averaging of the data will average out any 60 Hz noise to zero. For 50-Hz power noise, collect the readings over a time period equal to $i/50$ s. This averaging has the same filtering effect as the integrating voltmeter.

Filtering

Of course, one method of removing noise from an electrical signal is with a hardware filter. There are a couple of options. First, you can use commercial signal conditioners that implement low-pass filters. Or, for simple filtering needs (moderate amounts of noise), you might consider building a simple RC filter on the input of your DAQ board. Figure 18.47 shows a single-pole RC filter that you could easily build and would attenuate signals with a frequency higher than the cutoff frequency F_c . F_c will be equal to

$$\frac{1}{2\pi RC}$$

For $R = 5 \text{ k}\Omega$ and $C = 4.7 \text{ }\mu\text{F}$, the cutoff frequency can be calculated as

$$F_c = \frac{1}{2\pi RC} = \frac{1}{2\pi(5000 \Omega)(4.7 \cdot 10^{-6})} = 6.8 \text{ Hz}$$

Figure 18.47 also shows the transfer function, which shows the attenuation of the signal (defined as $V_{\text{out}}/V_{\text{in}}$) as a function of frequency. If a signal of frequency F_c , for example, is applied to the input, the signal output of the RC filter will be equal to $0.707(V_{\text{in}})$. The equation that tells us the amount of attenuation as a function of input frequency F_{in} , for the RC filter is

$$\left| \frac{V_{\text{out}}}{V_{\text{in}}} \right| = \frac{1}{\sqrt{1 + (F_{\text{in}}/F_c)^2}}$$

For the single-pole RC filter with $F_c = 6.8 \text{ Hz}$ subject to 60-Hz noise input, the equation above is calculated to be 0.11. Therefore, 60-Hz noise introduced into the signal will be attenuated by 89%.

Grounding

Another very common source of problems in DAQ systems is grounding. In fact, noisy measurement problems are often due to improper grounding of the measurement circuit. You can avoid most grounding

problems with the following steps before you configure your DAQ system:

1. Determine your signal source type—grounded or floating.
2. Identify and use the proper input measurement mode—nonreferenced (differential or nonreferenced single ended) or ground referenced (single ended).
3. If using a differential measurement system with a floating signal source, provide a ground reference for the signal.

Grounded and Floating Signal Sources

Signal sources can be grouped into two types, *grounded* or *floating*. A grounded source is one in which the voltage signal is referenced to the building system ground. Because they are connected to the building ground, they share a common ground with the DAQ board. The most common examples of a grounded source are devices that plug into the building ground, such as signal generators and power supplies.

A floating source is a source in which the voltage signal is not referred to an absolute reference, such as Earth or building ground. Some common examples of floating signal sources are batteries, battery-powered signal sources, thermocouples, transformers, isolation amplifiers, and any instrument that explicitly floats its output signal. Notice that neither terminal of the source is referred to the electrical outlet ground. Thus, each terminal is independent of Earth.

Types of Measurement Inputs

In general, with regards to ground-referencing of the inputs, there are three types of measurement systems. Following is a description of each type.

Differential Inputs

A differential, or nonreferenced, measurement system has neither of its inputs tied to a fixed reference such as Earth or building ground. DAQ boards with instrumentation amplifiers can be configured as differential measurement systems.

An ideal differential measurement system responds only to the potential *difference* between its two terminals, the (+) and (–) inputs. Any voltage measured with respect to the instrumentation amplifier ground present at both amplifier inputs is referred to as a common-mode voltage. The term *common-mode* voltage range measures the ability of a DAQ board in differential mode to reject the common-mode voltage signal.

Ground-Referenced Inputs

A grounded or ground-referenced measurement system is similar to a grounded source, in that the measurement is made with respect to ground. This is also referred to as a *ground-referenced single-ended* (GRSE) measurement system.

Nonreferenced Single-Ended Inputs

A variant of the single-ended measurement technique, known as *nonreferenced single-ended* (NRSE) measurement system, is often found in DAQ boards. In an NRSE measurement system, all measurements are still made with respect to a single-node analog sense, but the potential at this node can vary with respect to the measurement system ground.

Now that we have identified the different types of signal sources and measurement systems, we can discuss the proper measurement system for each type of signal source.

Measuring Grounded Signal Sources, Avoiding Loops

A grounded signal source is best measured with a differential or NRSE measurement system. With this configuration, the measured voltage V_m is the sum of the signal voltage V_s and the potential difference ΔV_g that exists between the signal source ground and the measurement system ground. This potential difference is generally not a DC level; thus, the result is a noisy measurement system often showing power-line frequency (50 or 60 Hz) components in the readings. Ground-loop introduced noise may have both AC and DC components, thus introducing offset errors as well as noise in the measurements. The potential

difference between the two grounds causes a current to flow in the interconnection. This current is called *ground-loop* current.

The preferable input mode for a grounded signal is differential or NRSE mode. With either of these configurations, any potential difference between references of the source and the measuring device appears as common-mode voltage to the measurement system and is subtracted from the measured signal.

Measuring Floating Signals

You can use differential or single-ended inputs to measure a floating signal source. With a ground-referenced input, the DAQ board provides the one ground reference. When using differential inputs to measure signals that are not ground referenced, however, you must explicitly provide a ground reference to make accurate measurements. The differential input can be referenced by simple grounding of the (–) lead of the signal input. Alternatively, resistors can be connected from each signal lead to ground. This configuration maintains a balanced input and may be desirable for high-impedance signal sources. Many signal conditioning accessories include provisions for installing these resistors or direct connections to ground. [Figure 18.48](#) summarizes the analog input connections.

Basic Signal Conditioning Functions

In general, signal conditioners exist to interface raw signals from transducers to a general-purpose measurement device, such as a plug-in DAQ board, while simultaneously boosting the quality and reliability of the measurement. To accomplish this goal, signal conditioners perform a number of functions, including the following.

Signal Amplification

Many transducers output very small voltages that can be difficult to measure accurately. For example, a J-type thermocouple signal varies only about $50 \mu\text{V}/^\circ\text{C}$ over most of its range. Most signal conditioners, therefore, include amplifiers to boost the signal level to better match the input range of the analog-to-digital converter and improve resolution and sensitivity. Although many DAQ boards and I/O devices include onboard amplifiers for this reason, it may be necessary to locate an additional signal conditioner with amplification near the source of low-level signals, such as thermocouples, to increase their immunity to electrical noise from the environment. Otherwise, any small amount of noise picked up on lead wires can corrupt your data.

Filtering

Additionally, signal conditioners can include filters to reject unwanted noise within a certain frequency range. For example, most conditioners include low-pass filters to reduce high-frequency noise, such as the very common 60- or 50-Hz periodic noise from power systems or machinery. Some signal conditioners that are used for more dynamic measurements, such as vibration monitoring, include special antialiasing that feature programmable bandwidth (variable according to the sampling rate) and very sharp filter rolloff.

Isolation

One of the most common cause of measurement problems, noise, and damaged I/O equipment is improper grounding of the system. These nagging problems tend to disappear when isolated signal conditioners are introduced into the measurement system. Isolated conditioners pass the signal from its source to the measurement device without a galvanic or physical connection. Besides breaking ground loops, isolation blocks high-voltage surges and rejects high common-mode voltage, protecting expensive DAQ instrumentation.

For example, suppose you are to monitor the temperature of an extrusion process. Although you are using thermocouples with output signals of 0 and 50 mV, the thermocouples are soldered to the extruder. The extruder machines are powered by a dedicated power system and your thermocouple leads are actually sitting at 50 V. Connecting the thermocouple leads directly to nonisolated DAQ board would probably damage the board. However, you can connect the thermocouple leads to an isolated signal, which rejects the common-mode voltage (50 V), safely passing the differential 50-mV differential signal on the DAQ board for measurement.

	SIGNAL SOURCE TYPE	
	FLOATING SIGNAL SOURCE (NOT CONNECTED TO BUILDING GROUND)	GROUNDING SIGNAL SOURCE
INPUT CONFIGURATION	EXAMPLES • THERMOCOUPLES • SIGNAL CONDITIONING WITH ISOLATED OUTPUTS • BATTERY DEVICES	EXAMPLES • INSTRUMENTS WITH NONISOLATED INPUTS
DIFFERENTIAL (DIFF)	 <p>TWO RESISTORS ($10\text{ k}\Omega < R < 100\text{ k}\Omega$) PROVIDE RETURN PATHS TO GROUND FOR BIAS CURRENTS</p>	
SINGLE-ENDED—GROUND REFERENCED (GRSE)		<p style="text-align: center;">NOT RECOMMENDED</p>  <p style="text-align: center;">GROUND-LOOP LOSSES, V_g ARE ADDED TO MEASURED SIGNAL</p>
SINGLE-ENDED—NONREFERENCED (NRSE)		

FIGURE 18.48 Summary of connections of grounded and floating signal sources.

A common method for circuit isolation is using optical, capacitive, or transformer isolators. Capacitive and transformer isolators modulate the signal to convert it from a voltage to a frequency value. The frequency signal is then coupled across capacitors or a transformer, where it is then converted back to the proper voltage value. Optical isolators, commonly used for digital signals, use LEDs to convert the voltage on/off information into light signals to couple the signal across the isolation barrier.

Transducer Excitation and Interfacing

Many types of sensors and transducers have particular signal conditioning requirements. For example, thermocouples require cold-junction compensation for the thermoelectric voltages created where the thermocouple wires are connected to the data acquisition equipment. Resistive temperature devices (RTDs) require an accurate current excitation source to convert their small changes in electrical resistance into measurable changes in voltage. To avoid errors caused by the resistance in the lead wires, RTDs are often used in a 4-wire configuration. The 4-wire RTD measurement avoids lead resistance errors because two additional leads carry current to the RTD device, so that current does not flow in the sense, or

measurement. Strain gauge transducers, on the other hand, are used in a Wheatstone bridge configuration with a constant voltage or current power source. The signal conditioning requirements for these and other common transducers are listed in [Table 18.2](#).

Linearization

Most sensors exhibit an output that is nonlinear with respect to the measurand. Therefore, many signal conditioners include circuitry or onboard intelligence to linearize the transfer function of the sensor. This onboard linearization is designed to offload some of the processing requirements of the DAQ system. With the increased use of PCs, however, this need is diminished and you can easily perform this linearization function in software. Unlike hardware linearization, software linearization is a very flexible solution, making it possible for a single signal conditioning module to be easily adapted via software for a wide variety of sensors. In fact, you can even implement your own customized transducer linearization routines if necessary.

Variety of Signal Conditioning Architectures

Signal conditioning systems come in all different forms, ranging from single-channel I/O modules to multichannel chassis-based systems with sophisticated signal routing capabilities. In addition, several products commonly classified as signal conditioners include an onboard ADC with digital communications interface. Here, we will concentrate on nondigitizing conditioning systems used as a front-end for data acquisition and control systems, such as plug-in DAQ boards.

The typical single-channel I/O module is a fixed-function conditioner designed for a particular type of transducer and signal range. You cable the conditioned output signal, usually a voltage signal, directly to a DAQ board input channel. Some modules are DIN rail-mountable, whereas others install into a backplane that holds 8–16 modules. Newer versions of the single-channel modules feature programmability and added intelligence for scaling and diagnostics. Because the modules do not incorporate signal multiplexing, they are best suited for applications with fewer I/O channels.

Many DAQ board vendors supply specialized signal conditioning boards for use with their DAQ boards. These signal conditioning boards, usually designed for a particular transducer type, tend to provide a less flexible system. Meanwhile, other DAQ vendors incorporate signal conditioning directly on the PC plug-in DAQ board. Although this approach can provide a low-cost system for simpler applications, the benefits of locating your high-voltage isolation barrier inside the PC are questionable. In addition, you do not have the option of amplifying your low-level sensor signals before they enter the potentially noisy PC.

Signal Conditioners Offer I/O Expansion

A final class of signal conditioners incorporate signal multiplexing to significantly expand the I/O capabilities of the DAQ system. These systems consist of a chassis that houses a variety of signal conditioning modules. Instead of simply passing the conditioned signals to an outgoing connector, each module multiplexes the conditioned signals onto a single analog output channel. You can cable the multiplexed output directly to a DAQ board or pass it to the chassis backplane bus. This backplane bus routes the conditioned analog signals, as well as digital communications and timing control signals, among the modules. Such a system is expandable; adding channels is accomplished by plugging a new multiplexing module into the backplane bus. Because the bus also incorporates a digital communications path, you can also incorporate digital I/O and analog output modules into the same chassis.

The multiplexing architecture of these signal conditioning systems is especially well suited for applications involving larger numbers of channels. For example, some systems can multiplex 3072 channels into a single PC plug-in DAQ board. More importantly, these multiplexing signal conditioners offer significant advantages in cost and physical space requirements. By switching multiple inputs into a single processing block, including amplification, filtering, isolation, and ADC, you can achieve a very low cost per channel not attainable with single-channel modules. Even though single-channel modules are being developed that are smaller and slimmer, systems with a multiplexing architecture will always be able to pack many more I/O channels into a given physical space.

Defining Terms

Alias: A false lower frequency component that appears in sampled data acquired at too low a sampling rate.

Conversion time: The time required, in an analog input or output system, from the moment a channel is interrogated (such as with a read instruction) to the moment that accurate data are available.

Data acquisition (DAQ): (1) Collecting and measuring electrical signals from sensors, transducers, and test probes or fixtures and inputting them to a computer for processing. (2) Collecting and measuring the same kinds of electrical signals with A/D and/or DIO boards plugged into a PC, and possibly generating control signals with D/A and/or DIO boards in the same PC.

Differential nonlinearity (DNL): A measure in LSB of the worst-case deviation of code widths from their ideal value of 1 LSB.

Integral nonlinearity (INL): A measure in LSB of the worst-case deviation from the ideal A/D or D/A transfer characteristic of the analog I/O circuitry.

Nyquist sampling theorem: A law of sampling theory stating that if a continuous bandwidth-limited signal contains no frequency components higher than half the frequency at which it is sampled, then the original signal can be recovered without distortion.

Relative accuracy: A measure in LSB of the accuracy of an ADC. It includes all nonlinearity and quantization errors. It does not include offset and gain errors of the circuitry feeding the ADC.

18.3 Process Dynamics and Control

Thomas F. Edgar and Juergen Hahn

18.3.1 Introduction

The field of process dynamics and control is concerned with the analysis of dynamic behavior of processes, process simulation, design of automatic controllers, and associated instrumentation. Process control as practiced in the process industries has undergone significant changes since it was first introduced in the 1940s. Perhaps the most significant influence on the changes in process control technology has been the introduction of digital computers and instruments with greater capabilities than their analog predecessors. During the past 25 years automatic control has assumed increased importance in the process industries, which has led to the application of more sophisticated techniques (Seborg, Edgar, and Mellichamp, 2004; Ogunnaike and Ray, 1995).

For instrumenting and controlling a modern plant, it is necessary that an engineer has an understanding of the time-dependent behavior of typical processes. This in turn requires an appreciation of how

mathematical tools can be employed in analysis and design of automatic control systems. In this chapter we present the basic ideas involved in developing dynamic models for typical processes and then discuss the use of control valves and proportional-integral-derivative (PID) feedback controllers for process control. Next, various types of advanced control methods that have seen commercial use are reviewed. Finally, some comments on computer control are included. For a thorough discussion of process instrumentation and measurement devices, the reader is referred to other entries in the section, "Control and Instrumentation Technology," in this handbook.

18.3.2 Objectives of Process Control

The main economic objective of process control is to achieve maximum productivity or efficiency while maintaining a satisfactory level of product quality. Manufacturing facilities in the production of chemicals, paper, metals, power, food, and pharmaceuticals require accurate and precise control systems. Although the methods of production vary from industry to industry, the principles of automatic control are generic in nature and can be universally applied, regardless of the size of the plant.

Consider the control of the stirred tank reactor shown in Fig. 18.49. This system can be used to introduce basic concepts and definitions in process control, as given by the following:

1. *Controlled variables:* These are the variables that quantify the performance or quality of the final product, which are also called output variables. In Fig. 18.49, the controlled variables are the tank temperature T and the liquid level in the tank h . Controlling the temperature allows the chemical reaction to proceed at a specified rate. The tank level determines the residence time in the reactor. The desired operating point for each controlled variable is called the *set point*.
2. *Manipulated variables:* These input variables are adjusted dynamically to keep the controlled variables at their setpoints. There are two manipulated variables in Fig. 18.49, namely, the exit flow rate w_o and the steam pressure P_s to the heat transfer coil in the tank.
3. *Disturbance variables:* These are also called load variables and represent input variables that can cause the controlled variables to deviate from their respective set points. For the stirred tank heater, both the feed rate w_i and feed temperature T_i can change, causing the tank level and exit temperature to move away from the set points.

In the design of controllers for this process, two cases can be evaluated:

1. *Set point change:* This involves carrying out a change in the operating conditions, e.g., from a tank exit temperature of 125 to 150°C while holding the level constant. The set-point signal is changed, and the heat transfer rate is adjusted appropriately to achieve the new operating conditions. The changing of set points is also called *servomechanism* (or servo) control, and it can require a time span as short as a few seconds to as long as several hours to carry out, depending on the process design variables. In Fig. 18.49, such design variables could include the flow rate and the tank holdup.

FIGURE 18.49 Flowsheet of a continuous stirred tank reactor.

2. *Disturbance change*: This case relates to the process transient behavior when a disturbance enters, also called *regulatory control*. A control system should be able to return each controlled variable back to its set point.

Several other definitions need to be discussed here. *Steady-state* behavior pertains to the case where there is no variation in the process variables with respect to time. If the system is in equilibrium (at steady state), it can be described by algebraic equations, such as material and energy balances. *Unsteady-state* (dynamic) behavior occurs when the process variables change as a function of time. The required mathematical model for this case includes ordinary differential equations as well as algebraic relationships.

Three further classifications deal with how process control is implemented, namely:

- Open-loop or manual control
- Closed-loop or **feedback control**
- **Feedforward control**

Manual control implies that the operator makes the changes in manipulated variable, which is used occasionally. Feedback control connotes that the manipulated variable is changed automatically in response to the error between the set point and controlled variable. The second approach serves as the basis for most automatic control schemes. Feedforward control is a technique where the manipulated variable is changed as a function of a disturbance variable. Both feedback and feedforward control are discussed in later sections of this chapter.

18.3.3 Development of a Mathematical Model

There are a number of modeling approaches that can be used with process control systems. Whereas mathematical models based on the chemistry and physics of the system represent one alternative, the typical process control model utilizes an empirical input/output relationship, the so-called black-box model. These models are found by experimental tests of the process. Mathematical models of the control system may include not only the process but also the controller, the final control element, and other electronic components such as measurement devices and transducers. Once these component models have been determined, one can proceed to analyze the overall system dynamics, the effect of different controllers in the operating process configuration, and the stability of the system, as well as obtain other useful information.

Mathematical models provide a convenient and compact way of expressing the behavior of a process as a function of process physical parameters and process inputs. The same mathematical model can be expressed in several ways; for example, a continuous-time model based on a differential equation can be converted to a discrete-time system, or it can be transformed to a different type of independent variable altogether (e.g., Laplace transforms or z transforms). Transform models generally feature a simplified notation, which greatly facilitates analysis of complicated systems.

A simple dynamic system with one input and one output can be represented by equations of the form

$$dy/dt = f(y, u) \quad (18.1)$$

where y is the output, u is the input, and t is time. The time solution to this equation can be found by integrating Eq. (18.1) for a given input $u(t)$, based on a specified initial condition for the output $y(0)$. By letting $dy/dt = 0$, steady-state or equilibrium value(s) of y can be found for each selected value of u , the input, by solving the algebraic equation

$$f(y, u) = 0 \quad (18.2)$$

Theoretical models of chemical processes normally involve sets of nonlinear differential equations that arise from mass and energy balances, thermodynamics, reaction kinetics, transport phenomena, and physical property relationships. Because of the difficulty of developing such theoretical models, simpler models are usually sought for the purposes of control, either by linearization of the nonlinear models or by making simplifying assumptions. On the other hand, a less time-consuming approach involves developing black

box models, which are obtained by fitting experimental input-output data. This latter approach has been the historical basis of process control practice. During the past 10 years, however, there has been increasing use of fundamental models in design and control, largely due to the availability of modeling software packages.

Denoting K as the process gain, the simplest dynamic model used in process control is a first-order linear differential equation:

$$\tau \frac{dy}{dt} = -y + Ku \quad (18.3)$$

where τ is the time constant and K is the process gain.

At steady state, $y_{ss} = Ku$. Linear dynamic models such as Eq. (18.3) provide a theoretical means to determine the time scale of the process. For a step change in $u (= M)$, the solution to Eq. (18.3) can be found analytically,

$$y(t) = KM(1 - e^{-t/\tau}) \quad (18.4)$$

From Eq. (18.4) we can conclude that the response of y reaches 63.2% of its final value when $t = \tau(1 - e^{-1}) = 0.632\tau$. In this way, τ determines the speed of response for the system.

Experience in the process industries indicates that there are a limited number of expected dynamic behaviors that actually influence the controller design step. These behaviors can be categorized using the step response and are based on a transfer function representation of the process model, which is assumed to be linear or a linear approximation of a nonlinear model. A transfer function is found by taking the Laplace transform of the ordinary differential equation that describes the system; the mathematical definition of the Laplace transform is

$$L(f(t)) = \int_0^{\infty} f(t)e^{-st} dt \quad (18.5)$$

where $f(t)$ is a specified function of time.

The chief mathematical advantage of the Laplace transform is the conversion of the differential equation (such as Eq. (18.1)) to an algebraic equation. The resulting equation can be rearranged as a transfer function,

$$Y(s) = G(s)U(s) \quad (18.6)$$

where

$U(s)$ = transform of the input variable

$Y(s)$ = transform of the output variable

$G(s)$ = transfer function

$G(s)$ describes the dynamic characteristics of the process. For linear systems it is independent of the input variable, so it applies for any time-dependent input signal. For the model in Eq. (18.3), the transfer function is

$$G(s) = \frac{K}{\tau s + 1} = \frac{Y(s)}{U(s)} \quad (18.7)$$

where K is the process gain and τ the time constant already mentioned.

Transfer functions can also be used to describe the dynamic behavior of instruments, controllers, and valves. For a temperature transmitter the steady-state gain is simply the output span divided by the input span; an electronic transmitter which has a 4–20 mA output and a 100–200°F temperature input range gives a gain of $(20 - 4)/(200 - 100) = 0.16$ mA/°F. Sensors usually have simple dynamics, typically described by a first-order transfer function. The characteristics of control valves are more complicated and are discussed in the next section.

The order of the transfer function is the power of the polynomial in s in the denominator of $G(s)$ and is equivalent to the order of the differential equation describing the process. There are a limited number of dynamic transfer functions that are important for process control; Fig. 18.50 shows the dynamic response

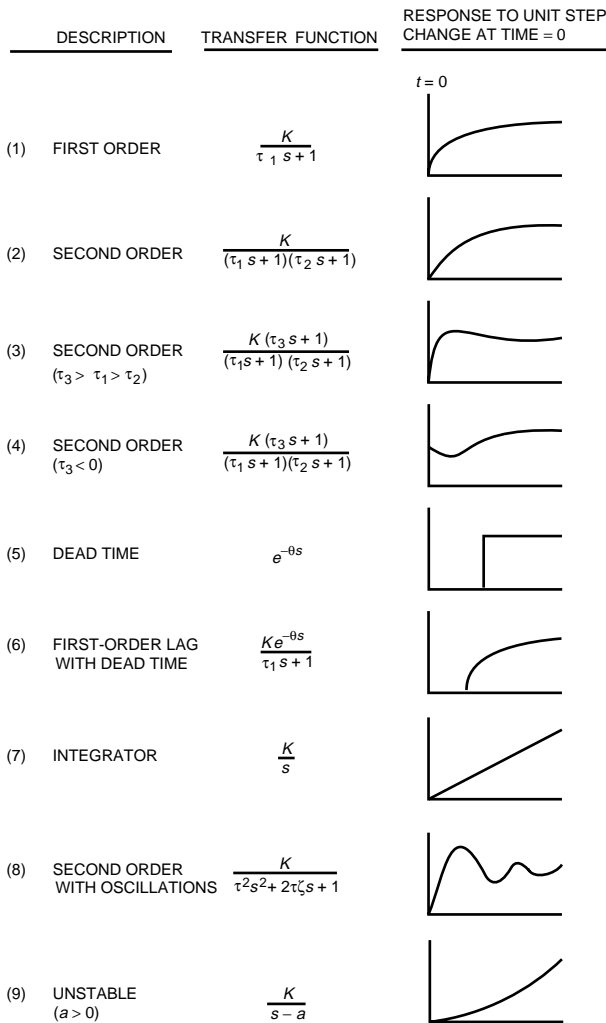

FIGURE 18.50 Common transfer functions and dynamic step response.

of nine different cases that result from a step change in the input variable. Simple approximate models are usually developed from experimental tests, and the model parameters are fitted either graphically or by nonlinear regression. In Fig. 18.50 only first- and second-order models are used. Some comments on each case are given next:

Case 1

This is the first-order system discussed previously, which is the analog of a resistance-capacitance circuit in electronics. It is mainly applicable to responses of instruments (sensors and valves) but usually is inadequate to describe dynamic behavior of actual chemical processes.

Case 2

The second-order system response provides a better approximation for many real processes dynamics, such as chemical reactors and distillation columns.

Case 3

Overshoot can occur in some open-loop systems as shown here, but this case is relatively rare. Some controllers exhibit this behavior.

Case 4

This behavior is called inverse response, where the output initially goes the opposite direction to the final value. This wrong-way behavior is seen in boilers and distillation columns.

Case 5

Pure delay or dead time usually occurs due to transportation lag, such as flow through a pipe. For a velocity v and distance L , $\theta = L/v$. Another case is a measurement delay, such as for a gas or liquid chromatograph.

Case 6

This is a more realistic response than case 1 because it allows for a time delay as well as first-order behavior, and can be applied to many chemical processes. The delay time may not be clearly identified as transport lag but may be imbedded in higher order dynamics. Hence, this is an approximate but very useful model, especially for staged systems such as distillation or extraction columns. An extension of this model is second order plus time-delay, the response of which is equivalent to case 2 or case 4 with an initial time delay. The advantage over first-order models is that an additional model parameter can give greater accuracy in fitting process data.

Case 7

The integrator describes the behavior of level systems, where the step input (such as a flow change) causes the level to increase with constant slope until the flow is reduced to its original value. There is no time constant here because the level does not reach steady state for a step input but continues to increase until the step input is terminated (or the vessel overflows).

Case 8

Oscillation in the step response is rare for chemical processes under open-loop or manual conditions. When feedback control is implemented, with processes described by cases 2–6, the occurrence of oscillation is quite common. In fact, a well-tuned feedback controller exhibits some degree of oscillation, as discussed later. The time constants for this case are not real values but are imaginary numbers.

Case 9

If any time constant is negative (τ in this case is not physically meaningful), the response is unstable. The output response becomes larger with time and is unbounded. No real system actually behaves this way since some constraint will eventually be reached; for example, a safety valve will open. A linear process is at the limit of instability if it oscillates without decay. Most processes are stable and do not require a controller for stability; however, such self-regulating processes may exhibit very slow responses unless feedback control is applied. On the other hand, when feedback control is used with some processes, instability can occur if the controller is incorrectly designed (see later discussion on controller tuning). There are a few processes, such as chemical reactors, which may be unstable in the open loop, but these can be stabilized by feedback control.

In summary, with all of the various dynamic behaviors shown in Fig. 18.50, it is important for plant engineers, instrument specialists, and even some operators to understand the general dynamic characteristics of a process. It is also crucial that they know how various processes respond under the influence of feedback control.

18.3.4 Final Control Elements

A final control element is a device that receives the manipulated variable from the controller as input and takes action that influences the process in the desired manner. In the process industries valves and pumps are the most common final control elements, because of the necessity to adjust a fluid flow rate such as coolant, steam, or the main process stream.

Control Valves

The control valve is designed to be remotely positioned by the controller output, which is usually an air pressure signal. The valve design contains an opening with variable cross sectional area through which the

FIGURE 18.51 Inherent control valve characteristics.

fluid can flow. A stem that travels up or down according to a change in the manipulated variable changes the area of the opening and thereby the flowrate. At the end of the stem is a plug of specific shape, which fits into a seat or ring on the perimeter of the valve port. This plug/seat combination is called the valve trim, and it determines the steady-state gain characteristics of the control valve. Based on safety considerations the control valve can be configured to be either air-to-open or air-to-close.

The inherent characteristics of control valves allow classification into three main groups, based on the relationship between valve flow and valve position under constant pressure: linear, equal-percentage, and quick opening (Seborg, Edgar, and Mellichamp, 2004; see Fig. 18.51). Usually in-plant testing is used to determine the actual valve characteristics because the dynamics of the valve can depend on other flow resistances in the process.

The response time of a pneumatic valve is related to the distance from the actuator to the valve, because the pneumatic signal has to travel the distance between the actuator and the valve. It is important for the design of the process that the response time of the valve is at least one order of magnitude faster than the process. Usually valve response times are several seconds, which is small compared to process time constants of minutes and hours. Pneumatic valve performance often suffers from nonideal behavior such as valve hysteresis. In order to achieve better reproducibility and a faster response a valve positioner can be installed to control the actual stem position rather than the diaphragm air pressure (Edgar, Smith, Shinskey, Gassman, Schafbuch, McAvoy, and Seborg, 1997).

Adjustable Speed Pumps

Instead of using fixed speed pumps and then throttling the process with a control valve, an adjustable speed pump can be used as the final control element. In these pumps speed can be varied by using variable-speed drivers such as turbines or electric motors. Adjustable speed pumps offer energy savings as well as performance advantages over throttling valves to offset their higher cost. One of these performance advantages is that, unlike a throttling valve, an adjustable pump does not contain dead time for small amplitude responses. Furthermore, nonlinearities associated with friction in the valve are not present in electronic adjustable speed pumps. However, adjustable speed pumps do not offer shutoff capability like control valves and extra flow check valves or automated on/off valves may be required.

18.3.5 Feedback Control Systems

Feedback control is a fundamental concept that is employed in PID controllers as well as in advanced process control techniques. Figure 18.52 shows a simplified instrumentation diagram for feedback control of the stirred tank discussed earlier, where the inlet flow is equal to the outlet flow (hence, no level control is needed) and outlet temperature is controlled by the steam pressure. Figure 18.53 shows a generic block diagram for a feedback control system. In feedback control the controlled variable is measured

FIGURE 18.52 Instrumentation diagram of a temperature control system for a stirred tank reactor; symbols: ≠ electrical instrument line, TT temperature transmitter, TRC temperature recorder-controller.

and compared to the set point. The resulting error signal is then used by the controller to calculate the appropriate corrective action for the manipulated variable. The manipulated variable influences the controlled variable through the process, which is dynamic in nature.

In many industrial control problems, notably those involving temperature, pressure, and flow control, measurements of the controlled variable are available, and the manipulated variable is adjusted via a control valve. In feedback control, corrective action is taken regardless of the source of the disturbance. Its chief drawback is that no corrective action is taken until after the controlled variable deviates from the set point. Feedback control may also result in undesirable oscillations in the controlled variable if the controller is not tuned properly, that is, if the adjustable controller parameters are not set at appropriate values. The tuning of the controller can be aided by using a mathematical model of the dynamic process, although an experienced control engineer can use trial-and-error tuning to achieve satisfactory performance in many cases. Next, we discuss the two types of controllers used in most commercial applications.

On-Off Controllers

An on-off controller is the simplest type of feedback controller and is widely used in the thermostats of home heating systems and in domestic refrigerators because of its low cost. This type of controller is seldom used in industrial plants, however, because it causes continuous cycling of the controlled variable and excessive wear on the control valve.

In on-off control, the controller output has only two possible values:

$$p(t) = \begin{cases} p_{\max} & \text{if } e > 0 \\ p_{\min} & \text{if } e < 0 \end{cases} \tag{18.8}$$

where p_{\max} and p_{\min} denote the on and off values, respectively, and e is the error or difference between the controlled variable and its set point.

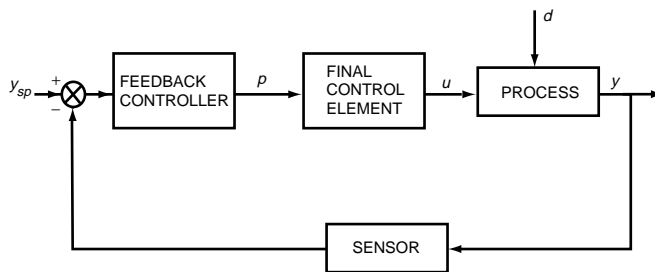

FIGURE 18.53 Block diagram for feedback control structure.

Three Mode (PID) Controllers

Most applications of feedback control employ a controller with three modes: *proportional* (P), *integral* (I), and *derivative* (D). The ideal *PID controller* equation is

$$p(t) = \bar{p} + K_c \left[e(t) + \frac{1}{\tau_I} \int_0^t e(t') dt' + \tau_D \frac{de}{dt} \right] \quad (18.9)$$

where p is the controller output, e is the error in the controlled variable, and \bar{p} is the bias, which is set at the desired controller output when the error signal is zero. The relative influence of each mode is determined by the parameters K_c , τ_I , and τ_D .

The PID controller input and output signals are continuous signals which are either pneumatic or electrical. The standard range for pneumatic signals is 3–15 psig, whereas several ranges are available for electronic controllers including 4–20 mA and 1–5 V. Thus, the controllers are designed to be compatible with conventional transmitters and control valves. If the PID controller is implemented as part of a digital control system, the discrete form of the PID equation is used,

$$p_n = \bar{p} + K_c \left[e_n + \frac{\Delta t}{\tau_I} \sum_{k=0}^n e_k + \frac{\tau_D}{\Delta t} (e_n - e_{n-1}) \right] \quad (18.10)$$

where Δt is the sampling period for the control calculations and n denotes the current sampling time. Digital signals are scaled from 0 to 10 V DC.

The principle of proportional action requires that the amount of change in the manipulated variable (e.g., opening or closing of the control valve) vary directly with the size of the error. The controller gain K_c affects the sensitivity of the corrective action and is usually selected after the controller has been installed. The actual input-output behavior of a proportional controller has upper and lower bounds; the controller output saturates when the limits of 3 or 15 psig are reached. The sign of K_c depends on whether the controller is direct acting or reverse acting, that is, whether the control valve is air-to-open or air-to-close.

Integral action in the controller brings the controlled variable back to the set point in the presence of a sustained upset or disturbance. Because the elimination of offset (steady-state error) is an important control objective, integral action is normally employed, even though it may cause more oscillation. A potential difficulty associated with integral action is a phenomenon known as *reset windup*. If a sustained error occurs, then the integral term in Eq. (18.9) becomes quite large and the controller output eventually saturates. Reset windup commonly occurs during the start up of a batch process or after a large set-point change. Reset windup also occurs as a consequence of a large sustained load disturbance that is beyond the range of the manipulated variable. In this situation the physical limitations on the manipulated variable (e.g., control valve fully open or completely shut) prevent the controller from reducing the error signal to zero. Fortunately, many commercial controllers provide antireset windup by disabling the integral mode when the controller output is at a saturation limit.

Derivative control action is also referred to as *rate action*, *preact*, or *anticipatory control*. Its function is to anticipate the future behavior of the error signal by computing its rate of change; thus, the shape of the error signal influences the controller output. Derivative action is never used alone, but in conjunction with proportional and integral control. Derivative control is used to improve the dynamic response of the controlled variable by decreasing the process response time. If the process measurement is noisy, however, derivative action will amplify the noise unless the measurement is filtered. Consequently, derivative action is seldom used in flow controllers because flow control loops respond quickly and flow measurements tend to be noisy. In the chemical industry, there are more PI control loops than PID.

To illustrate the influence of each controller mode, consider the control system regulatory responses shown in Fig. 18.54. These curves illustrate the typical response of a controlled process for different types of feedback control after the process experiences a sustained disturbance. Without control the process slowly reaches a new steady state, which differs from the original steady state. The effect of proportional control is to speed up the process response and reduce the error from the set point at steady state, or offset. The addition of integral control eliminates offset but tends to make the response more oscillatory.

Adding derivative action reduces the degree of oscillation and the response time, that is, the time it takes the process to reach steady state. Although there are exceptions to Fig. 18.54, the responses shown are typical of what occurs in practice.

Stability Considerations

An important consequence of feedback control is that it can cause oscillations in closed-loop systems. If the oscillations damp out quickly, then the control system performance is generally considered to be acceptable. In some situations, however, the oscillations may persist or their amplitudes may increase with time until a physical bound is reached, such as a control valve being fully open or completely shut. In the latter situation, the closed-loop system is said to be unstable. If the closed-loop response is unstable or too oscillatory, this undesirable behavior can usually be eliminated by proper adjustment of the PID controller constants, K_c , τ_I , and τ_D . Consider the closed-loop response to a unit step change in setpoint for various values of controller gain K_c . For small values of K_c , say K_{c1} and K_{c2} , typical closed-loop responses are shown in Fig. 18.55. If the controller gain is increased to a value of K_{c3} , the sustained oscillation of Fig. 18.56 results; a larger gain, K_{c4} produces the unstable response shown in Fig. 18.56. Note that the amplitude of the unstable oscillation does not continue to grow indefinitely because a physical limit will eventually be reached, as previously noted. In general as the controller gain increases, the closed-loop response typically becomes more oscillatory and, for large values of K_c , can become unstable.

The conditions under which a feedback control system becomes unstable can be determined theoretically using a number of different techniques (Seborg, Edgar, and Mellichamp, 2004).

FIGURE 18.54 Response for a step change in disturbance with tuned P, PI, and PID controllers and with no control.

FIGURE 18.55 Closed-loop response for different values of the controller gain.

FIGURE 18.56 Transition to instability as controller gain increases.

Manual/Automatic Control Modes

In certain situations the plant operator may wish to override the automatic mode and adjust the controller output manually. In this case there is no feedback loop. This manual mode of operation is very useful during plant start-up, shut-down, or in emergency situations. Testing of a process to obtain a mathematical model is also carried out in the manual mode. Commercial controllers have a manual automatic switch for switching from automatic mode to manual mode and vice versa. Bumpless transfers, which do not upset the process, can be achieved with commercial controllers.

Tuning of PID Controllers

Before tuning a controller, one needs to ask several questions about the process control system:

- Are there any potential safety problems with the nature of the closed-loop response?
- Are oscillations permissible?
- What types of disturbances or set-point changes are expected?

There are several approaches that can be used to tune PID controllers, including model-based correlations, response specification, and frequency response (Seborg, Edgar, and Mellichamp, 2004; Ogunnaike and Ray, 1995). One approach that has recently received much attention is model-based controller design. Model-based control requires that a dynamic model of the process is available. The dynamic model can be empirical, such as the popular first-order plus time delay type of model, or it can be of higher order. For most processes it is possible to find a range of controller parameters (K_c , τ_I , τ_D) that give closed-loop stability; in fact, most design methods provide a reasonable margin of safety for stability and the controller parameters are chosen in order to meet dynamic performance criteria in addition to guaranteeing stability.

One well-known technique for determining an empirical model of a process is the *process reaction curve* (PRC) method. In the PRC technique, the actual process is operated under manual control, and a step change in the controller output (Δp) is carried out. The size of the step is typically 5% of the span, depending on noise levels for the process variables. One should be careful to take data when other plant fluctuations are minimized. For many processes, the response of the system Δy (change in the measured value of the controlled variable using a sensor) follows the curve shown in Fig. 18.57 (see case 6 in Fig. 18.50). Also shown is the graphical fit by a first-order plus time delay model, which is described by three parameters:

1. the process gain K
2. the time delay θ
3. the dominant time constant τ

While nonlinear regression can be employed to find K , θ , and τ from step response data, graphical analysis of the step response can provide good estimates of θ and τ . In Fig. 18.57 the process gain is a steady-state characteristic of the process and is simply the ratio $\Delta y/\Delta p$. The time delay θ is the time elapsed before Δy deviates from zero. The time to reach 63% of the final response is equal to $\theta + \tau$.

A variety of different tuning rules exists which are based on the assumption that the model can be accurately approximated by a first-order plus time delay model. One popular approach, which is not

FIGURE 18.57 Process reaction curve for model-based tuning technique; tuning parameters found in Table 18.5 are defined by

$$K = \frac{\text{change in output (at steady state)}}{\text{change in controller output (at steady state)}}$$

$$= \frac{\Delta y}{\Delta p}$$

$$\tau = \Delta y/S$$

θ = amount of time until process responds (delay time).

TABLE 18.5 IMC Tuning Relations for First-Order Plus Time Delay Model

Controller Type	K_C	τ_I	τ_D
PI	$\frac{\tau}{K(\tau_C + \theta)}$	τ	—
PID	$\frac{\tau + \frac{\theta}{2}}{K(\tau_C + \frac{\theta}{2})}$	$\tau + \frac{\theta}{2}$	$\frac{\tau\theta}{2\tau + \theta}$

restricted to this type of model but nevertheless achieves good performance for it, is internal model control (IMC) (Rivera, Morari, and Skogestad, 1986; Bequette, 2003; Seborg, Edgar, Mellichamp, 2004). Controller tuning using IMC requires only choosing the value of the desired time constant of the closed-loop system, τ_c , in order to compute the values of the three controller tuning parameters, K_C , τ_I , τ_D . The value of τ_c can be further adjusted based on simulation or experimental behavior. The tuning relations for a PI and PID controller for a process which is described by a first-order plus time delay model are shown in Table 18.5 (Chien and Fruehauf, 1990). Tuning relations for other types of process models can be found in Seborg, Edgar, Mellichamp (2004).

Another popular tuning method uses integral error criteria such as the time-weighted integral absolute error (ITAE). The controller parameters are selected in order to minimize the integral of the error. ITAE weights errors at later times more heavily, giving a faster response. Seborg, Edgar, and Mellichamp (2004) have tabulated power law correlations for these PID controller settings for a range of first-order model parameters K , τ , and θ .

Other plant testing and controller design approaches such as frequency response can also be used for more complicated models; refer to Seborg, Edgar, and Mellichamp (2004) for more details.

On-Line Tuning

The model-based tuning of PID controllers presumes that the model is accurate; thus these settings are only a first estimate of the best parameters for an actual operating process. Minor on-line adjustments of K_C , τ_I , and τ_D are usually required. Another technique, called continuous cycling, actually operates the loop at the point of instability, but this approach has obvious safety and operational problems, so it is not used much today. A recent improvement on continuous cycling uses a relay feedback configuration, which puts the loop into a controlled oscillation. The amplitude and period of the oscillation can be used to set proportional and integral settings.

18.3.6 Advanced Control Techniques

Although the single-loop PID controller is satisfactory in many process applications, it does not perform well for processes with slow dynamics, time delays, frequent disturbances, or multivariable interactions. We discuss several advanced control methods next, which can be implemented via computer control.

One of the disadvantages of using conventional feedback control for processes with large time lags or delays is that disturbances are not recognized until after the controlled variable deviates from its setpoint. One way to improve the dynamic response to disturbances is by using a secondary measurement point and a secondary controller; the secondary measurement point is located so that it recognizes the upset condition before the primary controlled variable is affected.

One such approach is called **cascade control**, which is routinely used in most modern computer control systems. Consider a chemical reactor, where reactor temperature is to be controlled by coolant flow to the jacket of the reactor (Fig. 18.58). The reactor temperature can be influenced by changes in disturbance variables such as feed rate or feed temperature; a feedback controller could be employed to compensate for such disturbances by adjusting a valve on the coolant flow to the reactor jacket. However, suppose an increase occurs in the coolant temperature as a result of changes in the plant coolant system. This will cause a change in the reactor temperature measurement, although such a change will not occur quickly, and the corrective action taken by the controller will be delayed.

FIGURE 18.58 Conventional control of an exothermic chemical reactor.

Cascade control is one solution to this problem (see Fig. 18.59). Here the jacket temperature is measured and an error signal is sent from this point to the coolant control valve; this reduces coolant flow, maintaining the heat transfer rate to the reactor at a constant level and rejecting the disturbance. The cascade control configuration will also adjust the setting of the coolant control valve when an error occurs in reactor temperature. The cascade control scheme shown in Fig. 18.59 contains two controllers. The primary controller is the reactor temperature coolant temperature controller. It measures the reactor temperature, compares it to the setpoint, and computes an output that is the setpoint for the coolant flow rate controller. This secondary controller (usually a proportional only controller) compares the setpoint to the coolant

FIGURE 18.59 Cascade control of an exothermic chemical reactor.

temperature measurement and adjusts the valve. The principal advantage of cascade control is that the secondary measurement (jacket temperature) is located closer to a potential disturbance in order to improve the closed-loop response. See Shinskey (1996) for a discussion of other applications of cascade control.

Multivariable Control

Many processes contain several manipulated variables and controlled variables and are called multivariable systems. An example of a multivariable process was shown in Fig. 18.49, where there are two manipulated variables (flow rate and heat transfer rate) and two controlled variables (tank level and temperature). In many applications we can treat a multivariable process with a set of single-loop controllers by pairing inputs and outputs in the most favorable way. Then each loop can be tuned separately using the techniques mentioned previously. One design method employs the relative gain array (McAvoy, 1983). This formula provides guidelines on which variable pairings should be selected for feedback control as well as gives a measure of the potential quality of control for such a multiloop configuration.

If the loop interactions are not severe, then each single-loop controller can be designed using the techniques described earlier in this section. However, the presence of strong interactions requires that the controllers be detuned to reduce oscillations. A better approach is to utilize **multivariable control** techniques, such as model predictive control. Multivariable control is often used in distillation towers as well as in refinery operations such as cracking or reforming.

Model Predictive Control

The model-based control strategy that has been most widely applied in the process industries is **model predictive control (MPC)**. It is a general method that is especially well suited for difficult multi-input, multi-output (MIMO) control problems where there are significant interactions between the manipulated inputs and the controlled outputs. Unlike other model-based control strategies, MPC can easily accommodate inequality constraints on input and output variables such as upper and lower limits, or rate of change limits (Ogunnaike and Ray, 1995). These problems are addressed by MPC by solving an optimization problem (Seborg, Edgar, and Mellichamp, 2004). One formulation of an objective function to be minimized is shown below:

$$J = \sum_{k=0}^{P-1} (y_{sp} - y_k)^T \mathbf{Q} (y_{sp} - y_k) + \sum_{k=0}^{M-1} \Delta u_k^T \mathbf{R} \Delta u_k \quad (18.11)$$

where y_k refers to the output vector at time k , y_{sp} is the set point for this output, $\Delta u_k = u_k - u_{k-1}$ is the change of the input between time steps $k - 1$ and k , and \mathbf{Q} and \mathbf{R} are weighting matrices. This objective function will penalize deviations of the controlled variable from the desired set point over the prediction horizon of length P as well as changes in the manipulated variable over the control horizon of length M . The optimization determines a future input trajectory that minimizes the objective function subject to constraints on the manipulated as well as the controlled variables. The predictions y_k are made based upon a model of the plant. This plant model will be updated using deviations between the predicted output and the real plant output from past data. An illustration of the trajectories for the manipulated (discrete trajectory) as well as the controlled variables (continuous trajectory) are shown in Figure 18.60.

A variety of different types of models can be used for the prediction. Choosing an appropriate model type is dependent upon the application to be controlled. The model can be based upon first-principles or it can be an empirical model. Also, the supplied model can be either linear or nonlinear, as long as the model predictive control software supports this type of model. Most industrial applications of MPC have relied on linear empirical models, because they can more easily be identified and solved and approximate most processes fairly well. Also, many MPC implementations change set points in order to move the plant to a desired steady state; the actual control changes are implemented by PID controllers in response to the set points. There are over 1000 applications of MPC techniques in oil refineries and petrochemical plants around the world. Thus, MPC has had a substantial impact and is currently the method of choice for difficult constrained multivariable control problems in these industries (Qin and Badgwell, 2003).

FIGURE 18.60 Past inputs and trajectories are used for forecasting future control action.

A key reason why MPC has become a major commercial and technical success is that there are numerous vendors who are licensed to market MPC products and install them on a turnkey basis. Consequently, even medium-sized companies are able to take advantage of this new technology. Payout times of 3–12 months have been reported. Refer to Maciejowski (2002) for further details on model predictive control.

Feedforward Control

If the process exhibits slow dynamic response and disturbances are frequent, then the addition of feedforward control with feedback control may be advantageous. Feedforward control differs from feedback control in that the primary disturbance is measured via a sensor and the manipulated variable is adjusted so that the controlled variable does not change (see Fig. 18.61). To determine the appropriate settings for the manipulated variable, one must develop mathematical models which relate:

- The effect of the manipulated variable on the controlled variable.
- The effect of the disturbance on the controlled variable.

FIGURE 18.61 Block diagram for feedforward control configuration. The controller calculates the manipulated variable u needed to counteract the system upset introduced through the disturbance d . By taking control action based on measured disturbances, rather than controlled variable error, the controller can reject disturbances before they affect the controlled variable y .

These models can be based on steady-state or dynamic analysis. The performance of the feedforward controller depends on the accuracy of both models. If the models are exact, then feedforward control offers the potential of perfect control, that is, holding the controlled variable precisely at the setpoint at all times because of the ability to predict the appropriate control action. However, because most mathematical models are only approximate and not all disturbances are measurable, it is standard practice to utilize

TABLE 18.6 Relative Advantages and Disadvantages of Feedback and Feedforward

Advantages	Disadvantages
<i>Feedforward</i>	
1. Acts before the effect of a disturbance has been felt by the system.	1. Requires identification of all possible disturbances and their direct measurement.
2. Good for systems with large time constant or deadtime.	2. Cannot cope with unmeasured disturbances.
3. It does not introduce instability in the closed-loop response.	3. Sensitive to process/model error.
<i>Feedback</i>	
1. It does not require identification and measurement of any disturbance.	1. Control action is not taken until the effect of the disturbance has been felt by the system.
2. It is relatively insensitive to process/model errors.	2. It is unsatisfactory for processes with large time constants.
	3. It may cause instability in the closed-loop response.

feedforward control in conjunction with feedback control. Table 18.6 lists the relative advantages and disadvantages of feedforward and feedback control. By combining the two control methods, the strengths of both schemes can be utilized.

The tuning of the controller in the feedback loop can be theoretically performed independent of the feedforward loop, that is, the feedforward loop does not introduce instability in the closed-loop response. For more information on feedforward/feedback control applications and design of such controllers, refer to Shinsky (1996).

Adaptive Control and Autotuning

Process control problems inevitably require on-line tuning of the controller constants to achieve a satisfactory degree of control. If the process operating conditions or the environment changes significantly, the controller may have to be retuned. If these changes occur quite frequently, then **adaptive control** techniques should be considered. An adaptive control system is one in which the controller parameters are adjusted automatically to compensate for changing process conditions (Astrom and Wittenmark, 1994). Several adaptive controllers have been field-tested and commercialized in the U.S. and abroad.

Most commercial control systems have an autotuning function that is based on placing the process in a controlled oscillation at very low amplitude, comparable with that of the noise level of the process. This is done via a relay-type step function with hysteresis. The autotuner identifies the dynamic parameters of the process (the ultimate gain and period) and automatically calculates K_c , τ_I , and τ_D using empirical tuning rules. Gain scheduling can also be implemented with this controller, using several sets of PI or PID controller parameters.

Statistical Process Control

Statistical process control (SPC), also called statistical quality control (SQC), has found widespread application in recent years due to the growing focus on increased productivity. Another reason for its increasing use is that feedback control cannot be applied to many processes due to a lack of on-line measurements as is the case in many microelectronics fabrication processes. However, it is important to know if these processes are operating satisfactorily. While SPC is unable to take corrective action while the process is moving away from the desired target, it can serve as an indicator that product quality might not be satisfactory and that corrective action should be taken for future plant operations.

For a process that is operating satisfactorily the variation of product quality will fall within acceptable bounds. These bounds usually correspond to the minimum and maximum values of a specified product property. Normal operating data can be used to compute the mean \bar{y} and the standard deviation σ of a

given process variable from a series of n observations y_1, y_2, \dots, y_n as follows:

$$\bar{y} = \frac{1}{n} \sum_{i=1}^n y_i \quad (18.12)$$

$$\sigma = \left[\frac{1}{n-1} \sum_{i=1}^n (y_i - \bar{y})^2 \right]^{1/2} \quad (18.13)$$

The standard deviation is a measure for how the values of y spread around their mean. A large value of σ indicates that wide variations in y occur. Assuming the process variable follows a normal probability distribution, then 99.7% of all observations should lie within an upper limit of $\bar{y} + 3\sigma$ and a lower limit of $\bar{y} - 3\sigma$. These limits can be used to determine the quality of the control. If all data from a process lie within the $\pm 3\sigma$ limits, then it can be concluded that nothing unusual has happened during the recorded time period, the process environment is relatively unchanged, and the product quality lies within specifications. On the other hand, if repeated violations of the limits occur, then the conclusion can be drawn that the process is out of control and that the process environment has changed. Once this has been determined, the process operator can take action in order to adjust operating conditions to counteract undesired changes that have occurred in the process conditions.

There are several specific rules that determine if a process is out of control. Some of the more widely used ones are the Western-Electric rules that state that a process is out of control if process data include

- One measurement outside the $\pm 3\sigma$ control limit
- Any seven consecutive measurements lying on the same side of the mean
- A decreasing or increasing trend for any seven consecutive measurements
- Any nonrandom pattern in the process measurements

These rules can be applied to data in a control chart, such as a shown in Figure 18.62, where pressure measurements are plotted over a time horizon. It is then possible to read off from the control chart if the process is out of control or if it is operating within normal parameters.

FIGURE 18.62 Control chart for SPC. Dashed lines indicate the $\pm 3\sigma$ levels for the process variables.

Because a process that is out of control can have important economic consequences, such as product waste and customer dissatisfaction, it is important to keep track of the state of the process. Statistical process control provides a convenient method to continuously monitor process performance and product quality. However, it differs from automatic process control (such as feedback control) in that it serves as an indicator that the process is not operating within normal parameters. SPC does not automatically provide a controller setting that will bring the process back to its desired operating point or target.

More details on SPC can be found in References (Seborg, Edgar, and Mellichamp, 2004; Ogunnaike and Ray, 1995; Montgomery, 2001; Grant and Leavenworth, 1996).

18.3.7 Computer Control Systems

Distributed Control Systems (DCS)

Microcomputer-based subsystems are standard in most computer control systems available today. The digital subsystems are interconnected through a digital communications network. Such systems are referred to as distributed digital instrumentation and control systems because of the network approach used to monitor and control the process.

Figure 18.63 depicts a representative **distributed control system** (Seborg, Edgar, and Mellichamp, 2004). The DCS system consists of many commonly used DCS components, including multiplexers (MUXs), single-loop and multiple-loop controllers, PLCs, and smart devices. A system includes some or all of the following components:

1. Control network. The control network is the communication link between the individual components of a network. Coaxial cable and, more recently, fiber-optic cable have often been used. A redundant pair of cables (dual redundant highway) is normally supplied to reduce the possibility of link failure.
2. Workstations. Workstations are the most powerful computers in the system, and act both as an arbitrator unit to route internodal communications and the database server. Various peripheral devices are coordinated through the workstations. Computationally intensive tasks, such as real-time optimization or model predictive control, are implemented in a workstation.
3. Real-time clocks. Process control systems must respond to events in a timely manner and should have the capability of real-time control.
4. Operator stations. Operator stations typically consist of color graphics monitors with special keyboards to perform dedicated functions. Operators supervise and control processes from these workstations. Operator stations may be connected directly to printers for alarm logging, printing reports, or process graphics.
5. Engineering Workstations. They are similar to operator stations but can also be used as programming terminals to develop system software and applications programs.
6. Remote control units (RCUs). These components are used to implement basic control functions such as PID control. Some RCUs may be configured to acquire or supply set points to single-loop controllers. Radio telemetry (wireless) may be installed to communicate with MUX units located at great distances.
7. Programmable logic controllers (PLCs). These digital devices are used to control batch and sequential processes, but can also implement PID control.
8. Application stations. These separate computers run application software such as databases, spreadsheets, financial software, and simulation software via an OPC interface. OPC is an acronym for object linking and embedding for process control, a software architecture based on standard interfaces. These stations can be used for e-mail and as webservers, for remote diagnosis, configuration, and even for operation of devices that have an IP (Internet protocol) address. Applications stations can communicate with the main database contained in on-line mass storage systems.
9. Mass storage devices. *Typically*, hard disk drives are used to store active data, including on-line and historical databases and nonmemory resident programs. Memory resident programs are also stored to allow loading at system start-up.

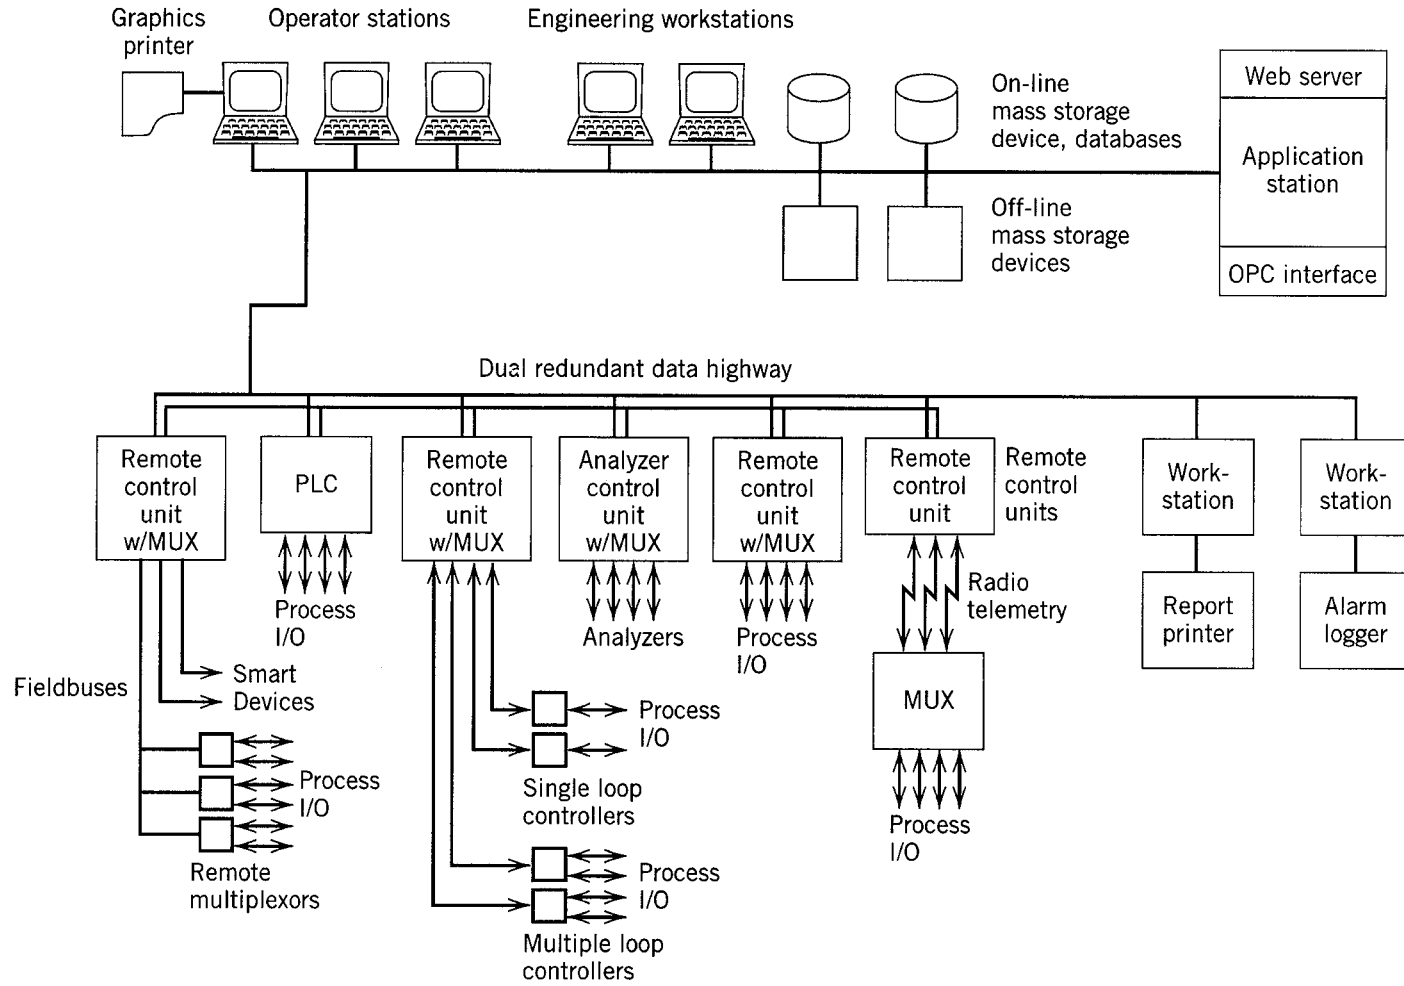

FIGURE 18.63 A typical distributed control system (DCS).

10. Fieldbuses/smart devices. An increasing number of field-mounted devices are available that support digital communication of the process I/O in addition to, or in place of, the traditional 4–20 mA current signal. These devices have greater functionality, resulting in reduced setup time, improved control, combined functionality of separate devices, and control-valve diagnostic capabilities.

Supervisory Control/Real-Time Optimization

The selection of set points in a distributed control network is called **supervisory control**. These set points may be determined in a control computer and then transmitted to specific devices (digital or analog controllers) in each control loop. Most supervisory control strategies are based on real-time optimization (RTO) calculations, wherein the set points (operating conditions) are determined by profitability analysis, that is, maximizing the difference between product value (income) and operating costs. For more details on real-time optimization methods such as linear and nonlinear programming or other search techniques see Seborg, Edgar, and Mellichamp (2004). RTO is often used in conjunction with model predictive control.

Batch Control

The increased availability of digital computer control and the emerging specialty chemical business has made **batch control** a very important component in process plants. Batch operations are of a start-stop nature; however, startup and shutdown of continuous plants must be treated in a similar fashion. Feedback control is of some value for batch processing, but it is more useful for operation near a set point in continuous operations.

The majority of batch steps encompass a wide variety of time-based operating conditions, which are sequential in nature. They can only be managed via a computer control system. Consider the operation of a batch reactor. The operation may include charging the reactor with several reactants (the recipe), applying the heat required to reach the desired reaction temperature, maintaining a specified level of operation until the reaction reaches completion, stopping the reaction, removing the product, and preparing the reactor for another batch.

Discrete functions are implemented via hardware or software to control discrete devices such as on/off valves, pumps, or agitators, based on status (on/off) of equipment or values of process variables. Interlock control can be provided via automatic actuation of a particular device only if certain process conditions sensed by various instruments are met. The two categories of interlocks are safety and permissive interlocks. Safety interlocks are designed to ensure the safety of operating personnel and to protect plant equipment. These types of fail-safe interlocks are associated with equipment malfunction or shutdown. Permissive interlocks establish orderly startup and shutdown of equipment. This prevents accumulation of material in tanks before it is needed. The triggers in the instructions can be time related or process related (temperature, pressure, etc.). Sequencing requires an end condition to be reached before the system can proceed to the next step. More details on batch control system design have been reported by Rosenhof and Ghosh (1987) and Seborg, Edgar, and Mellichamp (2004).

Process Control Software

The introduction of high-level programming languages such as Fortran and Basic in the 1960s was considered a major breakthrough in the area of computer control. For process control applications, some companies have incorporated libraries of software routines for these languages, but others have developed speciality pseudo-languages. These implementations are characterized by their statement-oriented language structure. Although substantial savings in time and efforts can be realized, software development costs can be significant.

The most successful and user-friendly approach, which is now adopted by virtually all commercial systems, is the fill-in-the-forms or table-driven *process control languages* (PCL). The core of these languages is a number of basic functional blocks or software modules. All modules are defined as database points. Using a module is analogous to calling a subroutine in conventional programs.

In general, each module contains some inputs and an output. The programming involves softwiring outputs of blocks to inputs of other blocks. Some modules may require additional parameters to direct module execution. The users are required to fill in the sources of input values, the destinations of output

values, and the parameters in the blanks of forms/tables prepared for the modules. The source and destination blanks may be filled with process I/Os when appropriate. To connect modules, some systems require filling the tag names of modules originating or receiving data. The blanks in a pair of interconnecting modules are filled with the tag name of the same data point. A completed control strategy resembles a data flow diagram. All process control languages contain PID controller blocks. The digital PID controller is normally programmed to execute in velocity (difference) form. A pulse duration output may be used to receive the velocity output directly. In addition to the tuning constants, a typical digital PID controller contains some entries not normally found in analog controllers:

- When a process error is below certain tolerable deadband, the controller ceases modifying the output. This is referred to as *gap action*.
- The magnitude of change in a velocity output is limited by a change clamp.
- A pair of output clamps is used to restrict a positional output value from exceeding specified limits.
- The controller action can be disabled by triggering a binary deactivate input signal, during process startup, shutdown, or when some abnormal conditions exist.

Although modules are supplied and their internal configurations are different from system to system, their basic functionalities are the same

Another recent development has been the availability of flexible, yet powerful, software packages that support the controller design, controller testing, and implementation process. Probably, the most widely used program for this purpose is MATLAB[®] (The MathWorks, Inc.; www.mathworks.com), due to its flexibility. It allows one to implement and test controllers by either solving differential equations, using Laplace transforms, or with block diagrams. MATLAB[®] also provides a variety of routines that are commonly used for different controller design problems, e.g., optimal control, nonlinear control, optimization, etc. One of the main advantages of MATLAB[®] is that it is a programming language which provides control-related subroutines. This gives the process engineer flexibility with regard to the use of the software as well as how to extend or reuse already existing routines. It is also possible to exchange data with other software packages from within MATLAB[®].

Digital Field Communications

A group of computers can become networked once intercomputer communication is established. Prior to the 1980s, all system suppliers used proprietary protocols to network their systems. The recent introduction of standardized protocols is based on the ISO-OSI* seven-layer model. The manufacturing automation protocol (MAP), which adopted the ISO-OSI standards as its basis, specifies a broadband backbone local area network (LAN). Originally intended for discrete component systems, MAP has evolved to address the integration of DCSs used in process control as well. TCP/IP (transmission control protocol/internet protocol) has been adopted for communication between nodes that have different operating systems.

Microprocessor-based process equipment, such as smart instruments and single-loop controllers, are now available with digital communications capability and are used extensively in process plants. A **fieldbus**, which is a low-cost protocol, provides efficient communication between the DCS and these devices.

Presently, there are several regional and industry-based fieldbus standards, including the French standard (FIP), the German standard (Profibus), and proprietary standards by DCS vendors, generally in the U.S., led by the Fieldbus Foundation. As of 2004, international standards organizations had adopted all of these fieldbus standards rather than a single unifying standard.

Several manufacturers provide fieldbus controllers that reside in the final control element or measurement transmitter. A suitable communications modem is present in the device to interface with a proprietary PC-based, or hybrid analog/digital bus network. Case studies in implementing such digital systems have shown significant reductions in cost of installation (mostly cabling and connections) vs. traditional analog field communication.

An example of a hybrid analog/digital protocol that is open (not proprietary) and in use by several vendors is the highway addressable remote transducer (HART) protocol. Digital communications utilize the same two wires that provide the 4 to 20 mA process control signal without disrupting the actual process

signal. This is done by superimposing a frequency-dependent sinusoid ranging from -0.5 to $+0.5$ mA to represent a digital signal.

Defining Terms

Adaptive control: A control strategy that adjusts its control algorithm as the process changes.

Batch control: Control of a process where there is no inflow/outflow.

Cascade control: Nested multiloop strategy that uses intermediate measured variables to improve control.

Controlled variables: Measurable variables that quantify process performance.

Distributed control system: The standard computer architecture in process control, which involves multiple levels of computers.

Feedback control: A control structure where the controlled variable measurement is compared with the setpoint, generating an error acted upon by the controller.

Feedforward control: A control structure where the disturbance is measured directly and a control action is calculated to counteract it.

Fieldbus: A new communication protocol for digital communication between instruments and a central computer.

Manipulated variables: Input variables that can be adjusted to influence the controlled variables.

Model predictive control: An advanced control strategy that uses a model to optimize the loop performance.

Multivariable control: A control strategy for multiple inputs and multiple outputs.

Statistical process control: A control strategy that keeps a process between upper and lower limits (but not at the setpoint).

Supervisory control: The selection of set points, usually to maximize profitability or minimize costs.

Three-mode (PID) control: A feedback control algorithm that uses proportional, integral, and derivative action on the error signal.

18.4 Servo Systems

John E. McInroy

18.4.1 Introduction

During the past 60 years, many methods have been developed for accurately controlling dynamic systems. The vast majority of these systems employ sensors to measure what the system is actually doing. Then, based on these measurements, the input to the system is modified. These concepts were initially used in applications where only a single output was measured, and that measurement was used to modify a single input. For instance, position sensors measured the actual position of a motor, and the current or voltage put into the motor windings was modified based on these position readings. An early definition of these systems is the following:

A *servosystem* is defined as a combination of elements for the control of a source of power in which the output of the system, or some function of the output, is fed back for comparison with the input and the difference between these quantities is used in controlling the power (James, Nichols, and Phillips, 1947).

This definition is extremely broad and encompasses most of the concepts that are usually referred to today as the technical area of *control systems*. However, the technology and theory of control systems has changed significantly since that 1947 definition. There are now methods for controlling systems with multiple inputs and multiple outputs, many different design and optimization techniques, and intelligent control methodologies sometimes using neural networks and fuzzy logic. As these new theories have evolved, the definition of a servo system has gradually changed. Today, the term servo system often refers to motion control systems, usually employing electric motors. This change may have occurred simply because one of the most important applications of the early servo system theories was in rapid and accurate positioning. For the sake of brevity, this discussion will confine its treatment to motion control systems utilizing electric motors.

18.4.2 Principles of Operation

To obtain rapid and accurate motion control, servo systems employ the same basic principle just outlined, the principle of feedback. By measuring the output (usually the position or velocity of the motor) and feeding it back to the input, the performance can be improved. This output measurement is often subtracted

FIGURE 18.64 A typical closed loop motion control or servo system.

from a desired output signal to form an error signal. This error signal is then used to drive the motor. Figure 18.64 illustrates the components present in a typical system.

As the figure illustrates, each servo system consists of several separate components. First, a compensator takes the desired response (usually in terms of a position or velocity of the motor) and compares it to that measured by the sensing system. Based on this measurement, a new input for the motor is calculated. The compensator may be implemented with either analog or digital computing hardware. Since the compensator consists of computing electronics, it rarely has sufficient power to drive the motor directly. Consequently, the compensator’s output is used to command a power stage. The power stage amplifies that signal and drives the motor. There are a number of motors that can be used in servo systems. This chapter will briefly discuss DC motors, brushless DC motors, and hybrid stepping motors. To achieve a mechanical advantage, the motor shaft is usually connected to some gears that move the actual load. The performance of the motor is measured by either a single sensor or multiple sensors. Two common sensors, a tachometer (for velocity) and an encoder (for position), are shown. Finally, those measurements are fed back to the compensator.

Servo systems are called **closed-loop** devices because the feedback elements form a loop, as can be seen in Fig. 18.64. In contrast, **open-loop** motion control devices, which do not require sensors, have become popular for some applications. Figure 18.65 depicts an open-loop motion control system. Obviously, it is much easier and less expensive to implement an open-loop control system because far fewer components are involved. The compensator and sensors have been eliminated completely.

FIGURE 18.65 A typical open loop motion control system.

In addition, the power stage is often simplified because the signals it receives may not be as complex. For instance, switching transistors may replace linear amplifiers. On the other hand, it is difficult to construct an open-loop system with capabilities equal to a servo system’s capabilities. Table 18.7 compares open-loop and closed-loop systems.

TABLE 18.7 A Comparison of Open-loop and Closed-loop Control Systems

Open Loop	Closed Loop
Inherently stable	Potentially unstable
Requires no sensing	Requires sensing
Requires no compensator	Requires compensator
Power electronics simplified	Power electronics more complex
Sensitive to modeling errors	Much less sensitive to modeling
Poor disturbance rejection	Rejects unexpected disturbances
May have steady-state error	Steady-state error eliminated

TABLE 18.8 Some Trade-Offs Between Digital and Analog Compensators

Digital Compensation	Analog Compensation
Easily changed	Harder to change
Response limited by sampling time	Faster response
Does not drift	Drifting can change compensation
Can implement complex control laws	Limited to simple control laws
Naturally fits into digital systems	Naturally fits into analog systems

The following sections will briefly describe the components that together are used to create a servo system. The emphasis will be on motor control applications.

Compensator Design

The compensator in Fig. 18.64 is in some ways the brains of a servo system. It takes a desired position or velocity trajectory that the motor system needs to move through, and, by comparing it to the actual movement measured by the sensors, calculates the appropriate input. This calculation can be performed using either digital or analog computing technology. Unlike other areas of computing, in which digital computers long ago replaced analog devices, analog means still are useful today for servo systems. This is mainly because the calculations required are usually simple (a few additions, multiplications, and perhaps integrations) and they must be performed with the utmost speed. On the other hand, digital compensators are increasingly popular because they are easy to change and are capable of more sophisticated control strategies. Table 18.8 compares digital and analog control.

As Table 18.8 indicates, the choice of digital vs. analog compensation depends in part on the control law chosen, since more complex algorithms can be easily implemented on digital computers. If a digital compensator is chosen, then digital control design techniques should be used. These techniques are able to account for the sampling effects inherent in digital compensators. As a rule of thumb, analog design techniques may be used even for digital compensators as long as the sampling frequency used by that digital compensator is at least five times higher than the **bandwidth** of the servo system.

Once the hardware used to implement the compensator has been selected, a control algorithm, which combines the desired position and/or velocity trajectories with the measurements, must be found. Many design techniques have been developed for determining a control law. In general, these techniques require that the dynamics of the system be identified. This dynamic model may come from a physical understanding of the device. For instance, suppose our servo system is used to move a heavy camera. Since the camera is fairly rigid, it might be modeled accurately as a lumped mass. Similarly, the motor's rotor as well as the gearing will yield a mostly inertial load. The motor itself may be modeled as a device that inputs current and outputs torque. By putting these three observations together and writing elementary dynamics equations (e.g., Newton's laws) a set of differential equations that model the actual system can be found. Alternatively, a similar set of differential equations may be found by gathering input and output data (e.g., the motor's current input and the position and velocity output) and employing identification algorithms directly.

Once an adequate dynamic model has been found, it is possible to design a control law that will improve the servo system's behavior in some manner. There are many ways of measuring the performance. Some of the most commonly used and oldest performance measures describe the system's ability to respond to an instantaneous change, or a step. For instance, suppose you are covering a sports event and want to suddenly move the camera to catch the latest action. The camera should reach the desired angle as quickly as possible. The time it does take is termed **rise time**, t_r . In addition, it should stop as quickly as possible so that jitter in the picture will be minimized. The time required to stop is termed **settling time**, t_s . Finally, any excess oscillations will also increase jitter. The magnitude of the worst oscillation is called the **overshoot**. The overshoot divided by the total desired movement and multiplied by 100 gives the *percent overshoot*. These characteristics are depicted in Fig. 18.66.

A vast number of techniques have been developed for achieving these desirable characteristics. As an example, one particular method known as proportional integral derivative (PID) control will be considered.

FIGURE 18.66 Performance measures for a step response.

This method is selected because it is intuitive and fairly easy to tune. First, an error signal is formed by subtracting the actual position from the desired position. The error is then

$$e = \theta_d - \theta \quad (18.14)$$

Next, this error signal is operated on mathematically to determine the input to the motor.

The simplest form of this controller uses the following logic:

If the motor starts falling behind so $\theta_d > \theta$ and $e > 0$, then increase the input to catch up. If the motor is getting ahead, decrease the input to slow down.

The logic can be mathematically written in the formula

$$u = K_p e \quad (18.15)$$

where K_p is a constant number called the *proportional gain* because the input is made proportional to the error.

To make the motor respond faster, it is helpful to know how quickly the motor is falling behind (or getting ahead). This information is contained in the derivative of the error

$$\dot{e} = \dot{\theta}_d - \dot{\theta} \quad (18.16)$$

A derivative term can then be added to the control law to make the input equal

$$u = K_p e + K_D \dot{e} \quad (18.17)$$

Again, K_D is a constant number called the *derivative gain*.

Finally, it is often necessary that the servo system exhibit zero steady-state error. This quality can be achieved by adding a term due to the integral of the error. The reason this works can be understood by considering what would happen should a steady-state error occur. The integrator would keep increasing the input *ad infinitum*. Instead, an equilibrium point is reached with zero error. The complete PID control law is then

$$u = K_p e + K_I \int e dt + K_D \dot{e} \quad (18.18)$$

with K_I a constant called the *integral gain*.

The choice of the controller gains (K_p , K_I , and K_D) greatly influences the behavior of the servo system. If a good dynamic model has been found and it consists of linear time invariant differential (or difference) equations, then several methods may be employed for finding gains that best meet the performance requirements (the textbooks listed in the Further Information section provide an excellent and detailed treatment).

If not, the gains may be experimentally tuned using, for instance, the Ziegler–Nichols method (Franklin, Powell, and Workman, 1990). Care must be exercised when adjusting the gains because the system may become unstable. Figure 18.67 shows the response to a step change at $t = 5$ in the desired position for a properly tuned servo system. The position response quickly tracks the change. Figure 18.68 plots an unstable response resulting from incorrectly tuned gains. The position error increases rapidly. Obviously, this undesirable behavior can be very destructive.

Power Stage

A variety of devices are used to implement the power stage, depending on the actuator used to move the servo system. These range from small DC motors to larger AC motors and even more powerful hydraulic systems. This section will briefly discuss the power stage options for the smaller, electric driven servo systems.

There are two distinct methods for electronically implementing the power stage: linear amplifiers and switching amplifiers. Either of these methods typically takes a low-power signal (usually a voltage) as input, and outputs either a desired voltage or current level. This output is regulated so that the voltage or current level remains virtually unchanged despite large changes in the loading caused by the motor. The motor loading does change dramatically as the motor moves because the back electromotive force (EMF) is proportional to the motor velocity ω . For hybrid stepping motors, it is also modulated by either the sine or cosine of the motor position, θ . Figure 18.69 shows the equivalent electric circuit for the two phases of a hybrid stepping motor.

Despite their similarities, linear and switching amplifiers differ markedly in how they achieve voltage or current regulation. Linear amplifiers use a feedback strategy very similar to that described in the previous section. The result is a smooth, continuous output voltage or current. Switching amplifiers, on the other hand, can only turn the voltage to the motor fully on or off (or positive/negative). Consequently, every few microseconds the circuit checks a low-pass filtered version of the motor’s voltage or current level. If it is too high, the voltage is turned off. If it is too low, the voltage is turned on. This method works because the sampling is done on a microsecond scale, whereas the motor’s current or voltage can only change in a millisecond scale. All motors contain resistance and inductance due to the winding, and this resistor-inductor circuit acts

FIGURE 18.67 A stable response to a step command.

FIGURE 18.68 An unstable response to a step command.

FIGURE 18.69 The electrical equivalent circuit representing the two phases of a hybrid stepping motor.

as a low-pass filter. Thus, the motor filters out the high-frequency switching, and responds only to the low-frequency components contained within the switching. Care must be taken when using this technique to perform the switching at a frequency well beyond the bandwidth of the mechanical components so that the motor does not respond to the high-frequency switching.

If the desired output is a voltage, the amplifier is called a **pulse-width-modulated** (PWM) voltage amplifier. If the desired output is a current, the amplifier is usually termed a **current chopper**.

Both linear and switching amplifiers remain in use because each has particular advantages. Linear amplifiers do not introduce high-frequency harmonics to the system; thus, they can provide more accurate control with less vibrations. This is especially true if the servo system contains components that are somewhat flexible. On the other hand, if the system is rigid, the switching amplifier will provide satisfactory results at a lower cost.

Motor Choice

The choice of motor for a servo system can impact cost, complexity, and even the precision. Three motors will be described in this section. Although this is not by any means an exhaustive coverage, it will suffice for a variety of applications.

DC servomotors are the oldest and probably the most commonly used actuator for servo systems. The name arises because a constant (or DC) voltage applied to the motor input will produce motor movement. Over a linear range, these motors exhibit a torque that is proportional to the quantity of current flowing into the device. This can make the design of control laws particularly convenient since torque can often be easily included into the dynamic equations. The back EMF generated by the motor is strictly proportional to the motor velocity, and so a large input voltage is required to overcome this effect at large velocities. The chief disadvantage of the DC motor is caused by the brushes. Inside the motor, mechanical switching is performed with brushes. As you might imagine, these brushes are the first part of the motor to fail, since they are constantly rubbing and switching current. Consequently, they severely limit the reliability of DC motors as compared to other, more modern actuators. The brushes also limit the low-speed performance because the switching effects are not filtered out when the motor is turning slowly. Instead, the motor actually has time to react to each individual switching. For this reason, DC motors are normally run only at high speeds, and gearing is used to convert the speed to that needed for a particular application. Only very specialized designs of DC motors are suitable for highly precise direct drive applications in which no gearing is allowed.

One way to eliminate some of these problems is to use a brushless DC motor rather than an ordinary DC motor. The brushless DC operates in a manner identical to the DC motor. However, the motor construction is quite different. A typical brushless DC motor actually has three phases. Much like the DC motor, these phases are switched either on or off depending on the motor position. Whereas the DC motor accomplishes this switching mechanically with the brushes, the brushless DC contains Hall effect sensors. These sensors determine the position of the motor, then based on these measurements electronically perform the switching. The advantage is that brushes are no longer necessary. As a result, the brushless DC motor will last much longer than an ordinary DC motor. Unfortunately, since Hall effect sensors and more sophisticated switching electronics are required, brushless DC motors are more expensive than DC motors. In addition, since the basic principle still involves switching phases fully on or off, brushless DC motors also exhibit poor performance at low speeds.

Both types of DC motors have become popular because they respond linearly (over a nominal operating range) to an input current command in that the output torque is roughly proportional to the input current. This is convenient because it allows the direct use of linear control design techniques. It was also especially important during early servo system development because it is easy to implement with analog computing devices. Advances in microcontroller computing technology and nonlinear control design techniques now provide many more options. One of these is the use of hybrid stepping motors in servo systems. These motors were originally developed for open-loop operation. They have shown considerable promise for closed-loop operation as well. Hybrid stepping motors typically have two phases. These windings are labeled A and B in Fig. 18.70(a). These two windings are energized in the sequence shown in

FIGURE 18.70 The stepping sequence for a hybrid stepping motor.

Fig. 18.70(a) to Fig. 70(d), thus causing the permanent magnet rotor to turn. Although Fig. 18.70 shows only four separate energizations (called *steps*) of the windings to complete a revolution, clever mechanical arrangements allow the number of steps per revolution to be greatly increased. Typical hybrid stepping motors have 200 steps/revolution. Consequently, a complete revolution is performed by repeating the four step sequence shown in Fig. 18.70, 50 times.

One advantage of these motors is that they allow fairly accurate positioning in open loop. As long as the motor has sufficient torque capabilities to resist any external torques, the motor position remains within the commanded step. Since open-loop systems are far less complicated (and therefore less expensive), these motors offer an economical alternative to the traditional closed-loop servo system. On the other hand, there are some accompanying disadvantages to open-loop operation. First, since the winding currents are switched on and off to energize the coils in the proper sequence, the motor exhibits a jerky motion at low speeds, much like the DC motors. Second, if an unexpectedly large disturbance torque occurs, the motor can be knocked into the wrong position. Since the operation is open loop and therefore does not employ any position sensor, the system will not correct the position, but will keep running. Finally, the speed of response and damping can be improved using closed-loop techniques.

In addition to the open-loop uses of hybrid stepping motors, methods exist for operating these motors in a closed-in a closed-loop fashion (Lofthus et al., 1994). The principle difficulty arises because hybrid stepping motors are nonlinear devices, so the plethora of design techniques available in linear control theory cannot be directly applied. Fortunately, these motors can be made to behave in a linear fashion by modulating the input currents by sinusoidal functions of the motor position. For instance, the currents through the two windings (I_A and I_B) can be made equal to

$$I_A = -I_C \sin N\theta \tag{18.19}$$

$$I_B = I_C \cos N\theta \tag{18.20}$$

where N is the number of motor pole pairs (50 for the typical 200-step/revolution motor) and θ is the motor's angular position. Then the torque output by the motor is proportional to the new input, I_C . I_C can be determined using standard linear control designs such as the PID method outlined earlier.

In contrast to the DC motors, which employ current switching and therefore perform poorly at low speeds, this closed-loop method of controlling stepping motors performs quite accurately even at very low velocities. On the other hand, the generation of the sinusoidally modulated input currents requires both accurate position measurement and separate current choppers for each phase. Thus the implementation cost is somewhat higher than a servo system utilizing DC motors.

Gearing

As alluded to in the previous section, gearing is often used in servo systems so that the motor can operate in its optimum speed range while simultaneously obtaining the required speeds for the application. In addition, it allows the use of a much smaller motor due to the mechanical advantage. Along with these advantages come some disadvantages, the principle disadvantage being **backlash**. Backlash is caused by the small gaps that exist in gearing systems. In gearing systems, there always exist small gaps between a pair of mating gears. As a result of the gaps, the driven gear can wiggle independently from the driving gear. This wiggling is actually a nonlinear phenomena that can cause vibrations and decreases the accuracy that can be obtained. A similar effect occurs when using belt driven gearing because the belt stretches.

These inherent imperfections in gearing can become major problems if extreme accuracy is required in the servo system. Since these effects increase as the gear ratio increases, one way to reduce the effect of the gearing imperfections is to make the gear ratio as small as possible. Unfortunately, DC motors run smoother at higher speeds, so smaller gear ratios tend to accentuate the motor imperfections caused by switching. Consequently, a tradeoff between the inaccuracies caused by the gearing and the inaccuracies caused by the motor must be made. For highly precise systems, the gearing is sometimes completely eliminated. For such applications, a closed-loop hybrid stepping motor or a specialized DC motor are usually necessary to obtain good motion quality.

A Simple Example Application

To clarify some of the engineering choices that must be made when designing a servo system, a simple example of a servo system design for moving a camera will be discussed.

First, suppose the camera will be used in a surveillance application, to constantly pan back and forth across a store. For this application, an actual servo system employing feedback is probably not necessary and would prove too costly. The required precision is fairly low, and low cost is of the utmost importance. Consequently, an open-loop stepping motor powered by transistors switching on or off will probably be adequate. Alternatively, even a DC motor operated in open loop, with microswitches to determine when to reverse direction will suffice.

Now suppose the camera is used to visually inspect components as part of a robotic workcell. In this case, the requirements on precision are significantly higher. Consequently, a servo system using a geared DC motor and powered by a PWM voltage amplifier may be an appropriate choice. If the robotic workcell is used extensively, a more reliable system may be in order. Then a brushless DC motor may be substituted for a higher initial cost.

Finally, suppose the camera system is used to provide feedback to a surgeon performing intricate eye surgeries. In this case, an extremely precise and reliable system is required, and cost is a secondary consideration. To achieve the high accuracy, a direct drive system that does not use any gearing may provide exceptional results. Since the motor must move precisely at low speeds, simultaneously remaining very reliable, a closed-loop hybrid stepping motor may be used. To drive the hybrid stepping motor, either linear current amplifiers or current choppers (one for each of the two phases) will suffice. For this particular application, the hybrid stepping motor offers another advantage because it can be operated fairly accurately in open loop. Thus it offers redundancy if the compensator or sensors fail.

Defining Terms

Backlash: The errors introduced into geared systems due to unavoidable gaps between two mating gears.

Bandwidth: The frequency range over which the Bode plot of a system remains within 3 dB of its nominal value.

Closed-loop system: A system that measures its performance and uses that information to alter the input to the system.

Current chopper: A current amplifier that employs pulse-width-modulation.

Open-loop system: A system that does not use any measurements to alter the input to the system.

Overshoot: The peak magnitude of oscillations when responding to a step command.

Pulse-width-modulation: A means of digital-to-analog conversion that uses the average of high-frequency switchings. This can be performed at high-power levels.

Rise time: The time between an initial step command and the first instance of the system reaching that commanded level.

Settling time: The time between an initial step command and the system reaching equilibrium at the commanded level. Usually this is defined as staying within 2% of the commanded level.

18.5 Power Control and Switching

Gibson Morris, Jr.

18.5.1 Introduction

Control of electric power, or power conditioning, requires the conversion of electric power from one form to another, that is, DC to AC, one voltage level to another, and so on, by the switching characteristics of various electronic power devices. Some of these devices, such as silicon controlled rectifiers (SCRs),

can be operated as switches by applying control voltages to their controlling input (gate terminal of gate-turn-off thyristor (GTO)). Others, such as triggered vacuum and gas gap switches rely on over-voltages or triggering. For large power systems, control is exercised by supervisory control and data acquisition (SCADA) computer systems located at a central location. This master station communicates with remote stations in the system to acquire data and system status and to transmit control information. These centers support the two main objectives of power system control, that is, (1) stable (voltage and frequency) power and (2) economical utilization of the generation capabilities in the system. Typically, system control involves both the generation and load ends of a system. At generating plants this is accomplished by direct control to input to the prime mover, and systemwide it is accomplished by the control centers. Distributing control to the load end provides a localized response to changing requirements at subtransmission and distribution circuits. At this level, faults such as lightning strikes and short circuits can be responded to in a timely manner through relays, circuit breakers, and so forth, thereby protecting system assets.

Development of high-power switches was stimulated by the growth of the electric power distribution networks. Control and protection of these networks involved power handling capabilities in excess of 10^9 W. Lasers, X-ray equipment, particle accelerators, fusion research, and so forth, have required the switching of power in the form of fast rising pulses and at levels that can exceed 10^{12} W.

Power control and switching falls into the following general regimes:

- Electric power distribution at low frequencies
- Pulsed power characterized by fast rising pulses

Switches can be divided into two classes, opening switches and closing switches, with the following characteristics:

- Hold-off voltage
- Voltage drop during conduction
- dv/dt during opening or closing
- Trigger voltage requirement, if any
- Maximum current
- di/dt characteristics

Power electronic circuits can be classified as to function as follows:

- Diode rectifiers
- DC–DC converters
- AC–AC converters
- DC–AC converters
- AC–DC converters
- Switches

In general, these power circuits relate two external systems and, therefore, involve current and voltage relationships at the input and output ports of the power circuit. Thus, control of a power circuit must be defined in context to the external systems to which it is connected.

The switching characteristics of semiconductor devices introduce harmonics into the output of converters. These harmonics can affect the power quality of a circuit and reduction of these harmonics by the use of filters is often necessary. With the increasing utilization of semiconductor devices for power control and switching, the issue of power quality is becoming more important.

18.5.2 Electric Power Distribution

Control of a power system is required to keep the speed of machines constant and the voltage within specified limits under changing load conditions. Control schemes fall into several categories: control of excitation systems, turbine control, and faster fault clearing methods. Design strategies that reduce

system reactance are: minimum transformer reactance, compensation of transmission lines using series capacitance or shunt inductance, and additional transmission lines.

One of the principal components of the power distribution system is an AC generator driven by a turbine. Changing load conditions require changes on the torque on the shaft from the prime mover to the generator so that the generator can be kept at a constant speed. The field to the alternator must be adjusted to maintain a constant voltage.

This synchronous machine converts mechanical energy to electrical energy and consists of a stator, or armature, with an armature winding. This winding carries the current I_a supplied by the generator to a system. The rotor is mounted on a shaft that rotates inside the stator and has a winding, called the field winding, that is supplied by a DC current from the exciter. The magnetomotive force (mmf) produced by the field winding current combines with the mmf produced by the current in the armature winding to produce a flux that generates a voltage in the armature winding and provides the electromagnetic torque between the stator and the rotor. This torque opposes the torque of the prime mover, that is, steam or hydraulic turbine.

FIGURE 18.71 Basic power circuit.

The basic power circuit is illustrated in Fig. 18.71.

$$V_s = E_g - I_a X_g$$

An important factor in controlling the flow of reactive power is changing the exciter current. Normal excitation of a synchronous generator is given by

$$|E_g| \cos \delta = V_s$$

where δ is the torque or power angle between the generator voltage and the terminal voltage V_s .

Changing the DC exciter current will cause E_g to vary according to

$$I_a = \frac{|E_g| \angle \delta - |V_s| \angle 0}{j X_g} \quad \text{and} \quad I_a^* = \frac{|E_g| \angle -\delta - |V_s| \angle 0}{j X_g}$$

Power from the generator to a system is given by $|V_s| |I_a| \cos \theta$, where θ is the power factor angle. Increasing the exciter current increases E_g as shown in Fig. 18.72(a). Note the generator supplies lagging current to the system. In Fig. 18.72(b), the generator is underexcited and supplies leading current to the system, or the generator is drawing lagging current from the system.

If power input to a generator is increased with $|E_g|$ constant, the rotor speed will increase and the angle δ will increase. This increase in δ results in a large I_a and lower θ . The generator delivers more power to

FIGURE 18.72 Generator excitation.

an infinite bus given by

$$S = \frac{|V_s||E_g|\angle 90 - \delta - |V_s|^2\angle 90}{X_g} = P + jQ = V_s I_a^*$$

where

$$V_s = |V_s|\angle 0 \quad \text{and} \quad E_g = |E_g|\angle \delta$$

Real power

$$P = \text{Re}S = |V_s||E_g| \cos(90 - \delta) - |V_s|\frac{|E_g|}{X_g} \sin \delta$$

Reactive power

$$Q = \text{Im}S = [E_g \cos \delta - |V_s|]\frac{V_s}{X_g}$$

Note that for a small δ , a small change in δ results in a larger P than Q .

Reliable electric power service implies that the loads are fed at a constant voltage and frequency at all times. A stable power system is one in which the synchronous machines, if perturbed, return to their original state if there is no net change in power, or stabilize at a new state without loss of synchronization. The machine rotor angle is used to quantify stability, that is, if the difference in the angle between machines increases or oscillates for an extended period of time, the system is unstable. The swing equation, given by

$$J \delta_m = J \omega_m = T_a$$

governs the motion of the machine rotor. J is moment of inertia, δ_m is mechanical torque angle with respect to a rotating reference, ω_m is shaft angular velocity, and T_a is the accelerating torque. Two factors that act as criteria for the stability of a generating unit are the angular swing of the machine during and following fault conditions, and the time it takes to clear the transient swing.

Mechanical torques of the prime movers, steam or hydraulic, for large generators depend on rotor speed. In unregulated machines the torque speed characteristic is linear over the rated range of speeds. The prime mover speed of a machine will drop in response to an increased load, and the valve position must be opened to increase the speed of the machine. In a regulated machine (governor controlled) the speed control mechanism controls the throttle valves to the steam turbine or the gate position for a water turbine.

Automatic voltage regulation can be used to adjust the field winding current, thus changing E_g as the load on the machine is varied. If the power output of a generator is to be increased while an automatic voltage regulator holds the bus voltage at a constant value, the field winding current must be increased. The maximum voltage output of a machine is limited by the maximum voltage of the excitor supplying the field winding. Figure 18.73 illustrates control of a power-generating unit.

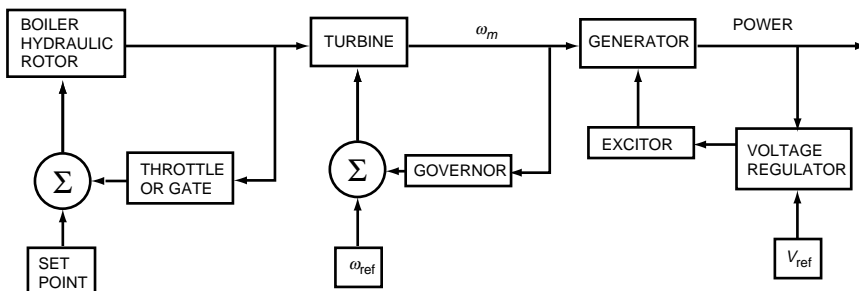

FIGURE 18.73 Generating unit control.

The performance of a transmission system can be improved by reactive compensation of a series or parallel type. Series compensation consists of banks of capacitors placed in series with each phase conductor of the line and is used to reduce the series impedance of the line, which is the principal cause of voltage drop. Shunt compensation consists of inductors placed from each line to neutral and is used to reduce the shunt susceptance of the line.

Circuit interrupting devices in power systems fall into three categories: fuses, switches, and circuit breakers. Design ratings of these devices are

- Power-frequency voltage of the circuit
- Maximum continuous current device can carry
- Maximum short-circuit current device can interrupt

The operation and control of a power system requires continual analysis of the system parameters to ensure optimal service at the cheapest production cost. Computer studies are essential to this goal. The IEEE Brown book (IEEE, 1980) is an excellent reference source for the power engineer. Stability studies, load flow studies, transient studies, and so forth, are detailed in this source, and the reader is encouraged to refer to this document for detailed information about different aspects of power control.

18.5.3 Pulsed Power

The generation of high-power pulses requires transferring energy stored in electric fields (capacitors) and magnetic fields (inductors). Capacitor charging requires high-voltage sources at relatively modest current ratings, whereas inductive charging requires high-current sources at relatively low voltages. Transferring this stored energy to a load requires switches capable of holding off high voltages, conducting high currents, and capable of producing pulses with nanosecond or less rise times. An example of the complexity of controlling high-power pulses is the current effort to generate power with energy derived from the fusion of elements. Ignition of the fusion process requires the simultaneous application of high-energy beams on a single target. Another example of the requirement for fast rising pulses is in the area of a detonator for nuclear weapons. Other applications include lasers, high-energy beams, energy weapons, medical equipment and high-voltage testing of insulators. Solid-state switches, such as SCRs, insulated-gate-bipolar transistors (IGBTs), GTOs, etc., although easy to control, are limited by their voltage/current ratings to the few kilovolt/kiloampere range. Therefore, switches that utilize vacuum, gas, or liquid as the dielectric are commonly used in pulsed power applications. These switches fall into two general categories, opening and closing switches (Fig. 18.74).

There are a number of systems that are utilized to produce fast rising pulses. The basic power energy transfer stage is shown in Fig. 18.75.

The maximum voltage on C_2 is given by

$$V_{c2max} = [V_0 C_1 / (C_1 + C_2)] [1 - e^{-\pi / 2\omega\tau}]$$

FIGURE 18.74 (a) Closing switch, (b) opening switch.

FIGURE 18.75 Basic power energy transfer stage.

where

$$\tau = L/R, \quad \omega^2 = ABS[1/LC - 1/(2\tau)^2]$$

and V_0 is initial voltage on C_1 . The output of this stage is switched to a subsequent stage with a closing switch. Utilizing this technique an energy transfer system can be designed for a particular load.

Another common high-voltage generating system found in almost all high-voltage testing facilities is the marx generator (Fig. 18.76). This system charges capacitors in parallel and then discharges them by switching them to a load in series. The switches are usually spherical electrodes with air as the dielectric. The first stage is the control stage and is triggered into conduction at the desired time.

For capacitive loads

$$V_{max} = [2NVC/(C + C_L)][1 - e^{-\pi/2\omega\tau}]$$

For resistive loads

$$V_{max} = (NV_0 R_L e^{-t/2\tau} / 2L\omega)(e^{+\omega t} - e^{-\omega t})$$

where $\tau = L/R$, V is charging voltage, N is number of stages, C_L is capacitance of load, C is capacitance of a single stage

$$\omega^2 = ((NC_L + C)/(NLCC_L)) - 1/(2\tau)^2$$

and the time at which the voltage is at a peak is given by

$$t = T_m = (1/2\omega)\ln[(1 + 2\omega\tau)/(1 - 2\omega\tau)]$$

The breakdown voltage for air gaps is given by $E = 24.5P + 6.7(P/R_{eff})^{1/2}$ kV/cm where R_{eff} is 0.115R for spherical electrodes and 0.23R for cylindrical electrodes and P is pressure in atmospheres. To increase the high-voltage characteristics of a switch other dielectrics can be used (Table 18.9).

Another common method of generating high-voltage pulses is to charge a transmission line and then switch the stored energy to a load with a closing switch, see Fig. 18.77. For an ideal pulse line the output voltage is given by

$$V = V_{charge}(1 - e^{-t/\tau})(Z_c + R)R$$

FIGURE 18.76 Marx high-voltage generator.

FIGURE 18.77 Transmission line for pulse forming.

TABLE 18.9 Relative Breakdown Field Compared to Air

Dielectric	Relative Breakdown Field
Air	1.0
Nitrogen	1.0
SF ₆	2.7
Freon	2.5
Hydrogen	0.5
30% SF ₆ , 70% air	2.0

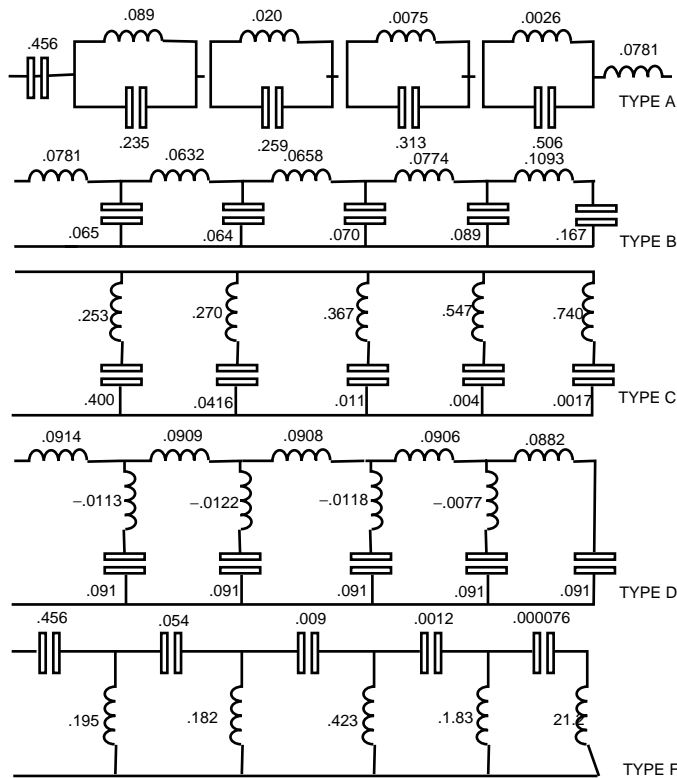

FIGURE 18.78 Pulse forming networks.

where Z_c is the characteristic impedance of the line, R is the load, and $\tau = L/(Z_c + R)$. The rise time of the pulse, $0.1V_{\max}$ to $0.9V_{\max}$, is 2.2τ .

There are a number of pulse forming networks (Fig. 18.78) that will produce pulses with near constant amplitudes and fast rise times. These networks approximate the ideal transmission line.

Another type of switch is the opening switch. Fuses and circuit breakers are examples of opening switches, although they are too slow for many pulsed power applications. Opening switches are capable of switching large currents but are difficult to design because during switch opening a significant voltage will develop across the switch. Interrupters used in the power industry rely on a current zero occurring while the switch is opening. If the switch configuration is not such that it can withstand the reoccurring voltage it will close. For pulsed power purposes it is necessary to interrupt currents in the kiloampere, range with nanosecond opening. One such switch is the plasma opening switch. In this switch the plasma channel that sustains conduction between electrodes is degraded to the point that it cannot sustain current flow and the switch opens. This switch is utilized in high-energy beam applications. Other methods such as magnetic interruption and explosive devices are used.

Although the power industry is at a mature stage, the pulsed power arena is a new and dynamic challenge for the power engineer. As more exotic requirements develop for the delivery of high energy in very short periods of time to loads, there will be an increasing demand for improvements in switching technology.

19.1 Fundamental Architecture

Joy S. Shetler

19.1.1 Introduction

The design space for computer **architectures** is fairly diverse and complicated. Each new architecture strives to fulfill a different set of goals and to carve out a niche in the computer world. A system can be composed of one or several processors. Many concepts apply to both multiple processor and single processor systems. Many researchers have concluded that further advances in computational speed and throughput will come from parallelism rather than relying heavily on technological innovation, as has occurred in the past. But implementation is still an important consideration for any computer system.

19.1.2 Defining a Computer Architecture

Some important attributes of a computer system are as follows:

- Structure of the control path(s)
- Structure of the data path(s)
- The memory organization
- The technology used in the implementation
- The number of clocks, that is, single clocked or dual clocked
- The clock speed(s)
- The degree of pipelining of the units
- The basic topology of the system
- The degree of parallelism within the control, data paths, and interconnection networks

In some cases, the **algorithms** used to execute an instruction are important as in the case of data flow architectures or systolic arrays. Some of these attributes are dependent on the other attributes and can change depending on the implementation of a system. For example, the relative clock speed may be dependent on the technology and the degree of **pipelining**. As more diverse and complicated systems are developed or proposed, the classification of a computer architecture becomes more difficult. The most often cited classification scheme, Flynn's taxonomy (Flynn, 1966) defined four distinct classes of computer architectures: *single instruction, single data* (SISD), *single instruction, multiple data* (SIMD), *multiple instruction, single data* (MISD), and *multiple instruction, multiple data*, (MIMD). A particular classification is distinguished by whether single or multiple paths exist in either the control or data paths. The benefits of this scheme are that it is simple and easy to apply. Its prevalent use to define computer architectures attests to its usefulness. Other classification schemes have been proposed, most of which define the parallelism incorporated in newer computer architectures in greater detail.

19.1.3 Single Processor Systems

A single processor system, depicted in Fig. 19.1 is usually composed of a controller, a data path, a memory, and an input/output unit. The functions of these units can be combined, and there are many names for each unit. The combined controller and data path are sometimes called the central processing unit (CPU). The data path is also called an arithmetic and logical unit (ALU).

Hardware parallelism can be incorporated within the processors through pipelining and the use of multiple functional units, as shown in Fig. 19.2. These methods allow instruction execution to be overlapped in time. Several instructions from the same instruction stream or *thread* could be executing in each pipeline stage for a pipelined system or in separate functional units for a system with multiple functional units.

FIGURE 19.1 Block diagram of a single processor system.

FIGURE 19.2 Methods of incorporating parallelism within a processor system: (a) pipelines, (b) multiple units.

Context is the information needed to execute a process within a processor and can include the contents of a program counter or instruction counter, stack pointers, instruction registers, data registers, or general purpose registers. The instruction, data, and general purpose registers are also sometimes called the register set. Context must be stored in the processor to minimize execution time. Some systems allow multiple instructions from a single stream to be active at the same time. Allowing multiple instructions per stream to be active simultaneously requires considerable hardware overhead to schedule and monitor the separate instructions from each stream.

Pipelined systems came into vogue during the 1970s. In a pipelined system, the operations that an instruction performs are broken up into stages, as shown in Fig. 19.3(a). Several instructions execute simultaneously in the pipeline, each in a different stage. If the total delay through the pipeline is D and there are n stages in the pipeline, then the minimum clock period would be D/n and, optimally, a new instruction would be completed every clock. A deeper pipeline would have a higher value of n and thus a faster clock cycle.

Today most commercial computers use pipelining to increase performance. Significant research has gone into minimizing the clock cycle in a pipeline, determining the problems associated with pipelining an instruction stream, and trying to overcome these problems through techniques such as prefetching instructions and data, compiler techniques, and caching of data and/or instructions. The delay through each stage of a pipeline is also determined by the complexity of the logic in each stage of the pipeline. In many cases, the actual pipeline delay is much larger than the optimal value, D/n , of the logic in each stage of the pipeline. Queues can be added between pipeline stages to absorb any differences in execution time

FIGURE 19.3 Comparison of the basic processor pipeline technique: (a) not pipelined, (b) pipelined.

FIGURE 19.4 A pipeline system with queues.

through the combinational logic or propagation delay between chips (Fig. 19.4). Asynchronous techniques including handshaking are sometimes used between the pipeline stages to transfer data between logic or chips running on different clocks.

It is generally accepted that, for computer hardware design, simpler is usually better. Systems that minimize the number of logic functions are easier to design, test, and debug, as well as less power consuming and faster (working at higher clock rates). There are two important architectures that utilize this concept most effectively, **reduced instruction set computers (RISC)** and SIMD machines. RISC architectures are used to tradeoff increased code length and fetching overhead for faster clock cycles and less instruction set complexity. SIMD architectures, described in the section on multiple processors, use single instruction streams to manipulate very large data sets on thousands of simple processors working in parallel.

RISC processors made an entrance during the early 1980s and continue to dominate small processor designs as of this writing. The performance p of a computer can be measured by the relationship

$$p = \left(\frac{\text{computations}}{\text{instruction}} \right) \left(\frac{\text{instructions}}{\text{cycle}} \right) \left(\frac{\text{cycles}}{\text{second}} \right)$$

The first component (computations/instruction) measures the complexity of the instructions being executed and varies according to the structure of the processor and the types of instructions currently being executed. The inverse of the component (instructions/cycle) is commonly quoted for single processor designs as **cycles per instruction (CPI)**. The inverse of the final component (cycles/second) can also be expressed as the clock period of the processor. In a RISC processor, only hardware for the most common operations is provided, reducing the number of computations per instruction and eliminating complex instructions. At compile time, several basic instructions are used to execute the same operations that had been performed by the complex instructions. Thus, a RISC processor will execute more instructions than a **complex instruction set computer (CISC)** processor. By simplifying the hardware, the clock cycle is reduced. If the delay associated with executing more instructions (RISC design) is less than the delay associated with an increased clock cycle for all instructions executed (CISC design), the total system performance is improved. Improved compiler design techniques and large on-chip caching has continued to contribute to higher performance RISC designs (Hennessy and Jouppi, 1991).

One reason that RISC architectures work better than traditional CISC machines is due to the use of large on-chip caches and register sets. Since locality of reference effects (described in the section on memory hierarchy) dominate most instruction and data reference behavior, the use of an on-chip cache and large register sets can reduce the number of instructions and data fetched per instruction execution. Most RISC machines use pipelining to overlap instruction execution, further reducing the clock period. Compiler techniques are used to exploit the natural parallelism inherent in sequentially executed programs.

A register window is a subset of registers used by a particular instruction. These registers are specified as inputs, outputs, or temporary registers to be used by that instruction. One set of instructions outputs become the next inputs in a register window for another instruction. This technique allows more efficient use of the registers and a greater degree of pipelining in some architectures.

Scaling these RISC concepts to large parallel processing systems poses many challenges. As larger, more complex problems are mapped into a RISC-based parallel processing system, communication and allocation of resources significantly affects the ability of the system to utilize its resources efficiently. Unless special routing chips are incorporated into the system, the processors may spend an inordinate amount of time handling requests for other processors or waiting for data and/or instructions. Using a large number of simple RISC processors means that cache accesses must be monitored (*snoopy caches*) or restricted (*directory-based caches*) to maintain data consistency across the system.

The types of problems that are difficult to execute using RISC architectures are those that do an inordinate amount of branching and those that use very large data sets. For these problems, the hit rate of large instruction or data caches may be very low. The overhead needed to fetch large numbers of new instructions or data from memory is significantly higher than the clock cycle, virtually starving the processor. Compiler techniques can only be used to a limited extent when manipulating large data sets.

Further increases in speed for a single stream, pipelined processor will probably come about from either increasing the pipeline depth, **superpipelining** or increasing the width of the data path or control path. The latter can be achieved by either issuing more than one instruction per cycle, **superscalar**, or by using a **very long instruction word (VLIW)** architecture in which many operations are performed in parallel by a single instruction. Some researchers have developed the idea of an orthogonal relationship between superscalar and superpipelined designs (Hennessy and Jouppi, 1991). In a superpipelined design, the pipeline depth is increased from the basic pipeline; whereas in a superscalar design, the horizontal width of the pipeline is increased (see Fig. 19.5).

To achieve an overall gain in performance, significant increases in speed due to superpipelining must be accompanied by highly utilized resources. Idle resources contribute little to performance while increasing overall system costs and power consumption. As pipeline depth increases, a single instruction stream cannot keep all of the pipeline stages in a processor fully utilized. Control and data dependencies within

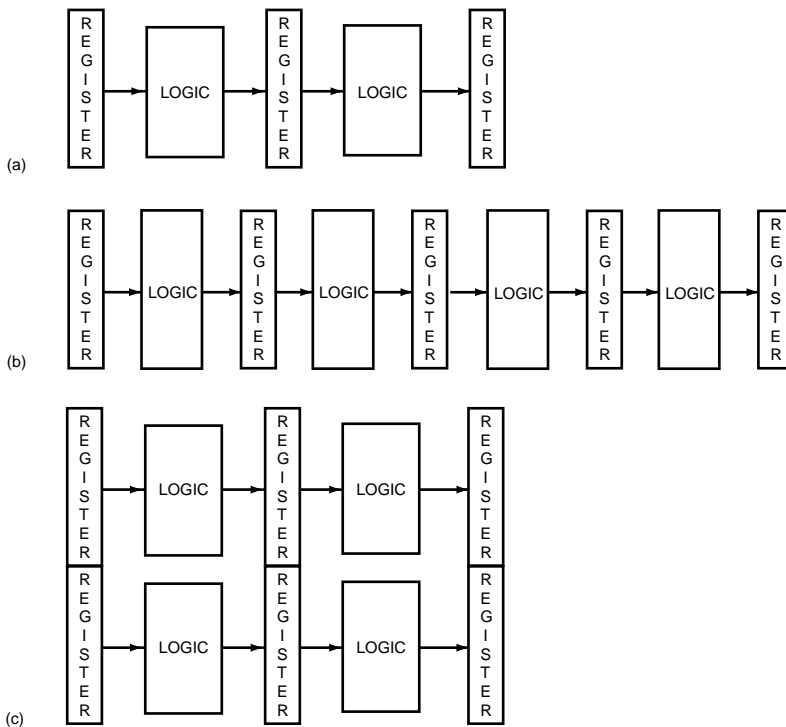

FIGURE 19.5 Superscalar and superpipelined systems: (a) pipelined, (b) superpipelined, (c) superscalar.

the instruction stream limit the number of instructions that can be active for a given instruction stream. *No operation* (NoOps) or null instructions are inserted into the pipeline, creating *bubbles*. Since a NoOp does not perform any useful work, processor cycles are wasted. Some strategies improve pipeline utilization using techniques such as prefetching a number of instructions or data, branch prediction, software pipelining, trace scheduling, alias analysis, and register renaming to keep the memory access overhead to a minimum. An undesirable consequence of this higher level of parallelism is that some prefetched instructions or data might not be used, causing the memory bandwidth to be inefficiently used to fetch useless information. In a single processor system this may be acceptable, but in a multiple processor system, such behavior can decrease the overall performance as the number of memory accesses increases.

Superscalar processors use multiple instruction issue logic to keep the processor busy. Essentially, two or three instructions are issued from a single stream on every clock cycle. This has the effect of widening the control path and part of the datapath in a processor. VLIW processors perform many operations in parallel using different types of functional units. Each instruction is composed of several operation fields and is very complex. The efficient use of these techniques depends on using compilers to partition the instructions in an instruction stream or building extra hardware to perform the partitioning at run time. Again both these techniques are limited by the amount of parallelism inherent in an individual instruction stream.

A solution to fully utilizing a pipeline is to use instructions from independent instruction streams or threads. (The execution of a piece of code specified by parallel constructs is called a thread.) Some machines allow multiple threads per program. A thread can be viewed as a unit of work that is either defined by the programmer or by a parallel compiler. During execution, a thread may spawn or create other threads as required by the parallel execution of a piece of code. Multithreading can mitigate the effects of long memory latencies in uniprocessor systems; the processor executes another thread while the memory system services cache misses for one thread. Multithreading can also be extended to multiprocessor systems, allowing the concurrent use of CPUs, network, and memory.

To get the most performance from **multithreaded** hardware, a compatible software environment is required. Developments in new computer languages and operating systems have provided these environments (Anderson, Lazowska, and Levy, 1989). Multithreaded architectures take advantage of these advances to obtain high-performance systems.

19.1.4 Multiple Processor Systems

Parallelism can be introduced into a computer system at several levels. Probably the simplest level is to have multiple processors in the system. If parallelism is to be incorporated at the processor level, usually one of the following structures is used: SIMD, MIMD, or multicomputers.

A SIMD structure allows several data streams to be acted on by the same instruction stream, as shown in Fig. 19.6(a). Some problems map well into a SIMD architecture, which uses a single instruction stream and avoids many of the pitfalls of coordinating multiple streams. Usually, this structure requires that the data be bit serial, and this structure is used extensively in applications such as computer graphics and image processing. The SIMD structure provides significant throughput for these problems. For many applications that require a single data stream to be manipulated by a single instruction stream, the SIMD structure works slower than the other structures because only one instruction stream is active at a time. To overcome this difficulty structures that could be classified as a combination SIMD/MIMD structure have been applied. In a SIMD system, one instruction stream may control thousands of data streams. Each operation is performed on all data streams simultaneously.

MIMD systems allow several processes to share a common set of processors and resources, as shown in Fig. 19.6(b). Multiple processors are joined together in a cooperating environment to execute programs. Typically, one process executes on each processor at a time. The difficulties with traditional MIMD architectures lie in fully utilizing the resources when instruction streams stall (due to data dependencies, control dependencies, synchronization problems, memory accesses, or I/O accesses) or in assigning new processes quickly once the current process has finished execution. An important problem with this structure is that

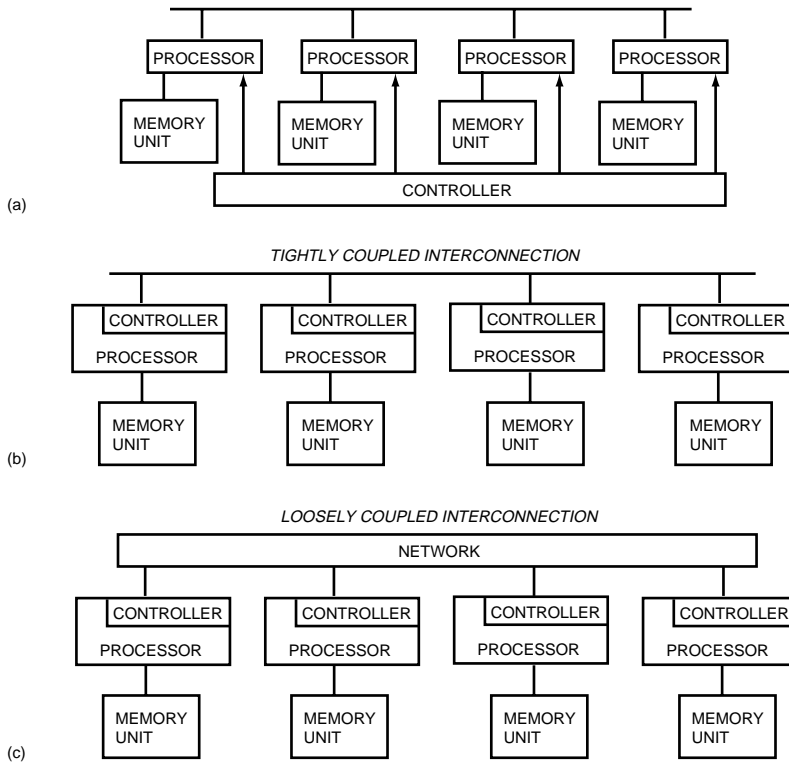

FIGURE 19.6 System level parallelism: (a) SIMD, (b) MIMD, (c) multicomputer.

processors may become idle due to improper load balancing. Implementing an operating system (OS) that can execute on the system without creating imbalances is important to maintain a high utilization of resources.

The next system, which is also popular due to its simple connectivity, is the distributed system or *multicomputer*. A network connects independent processors as shown in Fig. 19.6(c). Each processor is a separate entity, usually running an independent operating system process. A multicomputer will usually use message passing to exchange data and/or instruction streams between the processors. The main difficulties with the multicomputer are the latency involved in passing messages and the difficulty in mapping some algorithms to a distributed memory system.

19.1.5 Memory Hierarchy

High-performance computer systems use a multiple level memory hierarchy ranging from small, fast cache memory to larger, slower main memory to improve performance. Parallelism can be introduced into a system through the memory hierarchy as depicted in Fig. 19.7. A cache is a small, high-speed buffer used to temporarily hold those portions of memory that are currently in use in the processor.

FIGURE 19.7 A common method of incorporating parallelism into a system.

Cache memories take advantage of the property of temporal and spatial locality in program behavior. Temporal locality states that if an item is referenced one point in time, it will tend to be referenced again soon. Spatial locality refers to the likelihood that if an item is referenced, nearby items will tend to be referenced soon.

A cache miss will cause the processor to request the needed data from the slower main memory. The average access time depends on the cache miss rate, the number of cycles needed to fetch the data from the cache, and the number of cycles required to fetch data from main memory in case of a cache miss.

Caches can be divided into separate instruction and data caches or unified caches that contain both instructions and data. The former type of cache is usually associated with a Harvard style architecture in which there are separate memory ports for instructions and data.

In most approaches to instruction fetch, the single chip processor is provided with a simple on-chip instruction cache. On a cache miss, a request is made to external memory for instructions and these off-chip requests compete with data references for access to external memory.

Memory latency is a major problem for high-performance architectures. The disparity in on-chip to off-chip access latencies has prompted the suggestion (Hwang, 1993) that there are four complementary approaches to latency hiding:

- Prefetching techniques
- Using coherent caches
- Using relaxed memory consistency models
- Using multiple contexts or multithreading within a processor

To maximize the performance benefit of multiple instruction issue, memory access time has to be kept low and cache bandwidth has to be increased. Unfortunately, accessing the cache usually becomes a critical timing path for pipelined operation.

Extending caching into a multithreaded processor creates some new problems in cache design. In single-threaded caches, on a context switch (when the processor begins execution of another thread), the cache is flushed and the instructions from the new thread are fetched. A multithreaded cache supports at least two different instruction streams, using different arrays for different threads. Another strategy is to allow the threads to share the cache, making it unnecessary to flush the cache on a context switch. The state of the old thread is stored in the processor, which has different register files for each thread. The cache sends the thread number and the instruction to the processor's instruction buffers. To keep the execution units supplied with instructions, the processor requires several instructions per cycle to be fetched into its instruction buffers. In this variable instruction fetch scheme, an instruction cache access may be misaligned with respect to a cache line. To allow line crossing, an alignment network can be used to select the appropriate instructions to be forwarded to the instruction buffers. Performance is increased by eliminating the need for multiplexing the data bus, thus reducing the I/O delay in a critical timing path and providing simultaneous reads and writes into the cache. Although this operation seems relatively simple, several variables must be considered when designing a multithreaded cache such as: address translation and mapping, variable instruction and data fetching, cache line crossing, request protocols and queuing, line and block replacement strategies, and multiple access ports.

By placing caches, which contain a subset of the main memory, within each processor, several processors could be using the same memory data. When a processor modifies its cache, all other caches within the system with that data are affected. This usually requires that a snooping mechanism be used to update or invalidate data in the caches. These mechanisms usually add considerable hardware to the system and restrict the implementation of the interconnection network to a bus type network so that cache updates can be monitored.

19.1.6 Implementation Considerations

Rather than beginning by building a system and testing the behavior of a breadboard model, the first step is to simulate the behavior using simulation models that approximate the processor structures. The hardware should be modeled at two levels.

High level, hierarchical models provide useful analysis of different types of memory structures within the processor. Flows through the models and utilization parameters can be determined for different structures. *Low level, register transfer level (RTL)* simulation of specific structures usually give a more accurate picture

of the actual hardware's performance. These structures may include caches, register files, indexed instruction and data caches, memory controllers, and other elements. *Hardware description languages*, have been developed to represent a design at this level. After simulation and modeling of the design have been completed, the design can be implemented using various technologies.

Although significant technological advances have increased the circuit speed on integrated circuit (IC) chips, this increase in circuit speed is not projected to result in a similar increase in computer performance. The intrachip and interchip propagation delays are not improving at the same rate as the circuit speed. The latency imposed by the physical methods used to transfer the signals between faster logic has limited the computer performance increases that could be practically obtained from incorporating the logic into the designs.

$$\text{Delay}_{\text{circuit}} = \text{Delay}_{\text{interconnect}} + \text{Delay}_{\text{logic}}$$

An example of this phenomena is evident in pipelined systems, where the slowest pipe stage determines the clock rate of the entire system. This effect occurs between the parts of a hardware circuit. The relative speedup (obtained by making one part of the circuit faster) is determined by the slowest part of the circuit. Even if propagation delays through the fastest logic tended toward zero delay, the propagation delay through the interconnect would limit the speedup through the system or block of logic. So that the speedup for a system with zero logic delay compared to a system with some logic delay would be

$$\text{Speedup} = \frac{\text{Delay}_{\text{with logic}}}{\text{Delay}_{\text{without logic}}}$$

$$\text{Speedup} = \frac{\text{Delay}_{\text{interconnect}} + \text{Delay}_{\text{logic}}}{\text{Delay}_{\text{interconnect}}}$$

Rather than suggesting that further speedups due to technological innovation are impossible, these arguments show that new methods must be used that compensate for the latencies imposed by physical limitations. As demonstrated in Fig. 19.8, the time it takes for a signal to be transferred between chips

FIGURE 19.8 The relative propagation delays for different levels of packaging; propagation through interconnecting elements becomes longer relative to clock cycle on chip.

might be several times the clock period on a chip implemented in a high-speed circuits. The delay between chips is not only affected by the length of the interconnecting wires between the chips but also by the number and types of interconnections between the wires. Whenever signals must go through a via or pin to another type of material or package, mismatches in impedance and geometry can introduce reflections that affect the propagation delay through the path.

One way of synchronizing logic modules is to use self-timed circuits or **ternary logic** for the signal transfers. Ternary logic is compatible with some optical interconnection methods. Logic must be provided to translate the multiple valued signal back to a digital signal unless the entire system is designed in ternary logic. The overhead of designing the entire system in ternary logic is significant (50% increase in logic).

Pipelining the system so that one instruction is being transferred between chips while another instruction is executing is a promising technique to compensate for this latency. Pipelining techniques (Fig. 19.9) can be used to not only compensate for interconnect delay but also to monitor the inputs and outputs of a chip (when scan paths are designed into the latches), by inserting registers or latches at the inputs and outputs of the chips. This has the effect of increasing the length of the pipeline and the amount of logic, increasing the system latency, and increasing the layout area of the design. The main problems with this use of pipelining are clock synchronization and keeping the propagation delay through each pipeline stage symmetrical. Each register could be running on a different clock signal, each of which is *skewed* from the other, that is, one signal arrives at the pipeline register offset from the time that the other signal arrives at its pipeline register. Clock skew can cause erroneous values to be loaded into the next stage of the pipeline. For an optimal design, each pipeline stage would be symmetrical with respect to propagation delay. Any nonsymmetries result in longer clock periods to compensate for the worst-case propagation delay as mentioned previously. An ideal pipelined system must allow for clock skew and for differences in propagation delay through the stages of the pipeline.

FIGURE 19.9 Using pipelining to compensate for interconnect delays.

Packaging Considerations

Ensuring high-bandwidth interconnections between components in a computer system is extremely important and some (Keyes, 1991) consider computer systems development to be the principal driving force behind interconnection technology. During early empirical studies of the pinout problem, it was found that in many designs there is a relationship between the amount of logic that can be implemented within a design partition and the number of I/O pins,

$$I = AB^r$$

where

- I = the I/O pin count
- B = the logic block count
- A = the average size of the blocks
- r = the Rent exponent

This relationship has popularly become known as Rent's rule based on the unpublished work by E.F. Rent at IBM. Although considerable research has been undertaken to disprove Rent's rule or to find architectures that overcome the pinout limitations, in many cases, there is a limitation on the amount of logic that can be associated with a given number of pins. This relationship severely affects the designs of some high-speed

technologies where the pinout is fairly costly in terms of space and power consumption. Reduced pinout due to packaging constraints means that the logic must be kept simple and sparse for most designs.

RISC designs have benefited from the low number of pins and routing density available in VLSI chips. For a particular architecture certain relations between pinout and logic have been observed. Since the digital logic complexity available per interconnect is determined by empirical relationships, such as Rent's rule, reducing the complexity of a logic block (chip) will usually also reduce the number of interconnects (pins). Because of the simpler implementations, RISC chips have required less routing density and less pins than more complex designs.

Packaging techniques have been developed to provide increased pinout on IC chips. Most of these techniques have been developed for Si chip technology. These packaging techniques are beginning to spread to systems composed of other technologies. Most of the packaging techniques center around providing a higher density pinout by distributing pins across the chip instead of restricting the placement to the edges of the chip. Sometimes this involves using a *flip chip* technology, which turns the chip logic-side down on a board. Heat sinking—removing heat from the chip—becomes an issue as does being able to probe the logic.

Technology Considerations

Silicon semiconductor technology has been the most commonly used technology in computer systems during the past few decades. The types of Si chips available vary according to logic family such as n-channel metal-oxide semiconductor (NMOS), complementary metal-oxide semiconductor (CMOS), transistor transistor logic (TTL), and emitter coupled logic (ECL). Circuit densities and clock rates have continued to improve for these Si logic families, giving the computer designer increased performance without having to cope with entirely new design strategies. Higher speed technologies are preferred for high-end computer systems. Several technologies that hold promise for future computer systems include optical devices, gallium arsenide (GaAs) devices, superconductors, and quantum effect devices.

Many of the high-speed technologies are being developed using III–V materials. GaAs is the current favorite for most devices (sometimes used in combination with AlGaAs layers). Long and Butner (1990) provide a good introduction to the advantages and capabilities of GaAs circuits, including higher electron mobility (faster switching speeds), a semi-insulating substrate, and the major advantage of the suitability of GaAs semiconductors for optical systems. GaAs circuits are steadily increasing in circuit density to the VLSI level and becoming commercially available in large quantities. More designers are incorporating GaAs chips into speed-sensitive areas of their designs.

There are several GaAs circuit families. Some of the circuit families use only depletion mode field effect transistors (FETs), whereas others use both enhancement and depletion (E/D) mode FETs. Very large-scale integrated (VLSI) levels of integration are under development for *direct coupled FET logic* (DCFL) and *source coupled FET logic* (SCFL). By using enhancement and depletion mode FETs with no additional circuitry, DCFL is currently the fastest, simplest commercially available GaAs logic. SCFL (also using E/D FETs) provides high speed with greater drive capabilities but consumes more power and space than DCFL.

Several efforts are underway to harness photons for extremely fast interconnects and logic. Photons have a greater potential bandwidth than electrons, making optical interconnections attractive. Unlike electrons, photons have no charge and do not easily interact in most mediums. There are virtually no effects from crosstalk or electromagnetic fields on even very high densities of optical wires or signals. Although photon beams produce very high-quality signal transmission, the implementation of switching logic is difficult. The same immunity to interference that makes optics ideal for signal transmission makes switching logic difficult to implement. Most optical devices or systems under development exhibit high latencies in exchange for fast switching speeds. Optical interconnects, however, provide wider bandwidth interconnections for interchip or interprocessor communications. Optical interconnections have delays associated with converting signals from electrons to photons and back, increasing the propagation delay.

In a wire connection, the propagation characteristics limit the use of the wire to one pipeline stage. Reflected electrical signals must be dampened before a new signal can enter the wire, precluding the use of the wire by more than one digital signal during a time period. A wire interconnect would only act as

a single stage of a pipeline, as shown in Fig. 19.9. An optical interconnect, due to its signal propagation characteristics, allows a finer degree of pipelining. Once a signal enters the optical interconnect, new signals can enter at regular time intervals without causing interference between the signals. Thus, an optical interconnect can represent several pipeline stages in a design, as shown in Fig. 19.10.

Two types of optical interconnects are under development, fiber optic and free space. Fiber-optic systems provide high bandwidth interconnections at speeds comparable to wire interconnects. Faster switching signals can be transported through fiber-optic systems longer distances than traditional wire and via interconnects. Since the fundamental physical limit for propagation delay between any two locations is the speed of light, free-space optical systems are, the ultimate choice for interconnection technology. The major drawback with optical interconnects is that the technologies that are currently available have a much lower density per area than traditional interconnects.

In a fiber-optic system, cables run between source and destination. The cables are usually wide (distances on the order of 250- μm centers between cables are common), difficult to attach, and subject to vibration problems. The lightguide material must maintain its low loss through all subsequent carrier processing (including the fabrication of electrical wiring and the chip-attachment soldering procedures) and the material used must be compatible with the carriers' temperature coefficient of expansion over the IC's operational temperature range. A benefit of using a fiber-optic cable interconnect is that a simple switching function using devices, such as directional optical couplers, can be performed in the cable.

In free-space systems, using just a detector and light source, signals can be transferred from one board to another in free space. The problem of connecting fibers to the boards is removed in a free-space system but the beam destination is limited to next nearest boards. Alignment of detector and sender becomes critical for small feature sizes necessary to provide high-density transfer of signals. For both free-space and fiber-optic systems, lower density or positional limitations makes optical interconnects unattractive for some computer architectures.

The near-term application of optical interconnects are in interprocessor communications with optical storage being the next leading application area. There are significant propagation delays through the translation circuitry when converting signals between the optical and the electrical realms. There are two leading materials for optical interconnect systems, GaAs and InGaAsP/InGaAs/InP. GaAs laser systems are by far the most developed and well understood. InGaAsP/InGaAs/InP *optoelectronic integrated circuits* (OEICs) are the next leading contender with current technology capable of providing laser functions for long-distance applications such as fiber-optic links for metropolitan area networks and CATV distribution.

Lowering the temperature of chips and interconnect results in an improvement in FET circuit switching speed and a reduction in the interconnect resistance. The reduction in resistance causes lower attenuation and greater bandwidth in the interconnect. These effects occur both in normal conductors and superconductors at low temperatures. Room temperature operation is usually preferred because of the problems with maintaining a low-temperature system and the extra power required to lower the temperature. Heat generated by devices on the chip can cause local *hot spots* that affect the operation of other circuits. The development of high-temperature superconductors increased the interest in using high bandwidth superconductor interconnect with high-speed circuits to obtain a significant increase in system clock rate.

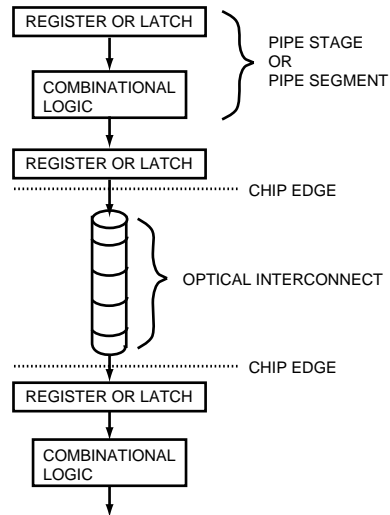

FIGURE 19.10 Using an optical connection in a pipeline system.

Wafer Scale Integration (WSI)

One way to overcome the pinout problem is to reduce the pinout between chips by fabricating the chip set for a design on a single wafer. The logic partitions, which would have been on separate chips, are connected through high-speed metal interconnect on the wafer. Research involving **wafer scale integration (WSI)** dates back to some very early (1960s) work on providing acceptable yield for small Si chips. As processing techniques improved, circuit densities increased to acceptable levels, negating the need for WSI chips in the fledgling Si IC industry.

The driving force behind current WSI efforts is the need to provide high bandwidth communications between logic modules without suffering the degradation in performance due to off-chip interconnections. The problems with WSI are adequate yield, heat sinking, and pinout. The latter two problems can be coped with through using advanced packaging techniques such as flip-chip packages and water-cooled jackets. Obtaining adequate yields for mass production of wafers is probably the largest obstacle for using WSI systems. Processing defects can wipe out large sections of logic on wafers. Most WSI approaches use replicated or redundant logic that can be reconfigured either statically or dynamically to replace defective logic. This technique results in a working wafer if enough spares are available to replace the defective logic.

Architectures that are compatible with WSI are simple with easily replicated structures. Random access memory (RAM) chip designs have had the most successful use of WSI. The rationale for this approach is that GaAs is about at the stage of development that Si was in the early 1960s and, hence, WSI would provide a vehicle for a large gate count implementation of a processor. Large wafers are impractical due to the fragility of GaAs. Packaging techniques using defect-free GaAs chips mounted on another material might be more viable for some designs than WSI, due to the fragility of GaAs, the limited size of the GaAs wafers, and the cost of GaAs material.

In hybrid WSI, defect-free chips are mounted on a substrate and interconnected through normal processing techniques. [Note: the term hybrid is also used to refer to microwave components. A hybrid WSI component is also called a *wafer transmission module* (WTM).] This pseudo-WSI provides the density and performance of on-chip connections without having to use repair mechanisms for yield enhancement. The interconnections are the same feature sizes and defect levels as normal IC processing. Only a few planes are available to route signals, keeping the interconnect density low. Hybrid WSI has been suggested as a way for GaAs chips with optoelectronic components to be integrated with high logic density Si chips.

Multichip Modules (MCMs)

Multichip modules (MCMs) hold great promise for high-performance interconnection of chips, providing high pinout and high manufacturable levels of parts. MCMs are very close in structure to hybrid WSI. Active die are attached directly to a substrate primarily used for interchip wiring, introducing an extra level of packaging between the single die and the printed circuit board (PCB). The main difference between MCMs and hybrid WSI is the size of the substrate and interconnect. The MCM substrate can be as large as a wafer but usually is smaller with several thin-film layers of wiring (up to 35 or more possible).

The feature size of the MCM interconnect is about 10 times that of the on-chip interconnect, reducing the interconnect disabled by processing defects to almost nil. By guaranteeing that only good die are attached to the substrates by burning-in the die under temperature and voltage, MCMs can be mass produced at acceptable yield levels. The basic MCM structure is shown in Fig. 19.11.

FIGURE 19.11 The basic MCM structure.

Defining Terms

Algorithm: A well-defined set of steps or processes used to solve a problem.

Architecture: The physical structure of a computer, its internal components (registers, memory, instruction set, input/output structure, etc.) and the way in which they interact.

Complex instruction set computer (CISC): A design style where there are few constraints on the types of instructions or addressing modes.

Context: The information needed to execute a process including the contents of program counters, address and data registers, and stack pointers

Cycles per instruction (CPI): A performance measurement used to judge the efficiency of a particular design.

Multithreaded: Several instruction streams or threads execute simultaneously.

Pipeline: Dividing up an instruction execution into overlapping steps that can be executed simultaneously with other instructions, each step represents a different pipeline stage.

Reduced instruction set computer (RISC): A design style where instructions are implemented for only the most frequently executed operations; addressing modes are limited to registers and special load/store modes to memory.

Superpipelined: A pipeline whose depth has been increased to allow more overlapped instruction execution.

Superscalar: Hardware capable of dynamically issuing more than one instruction per cycle.

Ternary logic: Digital logic with three valid voltage levels.

Very long instruction word (VLIW): Compiler techniques are used to concatenate many small instructions into a larger instruction word.

Wafer scale integration (WSI): Using an entire semiconductor wafer to implement a design without dicing the wafer into smaller chips.

19.2 Software Design and Development

Margaret H. Hamilton

19.2.1 Introduction

A computer system can be neatly compared with a biological entity called a superorganism. Composed of software, hardware, peopleware and their interconnectivity (such as the internet), and requiring all to survive, the silicon superorganism is itself a part of a larger superorganism, for example, the business. It could be a medical system including patients, drugs, drug companies, doctors, hospitals and health care centers; a space mission including the spacecraft, the laws of the universe, mission control and the astronauts; a system for researching genes including funding organizations, funds, researchers, research subjects, and genes; or a financial system including investors, money, politics, financial institutions, stock markets, and the health of the world economy.

Whether the business be government, academic, or commercial, the computer system, like its biological counterpart, must grow and adapt to meet fast changing requirements. Like other organisms, the business has both physical infrastructure and operational policies which guide, and occasionally constrain, its direction and the rate of evolution, which it can tolerate without becoming dysfunctional.

Unlike a biological superorganism, which may take many generations to effect even a minor hereditary modification, software is immediately modifiable and is, therefore, far superior in this respect to the biological entity in terms of evolutionary adaptability. Continuity of business rules and the physical infrastructure provides a natural tension between “how fast the software can change” and “how rapidly the overall system can accept change.”

As the brain of the silicon superorganism, software controls the action of the entire entity, keeping in mind, however, it was a human being that created the software.

In this chapter we will discuss the tenets of software, what it is and how it is developed, as well as the precepts of software engineering, which are the *methodologies* by which ideas are turned into software.

19.2.2 The Notion of Software

Software is the embodiment of logical processes, whether in support of business functions or in control of physical devices. The nature of software as an instantiation of process can apply very broadly, when modeling complex organizations, or very narrowly as when implementing a discrete numerical algorithm. In the former case, there can be significant linkages between re-engineering businesses to accelerate the rate of evolution—even to the point of building operational models which then transition into application suites and thence into narrowly focused implementation of algorithms. Software thus has a potentially wide range of application, and when well designed, it has a potentially long period of utilization.

Whereas some would define software as solely the code generated from programming language statements in the compilation process, a broader and more precise definition includes requirements, specifications, designs, program listings, documentation, procedures, rules, measurements, and data, as well as the tools and reusables used to create, test, optimize, and implement the software.

That there is more than one definition of software is a direct result of the confusion about the very process of software development itself. A 1991 study by the Software Engineering Institute (SEI) (1991) amplifies this rather startling problem. The SEI developed a methodology for classifying an organization's software process maturity into one of five levels that range from Level 1, the *initial level* (where there is no formalization of the software process), to Level 5, the *optimizing level* where methods, procedures, and metrics are in place with a focus toward continuous improvement in software reliability. The result of this study showed that fully 86% of organizations surveyed in the US were at Level 1 where the terms "ad hoc," "dependent on heroes," and "chaotic" are commonly applied. And, given the complexity of today's applications including those that are internet based, it would not be surprising to see the percentage of Level 1 organizations increase. Adding to the mix are the organizations that think the so called order mandated by some techniques serves only to bring about more chaos, confusion, and complexity; or at least spend many more dollars for what they believe delivers little, no, or negative benefit.

Creating order from this chaos requires an insightful understanding into the component parts of software as well as the development process. Borrowing again from the world of natural science, an entelechy is something complex that emerges when you put a large number of simple objects together. For example, one molecule of water is rather boring in its utter lack of activity. But pour a bunch of these molecules into a glass and you have a ring of ripples on the water's surface. If you combine enough of these molecules together, you wind up with an ocean. So, too, software: by itself, a line of code is a rather simple thing. But combine enough of them together and you wind up with the complexity of a program. Add additional programs and you wind up with a system that can put a person on the moon.

Although the whole is indeed bigger than the sum of its parts, one must still understand those parts if the whole is to work in an orderly and controlled fashion. Like a physical entity, software can "wear" as a result of maintenance, changes in the underlying system and updates made to accommodate the requirements of the ongoing user community. Entropy is a significant phenomenon in software, especially for Level 1 organizations.

Software at the lowest programming level is termed *source code*. This differs from *executable code* (i.e., that which can be executed directly by the hardware to perform one or more specified functions) in that it is written in one or more programming languages and cannot, by itself, be executed by the hardware until it is translated into machine executable code. A programming language is a set of words, letters, numerals, and abbreviated mnemonics, regulated by a specific syntax, used to describe a program (made up of lines of source code) to a computer. There are a wide variety of programming languages, many of them tailored for a specific type of application. C, one of today's more popular programming languages, is used in engineering as well as business environments, whereas object-oriented languages, such as C++ (Stroustrup, 1997) and Java (Gosling et al., 1996), have been gaining acceptance in both of these environments. In fact Java has become a language of choice for internet based applications. In the recent past, engineering applications have often used programming languages such as Fortran, Ada (for government applications) and HAL (for space applications) (Lickly, 1974), while commercial business applications have favored common business oriented language (COBOL). For the most part one finds that in any given organization there are no prescribed rules that dictate which languages are to be used. As one might expect, a wide diversity of languages is being deployed.

The programming language, whether that be C (Harbison, 1997), Java, COBOL, C++, C# or something else, provides the capability to code such logical constructs as that having to do with:

- *User interface*: Provides a mechanism whereby the ultimate end user can input, view, manipulate, and query information contained in an organization's computer systems. Studies have shown that productivity increases dramatically when visual user interfaces are provided. Known as *graphical user interfaces (GUIs)*, each operating system provides its own variation. Some common graphical standards are Motif for Unix (including Linux) systems, Aqua for the Macintosh Operating System and Microsoft Windows for PC-based systems.
- *Model calculations*: Perform the calculations or algorithms (step-by-step procedures for solving a problem) intended by a program, for example, process control, payroll calculations, or a Kalman Filter.

- *Program control*: Exerts control in the form of comparisons, branching, calling other programs, and iteration to carry out the logic of the program.
- *Message processing*: There are several varieties of message processing. Help-message processing is the construct by which the program responds to requests for help from the end user. Error-message processing is the automatic capability of the program to notify and then recover from an error during input, output, calculations, reporting, communications, etc. And, in object-oriented development environments, message processing implies the ability of program objects to pass information to other program objects.
- *Moving data*: Programs store data in a data structure. Data can be moved between data structures within a program; moved from an external database or file to an internal data structure or from user input to a program's internal data structures. Alternatively, data can be moved from an internal data structure to a database or even to the user interface of an end user. Sorting, searching, and formatting are data moving and related operations used to prepare the data for further operations.
- *Database*: A collection of data (objects) or information about a subject or related subjects, or a system (for example, an engine in a truck or a personnel department in an organization). A database can include objects such as forms and reports or a set of facts about the system (for example, the information in the personnel department needed about the employees in the company). A database is organized in such a way as to be easily accessible to computer users. Its data is a representation of facts, concepts, or instructions in a manner suitable for processing by computers. It can be displayed, updated, queried, and printed, and reports can be produced from it. A database can store data in several ways including in a relational, hierarchical, network, or object-oriented format.
- *Data declaration*: Describes the organization of a data structure to the program. An example would be associating a particular data structure with its type (for example, data about a particular employee might be of type person).
- *Object*: A person, place, or thing. An object contains data and a set of operations to manipulate data. When brought to life, it knows things (called *attributes*) and can do things (to change itself or interact with other objects). For example, in a robotics system an object may contain the functions to move its own armature to the right, while it is coordinating with another robot to transfer yet another object. Objects can communicate with each other through a communications medium (e.g., message passing, radio waves, internet).
- *Real time*: A software system that satisfies critical timing requirements. The correctness of the software depends on the results of computation, as well as on the time at which the results are produced. Real-time systems can have varied requirements such as performing a task within a specific deadline and processing data in connection with another process outside of the computer. Applications such as transaction processing, avionics, interactive office management, automobile systems, and video games are examples of real-time systems.
- *Distributed system*: Any system in which a number of independent interconnected processes can cooperate (for example processes on more than one computer). The client/server model is one of the most popular forms of distribution in use today. In this model, a client initiates a distributed activity and a server carries out that activity.
- *Simulation*: The representation of selected characteristics of the behavior of one physical or abstract system by another system. For example, a software program can simulate an airplane, an organization, a computer, or another software program.
- *Documentation*: Includes description of requirements, specification and design; it also includes comments that describe the operation of the program that is stored internally in the program, as well as written or generated documentation that describes how each program within the larger system operates.
- *Tools*: The computer programs used to design, develop, test, analyze, or maintain system designs of another computer program and its documentation. They include code generators, compilers,

editors, *database management systems (DBMS)*, GUI builders, simulators, debuggers, operating systems and software development, and systems engineering tools (some derived or repackaged from earlier tools that were referred to in the nineties as *computer aided software engineering (CASE)* tools), that combine a set of tools, including some of those listed above.

Although the reader should by now understand the dynamics of a line of source code, where that line of source code fits into the superorganism of software is dependent on many variables. This includes the industry the reader hails from as well as the software development paradigm used by the organization.

As a base unit, a line of code can be joined with other lines of code to form many things. In a traditional software environment many lines of code form a program, sometimes referred to as an application program or just plain application. But lines of source code by themselves cannot be executed. First, the source code must be run through a *compiler* to create *object code*. Next, the object code is run through a *linker*, which is used to construct *executable code*. Compilers are programs themselves. Their function is twofold. The compiler first checks the source code for obvious syntax errors and then, if it finds none, creates the object code for a specific operating system. Unix, Linux (a spinoff of Unix), and Windows are all examples of operating systems. An operating system can be thought of as a supervising program that manages the application programs that run under its control. Since operating systems (as well as computer architectures) can be different from each other, compiled source code for one operating system cannot be executed under a different operating system, without a recompilation.

Solving a complex business or engineering problem often requires more than one program. One or more programs that run in tandem to solve a common problem is known collectively as an application system (or system). The more modern technique of object-oriented development dispenses with the notion of the program altogether and replaces it with the concept of an object (Goldberg and Robson, 1983; Meyer and Bobrow, 1992; Stefik and Bobrow, 1985; Stroustrup, 1994).

Where a program can be considered a critical mass of code that performs many functions in the attempt to solve a problem with little consideration for object boundaries, an object is associated with the code to solve a particular set of functions having to do with just that type of object. By combining objects like molecules, it is possible to create more efficient systems than those created by traditional means. Software development becomes a speedier and less error-prone process as well. Since objects can be reused, once tested and implemented, they can be placed in a library for other developers to reuse. The more the objects in the library, the easier and quicker it is to develop new systems. And since the objects being reused have, in theory, already been warranted (i.e., they have been tested and made error free), there is less possibility that object-oriented systems will have major defects.

The process of building programs and/or objects is known as software development, or software engineering. It is composed of a series of steps or phases, collectively referred to as a development life cycle. The phases include (at a bare minimum): an analysis or requirements phase where the business or engineering problem is dissected and understood, a specification phase where decisions are made as to how the requirements will be fulfilled (e.g., deciding what functions are allocated to software and what functions are allocated to hardware); a design phase where everything from the GUI to the database to the algorithms to the output is designed; a programming (or implementation) phase where one or more tools are used to support the manual process of coding or to automatically generate code, a testing (debugging) phase where the code is tested against a business test case and errors in the program are found and corrected, an installation phase where the systems are placed in production, and a maintenance phase where modifications are made to the system. But different people develop systems in different ways. These different paradigms make up the opposing viewpoints of software engineering.

19.2.3 The Nature of Software Engineering

Engineers often use the term systems engineering to refer to the tasks of specifying, designing, and simulating a non-software system such as a bridge or electronic component. Although software may be used for simulation purposes, it is but one part of the systems engineering process. Software engineering, on the other hand, is concerned with the production of nothing but software. In the 1970s industry pundits

began to notice that the cost of producing large-scale systems was growing at a high rate and that many projects were failing or, at the very least, resulting in unreliable products. Dubbed the software crisis, its manifestations were legion, and the most important include

- *Programmer productivity:* In government in the 1980s, an average developer using C was expected to produce only 10 lines of production code per day (an average developer within a commercial organization was expected to produce 30 lines a month); today the benchmark is more like two to five lines a day while at the same time the need is dramatically higher than that, perhaps by several orders of magnitude, ending up with a huge backlog. The National Software Quality Experiment (NSQE) completed a 10-year research project in 2002 that compared the productivity of systems today with that of systems 10 years ago. The assumption at the outset was that the productivity of today's systems would be much higher given all the more "modern" tools including a proliferation of commercial packages and object-oriented languages that are now available; but they were wrong. Not only did the productivity not increase, it decreased (NSQE, 2002). Further NSQE concluded that there would need to be a significant breakout in the way software is designed and developed in order to achieve a factor of 10 reduction in defect rate.

Programmer productivity is dependent on a plethora of vagaries: from expertise to complexity of the problem to be coded to size of the program that is generated (Boehm, 1981). The science of measuring the quality and productivity of the software engineering process is called *metrics*. As in the diverse paradigms in software engineering itself, there are many paradigms of software measurement. Today's metric formulas are complex and often take into consideration the following: cost, time to market, productivity on prior projects, data communications, distributed functions, performance, heavily used configurations, transaction rates, online data entry, end user efficiency, online update, processing complexity, reusability, installation ease, operational ease, and multiplicity of operational sites.

- *Defect removal costs:* The same variables that affect programmer productivity affect the cost of debugging the programs and objects generated by those programmers. It has been observed that the testing and correcting of programs consumes a large share of the overall effort.
- *Development environment:* Development tools and development practices greatly affect the quantity and quality of software. Most of today's design and programming environments contain only a fragment of what is really needed to develop a complete system. Life cycle development environments provide a good example of this phenomena. Most of these tools can be described either as addressing the upper part of the life cycle (i.e., they handle the analysis and design) or the lower part of the life cycle (i.e., they handle code generation). There are few integrated tools on the market (i.e., that seamlessly handle both upper and lower functionalities). There are even fewer tools that add simulation, testing and cross-platform generation to the mix. And it would be hard put to find any tools that seamlessly integrate system design to software development.
- *GUI development:* Developing graphical user interfaces is a difficult and expensive process unless the proper tools are used. The movement of systems from a host-based environment to the workstation PC saw the entry of a plethora of GUI development programs onto the marketplace. But, unfortunately, the vast majority of these GUI-based tools do not have the capability of developing the entire system (i.e., the processing component as opposed to merely the front end). This leads to fragmented and error-prone systems. To be efficient, the GUI builder must be well integrated into the software development environment.

The result of these problems is that most of today's systems require more resources allocated to maintenance than to their original development. Lientz and Swanson (1980) demonstrate that the problem is, in fact, larger than the one originally discerned during the 1970s. Software development is indeed complex and the limitations on what can be produced by teams of software engineers given finite amounts of time, budgeted dollars, and talent have been amply documented (Jones, 1977).

Essentially the many paradigms of software engineering attempt to rectify the causes of declining productivity and quality. Unfortunately this fails because current paradigms treat symptoms rather than

the root problem. In fact, software engineering is itself extremely dependent on both the underlying systems software (for example, the operating systems) and hardware as well as the business environments upon which they sit.

SEI's process maturity grid very accurately pinpoints the root of most of our software development problems. The fact that a full 86% of the organizations studied, remain at the ad hoc or chaotic level indicates that only a few organizations (the remaining 14%) have adopted any formal process for software engineering. Simply put, 86% of all organizations react to a business problem by just writing code. If they do employ a software engineering discipline, in all likelihood, it is one that no longer fits the requirements of the ever evolving business environment.

In the 1970s, the structured methodology was popularized. Although there were variations on the theme (i.e., different versions of the structured technique included the popular Gane/Sarson method and Yourdon method), for the most part, it provided methodology to develop usable systems in an era of batch computing. In those days, on-line systems with even the dumbest of terminals were a radical concept and graphical user interfaces were as unthinkable as the fall of the Berlin Wall.

Although times have changed and today's hardware is a thousand times more powerful than when structured techniques were introduced, this technique still survives. And survives in spite of the fact that the authors of these techniques have moved on to more adaptable paradigms, and more modern software development and systems engineering environments have entered the market.

In 1981 Finkelstein and Martin (Martin, 1981) popularized information engineering for the more commercially oriented users (i.e., those whose problems to be solved tended to be more database centered), which, to this day, is quite popular amongst mainframe developers with an investment in CASE. Information engineering is essentially a refinement of the structured approach. Instead of focusing on the data so preeminent in the structured approach, however, information engineering focuses on the information needs of the entire organization. Here business experts define high-level information models, as well as detailed data models. Ultimately the system is designed from these models.

Both structured and information engineering methodologies have their roots in mainframe-oriented commercial applications. Today's migration to client/server technologies (where the organization's data can be spread across one or more geographically distributed servers while the end-user uses his or her GUI of choice to perform local processing) disables most of the utility of these methodologies. In fact, many issues now surfacing in more commercial applications are not unlike those addressed earlier in the more engineering oriented environments such as tele-communications and avionics. Client/server environments are characterized by their diversity. One organization may store its data on multiple databases, program in several programming languages, and use more than one operating system and, hence, different GUIs. Since software development complexity is increased a hundredfold in this new environment, a better methodology is required. Today's object-oriented techniques solve some of the problem. Given the complexity of client/server, code trapped in programs is not flexible enough to meet the needs of this type of environment. We have already discussed how coding via objects rather than large programs engenders flexibility as well as productivity and quality through reusability. But object-oriented development is a double-edged sword.

While it is true that to master this technique is to provide dramatic increases in productivity, the sad fact of the matter is that object-oriented development, if done inappropriately, can cause problems far greater than problems generated from structured techniques. The reason for this is simple: the stakes are higher. Object-oriented environments are more complex than any other, the business problems chosen to be solved by object-oriented techniques are far more complex than other types of problems, and there are no conventional object-oriented methodologies and corollary tools to help the development team develop systems that are truly reliable. There are many kinds of object orientation. But with this diversity comes some very real risks. As a result, the following developmental issues must be considered before the computer is even turned on.

Integration is a challenge and needs to be considered at the onset. With traditional systems, developers rely on mismatched modeling methods to capture aspects of even a single definition. Whether it be integration of object to object, module to module, phase to phase, or type of application to type of application, the process

can be an arduous one. The mismatch of evolving versions of point products (where a point product is able to be used for developing only an aspect of an application) used in design and development compounds the issue. Integration is usually left to the devices of myriad developers well into development. The resulting system is sometimes hard to understand and objects are difficult to trace. The biggest danger is that there is little correspondence to the real world. Interfaces are often incompatible and errors propagate throughout development. As a result, systems defined in this manner can be ambiguous and just plain incorrect.

Errors need to be minimized. Traditional methods as well as traditional object-oriented methods actually encourage the propagation of errors, such as reuse of unreliable objects with embedded and inherited errors. Internet viruses, worms, packet storms, trojans, and other malicious phenomenon are inexcusable and should be the exception not the rule. To be successful, errors must be eliminated from the very onset of the development process, including in the operating systems and related systems.

Languages need to be more formal. Whereas some languages are formal and others friendly, it is hard to find a language both *formal* and *friendly*. Within environments where more informal languages are used, lack of traceability and an overabundance of interface errors are a common occurrence. Within environments that have more formal languages their application has been found to be impractical for real world systems of any size or complexity. Recently, more modern software requirements languages have been introduced (for example, the Unified Modeling Language, UML (Booch et al., 1999), most of which are informal (or semi-formal); some of these languages were created by “integrating” several languages into one. Unfortunately, the bad comes with the good—often, more of what is not needed and less of what is needed; and since much of the formal part is missing, a common semantics needs to exist to reconcile differences and eliminate redundancies.

Flexibility for change and handling the unpredictable needs to be dealt with up front. Too often it is forgotten that the building of an application must take into account its evolution. In the real world, users change their minds, software development environments change and technologies change. Definitions of requirements in traditional development scenarios concentrate on the application needs of the user, but without consideration of the potential for the user’s needs or environment to change. Porting to a new environment becomes a new development for each new architecture, operating system, database, graphics environment, language, or language configuration. Because of this, critical functionality is often avoided for fear of the unknown, and maintenance, the most risky and expensive part of a system’s life cycle, is left unaccounted for during development. To address these issues, tools and techniques must be used to allow cross technology and changing technology solutions as well as provide for changing and evolving architectures.

The syndrome of locked-in design needs to be eliminated. Often, developers are forced to develop in terms of an implementation technology that does not have an open architecture, such as a specific database schema or a graphical user interface (GUI). Bad enough is to attempt an evolution of such a system; worse yet is to use parts of it as reusables for a system that does not rely on those technologies. Well thought out and formal business practices and their implementation will help to minimize this problem within an organization.

Developers must prepare for parallelism and distributed environments. Often, when it is not known that a system is targeted for a distributed environment, it is first defined and developed for a single processor environment and then changed/redeveloped for a distributed environment—an unproductive use of resources. Parallelism and distribution need to be dealt with at the very start of the project.

Resource allocation should be transparent to the user. Whether or not a system is allocated to distributed, asynchronous, or synchronous processors and whether or not two processors or ten processors are selected; with traditional methods it is still up to the designer and developer to be concerned with manually incorporating such detail into the application. There is no separation between the specification of what the system is to do vs. how the system does it. This results in far too much implementation detail to be included at the level of design. Once such a resource architecture becomes obsolete, it is necessary to redesign and redevelop those applications which have old designs embedded within them.

The creation of reliable reusable definitions must be promoted, especially those that are inherently provided. Traditional requirements definitions lack the facilities to help find, create, use and ensure commonality in systems. Modelers are forced to use informal and manual methods to find ways to divide a system into components natural for reuse. These components do not lend themselves to integration and, as a result,

they tend to be error-prone. Because these systems are not portable or adaptable, there is little incentive for reuse. In conventional methodologies, redundancy becomes a way of doing business. Even when methods are object oriented, developers are often left to their own devices to explicitly make their applications become object oriented; because these methods do not support all that which is inherent in an object.

Automation that minimizes manual work needs to replace “make work” automated solutions. In fact, automation itself is an inherently reusable process. If a system does not exist for reuse, it certainly does not exist for automation. But most of today’s development process is needlessly manual. Today’s systems are defined with insufficient intelligence for automated tools to use them as input. In fact, these automated tools concentrate on supporting the manual process instead of doing the real work. Typically, developers receive definitions that they manually turn into code. A process that could have been mechanized once for reuse is performed manually again and again. Under this scenario, even when automation attempts to do the real work, it is often incomplete across application domains or even within a domain, resulting in incomplete code, such as shell code (code that is an outline for real code). The generated code is often inefficient or hard wired to an architecture, a language, or even a version of a language. Often partial automations need to be integrated with incompatible partial automations or manual processes. Manual processes are needed to complete unfinished automations.

Run-time performance analysis (decisions between algorithms or architectures) should be based on formal definitions. Conventional system definitions contain insufficient information about a system’s run-time performance, including that concerning the decisions between algorithms or architectures. Design decisions where this separation is not taken into account thus depend on analysis of outputs from ad hoc implementations and associated testing scenarios. System definitions must consider how to separate the target system from its target environment.

Design integrity is the first step to usable systems. It is not known if a design is a good one until its implementation has failed or succeeded. Spiral development (an evolutionary approach) as opposed to waterfall development (where each phase of development is completed before the next phase is begun) helps address some of this issue. Usually, a system design is based on short-term considerations because knowledge is not reused from previous lessons learned. Development, ultimately, is driven toward failure.

Once issues like these are addressed, software costs less and takes less time to develop. But, time is of the essence. These issues are becoming more complex and even more critical as developers prepare for the distributed environments that go hand in hand with the increasing predominance of the internet.

Thus far this chapter has explained the derivation of software and attempted to show how it has evolved over time to become the true brains of any automated system. But like a human brain, this software brain must be carefully architected to promote productivity, foster quality, and enforce control and reusability.

Traditional software engineering paradigms fail to see the software development process from the larger perspective of the superorganism described at the beginning of this chapter. It is only when we see the software development process as made up of discrete but well-integrated components, can we begin to develop a methodology that can produce the very benefits that have been promised by the advent of software decades ago.

Software engineering, from this perspective, consists of a methodology as well as a series of tools with which to implement the solution to the business problem at hand. But even before the first tool can be applied, the software engineering methodology must be deployed to assist in specifying the requirements of the problem. How can this be accomplished successfully in the face of the problems outlined? How can it be accomplished in situations where organizations must develop systems that run across diverse and distributed hardware platforms, databases, programming languages, and GUIs when traditional methodologies make no provision for such diversity? And how can software be developed without having to fix or cure those myriad of problems that result “after the fact” of that software’s development?

To address these software issues, an organization has several options, ranging from one extreme to the other. The options include (1) keep doing things the same way; (2) add tools and techniques that support business as usual but provide relief in selected areas; (3) bring in more modern but traditional tools and techniques to replace existing ones; (4) use a new paradigm with the most advanced tools and techniques that formalizes the process of software development, while at the same time capitalizing on

software already developed; or (5) completely start over with a new paradigm that formalizes the process of software development and uses the most advanced tools and techniques.

19.2.4 A New Approach

The typical reaction to the well known problems and challenges of software and its development has been to lament the fact that this is the way software is and to accept it as a *“fait accompli.”* But, such a reaction is unacceptable. What is required is a radical revision of the way we build software—an approach that understands how to build systems using the right techniques at the right time. First and foremost, it is a preventative approach. This means it provides a framework for doing things in the right way the first time. Problems associated with traditional methods of design and development would be prevented “before the fact” just by the way a system is defined. Such an approach would concentrate on preventing problems of development from even happening; rather than letting them happen “after the fact” and fixing them after they have surfaced at the most inopportune and expensive point in time.

Consider such an approach in its application to a human system. To fill a tooth before it reaches the stage of a root canal is curative with respect to the cavity, but preventive with respect to the root canal. Preventing the cavity by proper diet prevents not only the root canal, but the cavity as well. To follow a cavity with a root canal is the most expensive alternative; to fill a cavity on time is the next most expensive; and to prevent these cavities in the first place is the least expensive option. Preventiveness is a relative concept. For any given system, be it human or software, one goal is to prevent, to the greatest extent and as early as possible, anything that could go wrong in the life cycle process.

With a preventative philosophy, systems would be carefully constructed to minimize development problems from the very outset. A system that could be developed with properties that controlled its very own design and development. One result would be reusable systems that promote automation. Each system definition would model both its application and its life cycle with built-in constraints—constraints that protect the developer, but yet do not take away his flexibility.

Such an approach could be used throughout a life cycle, starting with requirements and continuing with functional analysis, simulation, specification, analysis, design, system architecture design, algorithm development, implementation, configuration management, testing, maintenance, and reverse engineering. Its users would include end users, managers, system engineers, software engineers, and test engineers.

With this approach, the same language would be used to define any aspect of any system and integrate it with any other aspect. The crucial point is that these aspects are directly related to the real world and, therefore, the same language would be used to define system requirements, specifications, design, and detailed design for functional, resource, and resource allocation architectures throughout all levels and layers of seamless definition, including hardware, software, and peopleware. The same language would be used to define organizations of people, missile or banking systems, cognitive systems, as well as real-time or database environments and is therefore appropriate across industries, academia, or government.

The philosophy behind preventative systems is that reliable systems are defined in terms of reliable systems. Only reliable systems are used as building blocks, and only reliable systems are used as mechanisms to integrate these building blocks to form a new system. The new system becomes a reusable for building other systems.

Effective reuse is a preventative concept. That is, reusing something (e.g., requirements or code) that contains no errors to obtain a desired functionality avoids both the errors and the cost of developing a new system. It allows one to solve a given problem as early as possible, not at the last moment. But to make a system truly reusable, one must start not from the customary end of a life cycle, during the implementation or maintenance phase, but from the very beginning.

Preventative systems are the true realization of the entelechy construct where molecules of software naturally combine to form a whole, which is much greater than the sum of its parts. Or one can think of constructing systems from the tinker toys of our youth. One recalls that the child never errs in building magnificent structures from these tinkertoys. Indeed, tinker toys are built from blocks that are architected to be perpetually reusable, perfectly integratable, and infinitely user-friendly.

There is at least one approach that follows a preventative philosophy. Although not in the mainstream yet, it has been used successfully by research and “trail blazer” organizations and is now being adopted for more commercial use. With this approach there is the potential for users to design systems and build software with seamless integration, including from systems to software, with: no longer a need for the system designer or system engineer to understand the details of programming languages or operating systems; no interface errors; defect rates reduced by at least a factor of 10; correctness by built-in language properties; unambiguous requirements, specifications, design (removing complexity, chaos and confusion); guarantee of function integrity after implementation; complete traceability and evolvability (application to application, architecture to architecture, technology to technology); maximized reuse; generation of complete software solutions from system specifications (full life cycle automation including 100% production ready code for any kind or size of system); a set of tools, each of which is defined and automatically generated by itself; significantly higher reliability, higher productivity, and lower risk.

Most people would say this is not possible, at least in the foreseeable future. This is because it has not been possible with traditional environments. It is possible, however, in major part, because of a non-traditional systems design and software development paradigm and its associated universal systems language that has been derived and evolved over three decades from an empirical study of the Apollo on-board flight software effort. In addition to experience with Apollo and other real world systems, this paradigm also takes its roots from systems theory, formal methods, formal linguistics, and object technologies. We'll describe this technology and its background in order to illustrate by example the potential that preventative approaches have.

19.2.5 Apollo On-Board Flight Software Effort: Lessons Learned

The original purpose of the empirical study, which had its beginnings in 1968, was to learn from Apollo's flight software and its development in order to make use of this effort for future Apollo missions as well as for the then up and coming Skylab and Shuttle missions. A better way was needed to define and develop software systems than the ones being used and available, because the existing ones (just like the traditional ones today) did not solve the pressing problems. There was a driving desire to learn from experience; what could be done better for future systems and what should the designers and developers keep doing because they were doing it right. The search was in particular for a means to build ultra reliable software.

The results of the study took on multiple dimensions, not just for space missions but for systems in general; some of which were not so readily apparent for many years to come. The Apollo software, given what had to be accomplished and the time within which it had to be accomplished, was as complex as it could get; causing other software projects in the future to look (and be) less daunting than they might have been in comparison. The thought was if problems from a worst case scenario could be solved and simplified, the solutions might be able to be applied to all kinds of systems.

On hindsight, this was an ideal setting from which to understand systems and software and the kinds of problems that can occur and issues that need to be addressed. Because of the nature of the Apollo software there was the opportunity to make just about every kind of error possible, especially since the software was being developed concurrently with the planning of the space missions, the hardware, the simulator, and the training of the astronauts (demonstrating how much the flight software was part of a larger system of other software, hardware and peopleware); and since no one had been to the moon before there were many unknowns. In addition the developers were under the gun with what today would have been unrealistic expectations and schedules. This and what was accomplished (or not accomplished) provided a wealth of information from which to learn. Here are some examples:

It was found during the Apollo study that interface errors (errors resulting from ambiguous relationships, mismatches, conflicts in the system, poor communication, lack of coordination, inability to integrate) accounted for approximately 75% of all the errors found in the software during final testing, the Verification and Validation (V&V) phase (using traditional development methods the figure can be as high as 90%); interface errors include data flow, priority and timing errors from the highest levels of a system to the lowest

levels of a system, to the lowest level of detail. It was also determined that 44% of the errors were found by manual means (suggesting more areas for automation) and that 60% of the errors had unwittingly existed in earlier missions—missions that had already flown, though no errors occurred (made themselves known) during any flights. The fact that this many errors existed in earlier missions was down-right frightening. It meant lives were at stake during every mission that was flown. It meant more needed to be done in the area of reliability. Although no software problem ever occurred (or was known to occur) on any Apollo mission, it was only because of the dedication of the software team and the methods they used to develop and test the software.

A more detailed analysis of interface errors followed; especially since they not only accounted for the majority of errors but they were often the most subtle errors and therefore the hardest to find. The realization was made that integration problems could be solved if interface problems could be solved and if integration problems could be solved, there would be traceability. Each interface error was placed into a category according to the means that could have been taken to prevent it by the very way a system was defined. It was then established that there were ways to prevent certain errors from happening simply by changing the rules of definition. This work led to a theory and methodology for defining a system that would eliminate all interface errors.

It quickly became apparent that everything including software is a system and the issues of system design were one and the same as those of software. Many things contributed to this understanding of what is meant by the concept of “system.” During development of the flight software, once the software group implemented the requirements (“thrown over the wall” by system design experts to the software people), the software people necessarily became the new experts. This phenomenon forced the software experts to become system experts (and vice versa) suggesting that a system was a system whether in the form of higher level algorithms or software that implemented those algorithms.

Everyone learned to always expect the unexpected and this was reflected in every design; that is, they learned to think, plan and design in terms of error detection and recovery, reconfiguration in real time; and to always have backup systems. The recognition of the importance of determining and assigning (and ensuring) unique priorities of processes was established as part of this philosophy. Towards this end it was also established that a “kill and start over again” restart approach to error detection and recovery was far superior as opposed to a “pick up from where you left off” approach; and it simplified both the operation of the software as well as the development and testing of the software. The major impact a system design for one part of the software could have on another part further emphasized that everything involved was part of a system—the “what goes around comes around” syndrome. For example, choosing an asynchronous executive (one where higher priority processes can interrupt lower priority processes) for the flight software not only allowed for more flexibility during the actual flights but it also provided for more flexibility to make a change more safely and in a more modular fashion during development of the flight software.

It became obvious that testing was never over (even with many more levels of testing than with other kinds of applications; and with added testing by independent verification and validation organizations). This prompted a search for better methods of testing. Again, traditional methods were not solving the problem.

With the realization that most of the system design and software development processes could be mechanized (and the same generic processes were being performed throughout each of all phases of development), it became clear they could be automated. This suggested an environment that would do just that, automate what traditional systems still to this day do manually. In addition, for the space missions, software was being developed for many missions all at once and in various stages, leading the way to learn how to successfully perform distributed development.

It was learned during this process of evaluation of space flight software that traditional methods did not support developers in many areas and allowed too much freedom in other areas (such as freedom to make errors, both subtle and serious) and not enough freedom in other areas (such as areas that required an open architecture and the ability to reconfigure in real time to be successful). It further became clear that a new kind of language was needed to define a system having certain “built-in” properties not available in traditional languages; such as inherent reliability, integration, reuse, and open architecture

capabilities provided simply by the use of the language itself. In addition it was realized a set of tools could be developed to support such a language as well as take away tedious mechanical processes that could become automated, thus avoiding even further errors, reducing the need for much after the fact testing. It was only later understood the degree to which systems with “built-in reliability” could increase the productivity in their development, resulting in “built-in productivity.”

Lessons learned from this effort continue today. Key aspects are that systems are asynchronous in nature and this should be reflected inherently in the language used to define systems. Systems should be assumed to be event driven and every function to be applied should have a unique priority; real time event and priority driven behavior should be part of the way one specifies a system in a systems language and not defined on a case by case basis and in different programming languages with special purpose data types.

Rather than having a language whose purpose is to run a machine the language should naturally describe what objects there are and what actions they are taking. Objects are inherently distributed and their interactions asynchronous with real time, event-driven behavior. This implies that one could define a system and its own definition would have the necessary behaviors to characterize natural behavior in terms of real time execution semantics. Application developers would no longer need to explicitly define schedules of when events were to occur. Events would instead occur when objects interact with other objects. By describing the interactions between objects the schedule of events is inherently defined.

The result of this revelation was that a universal systems language could be used to tackle all aspects of a system: its planning, development, deployment, and evolution. This means that all the systems that work together during the system’s lifecycle can be defined and understood using the same semantics.

19.2.6 Development Before the Fact

Once the analysis of the Apollo effort was completed, the next step was to create (and evolve) a new mathematical paradigm from the “heart and soul” of Apollo; one that was preventative instead of curative in its approach. A theory was derived for defining a system such that the entire class of errors, known as interface errors, would be eliminated. The first generation technology derived from this theory concentrated on defining and building reliable systems in terms of functional hierarchies (Hamilton, 1986). Having realized the benefits of addressing one major issue, that is, reliability, just by the way a system is defined, the research effort continued over many years (and still continues) to evolve the philosophy of addressing this issue further as well as addressing other issues the same way, that is, using language mechanisms that inherently eliminate software problems. The result is a new generation technology called development before the fact (DBTF) (see Fig. 19.12) where systems are designed and built with preventative properties integrating all aspects of a system’s definition including the inherent integration of functional and type hierarchical networks, (Hamilton and Hackler, in press; Hamilton, 1994; Hamilton, 1994; Keyes, 2001), <<http://www.htius.com/>>.

Development before the fact is a system oriented object (SOO) approach based on a concept of control that is lacking in other software engineering paradigms. At the base of the theory that embodies every system are a set of axioms—universally recognized truths—and the design for every DBTF system is based on these axioms and on the assumption of a universal set of objects. Each axiom defines a relation of immediate domination. The union of the relations defined by the axioms is control. Among other things, the axioms establish the control relationships of an object for invocation, input and output, input and

FIGURE 19.12 The development-before-the-fact paradigm.

output access rights, error detection and recovery, and ordering during its developmental and operational states. Table 19.1 summarizes some of the properties of objects within these systems.

Combined with further research it became clear that the root problem with traditional approaches is that they support users in “fixing wrong things up rather than in “doing things the right way in the first place.” Instead of testing software to look for errors *after* the software is developed, with the new paradigm, software could now be defined to not allow errors in, in the first place; correctness could be accomplished by the very way software is defined, by “built-in” language properties; what had been created was a universal semantics for defining not just software systems but systems in general.

Once understood, it became clear that the characteristics of good design can be reused by incorporating them into a language for defining any system (not just a software system). The language is a formalism for representing the mathematics of systems. This language—actually a *meta*-language—is the key to DBTF. Its main attribute is to help the designer reduce the complexity and bring clarity into his thinking process, eventually turning it into the ultimate reusable, wisdom, itself. It is a universal systems language for defining systems, each system of which can be incorporated into the meta-language and then used to define other systems. A system defined with this language has properties that come along “for the ride” that in essence control its own destiny. Based on a theory (DBTF) that extends traditional mathematics of systems with a unique concept of control, this formal but friendly language has embodied within it a natural representation of the physics of time and space. 001AXES evolved as DBTF’s formal universal systems language, and the 001 Tool Suite as its automation.

TABLE 19.1 System Oriented Object Properties of Development Before the Fact

Quality	<i>Automation</i>
<i>Reliable</i>	Common definitions
<i>Affordable</i>	natural modularity
	natural separation (e.g., functional architecture from its resource architectures);
Reliable	dumb modules
In control and under control	an object is integrated with respect to structure, behavior and properties of control
Based on a set of axioms	integration in terms of structure and behavior
domain identification (intended, unintended)	type of mechanisms
ordering (priority and timing)	function maps (relate an object’s function to other functions)
access rights: incoming object (or relation), outgoing object (or relation)	object type maps (relate objects to objects)
replacement	structures of functions and types
Formal	category
consistent, logically complete	relativity
necessary and sufficient	instantiation
common semantic base	polymorphism
unique state identification	parent/child
Error free (based on formal definition of “error”)	being/doing
always gets the right answer at the right time and in the right place	having/not having
satisfies users and developers intent	abstraction
<i>Handles the unpredictable</i>	encapsulation
Predictable	replacement
	relation including function
Affordable	typing including classification
<i>Reusable</i>	form including both structure and behavior (for object types and functions)
Optimizes resources in operation and development in minimum time and space with best fit of objects to resources	derivation
	deduction
Reusable	inference
<i>Understandable, integratable and maintainable</i>	inheritance
<i>Flexible</i>	
Follows standards	

(continued)

TABLE 19.1 System Oriented Object Properties of Development Before the Fact (*Continued*)

Handles the unpredictable	Understandable, integratable, and maintainable
Throughout development and operation	<i>Reliable</i>
Without affecting unintended areas	A measurable history
Error detect and recover from the unexpected	Natural correspondence to real world
Interface with, change and reconfigure in asynchronous, distributed, real time environment	persistence, create and delete
	appear and disappear
Flexible	accessibility
Changeable without side effects	reference
Evolvable	assumes existence of objects
Durable	real time and space constraints
<i>Reliable</i>	representation
Extensible	<i>relativity, abstraction, derivation</i>
Ability to break up and put together	Provides user friendly definitions
one object to many: modularity, decomposition, instantiation	recognizes that one user's friendliness is another user's nightmare
many objects to one: composition, applicative Operators, integration, abstraction	hides unnecessary detail (<i>abstraction</i>)
Portable	variable, user selected syntax
secure	self teaching
diverse and changing layered developments	derived from a common semantic base
open architecture (implementation, resource allocation, and execution independence)	common definition mechanisms
plug-in (or be plugged into) or reconfiguration of different modules	Communicates with common semantics to all entities
adaptable for different organizations, applications, functionality, people, products	Defined to be simple as possible but not simpler
Automation	Defined with integration of all of its objects (and all aspects of these objects)
The ultimate form of reusable	Traceability of behavior and structure and their changes (maintenance) throughout its birth, life, and death
Formalize, mechanize, then automate it	Knows and able to reach the state of completion
its development	definition
that which automates its development	development of itself and that which develops it
	analysis
	design
	implementation
	instantiation
	testing
	maintenance

*All italicized words point to a reusable.

The creation of the concept of reuse definition scenarios during Apollo to save time in development and space in the software was a predecessor to the type of higher level language statements used within the systems language. This included horizontal and vertical reuse that led to a flexible open architecture within the DBTF environment.

Understanding the importance of metrics and the influence it could have on future software has had a major focus throughout this endeavor. What this approach represents, in essence, is the current state of a "reusable" originally based on and learned from Apollo followed by that learned from each of its evolving states. It reuses and builds on that which was (and is) observed to have been beneficial to inherit as well as the avoidance of that observed not to have been beneficial. That learned from history was and will continue to be put into practice for future projects. Someone once said "it is never surprising when something developed empirically turns out to have intimate connections with theory." Such is the case with DBTF .

19.2.7 Development Before the Fact Theory

Mathematical approaches have been known to be difficult to understand and use. They have also been known to be limited in their use for nontrivial systems as well as for much of the life cycle of a given system. What makes DBTF different in this respect is that the mathematics it is based on, has been extended for handling the class of systems that software falls into; the formalism along with its unfriendliness is "hidden"

under the covers by language mechanisms derived in terms of that formalism; and the technology based on this formalism has been put to practical use.

With DBTF, all models are defined using its language (and developed using its automated environment) as SOOs. A SOO is understood the same way without ambiguity by all other objects within its environment—including all users, models, and automated tools. Each SOO is made up of other SOOs. Every aspect of a SOO is integrated not the least of which is the integration of its object oriented parts with its function oriented parts and its timing oriented parts. Instead of systems being object-oriented, objects are systems-oriented. All systems are objects. All objects are systems. Because of this, many things heretofore not believed possible with traditional methods are possible, much of what seems counter intuitive with traditional approaches, that tend to be software centric, becomes intuitive with DBTF, which is system centric.

DBTF's automation provides the means to support a system designer or software developer in following its paradigm throughout a system's design or software development life cycle. Take for example, testing. The more a paradigm prevents errors from being made in the first place the less the need for testing and the higher the productivity. Before the fact testing is inherently part of every development step. Most errors are prevented because of that which is inherent or automated.

Unlike a language such as UML or Java that is limited to software, 001AXES is a systems language and as such can be used to state not just software phenomenon but any given system phenomenon. UML is a graphical software specification language. 001AXES is a graphical system specification language. They have different purposes. At some point UML users have to program in some programming language, but 001AXES users do not; a system can be completely specified and automatically generated with all of its functionality, object and timing behavior without a line of code being written. The intent of UML is to run a machine. The intent of 001AXES is to define (and if applicable, execute) a system software or otherwise.

Because 001AXES is a systems language, its semantics is more general than a software language. For example, 001AXES defined systems could run on a computer, person, autonomous robot, or an organization; whereas the content of the types (or classes) in a software language is based on a computer that runs software.

Because 001AXES is systemic in nature it capitalizes upon that which is common to all systems; including software, financial, political, biological, and physical systems. For software the semantics of 001AXES is mapped to appropriate constructs for each of a possible set of underlying programming language implementations. Unlike the DBTF approach, in general these more traditional development approaches emphasize a fragmented approach to the integrated specification of a system and its software, short changing integration and automation in the development process. A more detailed discussion of 001AXES and UML can be found in (Hamilton and Hackler, 2000).

19.2.8 Process

Derived from the combination of steps taken to solve the problems of traditional systems engineering and software development, each DBTF system is defined with built-in quality, built-in productivity and built-in control (like the biological superorganism). The process combines mathematical perfection with engineering precision. Its purpose is to facilitate the "doing things right in the first place" development style, avoiding the "fixing wrong things up" traditional approach. Its automation is developed with the following considerations: error prevention from the early stage of system definition, life cycle control of the system under development, and inherent reuse of highly reliable systems. The development life cycle is divided into a sequence of stages, including: requirements and design modeling by formal specification and analysis; automatic code generation based on consistent and logically complete models; test and execution; and simulation.

The first step is to define a model with the language. This process could be in any phase of the developmental life cycle, including problem analysis, operational scenarios, and design. The model is automatically analyzed to ensure that it was defined properly. This includes static analysis for preventive properties and dynamic analysis for user intent properties. In the next stage, the generic source code generator automatically generates a fully production-ready and fully integrated software implementation for any kind or size of application, consistent with the model, for a selected target environment in the language and architecture of choice. If the selected environment has already been configured, the generator selects that environment directly; otherwise, the generator is first configured for a new language and architecture.

Because of its open architecture, the generator can be configured to reside on any new architecture (or interface to any outside environment), e.g., to a language, communications package, an internet interface, a database package, or an operating system of choice; or it can be configured to interface to the users own legacy code. Once configured for a new environment, an existing system can be automatically regenerated to reside on that new environment. This open architecture approach, which lends itself to true component based development, provides more flexibility to the user when changing requirements or architectures; or when moving from an older technology to a newer one.

It then becomes possible to execute the resulting system. If it is software, the system can undergo testing for further user intent errors. It becomes operational after testing. Application changes are made to the requirements definition—not to the code. Target architecture changes are made to the configuration of the generator environment (which generates one of a possible set of implementations from the model)—not to the code. If the real system is hardware or peopleware, the software system serves as a simulation upon which the real system can be based. Once a system has been developed, the system and the process used to develop it are analyzed to understand how to improve the next round of system development.

Seamless integration is provided throughout from systems to software, requirements to design to code to tests to other requirements and back again; level to level, and layer to layer. The developer is able to trace from requirements to code and back again.

Given an automation that has these capabilities, it should be no surprise that it has been defined with itself and that it continues to automatically generate itself as it evolves with changing architectures and changing technologies. [Table 19.2](#) contains a summary of some of the differences between the more modern preventative paradigm and the traditional approach.

A relatively small set of things is needed to master the concepts behind DBTF. Everything else can be derived, leading to powerful reuse capabilities for building systems. It quickly becomes clear why it is no longer necessary to add features to the language or changes to a developed application in an ad hoc fashion, since each new aspect is ultimately and inherently derived from its mathematical foundations.

Although this approach addresses many of the challenges and solves many of the problems of traditional software environments, it could take time before this paradigm (or one with similar properties) is adopted by the more mainstream users, since it requires a change to the corporate culture. The same has been true in related fields. At the time when the computer was first invented and manual calculators were used for almost every computation; it has been said that it was believed by hardware pioneers like Ken Olson, founder of Digital Equipment Corporation, that there would only be a need for four computers in the world. It took awhile for the idea of computers and what they were capable of to catch on. Such could be the case for a more advanced software paradigm as well. That is, it could take awhile for software to be truly something to manufacture as opposed to being handcrafted as it is in today's traditional development environments.

19.2.9 Select the Right Paradigm and then Automate

Where software engineering fails is in its inability to grasp that not only the right paradigm (out of many paradigms) must be selected, but that the paradigm must be part of an environment that provides an inherent and integrated automated means to solve the problem at hand. What this means is that the paradigm must be coupled with an integrated set of tools with which to implement the results of utilizing the paradigm to design and develop the system. Essentially, the paradigm generates the model and a toolset must be provided to generate the system.

Businesses that expected a big productivity payoff from investing in technology are, in many cases, still waiting to collect. A substantial part of the problem stems from the manner in which organizations are building their automated systems. Although hardware capabilities have increased dramatically, organizations are still mired in the same methodologies that saw the rise of the behemoth mainframes. Obsolete methodologies simply cannot build new systems.

There are other changes as well. Users demand much more functionality and flexibility in their systems. And given the nature of many of the problems to be solved by this new technology, these systems must also be error free.

TABLE 19.2 A Comparison

Traditional (After the Fact)	DBTF (Development Before the Fact)
<i>Integration ad hoc, if at all</i>	<i>Integration</i>
Mismatched methods, objects, phases, products, architectures, applications and environment	Seamless life cycle: methods, objects, phases, products, architectures, applications and environment
System not integrated with software	System integrated with software
Function oriented <i>or</i> object oriented	System oriented objects: integration of function, timing, and object oriented
GUI not integrated with application	GUI integrated with application
Simulation not integrated with software code	Simulation integrated with software code
<i>Behavior uncertain until after delivery</i>	<i>Correctness by built-in language properties</i>
<i>Interface errors abound and infiltrate the system (over 75% of all errors)</i>	<i>No interface errors</i>
Most of those found are found after implementation	All found before implementation
Some found manually	All found by automatic and static analysis
Some found by dynamic runs analysis	
Some never found	Always found
<i>Ambiguous requirements, specifications, designs . . . introduce chaos, confusion and complexity</i>	<i>Unambiguous requirements, specifications, designs . . . remove chaos, confusion and complexity</i>
Informal or semi-formal language	Formal, but friendly language
Different phases, languages and tools	All phases, same language and tools
Different language for other systems than for software	Same language for software, hardware and any other system
<i>No guarantee of function integrity after implementation</i>	<i>Guarantee of function integrity after implementation</i>
<i>Inflexible: Systems not traceable or evolvable</i>	<i>Flexible: Systems traceable and evolvable</i>
Locked in bugs, requirements products, architectures, etc.	Open architecture
Painful transition from legacy	Smooth transition from legacy
Maintenance performed at code level	Maintenance performed at spec level
<i>Reuse not inherent</i>	<i>Inherent Reuse</i>
Reuse is adhoc	Every object a candidate for reuse
Customization and reuse are mutually exclusive	Customization increases the reuse pool
<i>Automation supports manual process instead of doing real work</i>	<i>Automation does real work</i>
Mostly manual: documentation, programming, test generation, traceability, integration	Automatic programming, documentation, test generation, traceability, integration
Limited, incomplete, fragmented, disparate and inefficient	100% code automatically generated for any kind of software
<i>Product x not defined and developed with itself</i>	<i>001 defined with and generated by itself</i>
	#1 in all evaluations
<i>Dollars wasted, error prone systems</i>	<i>Ultra-reliable systems with unprecedented productivity in their development</i>
High risk	Low risk
Not cost effective	10 to 1, 20 to 1, 50 to 1 . . . dollars saved/dollars made
Difficult to meet schedules	Minimum time to complete
Less of what you need and more of what you do not need	No more, no less of what you need

Where the biological superorganism has built-in control mechanisms fostering quality and productivity, up until now, the silicon superorganism has had none. Hence, the productivity paradox. Often, the only way to solve major issues or to survive tough times is through nontraditional paths or innovation. One must create new methods or new environments for using new methods. Innovation for success often starts with a look at mistakes from traditional systems. The first step is to recognize the true root problems, then categorize them according to how they might be prevented. Derivation of practical solutions is a logical next step. Iterations of the process entail looking for new problem areas in terms of the new solution environment and repeating the scenario. That is how DBTF came into being.

With DBTF, all aspects of system design and development are integrated with one systems language and its associated automation. Reuse naturally takes place throughout the life cycle. Objects, no matter how complex, can be reused and integrated. Environment configurations for different kinds of architectures can be reused. A newly developed system can be safely reused to increase even further the productivity of the systems developed with it.

This preventative approach can support a user in addressing many of the challenges presented in today's software development environments. There will, however, always be more to do to capitalize on this technology. That is part of what makes a technology like this so interesting to work with. Because it is based on a different premise or set of assumptions (axioms), a significant number of things can and will change because of it. There is the continuing opportunity for new research projects and new products. Some problems can be solved, because of the language, that could not be solved before. Software development, as we have known it, will never be the same. Many things will no longer need to exist—they, in fact, will be rendered extinct, just as that phenomenon occurs with the process of natural selection in the biological system. Techniques for bridging the gap from one phase of the life cycle to another become obsolete. Techniques for maintaining the source code as a separate process are no longer needed, since the source is automatically generated from the requirements specification. Verification, too, becomes obsolete. Techniques for managing paper documents give way to entering requirements and their changes directly into the requirements specification database. Testing procedures and tools for finding most errors are no longer needed because those errors no longer exist. Tools to support programming as a manual process are no longer needed.

Compared to development using traditional techniques, the productivity of DBTF developed systems has been shown to be significantly greater (DOD, 1992; Krut, 1993; Ouyang, 1995; Keyes, 2000). Upon further analysis, it was discovered that the productivity was greater the larger and more complex the system—the opposite of what one finds with traditional systems development. This is, in part, because of the high degree of DBTF's support of reuse. The larger a system, the more it has the opportunity to capitalize on reuse. As more reuse is employed, productivity *continues* to increase. Measuring productivity becomes a process of relativity—that is, relative to the last system developed.

Capitalizing on reusables within a DBTF environment is an ongoing area of research interest¹ (Hamilton, 2003–2004). An example is understanding the relationship between types of reusables and metrics. This takes into consideration that a reusable can be categorized in many ways. One is according to the manner in which its use saves time (which translates to how it impacts cost and schedules). More intelligent tradeoffs can then be made. The more we know about how some kinds of reusables are used, the more information we have to estimate costs for an overall system. Keep in mind, also, that the traditional methods for estimating time and costs for developing software are no longer valid for estimating systems developed with preventative techniques.

There are other reasons for this higher productivity as well, such as the savings realized and time saved due to tasks and processes that are no longer necessary with the use of this preventative approach. There is less to learn and less to do—less analysis, little or no implementation, less testing, less to manage, less to document, less to maintain, and less to integrate. This is because a major part of these areas has been automated or because of what inherently takes place because of the nature of the formal systems language.

The paradigm shift occurs once a designer realizes that many of the old tools are no longer needed to design and develop a system. For example, with one formal semantic language to define and integrate all aspects of a system, diverse modeling languages (and methodologies for using them), each of which defines only part of a system, are no longer necessary. There is no longer a need to reconcile multiple techniques with semantics that interfere with each other.

¹ An initial investigation of the form of a common software interface for use with common guidance systems under contract to ARES Corporation as a part of its contract with TACOM ARDEC, Mr. Nigel Gray, program manager. Mr. Gray is the originator of the Common Guidance Common Sense (CGCS) and Deeply Integrated Guidance and Navigation “smart munitions” and other military and aerospace system applications. The common software interface for these systems will provide a common means for user programming of the internal mission processor in these systems, independent of the embedded operating system (HTI, 2003–2004)

Software is a relatively young technological field that is still in a constant state of change. Changing from a traditional software environment to a preventative one is like going from the typewriter to the word processor. Whenever there is any major change, there is always the initial overhead needed for learning the new way of doing things. But, as with the word processor, progress begets progress.

In the end, it is the combination of the methodology and the technology that executes it that forms the foundation of successful software. Software is so ingrained in our society that its success or failure will dramatically influence both the operation and the success of businesses and government. For that reason, today's decisions about systems engineering and software development will have far reaching effects.

Collective experience strongly confirms that quality and productivity increase with the increased use of properties of preventative systems. In contrast to the "better late than never" after the fact philosophy, the preventative philosophy is to solve—or possible, prevent—a given problem as early as possible. This means finding a problem statically is better than finding it dynamically. Preventing it by the way a system is defined is even better. Better yet, is not having to define (and build) it at all.

Reusing a reliable system is better than reusing one that is not reliable. Automated reuse is better than manual reuse. Inherent reuse is better than automated reuse. Reuse that can evolve is better than one that cannot evolve. Best of all is reuse that approaches wisdom itself. Then, have the wisdom to use it. One such wisdom is that of applying a common systems paradigm to systems and software, unifying their understanding with a commonly held set of system semantics.

DBTF embodies a preventative systems approach, the language supports its representation, and its automation supports its application and use. Each is evolutionary (in fact, recursively so), with experience feeding the theory, the theory feeding the language, which in turn feeds the automation. All are used, in concert, to design systems and build software. The answer continues to be in the results just as in the biological system and the goal is that the systems of tomorrow will inherit the best of the systems of today.

Defining Terms

Data base management system (DBMS): The computer program that is used to control and provide rapid access to a database. A language is used with the DBMS to control the functions that a DBMS provides. For example, SQL is the language that is used to control all of the functions that a relational architecture based DBMS provides for its users, including data definition, data retrieval, data manipulation, access control, data sharing, and data integrity.

Graphical user interface (GUI): The ultimate user interface, by which the deployed system interfaces with the computer most productively, using visual means. Graphical user interfaces provide a series of intuitive, colorful, and graphical mechanisms which enable the end-user to view, update, and manipulate information.

Formal system: A system defined in terms of a known set of axioms (or assumptions); it is therefore mathematically based (for example, a DBTF system is based on a set of axioms of control). Some of its properties are that it is consistent and logically complete. A system is consistent if it can be shown that no assumption of the system contradicts any other assumption of that system. A system is logically complete if the assumptions of the method completely define a given set of properties. This assures that a model of the method has that set of properties. Other properties of the models defined with the method may not be provable from the method's assumptions. A logically complete system has a semantic basis (i.e., a way of expressing the meaning of that system's objects). In terms of the semantics of a DBTF system, this means it has no interface errors and is unambiguous, contains what is necessary and sufficient, and has a unique state identification.

Interface: A seam between objects, or programs, or systems. It is at this juncture that many errors surface. Software can interface with hardware, humans, and other software.

Methodology: A set of procedures, precepts, and constructs for the construction of software.

Metrics: A series of formulas which measure such things as quality and productivity.

Operating system: A program that manages the application programs that run under its control.

Software architecture: The structure and relationships among the components of software.

19.3 Neural Networks and Fuzzy Systems

Bogdan M. Wilamowski

19.3.1 Neural Networks and Fuzzy Systems

New and better electronic devices have inspired researchers to build intelligent machines operating in a fashion similar to the human nervous system. Fascination with this goal started when McCulloch and Pitts (1943) developed their model of an elementary computing neuron and when Hebb (1949) introduced his *learning rules*. A decade later Rosenblatt (1958) introduced the **perceptron** concept. In the early 1960s Widrow and Holf (1960, 1962) developed intelligent systems such as ADALINE and MADALINE. Nillson (1965) in his book *Learning Machines* summarized many developments of that time. The publication of the Minsky and Paper (1969) book, with some discouraging results, stopped for sometime the fascination with artificial neural networks, and achievements in the mathematical foundation of the **backpropagation** algorithm by Werbos (1974) went unnoticed. The current rapid growth in the area of neural networks started with the Hopfield (1982, 1984) recurrent network, Kohonen (1982) unsupervised training algorithms, and a description of the backpropagation algorithm by Rumelhart et al. (1986).

19.3.2 Neuron cell

A biological neuron is a complicated structure, which receives trains of pulses on hundreds of *excitatory* and *inhibitory* inputs. Those incoming pulses are summed with different weights (averaged) during the time period of *latent summation*. If the summed value is higher than a threshold, then the neuron itself is generating a pulse, which is sent to neighboring neurons. Because incoming pulses are summed with time, the neuron generates a pulse train with a higher frequency for higher positive excitation. In other words, if the value of the summed weighted inputs is higher, the neuron generates pulses more frequently. At the same time, each neuron is characterized by the nonexcitability for a certain time after the firing pulse. This so-called *refractory period* can be more accurately described as a phenomenon where after excitation the threshold value increases to a very high value and then decreases gradually with a certain time constant. The refractory period sets soft upper limits on the frequency of the output pulse train. In the biological neuron, information is sent in the form of frequency modulated pulse trains.

This description of neuron action leads to a very complex neuron model, which is not practical. McCulloch and Pitts (1943) show that even with a very simple neuron model, it is possible to build logic and memory circuits. Furthermore, these simple neurons with thresholds are usually more powerful than typical logic gates used in computers. The McCulloch-Pitts neuron model assumes that incoming and outgoing signals may have only binary values 0 and 1. If incoming signals summed through positive or negative weights have a value larger than threshold, then the neuron output is set to 1. Otherwise, it is set to 0.

$$T = \begin{cases} 1 & \text{if } net \geq T \\ 0 & \text{if } net < T \end{cases} \quad (19.1)$$

where T is the threshold and net value is the weighted sum of all incoming signals

$$net = \sum_{i=1}^n w_i x_i \quad (19.2)$$

FIGURE 19.13 OR, AND, NOT, and MEMORY operations using networks with McCulloch–Pitts neuron model.

FIGURE 19.14 Other logic functions realized with McCulloch–Pitts neuron model.

Examples of McCulloch-Pitts neurons realizing OR, AND, NOT, and MEMORY operations are shown in Fig. 19.13. Note that the structure of OR and AND gates can be identical. With the same structure, other logic functions can be realized, as Fig. 19.14 shows.

The perceptron model has a similar structure. Its input signals, the weights, and the thresholds could have any positive or negative values. Usually, instead of using variable threshold, one additional constant input with a negative or positive weight can be added to each neuron, as Fig. 19.15 shows. In this case, the threshold is always set to be zero and the net value is calculated as

$$net = \sum_{i=1}^n w_i x_i + w_{n+1} \tag{19.3}$$

where w_{n+1} has the same value as the required threshold and the opposite sign. Single-layer perceptrons were successfully used to solve many pattern classification problems. The hard threshold activation functions are given by

$$o = f(net) = \frac{\text{sgn}(net) + 1}{2} = \begin{cases} 1 & \text{if } net \geq 0 \\ 0 & \text{if } net < 0 \end{cases} \tag{19.4}$$

for **unipolar** neurons and

$$o = f(net) = \text{sgn}(net) = \begin{cases} 1 & \text{if } net \geq 0 \\ -1 & \text{if } net < 0 \end{cases} \tag{19.5}$$

for **bipolar** neurons. For these types of neurons, most of the known training algorithms are able to adjust weights only in single-layer networks.

FIGURE 19.15 Threshold implementation with an additional weight and constant input with +1 value: (a) Neuron with threshold T , (b) modified neuron with threshold $T = 0$ and additional weight equal to $-T$.

FIGURE 19.16 Typical activation functions: (a) hard threshold unipolar, (b) hard threshold bipolar, (c) continuous unipolar, (d) continuous bipolar.

Multilayer neural networks usually use continuous activation functions, either unipolar

$$o = f(net) = \frac{1}{1 + \exp(-\lambda net)} \tag{19.6}$$

or bipolar

$$o = f(net) = \tanh(0.5\lambda net) = \frac{2}{1 + \exp(-\lambda net)} - 1 \tag{19.7}$$

These continuous activation functions allow for the gradient-based training of multilayer networks. Typical activation functions are shown in Fig. 19.16. In the case when neurons with additional threshold input are used (Fig. 19.15(b)), the λ parameter can be eliminated from Eqs. (19.6) and (19.7) and the steepness of the neuron response can be controlled by the weight scaling only. Therefore, there is no real need to use neurons with variable gains.

Note, that even neuron models with continuous activation functions are far from an actual biological neuron, which operates with frequency modulated pulse trains.

19.3.3 Feedforward Neural Networks

Feedforward neural networks allow only one directional signal flow. Furthermore, most feedforward neural networks are organized in layers. An example of the three-layer feedforward neural network is shown in Fig. 19.17. This network consists of input nodes, two *hidden layers*, and an output layer.

FIGURE 19.17 An example of the three layer feedforward neural network, which is sometimes known also as the backpropagation network.

FIGURE 19.18 Illustration of the property of linear separation of patterns in the two-dimensional space by a single neuron.

A single neuron is capable of separating input patterns into two categories, and this separation is linear. For example, for the patterns shown in Fig. 19.18, the separation line is crossing x_1 and x_2 axes at points x_{10} and x_{20} . This separation can be achieved with a neuron having the following weights: $w_1 = 1/x_{10}$, $w_2 = 1/x_{20}$, and $w_3 = -1$. In general for n dimensions, the weights are

$$w_i = \frac{1}{x_{i0}} \quad \text{for} \quad w_{n+1} = -1 \tag{19.8}$$

One neuron can divide only linearly separated patterns. To select just one region in n -dimensional input space, more than $n + 1$ neurons should be used. If more input clusters are to be selected, then the number of neurons in the input (hidden) layer should be properly multiplied. If the number of neurons in the input (hidden) layer is not limited, then all classification problems can be solved using the three-layer network. An example of such a neural network, classifying three clusters in the two-dimensional space, is shown in Fig. 19.19. Neurons in the first hidden layer create the separation lines between input clusters. Neurons in the second hidden layer perform the AND operation, as shown in Fig. 19.13(b). Output neurons perform the OR operation as shown in Fig. 19.13(a), for each category. The linear separation property of neurons makes some problems specially difficult for neural networks, such as exclusive OR, parity computation for several bits, or to separate patterns laying on two neighboring spirals.

The feedforward neural network is also used for nonlinear transformation (mapping) of a multidimensional input variable into another multidimensional variable in the output. In theory, any input-output mapping should be possible if the neural network has enough neurons in hidden layers (size of output layer is set by the number of outputs required). In practice, this is not an easy task. Presently, there is no satisfactory method to define how many neurons should be used in hidden layers. Usually, this is found by the trial-and-error method. In general, it is known that if more neurons are used, more complicated

FIGURE 19.19 An example of the three layer neural network with two inputs for classification of three different clusters into one category. This network can be generalized and can be used for solution of all classification problems.

shapes can be mapped. On the other hand, networks with large numbers of neurons lose their ability for generalization, and it is more likely that such networks will also try to map noise supplied to the input.

19.3.4 Learning Algorithms for Neural Networks

Similarly to the biological neurons, the weights in artificial neurons are adjusted during a training procedure. Various learning algorithms were developed, and only a few are suitable for multilayer neuron networks. Some use only local signals in the neurons, others require information from outputs; some require a supervisor who knows what outputs should be for the given patterns, and other unsupervised algorithms need no such information. Common learning rules are described in the following sections.

Hebbian Learning Rule
