THE

ELECTRONICS

H A N D B O O K

SECOND EDITION

Editor-in-Chief
JERRY C. WHITAKER

Taylor & Francis
Taylor & Francis Group

Boca Raton London New York Singapore

A CRC title, part of the Taylor & Francis imprint, a member of the
Taylor & Francis Group, the academic division of T&F Informa plc.

Preface

The first edition of *The Electronics Handbook* was published in 1996. Between then and now, tremendous changes have occurred in electronics engineering. During this same period, the value of *The Electronics Handbook* has been recognized by thousands of readers all over the world, for which the editor and authors are very grateful.

The numerous changes in technology over the past few years have led to the publication of a second edition of *The Electronics Handbook*. This new edition builds upon the solid foundation of fundamental theory and practical applications of the original work. All chapters have been reviewed and updated as needed, and many new chapters have been added to explain new developments in electronics engineering.

The Electronics Handbook is intended for engineers and technicians involved in the design, production, installation, operation, and maintenance of electronic devices and systems. This publication covers a broad range of technologies with emphasis on practical applications. In general, the level of detail provided is limited to that necessary to design electronic systems based on the interconnection of operational elements and devices. References are provided throughout the handbook to direct readers to more detailed information on important subjects.

The purpose of *The Electronics Handbook* is to provide in a single volume a comprehensive reference for the practicing engineer in industry, government, and academia. The book is divided into 23 chapters that encompass the field of electronics. The goal is to provide the most up-to-date reference on subjects ranging from classical devices and circuits to emerging technologies and applications.

The fundamentals of electronics have evolved to include a wide range of knowledge, empirical data, and a broad range of practice. The focus of this handbook is on the key concepts, models, and equations that enable the engineer to analyze, design, and predict the behavior of complex electrical devices, circuits, instruments, and systems. The reader will find the key concepts of each subject defined, described, and illustrated; where appropriate, practical applications are given as well.

The level of conceptual development of each topic is challenging, but tutorial and relatively fundamental. Each chapter is written to enlighten the expert, refresh the knowledge of the experienced engineer, and educate the novice.

The information contained in this work is organized into 23 chapters, building a foundation from theory to materials to components to circuits to applications. The Handbook concludes with important chapters on reliability, safety, and engineering management.

At the conclusion of most chapters of the Handbook are three important entries of particular interest to readers:

- Defining Terms, which identifies key terms applicable to the field and their most common definitions
- References, which lists the papers and other resources used in the development of the chapter
- Further Information, which directs the reader to additional sources of in-depth information on the subject matter

These features, a trademark of the CRC Press Electrical Engineering Handbook Series, are a valuable aid to both experienced and novice engineers.

In a publication as large as this, locating the information desired in a rapid manner is important. Numerous aids are provided in this regard. A complete table of contents is given at the beginning of the book. In addition, an individual table of contents precedes each of the 23 chapters. A comprehensive subject index is also provided.

The Electronics Handbook is designed to provide answers to most inquiries and to direct the reader to further sources and references as needed. It is our hope that this publication will continue to serve you—the reader—with important, useful information for years to come.

Jerry C. Whitaker
Editor-in-Chief

Editor-in-Chief

Jerry C. Whitaker is Vice President of Standards Development at the Advanced Television Systems Committee (ATSC). Whitaker supports the work of the various ATSC technology and implementation committees and assists in the development of ATSC standards, recommended practices, and related documents. The ATSC is an international, nonprofit organization developing voluntary standards for digital television.

Whitaker is a Fellow of the Society of Broadcast Engineers and a Fellow of the Society of Motion Picture and Television Engineers. He is also the author and editor of more than 30 books on technical topics. His current CRC titles include:

- *The RF Transmission Systems Handbook*
- *The Electronic Systems Maintaining Handbook*
- *AC Power Systems Handbook*, 2nd edition
- *The Power Vacuum Tubes Handbook*

Whitaker is the former editorial director and associate publisher of *Broadcast Engineering* and *Video Systems* magazines.

Contents

Chapter 1 Fundamental Electrical Theory 1

1.1	Electromagnetic Spectrum <i>John Norgard</i>	2
1.2	Resonance <i>Michael D. Ciletti</i>	11
1.3	Electroacoustics <i>Eugene T. Patronis, Jr.</i>	20
1.4	Thermal Noise and Other Circuit Noise <i>Barry G. Douglass</i>	30
1.5	Logic Concepts and Design <i>George I. Cohn</i>	40
1.6	Digital Logic and Sequential Logic Circuits <i>George I. Cohn</i>	59
1.7	The Physical Nature of Sound <i>Floyd E. Toole, E. A. G. Shaw, Gilles A. Daigle, and Michel R. Stinson</i>	87
1.8	Principles of Light, Vision, and Photometry <i>Jerry C. Whitaker</i>	97

Chapter 2 Properties of Materials and Components 111

2.1	Circuit Fundamentals <i>John Choma, Jr. and Stuart K. Burgess</i>	112
2.2	Semiconductor Materials <i>Stuart K. Tewksbury</i>	122
2.3	Thermal Properties <i>David F. Besch</i>	144
2.4	Resistive Materials <i>Jan H. Mooij</i>	151
2.5	Magnetic Materials for Inductive Processes <i>Martin R. Parker and William E. Webb</i>	164

2.6	Capacitance and Capacitors <i>Igor M. Filanovsky</i>	175
2.7	Properties of Materials <i>James F. Shackelford</i>	200
2.8	International Standards and Constants	230

Chapter 3 Properties of Passive Components **239**

3.1	Crystal Oscillators <i>Jeffrey P. Tate and Patricia F. Mead</i>	239
3.2	Surface Acoustic Wave (SAW) Devices <i>Ardie D. Walser</i>	254
3.3	Electromechanical Devices <i>C. Sankaran</i>	269
3.4	Aural Pickup Devices <i>Roy W. Rising</i>	276
3.5	Aural Reproduction Devices <i>Michael Starling</i>	285

Chapter 4 Passive Electrical Circuit **309**

4.1	Coaxial Transmission Lines <i>Jerry C. Whitaker</i>	309
4.2	Waveguide <i>Kenneth R. Demarest</i>	319
4.3	Passive Microwave Devices <i>Michael B. Steer</i>	329
4.4	Passive Filters <i>Cecil Harrison</i>	339

Chapter 5 Electron Vacuum Devices **353**

5.1	Electron Tube Fundamentals <i>Clifford D. Ferris</i>	353
5.2	Power Grid Tubes <i>Jerry C. Whitaker</i>	367
5.3	Neutralization Techniques <i>Jerry C. Whitaker</i>	387

5.4	Amplifier Systems	
	<i>Jerry C. Whitaker</i>	397
5.5	Image Capture Devices	
	<i>Steve Epstein</i>	424
5.6	CRT Devices and Displays	
	<i>Jerry C. Whitaker</i>	430
5.7	Projection Systems	
	<i>Jerry C. Whitaker</i>	451

Chapter 6 Microwave Vacuum Devices **475**

6.1	Microwave Power Tubes	
	<i>Jerry C. Whitaker</i>	475
6.2	Klystron	
	<i>Robert R. Weirather</i>	482
6.3	Traveling Wave Tubes	
	<i>Thomas K. Ishii</i>	490
6.4	Other Microwave Vacuum Devices	
	<i>Thomas K. Ishii</i>	506
6.5	Operational Considerations for Microwave Tubes	
	<i>Jerry C. Whitaker</i>	521

Chapter 7 Semiconductor Devices and Circuits **529**

7.1	Semiconductors	
	<i>Sidney Soclof</i>	530
7.2	Bipolar Junction and Junction Field-Effect Transistors	
	<i>Sidney Soclof</i>	533
7.3	Metal-Oxide-Semiconductor Field-Effect Transistor	
	<i>John R. Brews</i>	545
7.4	Image Capture Devices	
	<i>Edward J. Delp, III</i>	558
7.5	Image Display Devices	
	<i>Jerry C. Whitaker</i>	565
7.6	Solid-State Amplifiers	
	<i>Timothy P. Hulick</i>	577
7.7	Operational Amplifiers	
	<i>Peter Aronhime</i>	611

7.8	Applications of Operational Amplifiers <i>Peter Aronhime</i>	641
7.9	Switched-Capacitor Circuits <i>Ezz I. El-Masry</i>	677
7.10	Semiconductor Failure Modes <i>Victor Meeldijk</i>	687

Chapter 8 Microelectronics **707**

8.1	Integrated Circuits <i>Tom Chen</i>	708
8.2	Integrated Circuit Design <i>Samuel O. Agbo and Eugene D. Fabricius</i>	716
8.3	Digital Logic Families <i>Robert J. Feugate, Jr.</i>	739
8.4	Memory Devices <i>Shih-Lien Lu</i>	755
8.5	Microprocessors <i>James G. Cottle</i>	775
8.6	D/A and A/D Converters <i>Susan A. Garrod</i>	784
8.7	Application-Specific Integrated Circuits <i>Constantine N. Anagnostopoulos and Paul P.K. Lee</i>	791
8.8	Digital Filters <i>Jonathon A. Chambers, Sawasd Tantaratana, and Bruce W. Bomar</i>	808
8.9	Multichip Module Technology <i>Paul D. Franzon</i>	832
8.10	Testing of Integrated Circuits <i>Wayne Needham</i>	844
8.11	Integrated Circuit Packages <i>Victor Meeldijk</i>	852

Chapter 9 Optoelectronics **875**

9.1	Optical Fiber <i>Ken A. Chauvin</i>	875
9.2	Fiber Optic Cable <i>Ken A. Chauvin</i>	905
9.3	Optical Transmitters <i>Charles H. Cox, III</i>	936

9.4	Optical Receivers	
	<i>Paul Kit-Lai Yu</i>	964
9.5	Optical System Design	
	<i>David E. Rittenhouse</i>	980

Chapter 10 Power Supplies and Regulation **1013**

10.1	Transformers	
	<i>Sadrul Ula</i>	1014
10.2	Rectifier and Filter Circuits	
	<i>T. S. Kalkur</i>	1026
10.3	Voltage Regulation	
	<i>Melissa S. Mattmuller</i>	1031
10.4	Switching Power Supplies	
	<i>Robert J. Hofinger</i>	1046
10.5	Inverters	
	<i>Ashoka K.S. Bhat</i>	1067
10.6	DC-to-DC Conversion	
	<i>Ashoka K.S. Bhat</i>	1081
10.7	Power Distribution and Control	
	<i>Badrul H. Chowdhury</i>	1094
10.8	Power System Protection Alternatives	
	<i>Jerry C. Whitaker</i>	1115
10.9	Standby Power Systems	
	<i>Jerry C. Whitaker</i>	1157
10.10	Facility Grounding	
	<i>Jerry C. Whitaker</i>	1184
10.11	Batteries	
	<i>Isidor Buchmann</i>	1246

Chapter 11 Packaging Electronic Systems **1259**

11.1	Printed Wiring Boards	
	<i>Ravindranath Kollipara and Vijai K. Tripathi</i>	1259
11.2	Hybrid Microelectronics Technology	
	<i>Jerry E. Sergent</i>	1276
11.3	Surface Mount Technology	
	<i>Glenn R. Blackwell</i>	1297

11.4	Shielding and EMI Considerations <i>Donald White</i>	1316
11.5	Heat Management <i>Zbigniew J. Staszak</i>	1329

Chapter 12 Communication Principles 1353

12.1	Intelligence Coding <i>Leon W. Couch, II</i>	1354
12.2	Amplitude Modulation <i>Robert Kubichek</i>	1368
12.3	Frequency Modulation <i>Ken Seymour</i>	1383
12.4	Pulse Modulation <i>Rodger E. Ziemer</i>	1397
12.5	Digital Modulation <i>Rodger E. Ziemer</i>	1410
12.6	Spread Spectrum Systems <i>Kurt L. Kosbar and William H. Tranter</i>	1434
12.7	Digital Coding Schemes <i>Oktay Alkin</i>	1449
12.8	Audio Compression Techniques <i>Fred Wylie</i>	1456
12.9	Aural Noise Reduction Systems <i>William J.J. Roberts and Yariv Ephraim</i>	1464
12.10	Video Compression Techniques <i>Gopal Lakhani</i>	1473

Chapter 13 Electromagnetic Radiation 1483

13.1	Antenna Principles <i>Pingjuan L. Werner, Anthony J. Ferraro, and Douglas H. Werner</i>	1483
13.2	Radio Wave Propagation <i>Gerhard J. Straub</i>	1516
13.3	Practical Antenna Systems <i>Jerry C. Whitaker</i>	1531
13.4	Combiners and Combining Networks <i>Robert A. Surette</i>	1560

Chapter 14 Information Recording and Storage 1577

14.1	Magnetic Tape	
	<i>David Stafford</i>	1577
14.2	Data Storage Systems	
	<i>Jerry C. Whitaker</i>	1586
14.3	Optical Storage Systems	
	<i>Praveen Asthana</i>	1592
14.4	Error Correction	
	<i>Fabrizio Pollara</i>	1608
14.5	Data Compression	
	<i>Jerome R. Breitenbach</i>	1619

Chapter 15 Wired Communications Systems 1635

15.1	Network Switching Concepts	
	<i>Tsong-Ho Wu</i>	1635
15.2	SONET	
	<i>Brent Allen</i>	1647
15.3	Facsimile Systems	
	<i>Rodger E. Ziemer</i>	1663

Chapter 16 Wireless Communications Systems 1667

16.1	Radio Broadcasting	
	<i>Dennis F. Doelitzsch</i>	1668
16.2	Digital Audio Broadcasting	
	<i>Stanley Salek and Almon H. Clegg</i>	1683
16.3	Audio Interconnection	
	<i>Roy W. Rising</i>	1698
16.4	Television and Video Production Systems	
	<i>Curtis J. Chan</i>	1708
16.5	ATSC Video, Audio, and PSIP Transmission	
	<i>Jerry C. Whitaker</i>	1732
16.6	Propagation Considerations for Mobile Radio Systems	
	<i>Michel D. Yacoub</i>	1757
16.7	Cellular Radio	
	<i>Harry E. Young</i>	1772
16.8	Satellite Communications	
	<i>Daniel F. DiFonzo</i>	1786

Chapter 17 Radar and Radionavigation 1801

17.1	Radar Principles <i>James M. Howell</i>	1801
17.2	Radar System Implementation <i>Melvin L. Belcher, Jr. and James A. Scheer</i>	1820
17.3	Electronic Navigation Systems <i>Benjamin B. Peterson</i>	1847
17.4	Underwater Sonar Systems <i>Sanjay K. Mehta, Clifford G. Carter, and Bernard E. McTaggart</i>	1878
17.5	Electronic Warfare and Countermeasures <i>Robert D. Hayes</i>	1896

Chapter 18 Control and Instrumentation Technology 1915

18.1	Measurement Techniques: Sensors and Transducers <i>Cecil Harrison</i>	1915
18.2	Data Acquisition <i>Edward McConnell and David Jernigan</i>	1938
18.3	Process Dynamics and Control <i>Thomas F. Edgar and Juergen Hahn</i>	1966
18.4	Servo Systems <i>John E. McInroy</i>	1988
18.5	Power Control and Switching <i>Gibson Morris, Jr.</i>	1996

Chapter 19 Computer Systems 2005

19.1	Fundamental Architecture <i>Joy S. Shetler</i>	2006
19.2	Software Design and Development <i>Margaret H. Hamilton</i>	2019
19.3	Neural Networks and Fuzzy Systems <i>Bogdan M. Wilamowski</i>	2039
19.4	Machine Vision <i>David A. Kosiba and Rangachar Kasturi</i>	2063
19.5	A Brief Survey of Speech Enhancement <i>Yariv Ephraim, Hanoch Lev-Ari, and William J.J. Roberts</i>	2088

19.6	Ad Hoc Networks <i>Michel D. Yacoub, Paulo Cardieri, Élvio João Leonardo, and Álvaro Augusto Machado Medeiros</i>	2097
19.7	Network Communication <i>James E. Goldman</i>	2118
19.8	Printing Technologies and Systems <i>John D. Meyer</i>	2145

Chapter 20 Signal Measurement, Analysis, and Testing **2163**

20.1	Audio Frequency Distortion Mechanisms and Analysis <i>Jerry C. Whitaker</i>	2164
20.2	Analog Video Measurements <i>Carl Bentz and Jerry C. Whitaker</i>	2177
20.3	Radio Frequency Distortion Mechanisms and Analysis <i>Samuel O. Agbo</i>	2194
20.4	Oscilloscopes <i>Jerry C. Whitaker</i>	2213
20.5	Spectrum Analysis <i>Jerry C. Whitaker</i>	2221
20.6	Fourier Waveform Analysis <i>Jerry C. Hamann and John W. Pierre</i>	2231
20.7	Digital Test Instruments <i>Jerry C. Whitaker</i>	2243

Chapter 21 Reliability Engineering **2257**

21.1	Probability and Statistics <i>Allan White and Hagbae Kim</i>	2257
21.2	Electronic Hardware Reliability <i>Michael Pecht and Iuliana Bordelon</i>	2281
21.3	Software Reliability <i>Carol Smidts</i>	2292

1.1 Electromagnetic Spectrum

John Norgard

1.1.1 Introduction

The **electromagnetic (EM) spectrum** consists of all forms of EM radiation, for example, EM waves propagating through space, from direct current (DC) to **light** to **gamma rays**. The EM spectrum can be arranged in order of frequency or wavelength into a number of regions, usually wide in extent, within which the EM waves have some specified common characteristics, for example, those characteristics relating to the production or detection of radiation. Note that in this section, specific frequency ranges are called bands; several contiguous frequency bands are called spectrums; and subfrequency ranges within a band are called segments. A common example is the spectrum of the radiant energy in white light, as dispersed by a prism, to produce a rainbow of its constituent colors.

The EM spectrum can be displayed as a function of frequency (or wavelength), as shown schematically in Fig. 1.1. In air, frequency and wavelength are inversely proportional ($f = c/\lambda$). The meter-kilogram-second (MKS) unit of frequency is the hertz (1 Hz = 1 cycle per second); the MKS unit of wavelength is the meter.

Frequency is also measured in the following subunits.

kilohertz	[1 kHz = 10^3 Hz]
megahertz	[1 MHz = 10^6 Hz]
gigahertz	[1 GHz = 10^9 Hz]
terahertz	[1 THz = 10^{12} Hz]

or, for very high frequencies,

electron volt	[1 eV $\sim 2.41 \times 10^{14}$ Hz]
---------------	--------------------------------------

Note that $\mathcal{E} = hf = qV$ where $h = 6.63 \times 10^{-34}$ Js (Planck's constant) and $q = 1.602 \times 10^{-19}$ C.

Wavelength is also measured in the following subunits.

centimeters	[1 cm = 10^{-2} m]
millimeters	[1 mm = 10^{-3} m]
micrometers	[1 μm = 10^{-6} m] (microns)
nanometers	[1 nm = 10^{-9} m]
Ångströms	[1 Å = 10^{-10} m]
picometers	[1 pm = 10^{-12} m]
femtometers	[1 fm = 10^{-15} m]
attometers	[1 am = 10^{-18} m]

1.1.2 Spectral Subregions

In this section, the EM spectrum is divided for convenience into three main subregions: (1) the optical spectrum, (2) the DC to light spectrum, and (3) the light to gamma ray spectrum.

The main subregions of the EM spectrum are now discussed, starting with the optical spectrum and continuing with the DC to light and the light to gamma ray spectrums. Note that the boundaries between

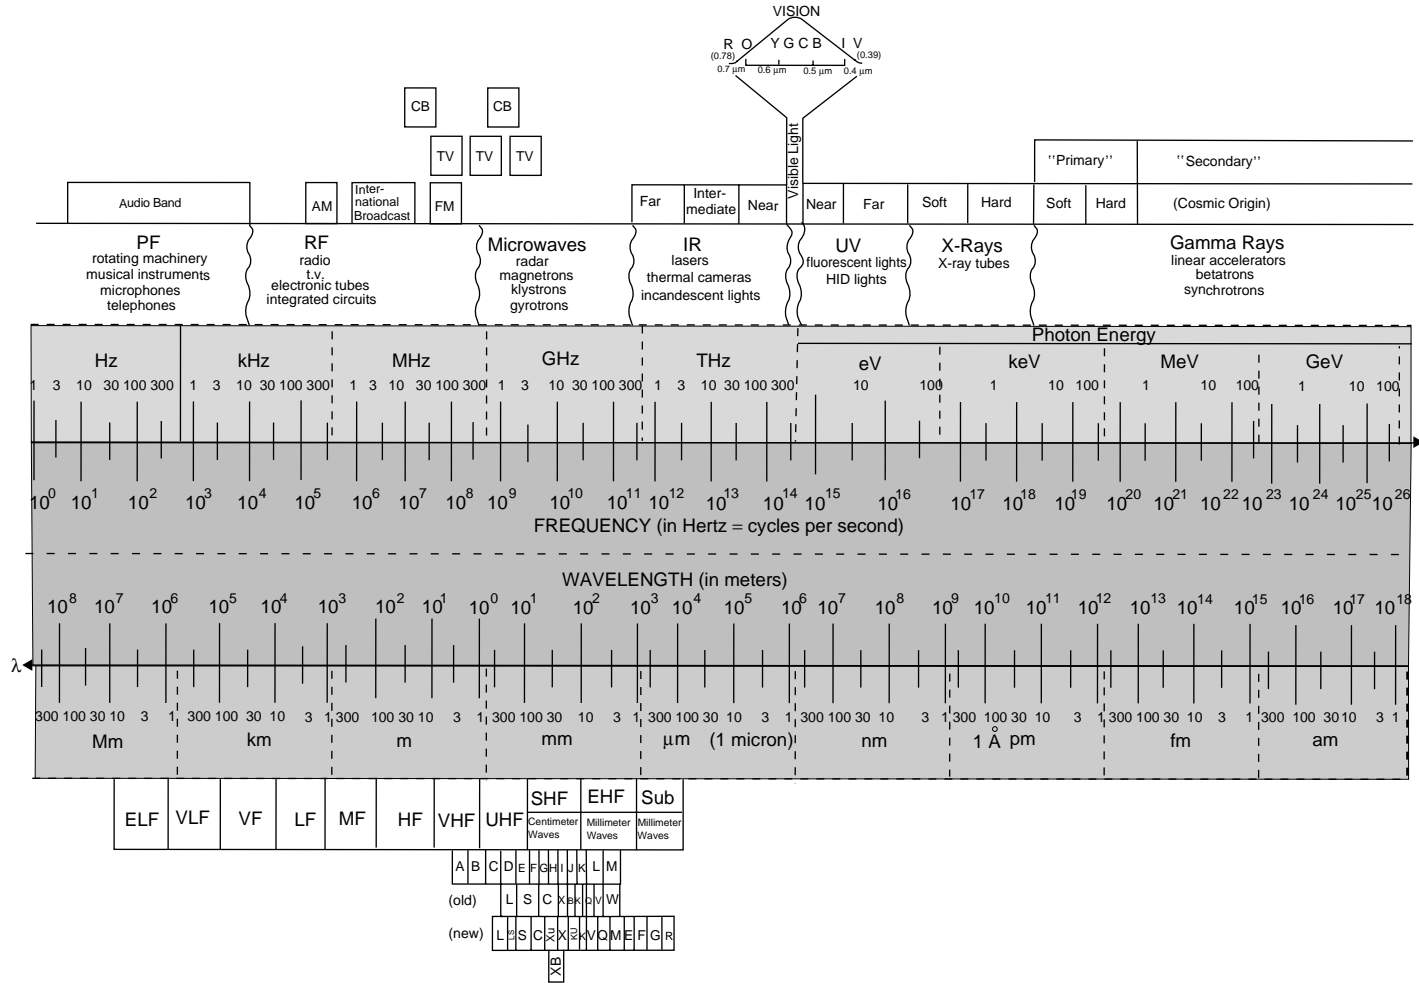

FIGURE 1.1 The electromagnetic spectrum.

some of the spectral regions are somewhat arbitrary. Some spectral bands have no sharp edges and merge into each other, and some spectral sequences overlap each other slightly.

Optical Spectrum

The optical spectrum is the middle frequency/wavelength region of the EM spectrum. It is defined here as the visible and near-visible regions of the EM spectrum and includes the following.

The infrared (IR) spectrum:	1 mm–0.7 μm	(300 GHz–429 THz)
The visible light spectrum:	0.7 μm –0.4 μm	(429 THz–750 THz)
The ultraviolet (UV) spectrum:	0.4 μm –circa 3 nm	(750 THz–circa 300 eV)

These regions of the EM spectrum are usually described in terms of their wavelengths.

Atomic and molecular radiation produce radiant light energy. Molecular radiation and radiation from hot bodies produce EM waves in the IR band. Atomic radiation (outer shell electrons) and radiation from arcs/sparks produce EM waves in the UV band.

Visible Light Spectrum

In the middle of the optical spectrum is the visible light spectrum, extending approximately from 0.4 μm (violet) up to 0.7 μm (red), that is, from 750 THz down to 429 THz. EM radiation in this region of the EM spectrum, when entering the eye, gives rise to visual sensations (colors), according to the spectral response of the eye [the spectral response of the eye is sometimes quoted as extending from 0.38 μm (violet) up to 0.75 or 0.78 μm (red), that is, from 790 THz down to 400 or 385 THz)], which responds only to radiant energy in the visible light band extending from the extreme long wavelength edge of red to the extreme short wavelength edge of violet.

This visible light spectrum is further subdivided into the various colors of the rainbow, namely (in decreasing wavelength/increasing frequency):

red	a primary color; peak intensity at 700.0 nm (429 THz)
orange	
yellow	
green	a primary color; peak intensity at 546.1 nm (549 THz)
cyan	
blue	a primary color; peak intensity at 435.8 nm (688 THz)
indigo	
violet	

IR Spectrum

The IR spectrum is the region of the EM spectrum lying immediately below the visible light spectrum. The IR spectrum consists of EM radiation with wavelengths extending between the longest visible red (circa 0.7 μm) and the shortest microwaves (circa 300–1000 μm , i.e., from 400 THz down to 1 THz–300 GHz).

The IR spectrum is further subdivided into the near, intermediate,* and far IR bands as follows:

1. *Near* IR band: 0.7 μm up to 3 μm (429 THz down to 100 THz)
2. *Intermediate* IR band: 3 μm up to 10 μm (100 THz down to 30 THz)
3. *Far* IR band: 10 μm up to 100 μm (30 THz down to 3 THz)

The submillimeter region of wavelengths is sometimes included in the very far region of the IR band.

4. Submillimeter: 100 μm up to 1 mm (3 THz down to 300 GHz)

EM radiation is produced by oscillating and rotating molecules and atoms. Therefore, all objects at temperatures above absolute zero emit EM radiation by virtue of their thermal motion (warmth) alone.

*Note some reference texts use 2.5 μm (120 THz) as the breakpoint between the near and the intermediate IR bands.

Objects near room temperature emit most of their radiation in the IR band. Even relatively cool objects, however, emit some **IR radiation**; hot objects, such as incandescent filaments, emit strong IR radiation.

IR radiation is sometimes incorrectly called radiant heat, because warm bodies emit IR radiation and bodies that absorb IR radiation are warmed. However, IR radiation is not itself heat. This EM radiation is called black body radiation. Such waves are emitted by all material objects. For example, the background cosmic radiation (2.7 K) emits microwaves; room temperature objects (295 K) emit IR rays; the sun (6000 K) emits yellow light; the solar corona 10^6 K emits **X rays**.

IR astronomy uses the $1\ \mu\text{m}$ –1 mm part of the IR band to study celestial objects by their IR emissions. IR detectors are used in night vision systems, intruder alarm systems, weather forecasting, and missile guidance systems. IR photography uses multilayered color film, with an IR sensitive emulsion in the wavelengths between 700 and 900 nm, for medical and forensic applications and for aerial surveying.

UV Spectrum

The UV spectrum is the region of the EM spectrum lying immediately above the visible light spectrum. The UV spectrum consists of EM radiation with wavelengths extending between the shortest visible violet (circa $0.4\ \mu\text{m}$) and the longest X rays (circa 3 nm), that is, from 750 THz (circa 3 eV) up to 125 eV (some reference texts use 4, 5, or 10 nm as the upper edge of the UV band.)

The UV spectrum is further subdivided into the near and the far UV bands as follows:

<i>Near</i> UV band:	$0.4\ \mu\text{m}$ down to 100 nm	(3 eV up to 10 eV)
<i>Far</i> UV band:	100 nm down to circa 3 nm	(10 eV up to circa 300 eV)

The far UV band is also referred to as the vacuum UV band, since air is opaque to all UV radiation in this region.

UV radiation is produced by electron transitions in atoms and molecules, as in a mercury discharge lamp. UV radiation from the sun causes tanning of the skin. Radiation in the UV range can cause fluorescence in some substances, can produce photographic and ionizing effects, and is easily detected.

In UV astronomy, the emissions of celestial bodies in the wavelength band between 50 and 320 nm are detected and analyzed to study the heavens. The hottest stars emit most of their radiation in the UV band.

DC to Light Spectrum

Below the IR spectrum are the lower frequency (longer wavelength) regions of the EM spectrum, subdivided generally into the following spectral regions (by frequency/wavelength).

<i>Microwave</i> spectrum:	300 GHz down to 300 MHz	(1 mm up to 1 m)
<i>Radio frequency (RF)</i> spectrum:	300 MHz down to 10 kHz	(1 m up to 30 km)
<i>Power/telephony</i> spectrum:	10 kHz down to DC	(30 km up to ∞)

Note that some reference works define the lower edge of the microwave spectrum at 1 GHz. The three regions of the EM spectrum are usually described in terms of their frequencies.

Radiations having wavelengths of the order of millimeters and centimeters are called **microwaves**; those still longer are called **radio waves** (or Hertzian waves).

Radiation from electronic devices produces EM waves in both the microwave and RF bands. Power frequency energy is generated by rotating machinery. Direct current is produced by batteries or rectified alternating current (AC).

Microwave Spectrum

The microwave spectrum is the region of wavelengths lying between the far IR/submillimeter regions and the conventional RF region. The boundaries of the microwave spectrum have not been definitely fixed, but it is commonly regarded as the region of the EM spectrum extending from about 1 mm to 1 m in wavelengths, that is, 300 GHz down to 300 MHz.

The microwave spectrum is further subdivided into the following segments.

<i>Millimeter waves:</i>	300 GHz down to 30 GHz	(1 mm up to 1 cm) extremely high-frequency (EHF) band
<i>Centimeter waves:</i>	30 GHz down to 3 GHz	(1 cm up to 10 cm) super high-frequency (SHF) band

Note that some reference articles consider the top edge of the millimeter region to stop at 100 GHz. The microwave spectrum usually includes the ultra high-frequency (UHF) band from 3 GHz down to 300 MHz (10 cm up to 1 m).

Microwaves are used in radar, in communication links spanning moderate distances, as radio carrier waves in radio broadcasting, for mechanical heating, and cooking in microwave ovens.

Radio Frequency Spectrum

The RF range of the EM spectrum is the wavelength band suitable for utilization in radio communications extending from 10 kHz to 300 MHz (some authors consider the RF band as extending from 10 kHz to 300 GHz, with the microwave band as a subset of the RF band from 300 MHz to 300 GHz.) Some of the radio waves serve as the carriers of the low-frequency audio signals; other radio waves are modulated by video and digital information. The amplitude modulated (AM) broadcasting band uses waves with frequencies between 550 and 1640 kHz; the frequency modulated (FM) broadcasting band uses waves with frequencies between 88 and 108 MHz.

In the U.S., the Federal Communications Commission (FCC) is responsible for assigning a range of frequencies, for example, a frequency band in the RF spectrum, to a broadcasting station or service. The International Telecommunications Union (ITU) coordinates frequency band allocation and cooperation on a worldwide basis.

Radio astronomy uses a radio telescope to receive and study radio waves naturally emitted by objects in space. Radio waves are emitted from hot gases (thermal radiation), from charged particles spiraling in magnetic fields (synchrotron radiation), and from excited atoms and molecules in space (spectral lines), such as the 21-cm line emitted by hydrogen gas.

Power Frequency/Telephone Spectrum

The power frequency (PF) range of the EM spectrum is the wavelength band suitable for generating, transmitting, and consuming low-frequency power, extending from 10 kHz down to DC (zero frequency). In the U.S., most power is generated at 60 Hz (some military applications use 400 Hz); in other countries, for example, in Europe, power is generated at 50 Hz.

Frequency Bands

The combined microwave, RF (Hertzian waves), and power/telephone spectra are subdivided into the following specific bands.

Extremely low-frequency (ELF) band:	30 Hz up to 300 Hz	(10 Mm down to 1 Mm)
Voice-frequency (VF) band:	300 Hz up to 3 kHz	(1 Mm down to 100 km)
Very low-frequency (VLF) band:	3 kHz up to 30 kHz	(100 km down to 10 km)
Low-frequency (LF) band:	30 kHz up to 300 kHz	(10 km down to 1 km)
Medium-frequency (MF) band:	300 kHz up to 3 MHz	(1 km down to 100 m)
High-frequency (HF) band:	3 MHz up to 30 MHz	(100 m down to 10 m)
Very high-frequency (VHF) band:	30 MHz up to 300 MHz	(10 m down to 1 m)
Ultra high-frequency (UHF) band:	300 MHz up to 3 GHz	(1 m down to 10 cm)
Super high-frequency (SHF) band:	3 GHz up to 30 GHz	(1 cm down to 1 cm)
Extremely high-frequency (EHF) band:	30 GHz up to 300 GHz	(1 cm down to 1 mm)

The upper portion of the UHF band, the SHF band, and the lower part of the EHF band are further subdivided into the following bands.

L band:	1 GHz up to 2 GHz	(30 cm down to 15 cm)
S band:	2 GHz up to 4 GHz	(15 cm down to 7.5 cm)
C band:	4 GHz up to 8 GHz	(7.5 cm down to 3.75 cm)
X band:	8 GHz up to 12 GHz	(3.75 cm down to 2.5 cm)
Ku band:	12 GHz up to 18 GHz	(2.5 cm down to 1.67 cm)
K band:	18 GHz up to 26.5 GHz	(1.67 cm down to 1.13 cm)
Ka band:	26.5 GHz up to 40 GHz	(1.13 cm down to 7.5 mm)
Q band:	32 GHz up to 50 GHz	(9.38 mm down to 6 mm)
U band:	40 GHz up to 60 GHz	(7.5 mm down to 5 mm)
V band:	50 GHz up to 75 GHz	(6 mm down to 4 mm)
W band:	75 GHz up to 100 GHz	(4 mm down to 3.33 mm)

An alternate and more detailed subdivision of the UHF, SHF, and EHF bands is as follows:

L band:	1.12 GHz up to 1.7 GHz	(26.8 cm down to 17.6 cm)
LS band:	1.7 GHz up to 2.6 GHz	(17.6 cm down to 11.5 cm)
S band:	2.6 GHz up to 3.95 GHz	(11.5 cm down to 7.59 cm)
C(G) band:	3.95 GHz up to 5.85 GHz	(7.59 cm down to 5.13 cm)
XN(J, XC) band:	5.85 GHz up to 8.2 GHz	(5.13 cm down to 3.66 cm)
XB(H, BL) band:	7.05 GHz up to 10 GHz	(4.26 cm down to 3 cm)
X band:	8.2 GHz up to 12.4 GHz	(3.66 cm down to 2.42 cm)
Ku(P) band:	12.4 GHz up to 18 GHz	(2.42 cm down to 1.67 cm)
K band:	18 GHz up to 26.5 GHz	(1.67 cm down to 1.13 cm)
V(R, Ka) band:	26.5 GHz up to 40 GHz	(1.13 cm down to 7.5 mm)
Q(V) band:	33 GHz up to 50 GHz	(9.09 mm down to 6 mm)
M(W) band:	50 GHz up to 75 GHz	(6 mm down to 4 mm)
E(Y) band:	60 GHz up to 90 GHz	(5 mm down to 3.33 mm)
F(N) band:	90 GHz up to 140 GHz	(3.33 mm down to 2.14 mm)
G(A) band:	140 GHz up to 220 GHz	(2.14 mm down to 1.36 mm)
R band:	220 GHz up to 325 GHz	(1.36 mm down to 0.923 mm)

The upper portion of the VHF band, the UHF and SHF bands, and the lower part of the EHF band have been more recently divided into the following bands.

A band:	100 MHz up to 250 MHz	(3 m down to 1.2 m)
B band:	250 MHz up to 500 MHz	(1.2 m down to 60 cm)
C band:	500 MHz up to 1 GHz	(60 cm down to 30 cm)
D band:	1 GHz up to 2 GHz	(30 cm down to 15 cm)
E band:	2 GHz up to 3 GHz	(15 cm down to 10 cm)
F band:	3 GHz up to 4 GHz	(10 cm down to 7.5 cm)
G band:	4 GHz up to 6 GHz	(7.5 cm down to 5 cm)
H band:	6 GHz up to 8 GHz	(5 cm down to 3.75 cm)
I band:	8 GHz up to 10 GHz	(3.75 cm down to 3 cm)
J band:	10 GHz up to 20 GHz	(3 cm down to 1.5 cm)
K band:	20 GHz up to 40 GHz	(1.5 cm down to 7.5 mm)
L band:	40 GHz up to 60 GHz	(7.5 mm down to 5 mm)
M band:	60 GHz up to 100 GHz	(5 mm down to 3 mm)

Several other frequency bands of interest (not exclusive) are now listed.

In the power spectrum:

Audio band: 10 Hz–10 kHz

In the RF spectrum:

Longwave broadcasting band:	150–290 kHz
AM broadcasting band:	550–1640 kHz (1.640 MHz) (107 Channels, 10-kHz separation)
International broadcasting band:	3–30 MHz
Shortwave broadcasting band:	5.95–26.1 MHz (8 bands)
VHF television (channels 2–4):	54–72 MHz
VHF television (channels 5–6):	76–88 MHz
FM broadcasting band:	88–108 MHz
VHF television (channels 7–13):	174–216 MHz
UHF television (channels 14–83):	470–890 MHz

In the *Microwave* spectrum (up to 40 GHz):

Aeronavigation:	0.96–1.215 GHz
Global positioning system (GPS) down link:	1.2276 GHz
Military communications (COM)/radar:	1.35–1.40 GHz
Miscellaneous COM/radar:	1.40–1.71 GHz
L-band telemetry:	1.435–1.535 GHz
GPS downlink:	1.57 GHz
Military COM (troposcatter/telemetry):	1.71–1.85 GHz
Commercial COM and private line of sight (LOS):	1.85–2.20 GHz
Microwave ovens:	2.45 GHz
Commercial COM/radar:	2.45–2.69 GHz
Instructional television:	2.50–2.69 GHz
Military radar (airport surveillance):	2.70–2.90 GHz
Maritime navigation radar:	2.90–3.10 GHz
Miscellaneous radars:	2.90–3.70 GHz
Commercial C-band satellite (SAT) COM downlink:	3.70–4.20 GHz
Radar altimeter:	4.20–4.40 GHz
Military COM (troposcatter):	4.40–4.99 GHz
Commercial microwave landing system:	5.00–5.25 GHz
Miscellaneous radars:	5.25–5.925 GHz
C-band weather radar:	5.35–5.47 GHz
Commercial C-band SAT COM uplink:	5.925–6.425 GHz
Commercial COM:	6.425–7.125 GHz
Mobile television links:	6.875–7.125 GHz
Military LOS COM:	7.125–7.25 GHz
Military SAT COM downlink:	7.25–7.75 GHz
Military LOS COM:	7.75–7.9 GHz
Military SAT COM uplink:	7.90–8.40 GHz
Miscellaneous radars:	8.50–10.55 GHz
Precision approach radar:	9.00–9.20 GHz
X-band weather radar (and maritime navigation radar):	9.30–9.50 GHz
Police radar:	10.525 GHz
Commercial mobile COM [LOS and electronic news gathering (ENG)]:	10.55–10.68 GHz
Common carrier LOS COM:	10.70–11.70 GHz
Commercial COM:	10.70–13.25 GHz
Commercial Ku-band SAT COM downlink:	11.70–12.20 GHz
Direct broadcast satellite (DBS) downlink and private LOS COM:	12.20–12.70 GHz
ENG and LOS COM:	12.75–13.25 GHz
Miscellaneous radars and SAT COM:	13.25–14.00 GHz
Commercial Ku-band SAT COM uplink:	14.00–14.50 GHz

Military COM (LOS, mobile, and Tactical):	14.50–15.35 GHz
Aeronavigation:	15.40–15.70 GHz
Miscellaneous radars:	15.70–17.70 GHz
DBS uplink:	17.30–17.80 GHz
Common carrier LOS COM:	17.70–19.70 GHz
Commercial COM (SAT COM and LOS):	17.70–20.20 GHz
Private LOS COM:	18.36–19.04 GHz
Military SAT COM:	20.20–21.20 GHz
Miscellaneous COM:	21.20–24.00 GHz
Police radar:	24.15 GHz
Navigation radar:	24.25–25.25 GHz
Military COM:	25.25–27.50 GHz
Commercial COM:	27.50–30.00 GHz
Military SAT COM:	30.00–31.00 GHz
Commercial COM:	31.00–31.20 GHz
Navigation radar:	31.80–33.40 GHz
Miscellaneous radars:	33.40–36.00 GHz
Military COM:	36.00–38.60 GHz
Commercial COM:	38.60–40.00 GHz

Light to Gamma Ray Spectrum

Above the UV spectrum are the higher frequency (shorter wavelength) regions of the EM spectrum, subdivided generally into the following spectral regions (by frequency/wavelength)

X-ray spectrum:	circa 300 eV up to circa 30 keV	(circa 3 nm down to 30 pm)	(circa 1×10^{17} Hz up to 1×10^{19} Hz)
Gamma ray spectrum:	circa 30 keV up to ∞	(30 pm down to 0 m)	(1×10^{19} Hz up to ∞)

These regions of the EM spectrum are usually described in terms of their photon energies in electron volts.

Note that **cosmic rays** (from astronomical sources) are not EM waves (rays) and, therefore, are not part of the EM spectrum. Cosmic rays are high-energy-charged particles (electrons, protons, and ions) of extraterrestrial origin moving through space that may have energies as high as 10^{20} eV. Cosmic rays have been traced to cataclysmic astrophysical/cosmological events, such as exploding stars and black holes. Cosmic rays are emitted by supernova remnants, pulsars, quasars, and radio galaxies. Cosmic rays collide with molecules in the Earth's upper atmosphere producing secondary cosmic rays and gamma rays of high energy. These gamma rays are sometimes called cosmic or secondary gamma rays. Cosmic rays are a useful source of high-energy particles for experiments. They also contribute to the natural background radiation.

Radiation from atomic inner shell excitations produces EM waves in the X-ray spectrum. Radiation from naturally radioactive nuclei produces EM waves in the gamma ray spectrum.

X-Ray Spectrum

The X-ray spectrum is further subdivided into the following segments.

Soft X rays:	circa 300 eV up to 10 keV	(circa 3 nm down to 10 nm)	(circa 1×10^{17} Hz up to 3×10^{18} Hz)
Hard X rays:	10 keV up to circa 30 keV	(10 nm down to circa 30 pm)	(3×10^{18} Hz up to circa 3×10^{19} Hz)

Because the physical nature of these rays was first unknown, this radiation was called X rays. The more powerful X rays are called hard X rays and are of high frequencies and, therefore, are more energetic; less powerful X rays are called soft X rays and have lower energies.

X rays are produced by transitions of electrons in the inner levels of excited atoms or by rapid deceleration of charged particles—Brehmsstrahlung breaking radiation. An important source of X rays is synchrotron radiation. X rays can also be produced when high-energy electrons from a heated filament cathode strike the surface of a target anode (usually tungsten) between which a high alternating voltage (approximately 100 kV) is applied.

X rays are a highly penetrating form of EM radiation and applications of X rays are based on their short wavelengths and their ability to easily pass through matter. X rays are very useful in crystallography for determining crystalline structure and in medicine for photographing the body. Since different parts of the body absorb X rays to a different extent, X rays passing through the body provide a visual image of its interior structure when striking a photographic plate. X rays are dangerous and can destroy living tissue and can cause severe skin burns; however, X rays are useful in the diagnosis and nondestructive testing of products for defects.

Gamma Ray Spectrum

The gamma ray spectrum is subdivided into the following segments.

Primary gamma rays:	circa 30 keV up to 3 MeV	(circa 30 pm down to 300 fm)	(circa 1×10^{19} Hz up to 1×10^{21} Hz)
Secondary gamma rays:	3 MeV up to ∞	(300 fm down to 0 m)	(1×10^{21} Hz up to ∞)

The primary gamma rays are further subdivided into the following segments.

Soft gamma rays:	circa 30 keV up to circa 300 keV	(circa 30 pm down to circa 3 pm)	(circa 1×10^{19} Hz up to circa 1×10^{20} Hz)
Hard gamma rays:	circa 300 keV up to 3 MeV	(circa 3 pm down to 300 fm)	(circa 1×10^{20} Hz up to 1×10^{21} Hz)

Secondary gamma rays are created from collisions of high-energy cosmic rays with particles in the Earth's upper atmosphere.

Gamma rays are essentially very energetic X rays. The distinction between the two is based on their origin. X rays are emitted during atomic processes involving energetic electrons; gamma rays are emitted by excited nuclei or other processes involving subatomic particles.

Gamma rays are emitted by the nucleus of radioactive material during the process of natural radioactive decay as a result of transitions from high-energy excited states to low-energy states in atomic nuclei. Cobalt 90 is a common gamma ray source (with a half-life of 5.26 years). Gamma rays are also produced by the interaction of high-energy electrons with matter. Cosmic gamma rays cannot penetrate the Earth's atmosphere.

Applications of gamma rays are used both in medicine and in industry. In medicine, gamma rays are used for cancer treatment, diagnoses, and prevention. Gamma ray emitting radioisotopes are used as tracers. In industry, gamma rays are used in the inspection of castings, seams, and welds.

Defining Terms

Cosmic rays: Highly penetrating particle rays from outer space. Primary cosmic rays that enter the Earth's upper atmosphere consist mainly of protons. Cosmic rays of low energy have their origin in the sun, those of high energy in galactic or extragalactic space, possibly as a result of supernova explosions. Collisions with atmospheric particles result in secondary cosmic rays (particles) and secondary gamma rays (EM waves).

Electromagnetic spectrum: EM radiant energy arranged in order of frequency or wavelength and divided into regions within which the waves have some common specified characteristics, for example, the waves are generated, received, detected, or recorded in a similar way.

Gamma rays: Electromagnetic radiation of very high energy (greater than 30 keV) emitted after nuclear reactions or by a radioactive atom when its nucleus is left in an excited state after emission of alpha or beta particles.

Infrared (IR) radiation: Electromagnetic radiations having wavelengths in the range, 0.7 nm (the long-wavelength limit of visible red light) to 1 mm (the shortest microwaves). A convenient subdivision is as follows: near, 0.7 μm to 2–5 μm ; intermediate, 2–5 μm to 10 μm ; far, 10 μm to 1 mm.

Light: White light, when split into a spectrum of colors, is composed of a continuous range of merging colors: red, orange, yellow, green, cyan, blue, indigo, and violet.

Microwaves: An electromagnetic wave that has a wavelength between approximately 0.3 cm (or 1 mm) and 30 (or 10) cm, corresponding to frequencies between 1 GHz (or 300 MHz) and 100 (or 300) GHz. Note that there are no well-defined boundaries distinguishing microwaves from infrared and radio and waves.

Radio waves: Electromagnetic radiation suitable for radio transmission in the range of frequencies from about 10 kHz to about 300 MHz.

Ultraviolet (UV) radiation: Electromagnetic radiations having wavelengths in the range from 0.4 nm (the shortest wavelength limit of visible violet light) to 3 nm (the longest X rays). A convenient subdivision is as follows: near, 0.4 μm to 100 nm; far, 100 nm to 3 nm.

X rays: Electromagnetic radiation of short wavelengths (circa 3 nm to 30 pm) produced when cathode rays impinge on matter.

1.2 Resonance

Michael D. Ciletti

1.2.1 Introduction

Resonant circuits play an important role in filters and tuning circuits for communications, radar, and many other electronics systems. In a typical application a resonant circuit is used to tune a radio or television to a particular station while blocking the signals that it receives simultaneously from other stations and sources of signals. Resonant circuits effect a frequency-dependent attenuation of signals, thus passing certain signals and rejecting others, including noise. Widespread use of resonant circuits in consumer, industrial, and defense electronics warrants their study. We will examine resonant circuits from the point of view of their frequency-domain and time-domain properties.

1.2.2 Frequency-Domain Description of Resonance

When a sinusoidal source is applied to a stable linear circuit all of the steady-state node voltages and branch currents in the circuit will be sinusoids having the same frequency as the input. A sinusoidal input signal produces a sinusoidal steady-state output (response). The steady-state response of a given node voltage or branch current, however, may have different amplitude and phase than those of the input signal. This relationship is illustrated by the block diagram in Fig. 1.2, in which the input signal $A_{in} \sin(\omega t + \phi_{in})$ produces a steady-state output signal (i.e., a voltage or current) $y_{ss}(t) = A_{out} \sin(\omega t + \phi_{out})$.

FIGURE 1.2 Input–output relationship for linear circuits in sinusoidal steady state.

In general, when a linear circuit’s input signal is the sinusoid $v_{in}(t) = A_{in} \sin(\omega t + \phi_{in})$ for $t \geq 0$, the steady-state output signal will be a sinusoid described by $y_{ss}(t) = A_{out} \sin(\omega t + \phi_{out})$. The magnitude and phase of the steady-state output signal are related to the magnitude and phase of the circuit’s input sinusoidal signal by

$$A_{out} = A_{in}|H(j\omega)|$$

and

$$\phi_{out} = \phi_{in} + \text{ang}H(j\omega)$$

where $|H(j\omega)|$ denotes the magnitude of the complex-valued s -domain input-output transfer function $H(s)$, and $\text{ang} H(j\omega)$ denotes the angle of $H(s)$, with both quantities evaluated at $s = j\omega$ in the complex plane. It is important to realize that the steady-state output signal will be a scaled and time-shifted copy of the input signal, as depicted in Fig. 1.3. The time t_{ss} denotes the time at which the circuit is considered to be in the steady state. The magnitude of the steady-state output signal $y_{ss}(t)$ is created by scaling the magnitude of the input signal by $|H(j\omega)|$; the phase angle of the steady-state output signal is created by adding the phase angle increment $\theta(j\omega) = \text{ang} H(j\omega)$ to the phase angle of the input signal. The steady-state output signal is translated relative to the input signal on the time axis by an amount $\tau = -\text{ang}H(j\omega)/\omega$.

FIGURE 1.3 Input-output signal relationships.

The relationship between a circuit’s sinusoidal input signal and its steady-state output signal can be represented in the frequency domain by the Bode magnitude and phase responses of the circuit [DeCarlo and Lin, 1995; Irwin 1995]. For example, the capacitor voltage in the simple RC circuit shown in Fig. 1.4 has the Bode magnitude $|H(j\omega)|$ and Bode phase response, $\theta(j\omega)$ shown in Fig. 1.5.

FIGURE 1.4 Three series RC circuit.

The s -domain input-output transfer function $H(s)$ relating the output (capacitor voltage) to the input source voltage in Fig. 1.4 is obtained by using voltage division with the **generalized impedances** (Ciletti, 1988) in the series RC circuit

$$H(s) = Z_C(s)/[Z_R(s) + Z_C(s)]$$

where $Z_C(s) = 1/(sC)$ and $Z_R(s) = R$. Making these substitutions leads to

$$H(s) = 1/(1 + sRC)$$

and

$$H(j\omega) = 1/(1 + j\omega RC)$$

with

$$|H(j\omega)| = 1/\sqrt{1 + \omega^2 R^2 C^2}$$

and

$$\theta(j\omega) = \text{ang}[H(j\omega)] = -\tan^{-1}(\omega RC)$$

(Note: Generalized (s -domain) impedances $Z(s)$ and admittances $Y(s)$ obey the same algebraic laws of series and parallel combination as do resistors, thereby simplifying circuit analysis.)

The Bode magnitude response shown in Fig. 1.5 for the response of the capacitor voltage in the RC circuit in Fig. 1.4 said to be a low-pass response, indicating that sinusoidal sources with low frequencies will be less attenuated in steady state than those with relatively high frequency. In fact, the graph of $|H(j\omega)|$ is considered to be relatively flat for $\omega \leq \omega_c$, with ω_c the so-called cutoff frequency of the filter.

The cutoff frequency of a filter is determined by the value of the circuit's components; here, $\omega_c = 1/(RC)$. The cutoff frequency of a low-pass filter has the significance that a sinusoid signal the frequency of which is outside of the passband of the filter contributes less than 50% of the power to the output than would a DC signal having the same input amplitude. At low frequencies the output signal's amplitude will be a close approximation to that of the input. We note that $|H(j0)| = 1$ and $|H(j\omega_c)| = 0.707$ for this circuit.

FIGURE 1.5 Bode magnitude and phase responses for a simple RC lowpass filter.

1.2.3 Series-Parallel RLC Resonant Filter

A circuit's ability to selectively attenuate signals at certain frequencies is determined by its topology and by the value of its physical components. For certain values of its components, a circuit's Bode magnitude response might be much sharper in shape than for other choices of components. When a circuit's Bode magnitude response exhibits a sharp characteristic the circuit is said to be in **resonance**.

The Bode magnitude response of the simple RC circuit will always have the shape shown in Fig. 1.5 and can never exhibit resonance. On the other hand, the capacitor voltage in the series or parallel RLC circuit shown in Fig. 1.6 has the sharp Bode magnitude response shown in Fig. 1.7 when $R = 10 \Omega$, $L = 1 \text{ H}$, and $C = 1 \text{ F}$ (frequency scaling can be used to obtain more realistic component values for a given cutoff frequency). This circuit is distinguished by its sharp Bode magnitude response and is said to be a resonant circuit. We note, however, that

FIGURE 1.6 Series-parallel resonant RLC circuit.

for other choices of its component values the same circuit might not exhibit the sharp Bode magnitude response that is characteristic of resonance (e.g., $R = 1 \Omega$, $L = 1 \text{ H}$, $C = 1 \text{ F}$). The resonant frequency of this circuit, ω_R , can be shown to be given by $\omega_R = 1/\sqrt{LC}$.

The **transfer function** relating the output voltage (across L and C) to the input voltage of the series/parallel RLC circuit is obtained as follows:

$$\begin{aligned} H(s) &= Z_{LC}(s)/[R + Z_{LC}(s)] \\ &= \{Z_L(s)Z_C(s)/[Z_L(s) + Z_C(s)]\}/\{R + Z_L(s)Z_C(s)/[Z_L(s) + Z_C(s)]\} \\ &= \{(sL)[1/(sC)]/[sL + 1/(sC)]\}/\{R + (sL)[1/(sC)]/[sL + 1/(sC)]\} \\ &= [s/(RC)]/[s^2 + s/(RC) + 1/(LC)] \end{aligned}$$

The utility of the resonant series-parallel circuit is demonstrated by considering the circuit's **steady-state response** to the signal $v_{in}(t) = A_1 \sin(0.5\omega_R t + \phi_1) + A_2 \sin(\omega_R t + \phi_2) + A_3 \sin(2\omega_R t + \phi_3)$. The steady-state output signal will be $y_{ss}(t) = A_1 |H(j0.5\omega_R)| \sin[0.5\omega_R t + \phi_1 + \theta_1(j\omega_R)] + A_2 |H(j\omega_R)| \sin[\omega_R t + \phi_2 + \theta_2(j\omega_R)] + A_3 |H(j2\omega_R)| \sin[2\omega_R t + \phi_3 + \theta_3(j\omega_R)]$, which can be approximated by

$$y_{ss}(t) \simeq A_2 |H(j\omega_R)| \sin[\omega_R t + \phi_2 + \theta_2(j\omega_R)]$$

The steady-state output signal is approximately a scaled and time-translated (phase-shifted) copy of the sinusoidal input signal; it consists primarily of a sinusoidal signal having frequency $\omega = \omega_R$. The components of the input signal at frequencies $0.5\omega_R$ rad/s and $2\omega_R$ rad/s will be effectively filtered by the circuit and make minimal contribution to the output voltage.

1.2.4 The Pole–Zero Pattern Description of Resonance

The pole-zero pattern of the input/output transfer function, $H(s)$, of a circuit is formed by plotting the location of the roots of the polynomials comprising the numerator and denominator of $H(s)$, when $H(s)$ is expressed as a ratio of two polynomials. The roots of the numerator polynomial are called the *zeros* of $H(s)$, and those of the denominator are called the *poles* of $H(s)$. The key relationship is that the location of the poles and zeros in the s plane determine the shape of the Bode magnitude and phase responses of the circuit. Figure 1.8 shows the pole-zero pattern of the resonant series-parallel RLC circuit. The Bode magnitude response is obtained by evaluating $H(s)$ at points $s = j\omega$ on the imaginary axis in the complex plane. The circuit's Bode response will be resonant if it has a pair of complex conjugate poles located relatively close to the imaginary axis in comparison to their distance from the real axis. The presence of the associated pole factors in the denominator of $|H(j\omega)|$ gives rise to the sharp resonant peak feature in the Bode magnitude response. (The distance of the complex poles from the real axis determines the frequency of the circuit's damped frequency of oscillation, and the distance of the pole pair determines the decay factor of the oscillation. The same is true of higher-order circuits having multiple repeated poles located near the j axis.

FIGURE 1.7 Bode magnitude response for a resonant series-parallel RLC circuit.

FIGURE 1.8 Pole-zero pattern of a resonant series-parallel RLC circuit.

1.2.5 Time-Domain Description of Resonance

Time-domain methods are often used to characterize linear circuits, and can also be used to describe resonance. When an electrical circuit exhibits an undamped oscillatory or slightly damped behavior it is said to be in *resonance*, and the waveforms of the voltages and currents in the circuit can oscillate indefinitely.

The response $y(t)$ of a linear circuit to an input signal $u_{in}(t)$ comprises the sum of two parts. The *zero-input response* $y_{ZIR}(t)$ is that part of $y(t)$ due solely to the energy that was stored in the circuit's capacitors and inductors before the input signal was applied. The *zero-state response* $y_{ZSR}(t)$ is the response that the circuit exhibits to the input signal when no energy is initially stored in the circuit. When a circuit has no initial stored energy it is said to be *initially relaxed*. For a linear circuit, $y(t) = y_{ZIR}(t) + y_{ZSR}(t)$, and $y(t)$ is called the *initial state response* of the circuit, denoted by $y_{ISR}(t)$. That is, the response of a linear circuit to an input signal is the sum of its response to its initial stored energy with the circuit's input signal set to zero and its response to the input signal when the circuit is initially relaxed.

The time-domain behavior of the zero-input response of a circuit is related to the frequency-domain property of resonance. In the case of a second-order circuit, its zero-input response will be overdamped, critically damped, or underdamped, depending on the value of the circuit's components. If the components are such that the response is highly underdamped, the circuit is said to be in resonance, and its zero-input response will be oscillatory in nature and will not decay rapidly. The relative proximity of the poles of the circuit's transfer function $H(s)$ to the j axis accounts for this oscillatory behavior. To see this, note that each distinct pair of complex poles in $H(s)$ contributes to $y_{ZIR}(t)$ a term having the following form:

$$y(t) = K e^{-\alpha t} \sin(\omega_d t + \psi).$$

[If $H(s)$ has repeated (multiple) complex poles at the same location, the expression for $y(t)$ also includes a polynomial factor in the variable t .] The damping factor α determines the time constant of the decay of $y(t)$, with $\tau = 1/|\alpha|$, and the damped frequency of oscillation ω_d determines the frequency of the oscillation. When $\omega_d \gg |\alpha|$ the circuit is said to be resonant, and the period of oscillation is small compared to the time constant of decay. The time-domain waveform of the response is said to exhibit ringing. The complex poles associated with ringing are relatively closer to the j axis than to the real axis.

1.2.6 Resonance and Energy Storage in Inductors and Capacitors

The physical phenomena of resonance is due to an exchange of energy between electric and magnetic fields. In passive RLC circuits, the energy can be stored in the electrical field of a capacitor and transferred to the magnetic field of an inductor, and vice versa. In an active circuit, such as an op-amp bandpass filter with no inductors, energy can be exchanged between capacitors.

The energy stored in a capacitor when charged to a voltage v is $W_c = 1/2Cv^2$; the energy stored in an inductor carrying a current i is $W_L = 1/2Li^2$. In a passive RLC circuit, resonance involves an alternating exchange between the inductor current and the capacitor voltage, with inductor current decreasing from a maximum value to a minimum value and capacitor voltage increasing from a minimum value to a maximum value. When this exchange occurs with relatively little dissipation of energy, the circuit is in resonance.

The Ideal Parallel LC Resonant Circuit

The ideal (lossless) LC circuit shown in Fig. 1.9 illustrates the physical nature of resonance in circuits. The circuit is assumed to consist of an ideal inductor and capacitor, that is, the inductor has no associated series resistance and the capacitor has no associated shunt leakage conductance.

In the configuration shown in Fig. 1.9, the capacitor and inductor share a common current and

FIGURE 1.9 Ideal LC resonant circuit.

have the same voltage across their terminals. The capacitor current is described by $i_C = Cdv/dt$, and the inductor voltage is described by $v = Ldi_L/dt$. The circuit topology imposes the condition that $i_L = -i_C$. These three relationships lead to the following differential equation model of the time-domain behavior of the circuit:

$$\frac{d^2v}{dt^2} + \frac{1}{LC}v = 0$$

The solution to this equation is a sinusoidal waveform having the parametric description

$$v(t) = K \sin(\omega t + \phi)$$

This can be verified by substituting the expression for $v(t)$ into the differential equation model and performing the indicated operations. The fact that $v(t)$ can be shown to have this form indicates that it is possible for this circuit to sustain oscillatory voltage and current waveforms indefinitely. When the parametric expression for $v(t)$ is substituted into the differential equation model the value of ω that is compatible with the solution of the equation is revealed to be $\omega = 1/\sqrt{LC}$. This is an example of the important fact that the frequency at which an electrical circuit exhibits resonance is determined by the physical value of its components. The remaining parameters of $v(t)$, K , and ϕ are determined by the initial energy stored in the circuit (i.e., the boundary conditions for the solution to the differential equation model of the behavior of the circuit's voltage).

Let v_0 and i_0 be the initial capacitor voltage and inductor current, respectively, and consider $t = 0^+$. Then the solution for $v(t)$ evaluated at $t = 0^+$ gives

$$v(0^+) = v_0 = K \sin \phi$$

and the capacitor current gives

$$i_C(0^+) = Cdv(0^+)/dt = -i_L(0^+) = -i_0 = C[K\omega \cos(\phi)]$$

These two conditions must be satisfied simultaneously. The values of K and ϕ can be determined by considering three cases of the values of v_0 and i_0 . Case 1: If $v_0 = 0$ then K must be nonzero for a nontrivial solution, and ϕ can be 0 or π . We choose $\phi = 0$ to satisfy the physical condition that $i_0 > 0 \Rightarrow Cdv(0^+)/dt < 0$. Also, $K = -i_0/(C\omega)$. Thus, for this case, $v_C(t) = -i_0/(\omega C) \sin(\omega t)$ and $i_L(t) = i_0 \cos(\omega t)$. The capacitor voltage and the inductor current are 90° out of phase. Case 2: Similarly, if $i_0 = 0$ then $v_C(t) = v_0 \sin(\omega t + \pi/2)$ and $i_L(t) - Cdv/dt = -Cv_0\omega \cos(\omega t + \pi/2) = Cv_0\omega \sin \omega t$. Case 3: When $v_0 \neq 0$ and $i_0 \neq 0$, we get

$$\phi = -\tan^{-1}(\omega C v_0 / i_0)$$

and

$$K = v_0 / \sin \phi$$

Two values of ϕ satisfy the first equation; the value for which the sign of $Cdv(0^+)/dt$ is compatible with the sign of i_0 must be chosen. This leads to the solution for $v(t)$

$$v(t) = \sqrt{[v_0^2 + i_0^2/(\omega^2 C^2)]} \sin(\omega t - \tan^{-1}(\omega C v_0 / i_0))$$

with $\omega = 1/\sqrt{LC}$.

The solution for the waveform of $v(t)$ depends on the initial capacitor voltage and inductor current, that is, the initial energy stored in the circuit's electric and magnetic fields. The exchange of energy between the circuit's electric and magnetic fields is evident from the phase relationship between the capacitor voltage and the inductor current. When the capacitor voltage is at a maximum or minimum value the inductor current is at a minimum or maximum value, and vice versa. When the energy stored in the capacitor's electric field is a maximum or minimum, the energy stored in the inductor's magnetic field is a zero, and vice versa.

The Ideal Series LC Resonant Circuit

The ideal (lossless) series LC section shown in Fig. 1.10 can exhibit resonance when imbedded in a circuit operating at the frequency $\omega = 1/\sqrt{LC}$. To see this, we question whether it is possible for the inductor and capacitor voltages to exactly cancel each other. Consider

FIGURE 1.10 Ideal series LC section.

$$0 = v_L(t) + v_C(t)$$

$$= L di/dt + v_C(t)$$

Taking the derivative and multiplying the terms by the factor C gives

$$0 = LCd^2i/dt + Cdv_C/dt$$

$$0 = LCd^2i/dt + Cdv_C/dt$$

$$0 = LCd^2i/dt + i(t)$$

The parametric form of the solution of this second-order differential equation is $i(t) = K \sin(\omega t + \phi)$, which is the same form that was found for the parallel resonant LC section. Substituting this expression into the equation and canceling terms gives $\omega^2 = 1/(LC)$, or $\omega = 1/\sqrt{LC}$, the frequency at which the cancellation of v_L by v_C occurs. When the series LC section is imbedded in a circuit whose sinusoidal source has the frequency $\omega = 1/\sqrt{LC}$, the steady-state voltage across the section $v_{LC}(t)$ will be zero. The resonant series LC section appears to be a short circuit. This feature can be exploited in a filter whose output voltage is measured as $v_{LC}(t)$ and which must reject a signal at or very near the frequency $\omega = 1/\sqrt{LC}$.

Parallel LC Section Impedance

The utility of the parallel resonant LC section shown in Fig. 1.11 can be understood by examining the impedance that the circuit presents to the circuit in which it is imbedded. We have $Z_{LC}(s) = Z_L Z_C / (Z_L + Z_C) = (s/C) / [s^2 + 1/(LC)]$. $Z_{LC}(s)$ has a pair of poles on the j axis in the s plane. In resonance, the circuit presents infinite impedance (i.e., an open circuit) to the external circuit in which it is imbedded, that is, when the source frequency is $\omega = 1/[\sqrt{LC}]$. The physical consequence of this is that i_{LC} must be zero in the sinusoidal steady state.

FIGURE 1.11 Impedance of a parallel LC section.

When the resonant LC section is imbedded within the circuit shown in Fig. 1.12, and the source frequency is the same as the resonant frequency of the section, the circuit looks like the voltage source is connected to a series circuit consisting of R_i in series with R_0 . All of the current from the source is delivered to the output resistor. At other frequencies, the impedance of the LC section provides a path for current to bypass R_0 . From this we can conclude, without formal proof, that the circuit implements a bandpass Bode magnitude characteristic like that in Fig. 1.7, but with its peak value scaled by voltage division to be $R_0/(R_i + R_0)$.

FIGURE 1.12 Bandpass filter circuit using a resonant LC section.

Parallel LC Bandstop Filter

The parallel LC section has widespread application in a variety of filters. The second-order (i.e., two independent energy storage elements) bandstop filter in Fig. 1.13 exploits the fact that the LC section is capable of blocking all current through it from the external circuit when it is operating at its resonant frequency.

When the frequency of the sinusoidal source, v_{in} , is the same frequency as the resonant frequency of the circuit, the LC section effectively blocks the steady-state flow of current to the load resistor R_0 . This can be confirmed by examining the s -domain transfer function between the source and the load. Using s -domain models for inductor impedance [$Z_L(s) = sL$] and capacitor impedance [$Z_C(s) = 1/(sC)$], we apply Kirchhoff's current and voltage laws to the circuit and, using series/parallel reduction as we would for resistors, find the following expression for $H(s)$:

$$H(s) = V_0(s)/V_{in}(s) = \frac{R_0}{R_i + R_0} \frac{s^2 + \frac{1}{LC}}{s^2 + \frac{s}{(R_i + R_0)C} + \frac{1}{LC}}$$

which fits the generic form of the transfer function for a second-order bandstop filter [Ciletti, 1988]

$$H(s) = \frac{s^2 + \omega_R^2}{s^2 + s\omega_b + \omega_R^2}$$

with $\omega_b = 1/[(R_i + R_0)C]$ and $\omega_R = 1/\sqrt{LC}$. The sharpness of the filter's Bode plot can be described in terms of the *resonant quality factor* $Q = \omega_R/\omega_b$. A large value of Q implies a highly resonant circuit. The pole-zero pattern of the generic second-order bandstop filter with $R_i = 10 \Omega$, $L = 1 \text{ H}$, $C = 1 \text{ F}$, and $R_0 = 1 \Omega$ is shown in Fig. 1.14; it has a pair of zeros located on the j axis in the s domain at $\pm j\omega_R$. The poles of the generic bandstop filter are located at $s = 1/2 - \omega_b \pm j\sqrt{(\omega_b^2 - 4\omega_R^2)}$. When Q is high, the poles are very close to the zeros of $H(s)$ and the filter sharply rejects signals with frequencies near ω_R . A sinusoidal input signal at this frequency is ideally blocked by the filter in the sense that its steady-state output signal will be zero.

The Bode magnitude response of the bandstop filter for $R_i = 10\omega$, $L = 1 \text{ H}$, $C = 1 \text{ F}$, and $R_0 = 1 \Omega$ is shown in Fig. 1.15. It is evident that careful selection of the circuit's component values will result in a selective bandstop filter, one that rejects signals in a very narrowband of frequencies.

The Lossy Parallel LC Bandpass Filter

The circuit shown in Fig. 1.16 is a bandpass filter. It has a physical inductor, that is, one that has a resistance in series with an ideal inductor. The inductor in a physical circuit will always have a resistance in series with an ideal inductor. The presence of the series resistor has the effect of moving the poles of $H(s)$ away from the j axis, thereby preventing the transfer function from exhibiting a perfect open circuit at resonance.

FIGURE 1.13 Bandstop filter using a resonant parallel resonant LC section.

FIGURE 1.14 Pole-zero pattern of a second order bandstop filter.

FIGURE 1.15 Bode magnitude response of a second-order bandstop filter.

This can be verified by deriving the impedance of the lossy parallel LC section: $Z_{LC}(s) = (1/C)(s + r/L)/[s^2 + sr/L + 1/(LC)]$. Note that the denominator of $Z_{LC}(s)$ cannot have poles on the j axis unless $r = 0$. The physical implication of this condition is that $Z_{LC}(s)$ will always have a nonzero value of I_{LC} in steady state, and $Z_{LC}(s)$ cannot behave like an ideal open circuit. In practice, when r is very small the circuit behaves for all practical purposes as an ideal LC section.

FIGURE 1.16 Lossy parallel LC filter.

Active Resonant Bandpass Filter

The op-amp circuit in Fig. 1.17 implements a bandpass filter without inductors. The input-output transfer function of this circuit can be obtained by using Kirchhoff's current law at the node common to R_1 , R_2 , C_1 , and C_2 , and by noting that C_2 and R_3 share a common current. Furthermore, the output voltage appears across R_3 . The transfer function $H(s)$, between the input voltage source and the output node of the filter is given by

FIGURE 1.17 Op-amp bandpass filter.

$$H(s) = \frac{-s/(R_1 C_1)}{s^2 + s\omega_b + \omega_p^2}$$

where $\omega_b = (C_1 + C_2)/(R_3 C_1 C_2)$ and $\omega_p^2 = (R_1 + R_2)/(R_1 R_2 R_3 C_1 C_2)$. The bandwidth of the filter is ω_b and the resonant frequency is ω_p . The design of a sharply resonant (high-Q) active bandpass filter will have $Q \gg 1$.

1.2.7 Physical Hazards with Resonant Circuits

The voltages and currents in a resonant circuit can be very high, and therefore warrant caution. Under the condition of resonance, the circuit in Fig. 1.11 (parallel LC) is such that the LC section looks like an open circuit to the circuit in which it is imbedded. However, the current that circulates between the inductor and the capacitor in the LC section itself can be quite large. This has implications for the size of the conductor that must conduct the resonant current and dissipate heat. Likewise, when the operating conditions of the series LC circuit in Fig. 1.10 place the circuit in resonance, the voltage v_{LC} must be zero, but v_L and v_C can be very large, especially in high-Q circuits, thereby posing a hazard to the careless handler of the circuit.

Defining Terms

Generalized impedance: An s -domain transfer function in which the input signal is current source and the output signal is a voltage in the circuit.

Resonance: A condition in which a circuit exhibits a highly selective frequency-dependent attenuation of sinusoidal input signals.

Steady-state response: The response of a circuit after a sufficient time has elapsed to allow the value of the transient response to become insignificant.

Transfer function: An s -domain function that determines the relationship between an exponential forcing function and the particular solution of a circuit's differential equation model. It also describes a relationship between the Laplace transform s -domain spectral representation of a circuit's input signal and the Laplace transform s -domain spectral description of its output signal when the circuit is initially at rest (no stored energy in its capacitors and inductors) and excited by the source.

1.3 Electroacoustics

Eugene T. Patronis, Jr.

1.3.1 Introduction

The laws of physics when applied to electrical, mechanical, acoustical, or other systems amount to expressions of ordinary or partial differential equations. The work of solving these equations can be tedious, and techniques have been developed over a period of time to both shorten and simplify the procedure in certain classes of problems. In particular, the area of electrical circuit analysis, early on the concept of lumped circuit elements each possessing an impedance property was introduced. This impedance property is the voltage-to-current ratio of the circuit element in question and was identifiable with a corresponding differential operator in the governing differential equation. The representation of each lumped circuit element by its associated impedance in effect converts the differential equation into a simpler algebraic equation. In electroacoustics this electrical circuit analysis technique is extended to include mechanical as well as acoustical circuit elements. There remain, however, certain situations in which this approach is not viable such as extended or distributed systems whose dimensions are comparable to or exceed the sound wavelength and those systems involving distant radiation phenomena. These systems must be handled by a more traditional approach. Some of the more important results of the most basic of these systems will be presented, first in a form that leads naturally to a completion of the description employing the techniques of electroacoustics.

1.3.2 Linear Acoustics

The equations of linear acoustics stem from Euler's equations for a perfect compressible fluid.

Newton's second law

$$\rho_0 \frac{\partial \mathbf{u}}{\partial t} + \nabla p = 0$$

Conservation of mass

$$\frac{\partial \rho}{\partial t} + \rho_0 \nabla \cdot \mathbf{u} = 0$$

from which we find the wave equations

$$\frac{\partial^2 p}{\partial t^2} = c^2 \nabla^2 p$$

$$\frac{\partial^2 \rho}{\partial t^2} = c^2 \nabla^2 \rho$$

$$\frac{\partial^2 \varphi}{\partial t^2} = c^2 \nabla^2 \varphi$$

where

$$\mathbf{u} = -\nabla \varphi \quad c^2 = \left(\frac{dp}{d\rho} \right)_0$$

When the fluid medium is air, the dependent variables in these equations are:

- p = **acoustic pressure**, which is the variation above or below static atmospheric pressure, Pa
- ρ = air density where ρ_0 is the static air density, kgm/m^3
- u = air particle velocity, m/s
- φ = scalar potential function from which the vector particle velocity is derivable, m^2/s
- c = sound phase velocity, m/s

1.3.3 Radiation Models

The classic starting point for treating acoustic radiation is the pulsating sphere of nominal radius a and surface area S that is alternately expanding and contracting such that the velocity of the spherical surface is directed along radial lines and has a sinusoidal dependence on the time such that $u = u_m \cos(\omega t)$, where u is the instantaneous surface velocity (m/s), u_m the surface velocity amplitude (m/s), and ω the angular frequency (rad/s). The wave equation can be solved quite readily for this simple geometry. Additionally, if the nominal radius of the sphere, a , is small compared with the wavelength, $a < l$, and the observation point is very distant from the center of the sphere, $r \gg l$, the radiation is isotropic with the acoustic pressure varying inversely with the radial distance r , as depicted in Fig. 1.18. In Fig. 1.18, p represents the acoustic pressure phasor at the observation point, except that the phase lag associated with wave propagation along the path from the source has been omitted. In addition to the pulsating sphere, Fig. 1.18 displays the results for an acoustic dipole composed of two identical pulsating spheres arranged so that

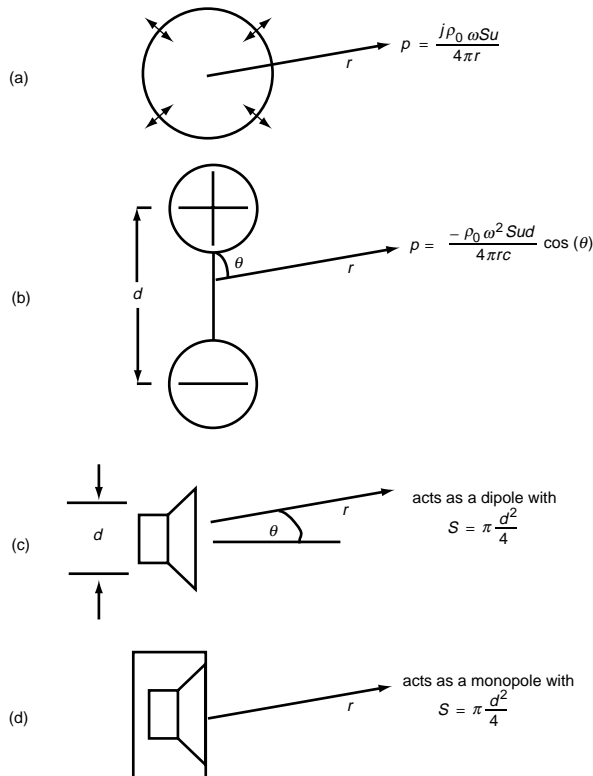

FIGURE 1.18 Radiation models: (a) pulsating sphere [acoustic monopole], (b) two out of polarity pulsation spheres [acoustic dipole], (c) bare loudspeaker, (d) back enclosed loudspeaker.

when one sphere expands the other contracts by an equal amount. Two practical sound sources and their properties at low frequencies are also displayed in Fig. 1.18. In each instance it is found that the acoustic pressure is directly proportional to the surface velocity of the radiator whether it be a theoretical sphere or a loudspeaker diaphragm. Attention will now be turned to a determination of this surface velocity for a typical loudspeaker structure.

1.3.4 Dynamic Low-Frequency Loudspeaker

Analysis will be made of a low-frequency transducer of the conventional type that consists of a piston in the form of a truncated cone of some lightweight but hopefully rigid material flush mounted in a sealed cabinet and arranged to radiate into a half-space. Half-space radiation doubles the acoustic pressure for a given velocity and is assumed because such devices are usually positioned close to at least one large plane surface such as a floor. To describe the piston motion and its subsequent radiation, knowledge is required not only of the acoustical behavior of the device but also of its purely mechanical and electrical properties as well. Figure 1.19 illustrates in a simplified form the features of the device construction that impact on its motional behavior.

The voice coil is a helical spiral of wire wound on a hollow cylinder with the entire assembly attached to the cone, which acts as a piston. The magnetic structure is arranged such that the magnetic flux passes radially through the cylindrical surface about which the voice coil is wound. This is achieved by having a permanent magnet attached to a cylindrical pole piece that is placed within and concentric with the voice coil former. A cylindrically symmetric magnetic return path straddles the outer surface of the voice coil such that the voice coil resides symmetrically in the magnetic air gap. The *spider* centers the voice coil within the magnetic gap whereas the *surround* centers the base of the cone in the overall supporting frame. Both the spider and the surround constitute the system suspension and behave as linear springs by supplying mechanical restoring force whenever the cone is displaced from its equilibrium position. Each of these elements contribute to the overall moving mass of the system and the suspension components additionally contribute mechanical friction that is dependent on the velocity of the moving system.

It is convenient to collect the pertinent factors and symbols together for ready reference, and this is done in Table 1.1.

The driving force experienced by the cone results from the interaction of the current in the voice coil conductor with the magnetic induction in the gap where the voice coil resides. This is an axially directed

FIGURE 1.19 Simplified loudspeaker construction.

TABLE 1.1 Loudspeaker Descriptive Factors

Factor Description	Symbol	Typical Value
Piston radius, m	a	0.10
Piston area, m^2	$S = \pi a^2$	0.0314
Mechanical moving mass, kgm	M	0.03
Suspension stiffness, N/m	K	3000
Suspension resistance, kgm/s	R_m	2.5
Electrical voice coil resistance, Ω	R_e	6
Electrical voice coil inductance, H	L_e	0.001
Magnetic induction in gap, T	B	1
Length of conductor in gap, m	l	10
Instantaneous voice coil current, A	i	
Enclosure interior air volume, m^3	V_0	0.045

force given by Bli . A restriction to sinusoidal time-dependent currents will greatly simplify the analysis without loss of generality. In this way time will enter as $e^{j\omega t}$, actually as the real part of $e^{j\omega t}$, and because the system is linear, differentiation with respect to time is replaced by multiplication by $j\omega$ and integration with respect to time is replaced by division by $j\omega$. Newton's second law of motion, which equates acceleration to the totality of forces divided by the moving mass, can now be written

$$j\omega u = F_t/M$$

where

- u = piston velocity, m/s
- F_t = total force acting on piston, N
- M = total moving mass, kgm

It is necessary at this point to delineate the individual forces acting on the piston.

Aside from the applied force F_a of the voice coil current, the piston experiences a restoring force F_s from the suspension whenever the piston is displaced from its equilibrium position, a frictional force F_f resulting from flexure of the spider and surround whenever the piston is in motion, a restoring force F_b resulting from compression or rarefaction of the air trapped in the sealed cabinet behind the loudspeaker cone whenever the piston is displaced from its equilibrium position, and a force of radiation F_r exerted by the air in front of the piston whenever the piston is moving so as to generate sound waves in the air. Table 1.2 collects all of these forces and indicates their relationship to the piston velocity which is to be considered the dependent variable in the following analysis.

TABLE 1.2 Forces Acting on Loudspeaker Cone

Force	Origin	Value
F_a	Applied	Bli
F_s	Suspension	$\frac{-Ku}{j\omega}$
F_b	Air in box	$\frac{-\rho_0 c^2 S^2 u}{V_0 j\omega}$
F_f	Motional friction	$-R_m u$
F_r	Radiation	$-\rho_0 c S \left[R_1 \left(\frac{2\omega a}{c} \right) + jX_1 \left(\frac{2\omega a}{c} \right) \right] u$

Source: Kinsler, L.E. and Frey, A.R. 1962. *Fundamentals of Acoustics*. Wiley, New York.

FIGURE 1.20 Equivalent circuit for an acoustical system.

It is now possible to write the equation of motion as a statement of Newton’s second law in the form

$$Mj\omega u = Bli - \frac{Ku}{j\omega} - \frac{\rho_0 c^2 S^2 u}{V_0 j\omega} - R_m u - \rho_0 c S \left[R_1 \left(\frac{2\omega a}{c} \right) + jX_1 \left(\frac{2\omega a}{c} \right) \right] u \quad (1.1)$$

The negative terms in this equation are forces that are oppositely directed to the piston velocity and, hence, oppose the motion. The term representing the force on the piston resulting from radiation is obscure and will be discussed later. For the moment, it is necessary to solve this equation for the piston velocity to obtain

$$u = \frac{Bli}{R_m + \rho_0 c S R_1 \left(\frac{2\omega a}{c} \right) + j \left[\omega M + \rho_0 c S X_1 \left(\frac{2\omega a}{c} \right) - \frac{K}{\omega} - \frac{\rho_0 c^2 S^2}{V_0 \omega} \right]} \quad (1.2)$$

or

$$u = \frac{Bli}{Z_m} \quad (1.3)$$

At this point it is possible to draw an analogy with an electrical system. In the electrical case the current is the ratio of the applied voltage to the complex circuit impedance. In this instance, if the velocity is identified with electrical current and the applied force with the applied voltage, the denominator of the velocity equation should be identified as a complex **mechanical impedance**. Additionally, in an electrical circuit consisting of several elements connected in series, the current is common to all elements and the applied voltage exists across series combination. In this mechanical circuit the velocity is the same for the voice coil, suspension, cone, and the air, and the force F_a exists across the combination. A possible analogous mechanical circuit thus appears as given in Fig. 1.20.

In Fig. 1.20 the positive mechanical reactances are symbolized by inductors and negative mechanical reactances are symbolized by capacitors as would be true in the analogous electrical situation. The constant applied force generator is symbolized as a voltage source. Also in Fig. 1.20, R_r is identified as $\rho_0 c S R_1 (2\omega a/c)$, whereas K_b is identified as $\rho_0 c^2 S^2 / V_0$ and M_r as $\rho_0 c S X_1 (2\omega a/c) / \omega$. Unlike the common electrical situation, however, those elements that stem from radiation phenomena, such as R_r and M_r , are themselves frequency dependent. This complication will be dealt with after the model has been more fully developed. The circuit of Fig. 1.20, though useful, can only be an intermediate result as it does not involve any of the purely electrical properties of the loudspeaker such as the voice coil resistance or self-inductance. In addition, whenever the voice coil is in motion it has induced in it a back electromotive force (emf) of size Blu that opposes the current in the voice coil. This situation is represented schematically in Fig. 1.21.

The current in the circuit of Fig. 1.21 is given by

$$i = \frac{(E - Blu)}{(R_e + j\omega L_e)}$$

FIGURE 1.21 Equivalent circuit of a voice coil in motion.

whereas from the former equation of motion we have the piston velocity [Equation (1.2)]. When i is eliminated from these two equations the result becomes

$$u = \frac{\frac{Ebl}{R_e + j\omega L_e}}{Z_m + \frac{B^2 l^2 (R_e - j\omega L_e)}{R_e^2 + \omega^2 L_e^2}}$$

In this result all of the electrical as well as acoustical properties have been transformed into equivalent mechanical terms, and the appropriate circuit appears as Fig. 1.22. In Fig. 1.22 all of the system properties have been expressed in mechanical terms. The generator on the left is a force generator supplying the driving force expressed in Newtons. All of the impedances, whether from electrical, mechanical, or acoustical origin, have been transformed to equivalent mechanical ohms, that is, kilograms/second. To proceed further it is necessary to finally address the complicated frequency-dependent behavior of the radiation impedance. The real part of the radiation impedance accounts for the fact that some mechanical energy is removed from the loudspeaker cone and is carried away by subsequent wave propagation in the surrounding air. The imaginary part of the radiation impedance accounts for the fact that there exists a cyclic lossless exchange of energy between the loudspeaker cone and the air in the immediate vicinity of the loudspeaker. The radiation resistance, in mechanical ohms, can be expressed as

$$R_r = \rho_0 c S R_1 \left(\frac{2\omega a}{c} \right)$$

whereas the radiation reactance can be expressed as

$$X_r = \rho_0 c S X_1 \left(\frac{2\omega a}{c} \right)$$

The details of the behavior of the functions R_1 and X_1 are presented in Fig. 1.23.

FIGURE 1.22 Overall equivalent circuit of a loudspeaker.

FIGURE 1.23 Piston impedance functions: (a) resistance function, (b) reactance function.

From Fig. 1.23, R_1 at low frequencies has a parabolic dependence on the frequency and, thus, grows as the square of the frequency, whereas at low frequencies X_1 has a linear dependence on the frequency. At high frequencies R_1 becomes constant at a value of 1, whereas X_1 slowly approaches 0. As a consequence, regardless of the frequency, both $R_r = \rho_0 c S R_1$ and $X_r = \rho_0 c S X_1$ will have a magnitude of $\rho_0 c S$ or very much lower.

1.3.5 Radiated Power

The model that has been developed can now usefully be employed to calculate the acoustical power radiated by the loudspeaker over a wide range of frequencies. The average radiated acoustical power can be expressed as

$$P = \frac{1}{2} u_m^2 R_r$$

where

- P = average power, W
- u_m = velocity amplitude, m/s
- R_r = radiation resistance, kgm/s

An examination will be made at very low frequencies, at the system low-frequency resonance frequency where the net series reactance becomes zero, at intermediate frequencies above resonance, and at high frequencies. For these frequencies the general model of Fig. 1.22 can be specialized into four cases as shown in Fig. 1.24. For very low frequencies, typically 20 Hz or less, the dominating series impedance is that associated with the combined stiffness of the suspension and the air in the sealed box. This presents an overall mechanical impedance whose magnitude is $(K + K_b)/\omega$, thus the velocity, which is proportional to the reciprocal of this quantity, increases directly as the frequency increases. The radiated power, however,

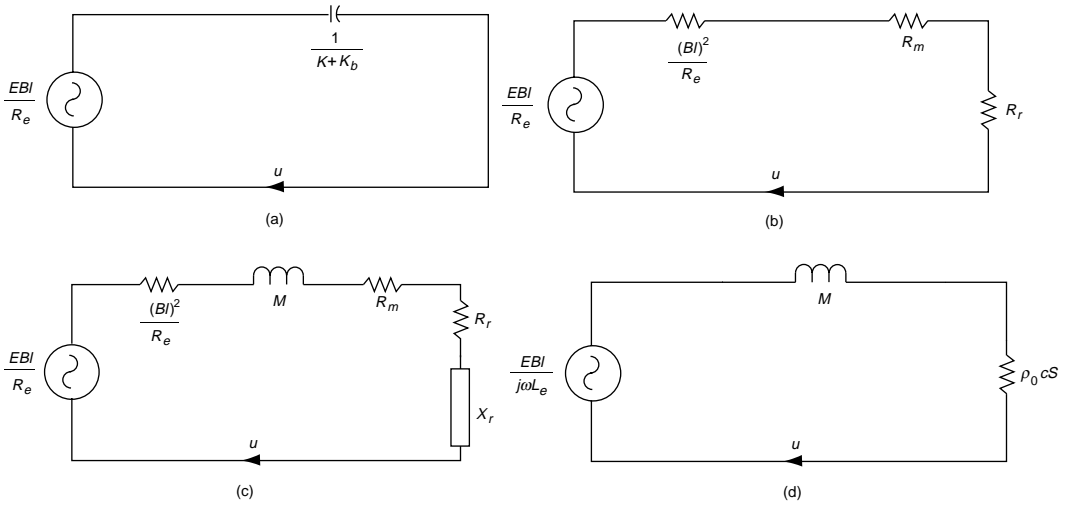

FIGURE 1.24 Specialized classes of the general model: (a) very low frequencies, (b) low frequency system resonance, (c) intermediate frequencies above resonance, (d) high frequency.

depends on the product of the velocity squared with the radiation resistance. The radiation resistance itself grows as the square of the frequency in this frequency range and, hence, the radiated power increases with the fourth power of the frequency or 12 dB per octave. In the Fig. 1.24(b) the operating frequency is such that the positive reactances of the moving mass and that contributed by radiation reactance are just annulled by the negative reactances of the suspension and the air in the box. For the typical values in Table 1.1 this occurs at about 70 Hz. The Fig. 1.24(c) describes a broad frequency range above resonance where the mass and radiation reactances dominate the circuit behavior. Both of these reactances are increasing linearly with frequency and, hence, the cone velocity decreases inversely with the frequency. The radiation resistance still increases as the square of the frequency in this range and, hence, the product $u_m^2 R_r$ will be a constant independent of frequency, as consequently will be the radiated power. This range extends from just above the resonance frequency to a few thousand hertz, that is, more for small pistons and less for large ones. Finally, in the high-frequency range of the Fig. 1.24(d), the radiation resistance has become the constant $\rho_0 c S$ while the output of the force generator falls inversely with the frequency and the mass reactance increases directly with the frequency. As a consequence, the velocity decreases as the square of the frequency and the radiated power falls as the fourth power of the frequency or -12 dB per octave. These results are shown in Fig. 1.25. In Fig. 1.25 the ordinate has been taken as $10 \text{ dB log } P/P_{\text{mid}}$, where P_{mid} is the power radiated at the midband of the device.

FIGURE 1.25 Loudspeaker power response by circuit analysis.

1.3.6 Acoustic Impedance

In the analysis of the purely acoustic parts of electromechanical acoustic systems the product of velocity with area is a commonly encountered quantity. This product $uS = U$ is termed the **volume velocity** and its dimensions are in cubic meter per second. The acoustic variable of principal interest is acoustic pressure and, hence, **acoustic impedance** is defined to be the complex ratio of acoustic pressure to volume velocity. An *acoustic ohm*, therefore, has the dimensions $\text{kgm}/(\text{m}^4 \text{ sec})$. The circuit of Fig. 1.22 in which the impedances are expressed in mechanical ohms and the generator is a force generator could as well have been described as employing a pressure generator with all impedances expressed in acoustic ohm equivalents. The value given in the figure for the generator simply needs to be divided by the piston area S whereas all of the impedance magnitudes given in the figure are to be divided by S^2 to accomplish the conversion to acoustic ohms.

1.3.7 Circuit Duals and Mobility Models

Two networks or circuits are termed *duals* if the loop equations of the one have the same mathematical form as the node equations of the other. In the electrical case, in going from a given circuit to its dual, series connections are replaced by parallel connections, resistance by conductance, inductance by capacitance, voltage by current, impedance by admittance, and voltage source by current source. Duality also applies to analogous circuit models because the basis for the construction of the circuit model is the mathematical form of the governing equation of the physical system being represented by the model in analogous form.

The mechanical and acoustic parts of the loudspeaker circuit of Fig. 1.22 can be represented by its dual as displayed in Fig. 1.26(a). In this circuit the applied force Bli flows in the circuit and the piston velocity u appears across the circuit. The complex ratio of the piston velocity to the applied force is the **mechanical admittance** or **mobility**, which is just the reciprocal of the former mechanical impedance, as

FIGURE 1.26 Mechanical and acoustical parts of the loudspeaker: (a) representation by dual, (b) addition of an ideal transformer, (c) incorporation of electrical aspects.

will be shown shortly. It should be observed that all former inductors have been replaced by capacitors, all former capacitors by inductors, and all former resistances by conductances of equal value, that is, G_m is R_m , etc.

In Fig. 1.26(a) the flow in each element is the quantity applied across the element multiplied by the admittance of the element. Hence, the total flow Bli is given by

$$Bli = u \left[G_m + j\omega M - \left(\frac{jK}{\omega} \right) - \left(\frac{jK_b}{\omega} \right) + G_r + j\omega M_r \right]$$

When the appropriate values are substituted for G_m and G_r and when K_b and M_r are replaced by the identifications given earlier, this equation becomes

$$Bli = u \left\{ R_m + \rho_0 c S R_1 \left(\frac{2\omega a}{c} \right) + j \left[\omega M + \rho c S X_1 \left(\frac{2\omega a}{c} \right) - \frac{K}{\omega} - \frac{\rho_0 c^2 S^2}{V_0 \omega} \right] \right\}$$

which when solved for u yields the former equation of motion (1.1) from which

$$\frac{u}{Bli} = \frac{1}{Z_m}$$

The advantage of this approach becomes apparent on examining Fig. 1.26(b) and Fig. 1.26(c). In Fig. 1.26(b) a hypothetical ideal transformer has been added that has a turns ratio of $B l : 1$. With a secondary current of Bli , the primary current of such a transformer will be the secondary current divided by the turns ratio or

$$\frac{Bli}{Bl} = i$$

This allows the natural incorporation of the purely electrical aspects of the loudspeaker system, as shown in Fig. 1.26(c). In Fig. 1.26(c) the voltage generator of emf E supplies the normal actual voice coil current i . The electrical impedance as viewed from the vantage point of this generator is the series combination of the voice coil impedance, $R_e + j\omega L_e$, with the impedance presented by the primary of the ideal transformer. This latter impedance is the square of the turns ratio multiplied by the impedance connected to the secondary of the transformer. This product is

$$\frac{(Bl)^2}{Z_m}$$

Therefore, the electrical generator sees a total electrical impedance given by

$$Z_e = R_e + j\omega L_e + \frac{(Bl)^2}{Z_m}$$

Recall from Fig. 1.21, Equation (1.3) and from the original equation of motion, Equation (1.2). When u is eliminated from these two equations, i is found to be

$$i = \frac{E}{R_e + j\omega L_e + \frac{(Bl)^2}{Z_m}}$$

The conclusion to be drawn is that the models of Fig. 1.22, as well as Fig. 1.26(c), both accurately describe the physical loudspeaker system, though in different terms. The choice of which model to employ in a given situation is really a matter of preference as they both yield the same results. Scientists with electrical backgrounds will probably prefer that of Fig. 1.26(c), however, as the terminology is more familiar.

Defining Terms

Acoustic impedance: The complex ratio of acoustic pressure to volume velocity.

Acoustic pressure: The pressure variation above or below static atmospheric pressure.

Mechanical impedance: The complex ratio of applied force to resulting velocity.

Mechanical mobility: The complex ratio of velocity to applied force.

Volume velocity: The product of surface area with surface velocity.

1.4 Thermal Noise and Other Circuit Noise

Barry G. Douglass

1.4.1 Introduction

All electronic circuits are affected by many factors, which cause their performance to be degraded from the ideal assumed in simple component models, in ways that can be controlled but not eliminated entirely. One limitation is the failure of the model to properly account for the real behavior of the components, either due to the oversimplified model description or variations in manufacture. Usually by careful design the engineer can work around the limitations of the model and produce a circuit the operation of which is very close to predictions. One source of performance degradation, which cannot be easily overcome, however, is called **noise**. When vacuum tubes first came into use in the early part of the 20th century, they were extensively used in radios as signal amplifiers and for other related signal conditioning functions. Thus, the measure of performance that was of greatest importance to electronic circuit designers was the quality of the sound produced at the radio speaker. It was immediately noticed that the sound coming from speakers not only consisted of the transmitted signal but also of popping, crackling, and hissing noises, which seemed to have no pattern and were distinctly different than the sounds that resulted from other interfering signal sources such as other radio stations using neighboring frequencies. This patternless or random signal was immediately labeled noise. This has become the standard term for signals that are random and that are combined with the circuit signal to affect the overall performance of the system.

As electronic engineers worked to discover the sources of this new phenomenon, they realized that part of it seems to come from the airwaves, in other words, it is part of the signal arriving at the receiver antenna, and part of it seems to be created internally by the circuit itself. The first type of internally generated noise to be detected is called **thermal noise**. This was discovered in vacuum tube triodes which were being used as signal amplifiers. Vacuum tube triodes have three filaments or plates in a single glass vacuum tube similar to a light bulb, and one of these filaments is purposely heated to a high temperature (several thousand degrees Fahrenheit) by passing a current through it just like the filament in a light bulb. This is necessary for proper conduction of electrons from the heated surface to either of the other two plates in the tube. In studying the noise problem, engineers discovered that as the element is heated, the noise level increases, even though the level of the incoming signal (the one being amplified) does not. If the noise were part of the incoming signal, it could only change as the amplified signal changed;

therefore, it must be created by the circuit itself. Since it is dependent on temperature, it is called thermal noise.

As the study of noise has progressed engineers have come to realize that there are many sources of noise in circuits, and not all of these are temperature dependent. The term thermal noise has come to mean any source of noise generated within a circuit that depends on temperature. More recently as digital logic circuits have acquired great importance in a wide variety of circuit applications, many of them well beyond the traditional field of data processing computers, some new manifestations of the noise phenomenon have appeared. In analyzing **digital circuits** it is often common to talk about **error** as opposed to noise. The distinction between error and noise is one of perspective. Traditional computer applications involve a large amount of processing of electronically stored data, with a very high standard of accuracy required in the results. Just as in other circuits occasional failures in the circuits occur; these being neither due to damage to the components, nor due to poor circuit design, but rather to the presence of noise in the circuit. Since a very high degree of accuracy is both required and achieved in computers, individual instances of error are notable and various techniques to detect and correct for such errors have been developed. Indeed, one of the reasons computerized circuits are coming into greater use in applications where other circuits have previously been used is the fact that these error correction techniques, which can only be practically implemented in digital logic systems, have become so sophisticated as to allow a much higher level of circuit performance in the presence of noise than is possible with other circuits.

In the following sections, we will study each type of internally generated noise in circuits and see how this noise impacts the performance of both digital and other (analog) circuits. Much of the analysis of noise is equally applicable to noise that originates before the input to a circuit; however, we are only interested here in noise that originates within a circuit and the way in which various circuit components alter the noise as it passes through the system.

1.4.2 Thermal Noise

By definition thermal noise is internally generated noise, which is temperature-dependent. Although first observed in vacuum tube devices because their amplifying capabilities tend to bring out thermal noise, it is also observed in semiconductor devices. It is a phenomenon due to the ohmic resistance of devices, which dissipate the energy lost in them as heat. Heat consists of random motion of molecules, which are more energetic as temperature increases. Since the motion is random, it is to be expected that as electrons pass through the ohmic device incurring resistance, there should be some random deviations in the rate of energy loss. This fluctuation has the effect of causing variation in the resulting current, which is noise. As the temperature of the device increases, the random motion of the molecules increases, and so does the corresponding noise level; therefore, it is known as thermal noise. In semiconductor diodes, bipolar junction transistors (BJTs), and field effect transistors (FETs), this noise is evident whenever the device is turned on and conducting current. Note that these devices also have their noiseless performance dependent on temperature; noise is strictly due to the variance in the current, which occurs at any given temperature.

From quantum mechanics it is found that an ohmic resistance R operating at absolute temperature T (in degrees kelvin) has a noise power spectral density $G(f)$ (in volts squared per hertz), which can be expressed as a function of frequency f (in hertz) as

$$G(f) = \frac{2Rhf}{e^{hf/kT} - 1} \quad (1.4)$$

where e is the Euler number, k is Boltzmann's constant = 1.37×10^{-23} J/K, h is Planck's constant = 6.62×10^{-34} Js. If room temperature, 295 K, is inserted for the operating temperature in Equation (1.4), it is found that until the infrared frequency range, which is well beyond the operating capacity of ordinary electronic circuit components, the noise power $G(f)$ remains nearly independent of frequency and can be adequately approximated as

$$G(f) = 2RkT \quad (1.5)$$

Note that $G(f)$ has units of volts squared per hertz. When delivered at a matched load with resistance R , the available noise power spectral density $G_a(f)$ becomes

$$G_a(f) = \frac{2RkT}{4R} = \frac{kT}{2} \quad (1.6)$$

This noise power spectral density expressed in Equation (1.5) and Equation (1.6) increases linearly with absolute temperature, and is independent of frequency. By solving Equation (1.6) for the temperature T , it is possible to determine it from the available noise spectral density. This can be extended to define a noise temperature T_N for any source of **white noise**, even nonthermal noise, in order to allow convenient calculations

$$T_N = \frac{2G_a(f)}{k} \quad (1.7)$$

This noise temperature may not correspond to any physical temperature, since a source of nonthermal white noise may produce far more white noise than would correspond to the thermal noise at its actual operating temperature. The fact that Equation (1.6) and Equation (1.7) are independent of resistance makes them easily extendable to transistors and diodes, which have varying resistances depending on the current they carry. Since source and load devices would be carrying the same current the formulas can be applied.

1.4.3 Shot Noise

Semiconductor devices display a type of noise that is temperature independent and is due to the fact that the current carrying mechanism involves randomly distributed doping impurities creating either excess electrons or positive charge-carrying holes in the n -doped or p -doped semiconductor. Because of the random distribution of the impurities, and even more because of the random way in which the carriers are swept across a p - n junction and then recombine, there is a variance in the operation of the junctions, which is called **shot noise**. It is similar to thermal white noise except that it is independent of temperature, and tends to fall off at frequencies above $1/t$, which is the reciprocal of the charge carrier lifetime t before recombining. Bipolar junction transistors and diodes tend to produce this kind of noise because of the fact that both devices have active p - n junctions while carrying current. In contrast, field effect transistors, which have either alternating p - n - p regions or n - p - n regions, are activated by converting the middle region between the two junctions from n to p or p to n by adding charge through a capacitor plate next to the region. In this way the junctions disappear and the random recombination does not take place; thus, FETs are relatively immune to shot noise.

In low-frequency applications, typically below a few kilohertz, some transistors exhibit so-called *burst* noise and *flicker* noise, which tend to fall off quickly with increasing frequency. These are not significant in applications above a few kilohertz, whereas at very high frequencies, transmission line effects and **capacitive coupling noise** begins to become very significant, especially in digital logic circuits, as will be discussed subsequently. The relationship between white noise and frequency-dependent burst and flicker noise is illustrated in Fig. 1.27.

FIGURE 1.27 A plot of signal power against frequency for white noise and frequency limited noise.

FIGURE 1.28 A block diagram modeling how noise is introduced to a signal during amplification.

1.4.4 Noise in Systems of Cascaded Stages

The noise level produced by thermal noise sources is not necessarily large; however, since source signal power may also be low it is usually necessary to amplify the source signal. Since noise is combined with the source signal, and both are then amplified, with more noise added at each successive stage of amplification, noise can become a very noticeable phenomenon. Consider a system as illustrated in Fig. 1.28, having a source signal power S_s with source noise power spectral density $n_s(f) = kT_s$ as input to an amplifier with gain g (the ratio of the amplified output to the input), and internal amplifier noise spectral density $n_i(f)$, operating over frequency bandwidth B . The effective noise temperature T_e of the amplifier is given as

$$T_e = \frac{1}{gkB} \int_0^\infty n_i(f)df \tag{1.8}$$

Thus, the output noise power is

$$N_o = gkB(T_s + T_e) \tag{1.9}$$

Now an amplifier with gain g and input signal power S_s will produce an output signal power $S_o = gS_s$. Hence, the output signal-to-noise ratio will be

$$\frac{S_o}{N_o} = \frac{S_s}{kB(T_s + T_e)} \tag{1.10}$$

The signal-to-noise ratio of the source within the same bandwidth is

$$\frac{S_s}{N_s} = \frac{S_s}{kBT_s} \tag{1.11}$$

The noise factor n_F is defined as the ratio of the source signal-to-noise ratio divided by the output signal-to-noise ratio, when the source noise temperature is set to ambient temperature T_0 . Combining Equation (1.10) and Equation (1.11) we get

$$n_F = 1 + \frac{T_e}{T_0} \tag{1.12}$$

or

$$T_e = T_0(n_F - 1) \tag{1.13}$$

Figure 1.29 illustrates a system of cascaded amplifier stages. In analog systems amplifiers with fixed bandwidth are a good model for all of the components in a cascaded system of C stages, so the preceding analysis for a single filtering amplifier stage can be easily extended so that Equation (1.12) and

FIGURE 1.29 A block diagram showing multiple stages of noisy components in a cascaded system.

Equation (1.13) become

$$\begin{aligned} n_F &= 1 + \frac{T_1}{T_0} + \frac{T_2}{g_1 T_0} + \cdots + \frac{T_C}{g_{C-1} T_0} \\ &= n_{F1} + \frac{n_{F2} - 1}{g_1} + \cdots + \frac{n_{F2} - 1}{g_1 \cdot g_{C-1}} \end{aligned} \quad (1.14)$$

and

$$T_e = T_1 + \frac{T_2}{g_1} + \cdots + \frac{T_2}{g_1 \cdot g_{C-1}} \quad (1.15)$$

Equation (1.15), which is called *Frii's formula*, combined with Equation (1.6) allows calculation of the internally generated noise power at the output to a system of cascaded stages. Note that this analysis applies only to analog systems; digital systems do not pass noise from one stage to the next in the same way as analog circuits. Typical values of effective noise temperature T_e in amplifiers range from 400 K up to 2000 K in integrated circuit amplifiers.

1.4.5 Noise-Induced Error in Digital Circuits

As described in the Introduction, digital logic circuits respond differently from analog circuits to the presence of noise, since any noise signal that falls below the threshold necessary to alter a single discrete bit of information to another (erroneous) discrete level will be completely rejected by the circuit. This provides the possibility of extremely high noise immunity for digital logic circuits. Furthermore, the extraordinary ease with which complex digital circuits can be constructed to perform a wide variety of functions has made them increasingly popular replacements for analog systems. In applications where the inputs and outputs of the system are to be analog, the digital logic circuits are preceded by an analog-to-digital converter (ADC) and followed by a digital-to-analog converter (DAC). The ADC encodes the analog signal values (usually voltage) as binary numbers and the DAC uses the binary numerical outputs of the digital system to create analog signal values.

To design complex circuits, which favor the digital approach, it is necessary to mount many extremely small devices on a single semiconductor chip substrate. These devices are closely packed together and, further, because of their size are extremely sensitive to small stray currents. Because of the dense packing and the associated network of interlaced wires, the circuits are susceptible to crosstalk between the various components. This crosstalk is primarily due to capacitive coupling between adjacent wires, since at the dimensions of chip circuitry inductance is normally too small to be significant. At the board level inductive coupling can be a problem; boards must be carefully designed so as to minimize the effects of inductance, such as by providing a ground plane next to the wires. At the board level, as circuit switching speed increases into the gigahertz range, the length of wires on boards approaches the wavelength of the electromagnetic waves of the switching pulses (as a rule of thumb, an electromagnetic wave travels about 6 in/ns in a wire, corresponding to a 1-GHz pulse duration). Therefore, line reflections from chip input terminations and sharp bends in wire runs can cause false pulses to become a problem. Care in terminating wires and rounding corners in wires is necessary to minimize this problem.

All of these concerns about capacitive coupling, inductive coupling, and transmission line effects can be managed in order to ensure that they do not become a major problem in operating digital logic. Nevertheless, their random nature, which results from the unpredictability of extremely complex systems,

FIGURE 1.30 A depiction of a noisy input signal to a digital circuit and the noiseless equivalent input as interpreted by the circuit.

means that it is never possible to guarantee that occasional errors due to these effects will not occur. These effects, in addition to the random thermal and other noise associated with semiconductor devices, conspire to create significant levels of noise at the inputs to logic circuit components. For this reason logic circuits must have **noise margins** built into their operating characteristics. For binary systems, where there are two logic levels, high and low, the devices have associated output voltages for each logic level or state. V_{OH} is the output voltage corresponding to a logic high state, and V_{OL} is the output voltage corresponding to a logic low state. At the input to each device is a component that measures the voltage and determines whether this is to be interpreted as a logic low input or a logic high input. The minimum voltage that is recognized by the device as a logic high input is called V_{IH} , whereas V_{IL} is the maximum voltage recognized as a logic low. These are depicted in Fig. 1.30. Obviously $V_{IL} < V_{IH}$. For the region of voltage in between these two voltages, that is to say if the input voltage V_I is $V_{IL} < V_I < V_{IH}$, then the circuit will behave erratically and produce erroneous output values. It is said that in this region the logic value is *indeterminate*. The noise margin high NM_H and noise margin low NM_L are determined as

$$NM_H = V_{OH} - V_{IH} \quad (1.16)$$

and

$$NM_L = V_{IL} - V_{OL} \quad (1.17)$$

and the overall noise margin NM is the minimum of NM_H and NM_L , since this will determine the noise level where an error can occur. This noise margin allows a certain level of noise to exist on the inputs to logic circuits without the noise affecting the correctness of the outputs of the devices, and so errors do not occur. However, it is important to note that noise, because it is a random process, has a distribution that because of the central limit theorem can be assumed, in general, to be Gaussian. Thus, regardless of how large a noise margin is designed into a digital logic device, some noise will occasionally create error; the noise margin can only be increased in order to reduce the error rate. Nevertheless, the fact that a mechanism exists to reduce the level of noise passing through the system represents a powerful tool for noise reduction, which is not available to the analog circuit designer. Note in Equation (1.9) that in an analog amplifier the noise is passed to the output amplified along with the input signal. In a digital logic circuit as long as the signal has a magnitude predictably larger than that of the noise, then it can be separated from the noise by the choice of a noise margin.

We have seen that noise on the input to a logic circuit can create errors in the output of the device. Individual errors may or may not be significant in a system, but given a continuous error rate passing to the system output the impact on the overall system performance will be similar to an equivalent output noise level in an analog system. The error rate (number of erroneous bits per unit time) as a fraction of the data rate (total number of data bits per unit time) gives a good indication of the impact of errors in a digital logic system.

There is another significant way in which errors can crop up in digital systems, which is very significant in systems that rely heavily on memory in processing information. When a large amount of digital information is to be stored, the cost of the storage circuits becomes important and, therefore, a choice is made to use the smallest, least expensive, and most densely compacted memory device available, which is the dynamic random access memory (DRAM). In this memory digital information is stored as a charge on a capacitor, by simply charging the capacitor to either one of the two logic voltages. Since this offers a very space-efficient way of dealing with logic information it is also being used in some more complex logic circuits, which are called dynamic logic circuits. Since the capacitors are accessed through transistors, the preceding discussion about noise in logic devices applies here as well. In addition, however, very small capacitors can be discharged by a single strike from an energetic **alpha particle**, which can originate externally to the system from cosmic rays and, also, which can occur naturally as a small amount of radiation in packaging and even the semiconductor substrate itself. Figure 1.31 illustrates how an alpha particle can penetrate through a charged surface region on a silicon chip, which can be the bottom plate of a semiconductor capacitor, and by charging the substrate directly below the surface region can cause the capacitor to lose its charge into the substrate. Since this discharging does not significantly damage the device, only causing loss of information, it is termed a *soft error*. Since this type of alpha particle occurs due to radioactivity in materials, care must be taken to use packaging with a minimum amount of radioactive material. Nevertheless, some radioactivity is unavoidable, and even with special techniques to avoid the effects of alpha particle impacts some soft errors will occur.

FIGURE 1.31 A depiction of an alpha particle crossing a MOSFET circuit component into the chip substrate.

As stated previously, any single bit of information can be used repeatedly, having a large impact on the overall error level in the system, and so the fact that such errors may be relatively uncommon can nevertheless not be counted on to make such errors insignificant.

The solution to dealing with errors in digital logic systems after they have occurred is to employ error-correcting coding techniques. Although the subject of error-correcting coding is well beyond the scope of this chapter, it is worth pointing out that these techniques are extremely powerful in reducing the impact of errors in overall system performance, and since they can be incorporated as software operations in a digital processing unit, they lend themselves very well to digital logic implementation. The strategy in error-correcting coding is to use extra information within the data stream to pin down errors by comparing copies of the data, which should be consistent for inconsistencies due to error. If, for example, two identical copies of a data stream become different, then one is in error. Note that if an error can be detected in transmission, it may be possible to request a retransmission, or if the error location can be pinned down exactly, then in a binary system an erroneous bit can be corrected since it can only have one other value besides the incorrect one. The references contain further reading on the subject.

1.4.6 Noise in Mixed Signal Systems

In the previous section it was shown how a noisy input signal can affect a digital logic circuit to become errors. Since in some applications the final output of an electronic circuit may be in digital form, these errors may be of great importance in themselves. It is also common, however, as stated earlier, for electronic systems to begin and end as analog circuits, but in between have digital logic subsections. Such a system is called a mixed signal system, and noise is a concern both at the input to the system and at the output. Noise at the input is converted into errors within the digital logic circuit; the data then picks up further errors as it is processed within the digital logic circuits, and when the conversion from the digital to the analog domain is finally made, these accumulated errors become noise once again at the digital logic

circuit's output. There are some mixed signal systems that combine digital and analog circuits on a single semiconductor chip substrate, and these can produce crosstalk, which originates within the digital logic circuits and creates noise within the analog circuit section. The most common of these are power supply noise and **ground bounce**.

When analog and digital circuits are closely linked to common ground and power supplies, it is possible to have temporary spikes occur in the power supply or even shifts in the grounding level through the chip substrate due to large power draw during switching of the digital portion of the circuit. Digital circuits are normally designed to switch in response to timing signals called clock pulses, and since the switching of digital circuits is random there is a probability in many cases that a large portion of the components will be switching state between high and low outputs, all in response to the same clock pulse. This can cause sudden temporary drain on the power supply and disturb the grounding of the substrate, to the point where neighboring analog components will pick up these disturbances as noise.

Further noise problems can occur due to errors in converting analog inputs into digital form. The circuits that perform these functions, called quantizing, rely on a process of comparing the analog input to a reference value created by the digital circuit and then converted back to analog. By such successive comparisons the digital circuit determines which digital value most closely matches the analog input. But digital-to-analog converters used in this process are subject to all of the noise problems of analog circuits since they are themselves analog devices, and rely on resistive components, which have thermal noise limitations; thus, the digital information necessarily enters the digital system with noise present. The quantizer merely converts the noisy signal to binary numbers, including the noise values unless they are below the quantizer precision. When the outputs are converted back to analog, they once again are subjected to noise from the digital-to-analog converter, so more noise is introduced. This places a limitation on the accuracy of digital-to-analog as well as analog-to-digital systems, and contributes to the overall noise level of mixed signal systems. This is distinct from quantization error, which is caused by the limited precision of the quantization process, which converts the continuous analog stream into discrete levels of digitally represented signal strength. There is a connection between the two, in that noise affects the accuracy of the digital-analog conversion processes and therefore dictates the highest level of meaningful precision that can be obtained, thereby establishing the number of digital data bits that will be used and the precision of the quantizer. Once the digital data is converted back to analog form, the quantization error becomes **quantization noise**, since the noise level cannot be less than the precision of the quantized data stream from which the analog output is generated. The total quantization noise level is determined as the greater of the quantized data precision and the inaccuracy due to the noise level occurring at the quantizer. Since there is no benefit in using quantization which is more precise than accurate, in general the quantization noise is determined by the quantizing precision. Thus, quantization noise is the noise level which equals the limit of precision of the digital data representation.

Determining the error rate of an individual digital circuit component can be straightforward once the noise distribution and noise margin of the component are known. The error probability for each input value is taken from the distribution of noise that exceeds the noise margin. Computing the effect of individual errors in a complex digital system on the overall output error rate is extremely difficult and can be intractable, so that designers normally rely on general estimates based on experience and testing. This results in a paradox that although digital systems offer unique capability to reduce the effect of noise in degrading the performance of electronic systems, one of their weakest points is the extreme difficulty of properly characterizing the level of noise.

1.4.7 Conclusions

This chapter has dealt exclusively with internally generated noise and its effects on electronic circuits, both digital and analog. This covers a large portion of the sources of circuit noise, though another equally important source is external natural phenomena such as cosmic rays, the solar wind, and lightning discharges. Fortunately the methods for analyzing the effects of these noise sources on the operation of

circuits is largely the same as for internal noise, once the extent of these sources has been characterized. To some degree all electronic circuits can be viewed as open systems with the environment forming either an integral part of the system as in the case of radio communication systems, or a peripheral influence in the case of nominally closed systems such as embedded controllers.

The treatment of the very important and extensive field of noise in electronic circuits has necessarily been introductory, and readers are urged to consult the suggestions for further reading to fill in the gaps left by this chapter. The areas of error-correcting coding and optical data transmission, while highly specialized, are fast increasing in importance, and they present their own unique challenges. Readers interested in acquiring a greater understanding of noise in the field of communications systems are urged to follow developments in these important areas.

Defining Terms

Alpha particle noise: This type of noise occurs exclusively in small semiconductor capacitors, when an energetic alpha particle, either from cosmic rays or from the packaging or substrate itself, traverses the capacitor, discharging it, thereby creating an error in the stored charge. Such an accumulation of errors in a digital system has the effect of creating a noise signal.

Analog circuits: These are circuits that process the input signal as a continuous range of values from some minimum to some maximum extremes. Active components (those with their own power source) in such circuits usually are used to amplify input signals without altering their shape (i.e., linear amplification). Thus noise at the input is faithfully reproduced at the output except amplified. Other components in analog circuits, usually involving capacitors and inductors, are used to filter out unwanted frequency ranges.

Capacitive coupling noise: In digital systems most circuit components consist of very small elements, which are very sensitive to correspondingly small voltage and current pulses such as those caused by crosstalk between neighboring wires, which are capacitively coupled. Although this can be regarded as a type of **interference**, typically the larger number of crisscrossing wires in a large system, in conjunction with independence of the various signals on the lines, results in a completely unpredictable crosstalk having all the characteristics of noise. It is generated internally within the circuit and is temperature independent. Analog circuits suffer much less from this type of noise because each component is normally handling much larger signals, and so small capacitive couplings are relatively insignificant.

Digital circuits: These are circuits that only allow a limited number of fixed signal levels at their inputs to be recognized as valid, and produce the same fixed signal levels at their outputs. The most common of these by far are binary circuits, which allow only two levels, such as a high voltage (e.g., 5 V) and a low voltage (e.g., 0 V). All other voltages are truncated to the nearest valid voltage level. Thus, noise at an input will be suppressed unless it is sufficient to move the signal from one valid level to another.

Error: A single error refers to a single event of a degraded signal propagating through a digital circuit as an incorrect voltage level. The collective noun error is sometimes used to refer to a pattern of repeated errors occurring in a digital circuit, in much the same way as noise occurs.

Ground bounce noise: Ground bounce occurs when a large number of semiconductor circuit components are mounted on a common semiconductor chip substrate, so that they are imperfectly insulated from each other. In normal operation the substrate should act as an insulator; however, during certain unusual fluctuations in signal levels the system power and ground connections can experience fluctuations, which affect the performance of each component in a random way that has the characteristics of noise, much like capacitive coupling.

Interference: This is the name given to any predictable, periodic signal that occurs in an electronic circuit in addition to the signal that the circuit is designed to process. This is distinguished from a noise signal by the fact that it occupies a relatively small frequency range, and since it is predictable it can often be filtered out. Usually interference comes from another electronic system such as an interfering radio source.

Noise: This is the name given to any random (i.e., without pattern) signal that occurs in an electronic circuit in addition to the signal that the circuit is designed to process.

Noise margin: In digital circuits this is the difference between the nominal noiseless signal value for a given allowable level and the threshold signal value, which will just barely be distinguishable from the next allowable signal level. For example, a typical MOSFET transistor-based logic device might have a nominal input voltage of 4.5 V for a logic high value, and a 3.5 V minimum voltage, which is still recognized as a logic high. Thus the logic high noise margin is $4.5 - 3.5 = 1$ V.

Quantization noise: This is a type of noise that occurs when an analog signal is converted into digital form by measuring and encoding the range of analog input signal values as a set of numbers, usually in the binary system, for manipulation in digital circuits, possibly followed by reconversion to analog form. Quantization noise is an example of how noise such as thermal noise can become part of a digital signal.

Shot noise: This is a type of circuit noise, which is not temperature dependent, and which is not white noise in the sense that it tends to diminish at higher frequencies. This usually occurs in components whose operation depends on a mean particle residence time for the active electrons within the device. The cutoff frequency above which noise disappears is closely related to the inverse of this characteristic particle residence time. It is called shot noise because in a radio it can make a sound similar to buckshot hitting a drum, as opposed to white noise, which tends to sound more like hissing (due to the higher-frequency content).

Thermal noise: This is any noise that is generated within a circuit and that is temperature dependent. It usually is due to the influence of temperature directly on the operating characteristics of circuit components, which because of the random motion of molecules as a result of temperature, in turn creates a random fluctuation of the signal being processed.

White noise: This is noise that has its energy evenly distributed over the entire frequency spectrum, within the frequency range of interest (typically below frequencies in the infrared range). Because noise is totally random it may seem inappropriate to refer to its frequency range, it is not really periodic in the ordinary sense. Nevertheless, by examining an oscilloscope trace for white noise, one can verify that every trace is different, as the noise never repeats itself, and yet each trace looks the same. Similarly, a television set, which is tuned to a dead frequency, displays never-ending snow, which always looks the same, yet clearly is always changing. There is a strong theoretical foundation to represent the frequency content of such signals as covering the frequency spectrum evenly. In this way the impact on other periodic signals can be analyzed. The term white noise arises from the fact that, similar to white light which has equal amounts of all light frequencies, white noise has equal amounts of noise at all frequencies within circuit operating ranges.

1.5 Logic Concepts and Design

George I. Cohn

1.5.1 Introduction

Digital logic deals with the representation, transmission, manipulation, and storage of digital information. A digital quantity has only certain discrete values in contrast with an analog quantity, which can have any value in an allowed continuum. The enormous advantage digital has over analog is its immunity to degradation by noise, if that noise does not exceed a tolerance threshold.

1.5.2 Digital Information Representation

Information can be characterized as qualitative or quantitative. Quantitative information requires a number system for its representation. Qualitative does not. In either case, however, digitalized information is represented by a finite set of different characters. Each character is a discrete quanta of information. The set of characters used constitutes the alphabet.

1.5.3 Number Systems

Quantitative information is represented by a number system. A character that represents quantitative information is called a **digit**. The number of different values which a digit may have is called the **radix**, designated

TABLE 1.3 Notation for Numbers

	Juxtaposition	Polynomial
Integer	$N = N_{n-1}N_{n-2} \cdots N_1N_0$	$N = \sum_{k=0}^{n-1} N_k R^k$
Fraction	$F = \cdot F_{-1}F_{-2} \cdots F_{-m+1}F_{-m}$	$F = \sum_{k=-m}^{-1} F_k R^k$
Real	$X = X_{n-1}X_{n-2} \cdots X_1X_0 \cdot X_{-1}X_{-2} \cdots X_{-m+1}X_{-m}$	$X = \sum_{k=-m}^{n-1} X_k R^k$

by R . The symbols that designate the different values a digit can have are called numeric characters. The most conventionally used numeric characters are 0, 1, 2, . . . , etc., with 0 representing the smallest value. The largest value that a digit may have in a number system is the **reduced radix**, $r = R - 1$. Different radix values characterize different number systems: with R different numeric character values the number system is R nary, with 2 it is binary, with 3 it is ternary, with 8 it is octal, with 10 it is decimal, and with 16 it is hexadecimal.

Any value that can be expressed solely in terms of digits is an **integer**. A negative integer is any integer obtained by subtracting a positive integer from a smaller integer. Any number obtained by dividing a number by a larger number is a **fraction**. A number that has both an integer part and a fraction part is a **real number**.

All of the digits in a *number system* have the same radix. The radix is the **base** of the number system. Presumably, the possession of 10 fingers has made the decimal number system the most convenient for humans to use. The characters representing the 10 values a decimal digit can have are: 0, 1, 2, 3, 4, 5, 6, 7, 8, and 9. The binary number system is most natural for digital electronic systems because a desired reliability for a system can be most economically achieved using elements with two stable states. The characters normally used to represent the two values a binary digit may have are 0 and 1. The hexadecimal number system (0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E, and F; $R = 16$) is of importance because it shortens by a factor of four the string of digits representing the binary information stored and manipulated in digital computers.

1.5.4 Number Representation

Numbers that require more than one digit can be represented in different formats, as shown in Table 1.3. Different formats facilitate execution of different procedures. Arithmetic is most conveniently done with the juxtaposition format. Theoretical developments are facilitated by the polynomial format.

1.5.5 Arithmetic

The most common arithmetic processes, addition, subtraction, multiplication, and division are conveniently implemented using juxtaposition notation. Development of formulation procedure is facilitated using the polynomial notation. Since the numbers are digital representations, the logic used to manipulate the numbers is *digital logic*. However, this is different than the logic of boolean algebra, which is what is usually meant by the term digital logic. The logic of the former is implemented in hardware by using the logic of the latter. The four basic arithmetic operations can be represented as functional procedures in equation form or in arithmetic manipulation form, as shown in Table 1.4.

The arithmetic processes in the binary system are based on the binary addition and multiplication tables given in Table 1.5.

Table 1.6 gives binary examples for each of the basic arithmetic operations.

1.5.6 Number Conversion from One Base to Another

The method of using series polynomial expansions for converting numbers from one base to another is illustrated in Table 1.7.

TABLE 1.4 Arithmetic Operations

	Algebraic Form	Arithmetic Form
Addition	Sum = Augend + Addend	$\begin{array}{r} \text{Augend} \\ + \text{Addend} \\ \hline \text{Sum} \end{array}$
Subtraction	Difference = Minuend – Subtrahend	$\begin{array}{r} \text{Minuend} \\ - \text{Subtrahend} \\ \hline \text{Difference} \end{array}$
Multiplication	Product = Multiplicand × Multiplier	$\begin{array}{r} \text{Multiplicand} \\ \times \text{Multiplier} \\ \hline \text{Product} \end{array}$
Division	Dividend/Divisor = Quotient + Remainder/Divisor	$\begin{array}{r} \text{Quotient} \quad \text{Remainder} \\ \text{Divisor} \overline{) \text{Dividend}} \end{array}$

TABLE 1.7 Series Polynomial Method for Converting Numbers Between Bases

Method	Sample Conversion From:	
	A Lower to a Higher Base	A Higher to a Lower Base
1. Express number in polynomial form in the given base	$101.1_2 = 1 \times 2^2 + 0 \times 2^1 + 1 \times 2^0 + 1 \times 2^{-1}$	$36.5_{10} = 3 \times 10^1 + 6 \times 10^0 + 5 \times 10^{-1}$
2. Convert radix and coefficients to the new base	$= 1 \times 4 + 0 \times 2 + 1 \times 1 + 1 \times 0.5$	$= 11 \times 1010^1 + 110 \times 1010^0 + 101 \times 1010^{-1}$
3. Evaluate terms in the new base	$= 4 + 0 + 1 + 0.5$	$= 11 \times 1010 + 110 + 101/1010$ $= 11110 + 110 + .1$
4. Add the terms	$101.1_2 = 5.5_{10}$	$36.5_{10} = 100100.1_2$

TABLE 1.8 Nested Polynomials

(a) Nested Polynomial via Iterated Factoring	(b) Lower Order Polynomials
$N = N_{n-1}R^{n-1} + N_{n-2}R^{n-2} + \dots + N_2R^2 + N_1R + N_0$	$N = N^{(1)}R + N_0$
$N = (N_{n-1}R^{n-2} + N_{n-2}R^{n-3} + \dots + N_2R + N_1)R + N_0$	$N^{(1)} = N^{(2)}R + N_1$
$N = ((N_{n-1}R^{n-3} + N_{n-2}R^{n-4} + \dots + N_2)R + N_1)R + N_0$	$N^{(2)} = N^{(3)}R + N_2$
\vdots	\vdots
\vdots	$N^{(n-2)} = N^{(n-3)}R + N_{n-2}$
$N = (\dots(N_{n-1})R + N_{n-2})R + \dots + N_2)R + N_1)R + N_0$	$N^{(n-1)} = N_{n-1}$

Evaluation of polynomials is more efficiently done with the *nested form*. The nested form is obtained from the series form by successive factoring of the variable from all terms in which it appears as shown in Table 1.8. The number of multiplications to evaluate the nested form increases linearly with the order of the polynomial, whereas the number of multiplications to evaluate the series form increases with the square of the order.

Conversion of integers between bases is more easily done using the lower order polynomials (Table 1.8(b)) obtained by nesting. The least significant digit of the number in the new base is the remainder obtained after dividing the number in the old base by the new radix. The next least significant digit is the remainder obtained by dividing the first reduced polynomial by the new radix. The process is repeated until the most significant digit in the new base is obtained as the remainder when the new radix no longer fits into the last reduced polynomial. This is more compactly represented with the arithmetic notation shown in Table 1.9 along with the same examples used to illustrate the polynomial series method.

$R^*F^{(m-1)} = F_{-m} \cdot$	$\underline{F_{-m}} \cdot$	$.125_{10} = .001_2$	$.100101_2 = .578125_{10}$

Conversion of a fraction from one base to another can be done by successive multiplications of the fraction by the radix in the base to which the fraction is to be converted. Each multiplication by the radix gives a product that has the digits shifted to the left by one position. This moves the most significant digit of the fraction to the left of the radix point placing that digit in the integer portion of the product, thereby isolating it from the fraction. This process is illustrated in algebraic form in the left column of Table 1.10 and in arithmetic form in the next column. Two sample numeric conversions are shown in the next two columns of Table 1.10.

Table 1.10 deals only with terminating fractions, that is, the remaining fractional part vanishes after a finite number of steps. For a nonterminating case the procedure is continued until a sufficient number of digits have been obtained to give the desired accuracy. A nonterminating case is illustrated in Table 1.11. A set of digits, which repeat *ad infinitum*, are designated by an underscore as shown in Table 1.11.

Conversion to base 2 from a base which is an integer power of 2 can be most simply accomplished by independent conversion of each successive digit, as illustrated in Table 1.12(a). Inversely, conversion from base 2 to a base 2^k can be simply accomplished by grouping the bits into sets of k bits each starting with the least significant bit for the integer portion and starting with the most significant bit for the fraction portion, as shown by the examples in Table 1.12(b).

$\underline{0} \cdot 8$	
$\times 2$	
$\underline{1} \cdot 6$	

1.5.7 Complements

Each number system has two conventionally used **complements**:

$$\begin{aligned} \text{radix complement of } N &= N^{RC} = R^n - N \\ \text{reduced radix complement of } N &= N^{rC} = N^{RC} - 1 \end{aligned}$$

TABLE 1.12 Conversions between Systems Where One Base Is an Integer Power of the Other Base

(a) Conversion from high base to lower base:
 $B_2 \cdot C_{5_{16}} = 1011 \ 0010 \ .1100 \ 0101_2$
 $62.75_8 = 110 \ 010 \ .111 \ 101_2$

(b) Conversion from lower base to high base:
 $11 \ 0010 \ 0100.0001 \ 1100 \ 01_2 = 324.1C4_{16}$
 $10 \ 110 \ 001.011 \ 111 \ 01_2 = 261.372_8$

where R is the radix and n is the number of digits in the number N . These equations provide complements for numbers having the magnitude N .

A positive number can be represented by a code in the two character machine language alphabet, 0 and 1, which is simply the positive number expressed in the base 2, that is, the code for the number is the number itself. A negative number requires that the sign be coded in the binary alphabet. This can be done by separately coding the sign and the magnitude or by coding the negative number as a single entity. Table 1.13 illustrates four different code types for negative numbers. Negative numbers can be represented in the sign magnitude form by using the leftmost digit as the code for the sign (+ for 0 and - for 1) and the rest of the digits as the code for the magnitude. Complements and biasing provide the means for coding the negative number as a single entity instead of having a discrete separate coding for the sign. The use of complements provides for essentially equal ranges of values for both positive and negative numbers. The biased representation can also provide essentially equal ranges for positive and negative values by choosing the biasing value to be essentially half of the largest binary number that could be represented with the available number of digits. The bias code is obtained by subtracting the biasing value from the code considered as a positive number, as shown in the rightmost column of Table 1.13.

Complements enable subtraction to be done by addition of the complement. If the result fits into the available field size the result is automatically correct. A diagnostic must be provided to show that the result is incorrect if **overflow** occurs, that is, the number does not fit in the available field. Table 1.14 illustrates arithmetic operations with and without complements. The two rightmost columns illustrate cases where the result overflows the 3-b field size for the magnitude. A condition can be represented in terms of two

TABLE 1.13 Number Representations

Signed Numbers via the Following Representations:

Available Codes	Positive Numbers	Sign Magnitude	One's Complement	Two's Complement	111 bias

4 binary digit working field (accommodates 3-b magnitude)	↓ designates positive number	↓ designates negative number	↓ designates negative number	↓ designates positive number
Result Veracity	+010 True	-010 True	-100 False	+100 False
Significant Carries	$C_0 = 1$ $C_1 = 1$	$C_0 = 0$ $C_1 = 0$	$C_0 = 0$ $C_1 = 1$	$C_0 = 1$ $C_1 = 0$
Veracity Condition	$C_0 \equiv C_1$ $C_0 \odot C_1 = 1$	$C_0 \equiv C_1$ $C_0 \odot C_1 = 1$	$C_0 \not\equiv C_1$ $C_0 \odot C_1 = 0$	$C_0 \not\equiv C_1$ $C_0 \odot C_1 = 0$

carry parameters:

- C_0 the output carry from the leftmost digit position
- C_1 , the output carry from the second leftmost digit position (the output carry from the magnitude field if sign magnitude representation is used)

If both of these carries are coincident (i.e., have the same value) the result fits in the available field and, hence, is correct. If these two carries are not coincident the result is incorrect.

1.5.8 Codes

Various types of **codes** have been developed for serving different purposes. There are codes that enable characters in an alphabet to be individually expressed in terms of codes in a smaller alphabet. For example, the alphabet of decimal numeric symbols can be expressed in terms of the binary alphabet by the **binary coded decimal (BCD)** or 8421 code shown in Table 1.15. The 8421 designation represents the weight given to each of the binary digits in the coding process.

TABLE 1.15 Sample Codes

Decimal Digits	BCD 8421	2421	2-out-of-5	Parity		Gray		
				Even	Odd	1-bit	2-bit	3-bit
0	0000	0000	00011	0000 0	0000 1	0	00	000
1	0001	0001	00101	0001 1	0001 0	1	01	001
2	0010	0010	00110	0010 1	0010 0		11	011
3	0011	0011	01001	0011 0	0011 1		10	010
4	0100	0100	01010	0100 1	0100 0			110
5	0101	1011	01100	0101 0	0101 1			111
6	0110	1100	10001	0100 1	0110 0			101
7	0111	1101	10010	0111 1	0111 0			100
8	1000	1110	10100	1000 1	1000 0			
9	1001	1111	11000	1001 0	1001 1			

FIGURE 1.32 Eight-segment position sensor with slightly misaligned contacts: (a) binary code physical configuration, (b) Gray code physical configuration.

There are codes that facilitate doing arithmetic. The 2421 code can also be used to represent the decimal numeric symbols. The 2421 code has the advantage that the code for the reduced radix complement is the same as the reduced radix complement of the code, and this is not true of the BCD code. Thus the 2421 code facilitates arithmetic with multiple individually coded digit numbers.

There are codes designed to detect errors that may occur in storage or transmission. Examples are the even and odd parity codes and the 2-out-of-5 code shown in Table 1.15. The 2-out-of-5 error detection code is such that each decimal value has exactly two high digit values. Parity code attaches an extra bit having a value such that the total number of high bits is odd if odd parity is used and the total number of bits is even if even parity is used. An even number of bit errors are not detectable by a single bit parity code. Hence, single bit parity codes are adequate only for sufficiently low bit error rates. Including a sufficient number of **parity bits** enables the detection and correction of all errors.

There are codes designed to prevent measurement misrepresentation due to small errors in sensor alignment. **Gray codes** are used for this purpose. A Gray code is one in which the codes for physically adjacent positions are also **logically adjacent**, that is, they differ in only one digit. Gray codes can be generated for any number of digits by reflecting the Gray code for the case with one less digit as shown in Table 1.15 for the case of 1, 2, and 3-bit codes. The advantage of a Gray scale coded lineal position sensor is illustrated in Fig. 1.32 for the eight-segment case.

1.5.9 Boolean Algebra

Boolean algebra provides a means to analyze and design binary systems and is based on the seven postulates given in Table 1.16. All other Boolean relationships are derived from these seven postulates. Expressed in graphical form, called *Venn diagrams*, the postulates appear more natural and logical. This benefit results from the two-dimensional pictorial representation freeing the expressions from the one-dimensional constraints imposed by lineal language format.

The OR and AND operations are normally designated by the arithmetic operator symbols + and · and referred to as sum and product operators in basic digital logic literature. However, in digital systems that perform arithmetic operations this notation is ambiguous and the symbols ∨ for OR and ∧ for AND eliminates the ambiguity between arithmetic and boolean operators. Understanding the conceptual meaning of these boolean operations is probably best provided by set theory, which uses the union operator ∪ for OR and the intersection operator ∩ for AND. An element in a set that is the union of sets is a member

TABLE 1.16 Boolean Postulates

Postulate	Name	Meaning	Forms	
			(a)	(b)
1	Definition	\exists a set $\{K\} = \{a, b, \dots\}$ of two or more elements and two binary operators $\exists\{K\} = \{a, b, a + b, a \cdot b, \dots\}$	OR $+$ \vee \cup	AND \bullet \wedge \cap
2	Substitution Law	$\text{expression}_1 = \text{expression}_2$ If one replaced by the other does not alter the value		
3	Identity Element	\exists identity elements for each operator	$a + 0 = a$	$a \bullet 1 = a$
4	Commutativity	For every a and b in K	$a + b = b + a$	$a \bullet b = b \bullet a$
5	Associativity	For every $a, b,$ and c in K	$a + (b + c) = (a + b) + c$	$a \bullet (b \bullet c) = (a \bullet b) \bullet c$
6	Distributivity	For every $a, b,$ and c in K	$a + (b \bullet c) = (a + b) \bullet (a + c)$	$a \bullet (b + c) = (a \bullet b) + (a \bullet c)$
7	Complement	For every a in K \exists a complement in $K \ni$	$a + \bar{a} = 1$	$a \bullet \bar{a} = 0$

of one set OR another of the sets in the union. An element in a set that is the intersection of sets is a member of one set AND a member of the other sets in the intersection.

A set of theorems derived from the postulates facilitates further developments. The theorems are summarized in Table 1.17. Use of the postulates is illustrated by the proof of a theorem in Fig. 1.33.

1)	$x + x = x + x$	IDENTITY
2)	$= (x + x) \cdot 1$	P3b IDENTITY ELEMENT EXISTENCE
3)	$= (x + x) \cdot (x + \bar{x})$	P7a COMPLEMENT EXISTENCE
4)	$= x + x \cdot \bar{x}$	P6a DISTRIBUTIVITY
5)	$= x + 0$	P7b COMPLEMENT EXISTENCE
6)	$= x$	P3a IDENTITY ELEMENT EXISTENCE

FIGURE 1.33 Proof of Theorem 8: Idempotency (a): $x + x = x$.

1.5.10 Boolean Functions

Boolean functions can be defined and represented in terms of boolean expressions and in terms of **truth tables** as illustrated in Fig. 1.34(a) and Fig. 1.34(c). Each form can be converted into the other form. The function values needed for the construction of the truth table can be obtained by evaluating the function as illustrated in Fig. 1.18(b). The reverse conversion will be illustrated subsequently.

TABLE 1.17 Boolean Theorems

Theorem		Forms	
		(a)	(b)
8	Idempotency	$a + a = a$	$a \bullet a = a$
9	Complement Theorem	$a + 1 = 1$	$a \bullet 0 = 0$
10	Absorption	$a + ab = a$	$a(a + b) = a$
11	Extra Element Elimination	$a + \bar{a}b = a + b$	$a(\bar{a} + b) = ab$
12	De Morgan's Theorem	$a \bar{+} b = \bar{a} \cdot \bar{b}$	$\bar{a}\bar{b} = \bar{a + b}$
13	Consensus	$ab + \bar{a}c + bc = ab + \bar{a}c$	$(a + b)(\bar{a} + c)(b + c) = (a + b)(\bar{a} + c)$
14	Complement Theorem 2	$ab + a\bar{b} = a$	$(a + b)(a + \bar{b}) = a$
15	Consensus 2	$ab + a\bar{b}c = ab + ac$	$(a + b)(a + \bar{b} + c) = (a + b)(a + c)$
16	Consensus 3	$ab + \bar{a}c = (a + c)(\bar{a} + b)$	$(a + b)(\bar{a} + c) = ac + \bar{a}b$

For a given number of variables there are a finite number of boolean functions. Since each boolean variable can have two values, 0 or 1, a set of n variables has 2^n different values. A boolean function has a specific value for each of the possible values that the independent variables can have. Since there are two possible values for each value of the independent variables there are 2^{2^n} different boolean functions of two variables. The number of functions increases very rapidly with the number of independent variables as shown in Table 1.18.

The 16 different boolean functions of two independent variables are defined in algebraic form in Table 1.19 and in truth table form in Table 1.20.

(a) $f(A, B, C) = AB + A\bar{C} + \bar{A}C$

(b) $f(0, 0, 1) = 0 \cdot 0 + 0 \cdot \bar{1} + \bar{0} \cdot 1$
 $= 0 \cdot 0 + 0 \cdot 0 + 1 \cdot 1$
 $= 0 + 0 + 1$
 $= 1$

1.5.11 Switching Circuits

Boolean functions can be performed by digital circuits. Circuits that perform complicated boolean functions can be subdivided into simpler circuits that perform simpler boolean functions. The circuits that perform the simplest boolean functions are taken as basic elements, called *gates* and are represented by specialized symbols. The circuit symbols for the gates that perform functions of two independent variables are shown in Table 1.19. The gates are identified by the adjective representing the operation they perform. The most common gates are the AND, OR, NAND, NOR, XOR and COIN gates. The only nontrivial single input gate is the inverter or NOT gate. Gates are the basic elements from which more complicated digital logic circuits are constructed.

A logic circuit whose steady-state outputs depend only on the present steady-state inputs (and not on any prior inputs) is called a *combinational logic circuit*. To depend on previous inputs would require memory, thus a combinational logic circuit has no memory elements.

Boolean algebra allows any combinational logic circuit to be constructed solely with AND, OR, and NOT gates. Any combinational logic circuit may also be constructed solely with NAND gates, as well as solely with NOR gates.

1.5.12 Expansion Forms

The **sum of products (SP)** is a basic form in which all boolean functions can be expressed. The **product of sums (PS)** is another basic form in which all boolean functions can be expressed. An illustrative example is given in Fig. 1.35(b) and Fig. 1.35(c) for the example given in Fig. 1.35(a).

Minterms are a special set of functions, none of which can be expressed in terms of the others. Each minterm has each of the variables in the complemented or the uncomplemented form ANDed together. An SP expansion in which only minterms appear is a canonical SP expansion. Figure 1.35(d) shows the development of the canonical SP expansion for the previous example. The canonical SP expansion may also be simply expressed by enumerating the minterms as shown in Fig. 1.35(f). Comparison of the truth table with the minterm expansion shows that each function value of 1 represents a minterm of the function and vice versa. All other function values are 0.

Maxterms are a special set of functions, none of which can be expressed in terms of the others. Each maxterm has each of the variables in the complemented or the uncomplemented form ORed together. A PS expansion in which only maxterms appear is a canonical PS expansion. Figure 1.35(e) shows the development of the canonical PS expansion for the previous example. The canonical PS expansion may also be simply expressed by enumerating the maxterms as shown in Fig. 1.35(g). Comparison of the truth table with the maxterm expansion shows that each function value of 0 represents a maxterm of the function and vice versa. All other function values are 1.

1.5.13 Realization

The different types of boolean expansions provide different circuits for implementing the generation of the function. A function expressed in the SP form is directly realized as an AND-OR **realization** as illustrated in Fig. 1.36(a). A function expressed in the PS form is directly realized as an OR-AND realization as illustrated

FIGURE 1.35 Examples of converting boolean functions between forms: (a) given example, (b) conversion to SP form, (c) conversion to PS form, (d) conversion to canonical SP form, (e) conversion to canonical PS form, (f) minterm notation/canonical SP form, (g) maxterm notation/canonical PS form.

in Fig. 1.36(b). By using involution and deMorgan’s theorem the SP expansion can be expressed in terms of NAND- NAND and the PS expansion can be expressed in terms of NOR-NOR as shown in Fig. 1.36(c) and Fig. 1.36(d). The variable inversions specified in the inputs can be supplied by either NAND or NOR gates as shown in Fig. 1.36(g) and Fig. 1.36(h), which then provide the NAND-NAND-NAND and the NOR-NOR-NOR circuits shown in Fig. 1.36(i) and Fig. 1.36(j).

1.5.14 Timing Diagrams

Timing diagrams are of two major types. A **microtiming diagram** has a time scale sufficiently expanded in space to display clearly the gate delay, such as shown in Fig. 1.37(a) for an AND gate. A **macrotiming diagram** has a time scale sufficiently contracted in space so that the gate delay is not noticeable, as shown in Fig. 1.37(b) for an AND gate.

The advantage of the macrotiming diagram is that larger time intervals can be represented in a given spatial size and they can be more quickly developed. The disadvantage is that they do not display the information required for speed limitation considerations.

1.5.15 Hazards

The variation in signal delays through different circuit elements in different paths may cause the output signal to fluctuate from that predicted by non-time-dependent truth tables for the elements. This fluctuation can cause an undesired result and, hence, is a *hazard*. This is illustrated in Fig. 1.38.

1.5.16 K-Map Formats

In a truth table the values of a boolean function are displayed in a one-dimensional array. A **K-map** contains the same information arranged in as many effective dimensions as there are independent variables in the function. The special form of the representation provides a simple procedure for minimizing the expression and, hence, the number of components required for realizing the function in a given form. The function

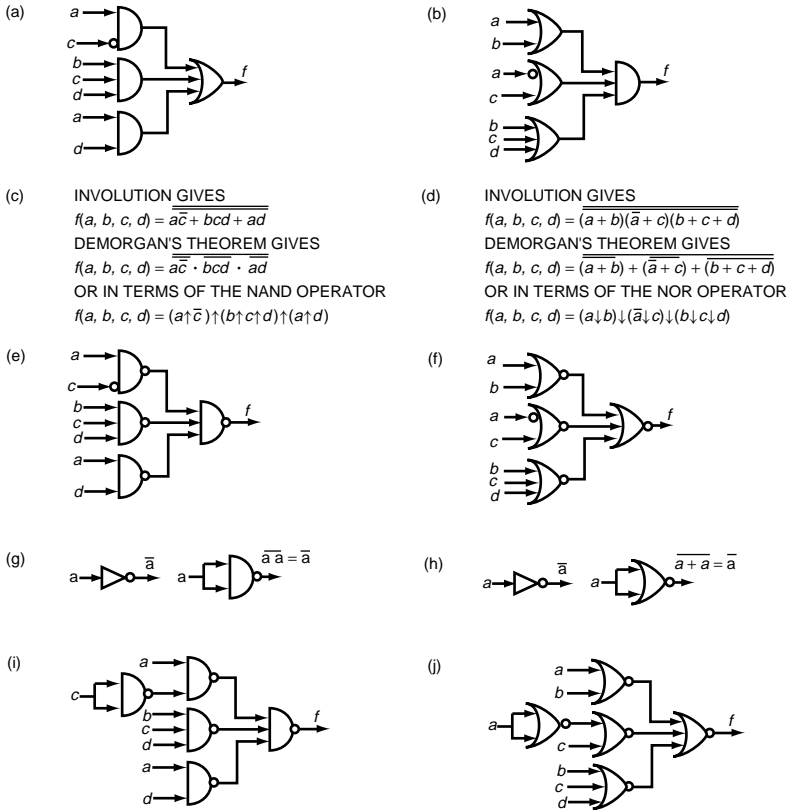

FIGURE 1.36 Examples of realizations based on various expansion forms: (a) AND-OR realization of $f(a, b, c, d) = a\bar{c} + bcd + ad$, (b) OR-AND realization of $f(a, b, c, d) = (a + b)(\bar{a} + c)(b + c + d)$, (c) AND-OR conversion to NAND-NAND, (d) OR-AND conversion to NOR-NOR, (e) NAND-NAND realization of $f(a, b, c, d) = a\bar{c} + bcd + ad$, (f) NOR-NOR realization of $f(a, b, c, d) = (a + b)(\bar{a} + c)(b + c + d)$, (g) NAND gate realization of NOT gate, (h) NOR gate realization of NOT gate, (i) NAND-NAND-NAND realization of $f(a, b, c, d) = a\bar{c} + bcd + ad$, (j) NOR-NOR-NOR realization of $f(a, b, c, d) = (a + b)(\bar{a} + c)(b + c + d)$.

is represented in a space that in a Venn diagram is called the *universal set*. The *K-map* is a special form of Venn diagram. The space is divided into two halves for each of the independent variables. The division of the space into halves is different for each independent variable. For one independent variable the space is divided into two different identical size regions, each of which represents a minterm of the function. For n independent variables the space is divided into 2^n different identical size regions, one for each of the 2^n minterms of the function. This and associated considerations are illustrated in a sequence of figures from Fig. 1.39 to Fig. 1.46.

FIGURE 1.37 Timing diagrams for the AND gate circuit: (a) microtiming diagram, (b) macrotiming diagram.

FIGURE 1.38 Example of a hazard (output variation) caused by unequal delay paths: (a) circuit for illustrating a hazard, (b) ideal case, no delays, $\tau_1 = \tau_2 = \tau_3 = 0$, no hazard introduced; (c) signal paths with different delays, $\tau_1 + \tau_2 + \tau_3 > \tau_3$, hazard introduced.

Figure 1.39 shows one-variable *K*-map formats. Figure 1.39(a) shows the space divided into two equal areas, one for each of the two minterms possible for a single variable. The squares could also be identified by the variable placed external to the space to designate the region that is the domain of the variable, with the unlabeled space being the domain of the complement of the variable, as shown in Fig. 1.39(b). Another way of identifying the regions is by means of the minterm number the area is for, as shown in Fig. 1.39(c). Still another way is to place the values the variable can have as a scale alongside the space, as shown in Fig. 1.39(d). The composite labeling, shown in Fig. 1.39(e), appears redundant but is often useful because of the different modes of thought used with the different label types. Putting the actual minterm expressions inside each square is too cluttering and is rarely used except as an aid in teaching the theory of *K*-maps. The use of minterm numbers, although widely used, also clutters up the diagram, and the methodology presented here makes their use superfluous once the concepts are understood.

FIGURE 1.39 One variable *K*-map forms: (a) internal minterm labels, (b) external domain label, (c) internal minterm number labels, (d) external scale label, (e) composite labeling.

The organization of a two-variable *K*-map format is illustrated in Fig. 1.40. The space is subdivided vertically into two domains for the variable *a* and its complement, and is subdivided horizontally for the variable *b* and its complement as shown in Fig. 1.40(a) and Fig. 1.40(b). The composite subdivisions for both variables together with the expressions for the two-variable minterms are shown in Fig. 1.40(c).

FIGURE 1.40 Two-variable *K*-map format construction: (a) domains for *a*, (b) domains for *b*, composite.

The different formats for identifying the areas for the two-variable case are shown in Fig. 1.41. Of particular interest is the comparison of the binary and decimal minterm number labels. The binary minterm number is simply the **catenation** of the vertical and horizontal scale number for the position. It is the use of this identity that makes internal labels in the square totally superfluous.

FIGURE 1.41 Two variable *K*-map formats: (a) minterm labels, (b) domain labels, (c) minterm binary labels, (d) minterm decimal labels, (e) scale labels, (f) composite labeling.

An alternate way of subdividing the space for the two-variable case is illustrated in Fig. 1.42 and labeling alternatives in Fig. 1.43. The configuration employed in Fig. 1.40 uses two dimensions for two variables, whereas the configuration employed in Fig. 1.42 uses one-dimension for two variables. The two dimensional configuration appears to be more logical and is more convenient to use than the one dimensional configuration for the case of two variables. For the case of a larger number of variables the configuration in Fig. 1.43 offers special advantages, as will be shown.

FIGURE 1.42 Two-variable *K*-map alternate format construction: (a) domains for *a*, (b) domains for *b*, (c) composite.

FIGURE 1.43 Two-variable *K*-map alternate format: (a) minterm labels, (b) composite labeling.

The organization of three-variable *K*-map formats is illustrated in Fig. 1.44. It is logical to introduce an additional space dimension for each additional independent variable as depicted in Fig. 1.44(a); however, the excessive inconvenience of working with such formats makes them impractical. To make the mapping process practical it must be laid out in two dimensions. This can be done in two ways. One way is to take the individual slices of the three-dimensional configuration and place them adjacent to each other as illustrated in Fig. 1.44(b). Another way is to use the one-dimensional form for two variables, illustrated in Fig. 1.43, as shown in Fig. 1.44(c). For the case of three and four independent variables the format given in Fig. 1.44(c) is more convenient and for further independent variables that of Fig. 1.44(b) is convenient. These are all illustrated in Fig. 1.46.

FIGURE 1.44 Three-variable *K*-map formats: (a) three dimensional, (b) three-dimensional left and right halves, (c) two dimensional.

Labeling for three independent variables is given in Fig. 1.45.

FIGURE 1.45 Three variable two dimensional *K*-map formats: (a) minterm labels, (b) composite labels.

The independent boolean variables in **conformal coordinate scales** have exactly the same order as in the boolean function argument list, as depicted in Fig. 1.46. Conformal assignment of the independent variables to the *K*-map coordinate scales makes the catenated position coordinates for a minterm (or maxterm) identical to the minterm (or maxterm) number. Utilization of this identity eliminates the need for the placement of minterm identification numbers in each square or for a separate position identification table. This significantly decreases the time required to construct *K*-maps and makes their construction less error prone. The minterm number, given by the catenation of the vertical and horizontal coordinate numbers, is obvious if the binary or octal number system is used.

1.5.17 *K*-Maps and Minimization

A function is mapped into the *K*-map format by entering the value for each of the minterms in the space for that minterm. The function values can be obtained in various ways such as from the truth table for the function, the boolean expression for the function, or from other means by which the function may be defined. An example is given for the truth table given in Fig. 1.35(a), which is repeated here in Fig. 1.47(a) and whose *K*-map is shown in various forms in Fig. 1.47(b) to Fig. 1.47(d).

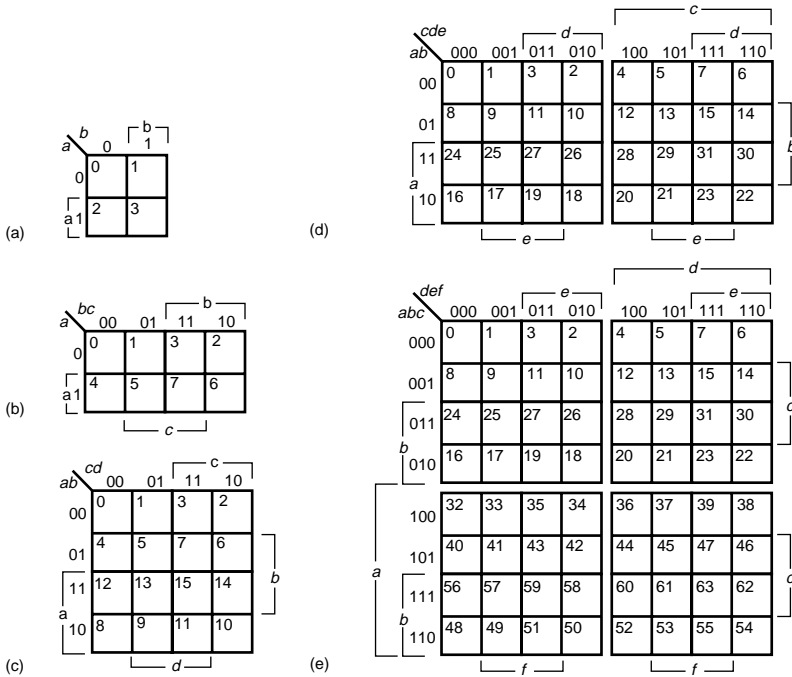

FIGURE 1.46 Formats for K -maps for functions of 2–6 independent variables with conformal coordinate scales: (a) two-variable case $f(a, b)$, three-variable case $f(a, b, c)$, (c) four-variable case $f(a, b, c, d)$, (d) five-variable case $f(a, b, c, d, e)$, (e) six-variable case $f(a, b, c, d, e, f)$.

The function can also be mapped into a conformally scaled K -map directly from the canonical expansion, this being essentially the same process as entering the minterms (or maxterms) from the truth table. The function may also be directly mapped from any PS or SP expansion form. Another means of obtaining the K -map is to formulate it as a function table, as illustrated for the multiplication of 1- and 2-b numbers in Fig. 1.48.

1.5.18 Minimization with K -Maps

The key feature of K -maps that renders them convenient for minimization is that minterms that are spatially adjacent in the horizontal or vertical directions are logically adjacent. Logically adjacent minterms are identical in all variables except one. This allows the two minterms to be combined into a single terms with one less variable. This is illustrated in Fig. 1.49. Two adjacent minterms combine into a first-order **implicant**.

FIGURE 1.47 Three-variable K -map example: (a) truth table, (b) K -map with all values shown, (c) minterm K -map, (d) maxterm K -map.

FIGURE 1.48 Examples of K -maps formulated as function tables: (a) K -map for the product of two 1-b numbers $P = x * y$; (b) composite K -map for the product of two 2-b numbers, $P_3 P_2 P_1 P_0 = x_1 x_0 * y_1 y_0$; (c) K -map for the digit P_3 of the product of two 2-b numbers; (d) K -map for the digit P_2 of the product of two 2-b numbers; (e) K -map for the digit P_1 of the product of two 2-b numbers; (f) K -map for the digit P_0 of the product of two 2-b numbers.

FIGURE 1.49 Example of minimization with a K -map: (a) sample K -map, (b) expression in minterms of function definition in (a), (c) simplification of the expression in (b), (d) simplification of the expression in (b) using single symbol minterm and implicant notation.

A first-order implicant is the combination of all of the independent variables but one. In this example the first-order implicant expressed in terms of minterms contains eight literals but the minimized expression contains only three literals. The circuit realization for the OR combination of the two minterms has two AND gates and one OR gate, whereas the realization for the equivalent implicant requires only a single AND gate.

The combination of minterms into first-order implicants can be represented more compactly by using the single symbol minterm notation with the subscript that identifies the particular minterm expressed in binary, as illustrated in Fig. 1.49(d).

Two adjacent first-order implicants can be combined into a second-order implicant as illustrated in Fig. 1.50. A second-order implicant contains all of the independent variables except two. In general, an

FIGURE 1.50 Example of minimization with K -map.

n th-order implicant contains all of the variables except n and requires an appropriately grouped set of 2^n minterms.

Minterms that are at opposite edges of the same row or column are logically adjacent since they differ in only one variable. If the plane space is rolled into a cylinder with opposite edges touching, then the logically adjacent edge pairs become physically adjacent. For larger numbers of variables using K -maps with parallel sheets the corresponding positions on different sheets are logically adjacent. If the sheets are considered as overlaid the corresponding squares are physically adjacent. The minimized expression is obtained by covering the all of the minterms with the fewest number of largest possible implicants. A minterm is a zero-order implicant. Figure 1.51 illustrates a variety of examples. A **don't care** is a value that never occurs or if it does occur it is not used, and hence, it does not matter what its value is. Don't cares are also included to illustrate that they can be used to simplify expressions by taking their values to maximize the order of the implicants.

Maxterm K -maps can also be utilized to obtain minimized expressions by combining maxterms into higher order implicants, as illustrated for the example in Fig. 1.52.

FIGURE 1.53 Illustration of the Quine–McClusky method of simultaneous minimization.

1.5.19 Quine–McCluskey Tabular Minimization

The K -map minimization method is too cumbersome for more than six variables and does not readily lend itself to computerization. A tabular method, which can be implemented for any number of variables and which lends itself to computer program implementation, consists of the following steps:

1. List all the minterms in the boolean function (with their binary code) organized into groups having the same number of 1s. The groups must be listed in consecutive order of the number of 1s.
2. Construct the list of first-order implicants. Use flags to indicate which minterms, don't cares, or implicants go with which functions. (Only minterms in adjacent groups have the possibility of being adjacent and, hence, this ordering method significantly reduces the labor of compiling the implicants.)
3. Construct the list of second-order implicants and the lists of all higher order implicants until no higher order implicants can be constructed.
4. Construct the *prime implicant chart*. The prime implicant chart shows what prime implicants cover which minterms.
5. Select the minimum number of largest prime implicants that cover the minterms.

This procedure is illustrated in Fig. 1.53 for the simultaneous minimization of two boolean functions.

Defining Terms

Base: The number a digit must be multiplied by to move it one digit to the left, also called the radix.

Binary coded decimal (BCD): Each decimal digit is expressed individually in binary form.

Catenation: Symbols strung together to form a larger sequence, as the characters in a word and the digits in a number.

Code: The representation in one alphabet of something in another (usually larger) alphabet.

Complement: The quantity obtained by subtracting a number from the largest quantity that can be expressed in the specified number of digits in a given number system.

Conformal: The same arrangement of a set of quantities in two different contexts.

Digit: A character that represents quantitative information.

Don't care: A function that can be taken either as a minterm or a maxterm at the convenience of the user.

Gray code: A set of codes having the property of logical adjacency.

Implicant: A first-order implicant is a pair of logically adjacent minterms. A second-order implicant is a set of logically adjacent first-order implicants and so on.

Integer: Any number that can be expressed solely in terms of digits.

Fraction: Any number divided by a larger number.

K -map: An arrangement of space into equal size units, each of which represents a minterm (or maxterm) such that each physically adjacent square is also logically adjacent.

Logically adjacent: Any two codes having the same number of digits for which they differ in the value of only one of the digits.

Macrotiming diagram: A graphical display showing how the waveforms vary with time but with a time scale that does not have sufficient resolution to display the delays introduced by the individual basic elements of the digital circuit.

Maxterm: A function of a set of boolean variables that has a low value for only one combination of variable values and has a high value for all other combinations of the variable values.

Microtiming diagram: A graphical display showing how the waveforms vary with time but with a time scale that has sufficient resolution to display clearly the delays introduced by the individual basic elements of the digital circuit.

Minterm: A function of a set of boolean variables that has a high value for only one combination of variable values and has a low value for all other combinations of the variable values.

Overflow: That part of a numerical operation that does not fit into the allocated field.

Parity bit: An extra bit catenated to a code and given a value such that the total number of high bits is even for even parity and odd for odd parity.

Product of sums (PS): The AND combination of terms, which are OR combinations of boolean variables.

Prime implicant: An implicant that is not part of a larger implicant.

Radix: The number of different values that a digit can have in a number system.

Reduced radix: The largest value a digit can have in a number system. It is one less than the radix.

Real number: A number that has a fractional part and an integer part.

Realization: A circuit that can produce the value of a function.

Sum of products (SP): The OR combination of terms, which are AND combinations of boolean variables.

Truth table: The table of values that a Boolean function can have for which the independent variables considered as a multidigit number are arranged in consecutive order.

1.6 Digital Logic and Sequential Logic Circuits

George I. Cohn

1.6.1 Combinational and Sequential Logic Circuits

A **combinational logic** circuit contains logic gates but does not contain storage elements. A symbolic representation of a multiple-input multiple-output combinational logic circuit is shown in Fig. 1.54(a). The outputs of a combinational logic circuit depend only on the present inputs to the circuit. A sequential

FIGURE 1.54 Logic circuits: (a) combinational, (b) sequential.

FIGURE 1.55 A combinational logic circuit with stable feedback is a sequential logic circuit.

logic circuit contains storage elements in addition to gates. A symbolic representation of a multiple-input multiple-output **sequential logic** circuit is shown in Fig. 1.54(b). The outputs of a sequential logic circuit depend on prior inputs as well as current inputs.

Combinational logic circuits with **feedback**, as shown in Fig. 1.55, with stable behavior can store information. Feedback provides one or more closed loops through the circuit. The outputs fed back as inputs may cause the outputs to change, thereby changing the inputs again, and so on. If the outputs keep changing without reaching a fixed equilibrium **state** the system is **unstable**. If the outputs settle to a fixed unchanging equilibrium state the system is **stable**. A combinational logic circuit with closed-loop feedback that is stable can store information and, hence, be used as a memory element. The current inputs produce the next outputs at a later time due to the propagation delays through the circuit. If the next outputs, which are fed back, are equal to the previous inputs due to feedback the system is in a stable state. If they are unequal they are in an unstable state since it is undergoing a transient variation. These conditions are shown in Table 1.21.

The system may eventually reach a stable state or it may not. Because of the variation in the delay time through the various elements of the system the state may not be predictable from the elementary tables employed for representation of the elements and the circuit. This may happen when more than one input is changed before an equilibrium condition is reached. This situation is avoided when the operation restriction is employed that only one input is changed at a time and that there is no further change in any input until equilibrium is established. In practice, this restraint must be removed or the design must be implemented so as to remove ambiguities. If two or more state variables change in a process the changes may not take place simultaneously. The phenomena can be considered a **race** as to which takes place first and this is referred to as a **race condition**. If the final state depends on which variable changes first the phenomena is a **critical race**. If the final state is independent of the order of change the phenomena is a **noncritical race**.

TABLE 1.21 System State

State	Condition
Stable	$y_i^{next} = y_i; \quad i = 0:k$
Unstable	$y_i^{next} \neq y_i; \quad i = 0:k$

FIGURE 1.57 NOR gate and NOR gate truth table: (a) for equilibrium conditions, (b) with gate delay time represented.

1.6.2 Set-Reset Latch

A simple combinational logic circuit with two NOR gates is shown in Fig. 1.56(a). This circuit with a feedback path providing a closed loop as shown in Fig. 1.56(b) has two stable states and, hence, can be used to store one binary digit of information. Since the gates function symmetrically it is convenient to draw the circuit in symmetric form as shown in Fig. 1.56(c), to convey the perception of symmetric behavior.

The circuit element characteristics are required to analyze this circuit to determine the conditions under which the behavior is stable and the conditions under which it is unstable. The NOR gate characteristics normally specified by the truth table in Fig. 1.57(a) correctly give the steady-state equilibrium characteristics. However, signals presented to the input terminals produce effects at the output terminals at a later time. The time delay for the effect to propagate through the device (called the *gate delay time* and represented by the symbol tau τ) has an important effect on the behavior of the circuit. Figure 1.57(b) shows the truth table labeled so that this delay is explicitly designated.

1.6.3 Latch Analysis with Difference Equations

The **latch** circuit shown in Fig. 1.56(c) is redrawn in Fig. 1.58 with the outputs represented in terms of the inputs, with the gate delay explicitly shown, and with the outputs expressed as first-order difference equations in terms of the inputs. The case for general inputs is shown in Fig. 1.58(a) and the special case for low inputs in Fig. 1.58(b). With low inputs the equations in Fig. 1.57(b) show that if the two outputs are complements, $O_2^t = \overline{O_1^t}$, that the system is stable, that is, $O_1^{t+\tau} = O_1^t$ and $O_2^{t+\tau} = O_2^t$. It also shows that if the two outputs are equal $O_2^t = O_1^t$ the system is unstable, that is, $O_1^{t+\tau} = \overline{O_1^t}$ and $O_2^{t+\tau} = \overline{O_2^t}$. Table 1.22 illustrates the development for the low input cases.

FIGURE 1.58 Two NOR gate latches: (a) arbitrary inputs, (b) low inputs.

TABLE 1.22 Output Status of Set-Reset Latch with Low Inputs

signal					
time	↓	I_1	O_1	O_2	I_2
Oscillatory for equal outputs:					
t		0	n	n	0
$t + \tau$		0	$1-n$	$1-n$	0
$t + 2\tau$		0	n	n	0
$t + 3\tau$		0	$1-n$	$1-n$	0
Stable for complementary outputs:					
t		0	k	$1-k$	0
$t + \tau$		0	k	$1-k$	0

TABLE 1.23 Stabilization of Set-Reset Latch with a High Input

signal					
time	↓	I_1	O_1	O_2	I_2
t		1	k	k	0
$t + \tau$		1	0	$1-k$	0
$t + 2\tau$		1	0	1	0
$t + 3\tau$		0	0	1	0

A high signal into either input stabilizes the circuit. Because of the circuit symmetry it is only necessary to demonstrate this for one case. This behavior is shown by the output status chart of Table 1.23.

A **set-reset** (SR) latch in a stable state is changed to a different stable state by a high external input to the gate, which has the initially high output. The new state remains stable with the new value and continues to remain stable when the external input is removed. If the external input to a gate is less than the other gate's output there is no change in state. This output status is charted in Table 1.24.

With both inputs high, both outputs are driven low and will remain low as long as both high inputs are in place. The circuit becomes oscillatory one gate delay after the pair of high inputs are removed.

1.6.4 Microtiming Diagram Construction

Timing diagrams were introduced in Chapter 1.5, Section 1.5.14. The circuit example in Fig. 1.58 has four waveforms in the timing diagram, one for each distinct wire. The signals supplied from external sources, that is, **excitations** or driving functions, are the independent electrical variables, which have to be

TABLE 1.24 Effect of a High Input on a Stable Set-Reset Latch

signal					
time	↓	I_1	O_1	O_2	I_2
State change:					
t		1	1	0	0
$t + \tau$		1	0	0	0
$t + 2\tau$		1	0	1	0
$t + 3\tau$		0	0	1	0
No effect:					
t		1	0	1	0
$t + \tau$		1	0	1	0

FIGURE 1.59 Microtiming diagram example for the set-reset latch: (a) specified driving and initial conditions, (b) output-2 advanced to t_2 , (c) output-1 advanced to t_2 , (d) outputs advanced to t_{10} .

prespecified for the time duration of interest in order to construct the timing diagram. The waveforms on all of the wires that are not directly connected to the input terminal are the dependent electrical variables that have to be determined for the timing diagram. The initial conditions, that is, the initial values of the dependent variables, must also be specified prior to the construction of the timing diagram.

Construction of a microtiming diagram for the circuit given in Fig. 1.58 is illustrated. If the initial conditions of the dependent variable waveforms are not specified, then it would be necessary to develop the timing diagrams for each of the possible sets of initial conditions in order to have the complete set of possible responses of the system to the specified driving functions. The construction process is illustrated for the initial conditions given in Fig. 1.59(a). Normally, the set of driving waveforms would be given in one group and the dependent variable waveforms in a subsequent group. However, the arrangement given in Fig. 1.59(a) facilitates the development of the microtiming diagram for this example.

Physically the waveforms develop simultaneously with time. The procedure for reasoning out the dependent variable waveforms is facilitated by using discrete time steps having a quantized value equal to the gate delay $\tau = t_n - t_{n-1}$ since it takes a gate delay for a cause at the input terminals of a gate to produce an effect at the output terminal, shown by the gate equations in Fig. 1.58.

Since the effect waveform is due to the cause waveforms a gate delay earlier, the causal arrows in Fig. 1.59(b) and Fig. 1.59(c) show the waveform values at the arrow tails that cause the waveform values at the arrow tip. The advancement of output-2 by one gate delay is shown in Fig. 1.59(b). Since any high input to a NOR gate drives the output low it is only necessary to consider a single high input to determine a low gate output. If all of the inputs to a NOR gate are low the output is driven high one gate delay later as shown in Fig. 1.59(c) for the advancement of output-1 by one gate delay. This process is continued until the timing diagram has been constructed for the time range of interest as shown in Fig. 1.59(d).

The microtiming diagram shows that whenever the outputs are in an equilibrium state they are complements of each other. The noncomplementary condition occurs only for a portion of the interval during which the transient transition between states takes place. In the timing diagram shown a transient transition between states occurs when a high input signal is supplied to the gate which has the high output.

1.6.5 Set-Reset Latch Nomenclature

The symbol Q is standard notation for representing the state terminal. Either output terminal can be arbitrarily selected as the state terminal. The signal at the state terminal represents the state of the circuit. Since the other terminal always provides the complement of the state during equilibrium and since the output is used in computers only when the storage element is in equilibrium, the complement of Q is a satisfactory notation for the other output terminal.

For the circuit given in Fig. 1.58, output-terminal-2 is arbitrarily chosen as the state terminal. Since output-2 is initially low, the circuit is initially in the low state. The high signal into input-terminal-1 causes a transition to the high state. Therefore, input-terminal-1 is called the S or *set terminal*. Once the transition to the high state has been made, the circuit remains in this state. Further high input signals to the S terminal cause no further change since the circuit is already in the high state. When the circuit is in the high state, a high signal into input-terminal-2 causes a transition to the low state. Therefore, input-terminal-2 is called the R or *reset terminal*. With this standard nomenclature for the terminals the *set-reset latch* circuit is shown in Fig. 1.60(a). The standard *single-block symbol* (SBS) representation for a set-reset latch is shown in Fig. 1.60(b). In the SBS notation the Q terminal is placed opposite the S terminal rather than opposite to the R terminal as in the circuit diagram.

FIGURE 1.60 The set-reset (SR) latch: (a) circuit diagram, (b) SBS representation.

1.6.6 Set-Reset Latch Truth Table

The current state and the input signals are the independent variables that determine the next state, which is the *dependent variable*. The input signals are the driving functions that command the device to change its state. A high input signal to the S terminal commands the device to be set, that is, to go to the high state. A high input signal to the R terminal commands the device to be reset, that is, to go to the low state. The SR latch operation is given in **state diagram** form in Fig. 1.61. A complete set of transition command combinations is given in Table 1.25.

1.6.7 Set-Reset Latch Macrotiming Diagram

To better observe the differences between micro- and macrotiming diagrams, corresponding examples are directly compared. The microtiming diagram in Fig. 1.59(d) is redrawn in Fig. 1.62(a) with the input and output waveforms separately grouped. Figure 1.62(b) gives the corresponding macrotiming diagram, which neglects the propagation delay through the gates.

FIGURE 1.61 State diagram with explicit transition commands: (a) state diagram element, (b) SR latch state diagram.

1	1	1	?	

1.6.8 JK Latch

The SR latch’s undesirable behavior resulting when both inputs are high can be eliminated by using AND gates in the input leads to block the simultaneous application of both high input signals, as shown in Fig. 1.63(a). The input AND gate layer is controlled by the state and complementary state signals. This causes the state to complement whenever both inputs are high. The single block symbol for the JK latch is shown in Fig. 1.63(b). The truth table for the JK latch differs from that of the SR latch only in the last two entries as shown in Fig. 1.63(c).

1.6.9 T Latch

Combining the two inputs of a JK latch into a single input gives a latch that changes state when a high signal is applied. This action is called *toggling* and, hence, it is called a toggle or *T latch*. The circuit, symbol, and truth table are shown in Fig. 1.64.

FIGURE 1.62 Example timing diagrams for an asynchronous SR latch: (a) microtiming diagram, (b) macrotiming diagram.

FIGURE 1.63 The JK latch: (a) JK latch circuit, (b) JK latch SBS representation, (c) JK latch truth table.

FIGURE 1.64 The T latch: (a) T latch circuit, (b) T latch SBS representation, (c) T latch truth table.

1.6.10 D Latch

A latch that stores the signal on an input data line is a data or D latch. A circuit that can accomplish this is shown in Fig. 1.65 along with its symbol representation and truth table. The D latch requires a second input, called a control signal and is sometimes a clock pulse, to control when the input signal is placed in storage.

1.6.11 Synchronous Latches

The circuit shown in Fig. 1.60 is an **asynchronous** set-reset latch, it responds whenever the input signal is applied. In a system using a multiplicity of such latches there may be significant variations in the arrival time of the input signals. In some applications it is desirable to have the latches respond simultaneously even though there is a variation in the input signal arrival times. Simultaneity is obtained by synchronizing the actions. This is done by the use of a common synchronizing signal, usually the *clock signal*. Latches that require a synchronizing signal for their activation are referred to as **synchronous** latches such as depicted in Fig. 1.66. It is advantageous to use the SBS for a latch that is an element in a more complex circuit. A macrotiming diagram example for a synchronous SR latch is shown in Fig. 1.67.

The complete truth table for the synchronous SR latch is given in Fig. 1.68. A truth table is more than doubled in size (twice the length plus one column) by the incorporation of each additional input variable. Since there are no changes that occur in the absence of a clock pulse, the abbreviated truth table contains all of the required information and is less than half the size.

1.6.12 Master-Slave Flip-Flops

It is often desirable to process information stored in memory elements and then restore the information in the memory element. If the memory element is a latch, such as shown in Fig. 1.69, the feedback would cause a problem. Signals can propagate around such a feedback loop an unknown number of times causing unknown results at the time the control pulse is turned off, breaking the feedback loop.

FIGURE 1.68 Synchronous SR latch truth-tables: (a) complete, (b) abbreviated.

A storage element that allows only one transit of the signal eliminates this indeterminacy. This can be provided by a two-stage configuration such as illustrated in Fig. 1.70. The first stage, called the **master**, receives the information when it is gated into the master stage by the control pulse. When the control pulse is high, the gating control signal to the second stage, called the **slave**, is low. Consequently, the slave cannot receive new information until the control pulse goes off, that is, becomes low. At this time the information received by the master is passed on to the slave. The information passed on to the slave becomes available at the output terminals just after the trailing edge of the control pulse occurs. The master-slave (MS) two-latch cascade is called a **flip-flop** (FF). Since this particular design provides the information gated into storage at the output terminal when the trailing edge of the gating pulse occurs, it is called a **trailing-edge-triggered** (TET) flip-flop. A macrotiming diagram for the trailing-edge-triggered flip-flop is shown in Fig. 1.71.

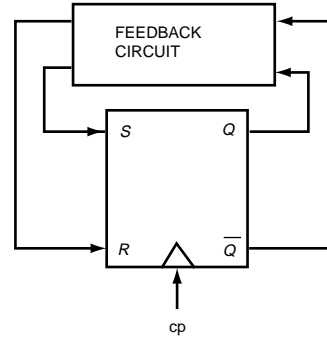

FIGURE 1.69 A synchronous SR latch with external feedback.

Each type of latch has a corresponding type of flip-flop. The single block symbols for the corresponding FFs are given in Fig. 1.72.

1.6.13 Standard Master-Slave Data Flip-Flop

It is convenient to have data flip-flops that have a simple direct means for initializing them to either the high or the low state. For this purpose the standard *D* FF is provided with separate *S* and *R* input terminals, as shown in Fig. 1.73, so that it can be directly set or reset independently of the data input terminal.

FIGURE 1.70 Trailing-edge triggered master-slave (MS) SR-FF: (a) circuit diagram, (b) SBS representation.

FIGURE 1.71 Macrotiming diagram for a trailing-edge-triggered MS SR-FF.

The standard *D* FF, thus, can be either used as an asynchronous SR latch by using terminals *S* and *R* (without signals to terminals *D* and *C*), or can be used as a *D* FF by using terminals *D* and *C* (without signals to terminals *R* and *S*).

1.6.14 Sequential Logic System Description

Sequential logic circuits differs from combinational logic circuits by containing memory. A sequential logic circuit output consequently depends on prior inputs as well as the current inputs. For the purpose of digital systems the state of a wire (or terminal) is the value of the signal on it. The state of a circuit is the set of signals on the set of wires in the circuit. Since each wire is connected to an output terminal of an element in the circuit, the set of signals at the output terminals of the elements comprising the circuit represent the state of the circuit. If the element is a gate, then the output is given by the current inputs of the gate. Hence, a sufficient description of the system is given by the set of values of the signals at the output terminals of the memory elements in the circuit. Hence, the state of the circuit is represented by the collected states of the set of memory elements comprising the circuit.

If the output is a function of the input as well as the state, the system is referred to as a **Mealy model**, Fig. 1.74(a). If the output is only a function of the state the system, it is referred to as a **Moore model**, Fig. 1.74(b).

The behavior of a system can be represented by its sequence of states induced and the outputs produced in response to the inputs. This can be represented by a state diagram, which shows the possible states, and the transitions between the states, and the outputs produced in response to the inputs. The basic elements of the state diagram are shown in Fig. 1.75(a). For the Mealy model the output is designated in the transition arrow as shown in Fig. 1.75(b). For the Moore model the output is designated in the state

circle as shown in Fig. 1.75(c). An example of a four-state system is illustrated in the state diagrams in Fig. 1.76.

The information in the state diagrams can also be expressed in a tabular form called a **state table**. Figure 1.77 shows the tabular form of the state diagrams in Fig. 1.76.

Given that there are no critical race conditions, that only one input at a time is changed, and that no changes are initiated unless the system is in equilibrium, the state table or state diagram allows the prediction of the behavior of the system for the specification of the input sequence and the initial state. An example is given in Fig. 1.78.

1.6.15 Analysis of Synchronous Sequential Logic Circuits

The general procedure for analyzing synchronous sequential circuits is given by the flow chart in Fig. 1.79. As an example of analysis consider the circuit shown in Fig. 1.80(a). The excitation K-maps, the output K-map, the **excitation table**, the FF truth tables, the **transition table**, the state table, the state diagram, and an output sequence example are shown in the successive parts of Fig. 1.80.

1.6.16 Synthesis of Synchronous Sequential Logic Circuits

The general procedure for the synthesis of synchronous sequential circuits is shown in Fig. 1.81.

The design process is illustrated in Fig. 1.82 for a 0111 sequence detector. This figure displays each of the steps in the synthesis process starting with the state diagram specification of the sequence detector in Fig. 1.82(a). Letters are initially assigned to represent the states. The considerations required for assigning binary code representations for the states require considerations that are covered later in this chapter. The machine is initialized to be in state *D*. If the first input is a 1 the machine remains in state *D*. The system

is placed in state *A* to designate that a 0 has been received, in state *B* to designate that the sequence 01 has been received, state *C* to designate the sequence 011 has been received, and state *D* when the sequence 0111 has been received. The system outputs a 1 when the transition to state *D* is made to signify that the desired sequence has been detected, otherwise the output is 0. The character state and the binary state diagrams are constructed next, as shown in Fig. 1.82(b) and Fig. 1.82(c). Since there are four states the number of storage elements required is two. This first example will illustrate the procedure without considering the problems of minimizing the number of states or of making optimum code assignments. Hence, the Gray scale code is assigned without changing the state table configuration as shown in Fig. 1.82(c). The transition table is extracted from the binary state table and is shown in Fig. 1.82(d). For illustrative purposes these will be chosen as *JK* and *D* flip-flops. To determine the excitation table it is necessary to have the input tables for these flip-flops given in Fig. 1.82(e) and Fig. 1.82(f). Consequently, the excitation table is that shown in part Fig. 1.82(g). The excitations are then separated into individual K-maps shown in Fig. 1.82(h) to Fig. 1.82(j). The output K-map is taken from Fig. 1.82(c) and shown in Fig. 1.82(k). The resulting circuit diagram specified by the K-maps is shown in Fig. 1.82(l).

1.6.17 Equivalent States

Minimizing the number of states minimizes the number of storage elements required and, hence, simplifies the circuit, which reduces its cost, increases its reliability, and increases its speed. States that are **equivalent** to other **states** can be eliminated. Two states are equivalent if and only if for every possible input:

- they produce the same output
- the next states are equivalent.

If starting from two different states a sequence of *k* inputs produces the same sequence of outputs the two states are *k* equivalent. If the states are *k* equivalent for all *k*, then the states are equivalent. Three techniques for determining equivalency are:

- Inspection
- Partitioning
- Implication table

Inspection can easily be done for cases in which single step comparisons can be made. For example, if two states have the same next states as well as the same output they are the same state. This is illustrated in Fig. 1.83, which shows that states *A* *C* are the same.

		<i>x</i>	
		0	1
<i>Q</i>	<i>A</i>	A/0	B/1
	<i>B</i>	C/1	D/0
	<i>C</i>	A/0	B/1
	<i>D</i>	A/0	D/0

FIGURE 1.83 State table for a machine, which has equivalent states that are apparent by inspection.

1.6.18 Partitioning

Partitioning provides a straightforward procedure for determining equivalency for any amount of complexity. Successive partitioning steps produce smaller partitions. If the next step does not yield any smaller partitions no further steps will yield any smaller partitions and, hence, the partitioning process is then complete. All states that are in the same partition after *k* steps are *k* equivalent. All states that are in the same partition when no further partitioning can be accomplished are equivalent. States that are not in the same final partition are not equivalent. The **partition table** resulting from the partitioning process, shown

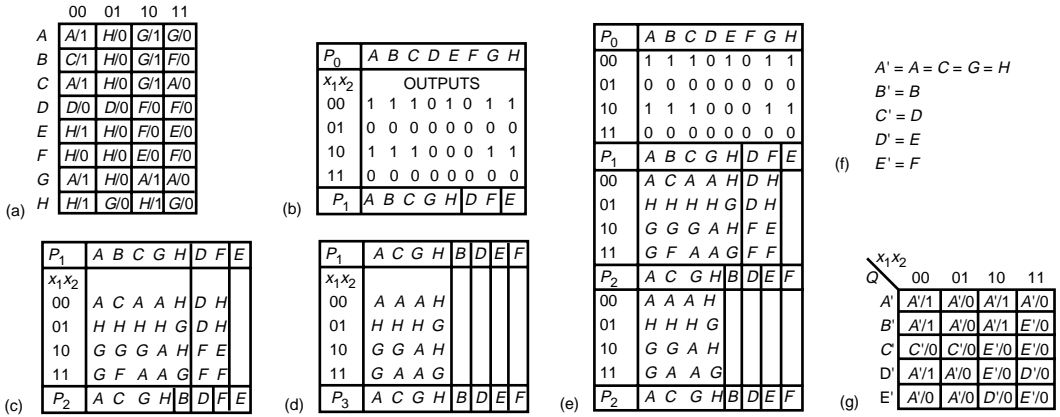

FIGURE 1.84 Partition table construction process: (a) sample machine state table, (b) first partition step, (c) second partition step, (d) third partition step, (e) composite partition table, (f) reduced state assignments, (g) reduced state table.

in Fig. 1.84, is illustrated in Fig. 1.84(e) for the machine whose state table is shown in Fig. 1.84(a). The first partitioning step is based on the output. If two states have the same outputs for all possible inputs they are *1-equivalent*. Figure 1.84(b) displays the outputs for all possible inputs organized into a format that facilitates the required comparisons. States A, B, C, G, and H all have the same outputs and, hence, belong in the same level-1 partition. Likewise, D and F have the same outputs and, hence, belong in the same level-1 partition. At this point only state E is shown not to be equivalent to any other state and, hence, is in a level-1 partition by itself. The level-2 partitions are based on comparisons of the next states that each state can make a transition to. Figure 1.84(c) displays the next states for all possible inputs organized into a format that facilitates the required comparisons. In the level-1 partition /D, F/ with a 00 input D goes to D but F goes to H. Since D and H are not in the same level-1 partition, D and F are not in the same level-2 partition and, hence, D and F are not equivalent. Similarly, B is in a different level-2 partition from A, C, G, and H. Once a state is in a partition by itself, there are no other states equivalent to it.

States that have a given equivalence level with other states have to be examined for partitioning at the next level. This is done for the level-2 partition /A, C, G, H/ in Fig. 1.84(d). The level-3 partitioning process produced no additional partition and, hence, no further partitioning is possible. Consequently states C, G, and H are all equivalent to state A and, hence, can be eliminated from the state table to produce a reduced state table. The states are lettered consecutively but distinguished with primes from the states of the original machine as shown in Fig. 1.84(f). The reduced state table is given in Fig. 1.84(g). In practice the individual partitions are not done in separate tables, but in one composite table as shown in Fig. 1.84(e).

1.6.19 Implication Table

An implication table contains a triangular array of squares such that there is one square for each pair of states as shown in Fig. 1.85. Notation is placed in each square to indicate that the pair of states are not equivalent, may be equivalent, or are equivalent. The first step in the process consists of placing an X in those cells representing states that are not equivalent because they do not have identical outputs for the same inputs, as shown in Fig. 1.86(a) for the machine defined in Fig. 1.84(a). The second step in the process is to list in each cell the pairs of states that must be equivalent if the pair represented by that cell is to be equivalent, as shown in Fig. 1.86(b). If a pair required for equivalence is not equivalent then the lack of equivalence is designated by a / drawn across the square, as shown in Fig. 1.86(c). The next sweep rules out one additional pair, B, G, as shown in Fig. 1.86(d). The array is successively scanned to check

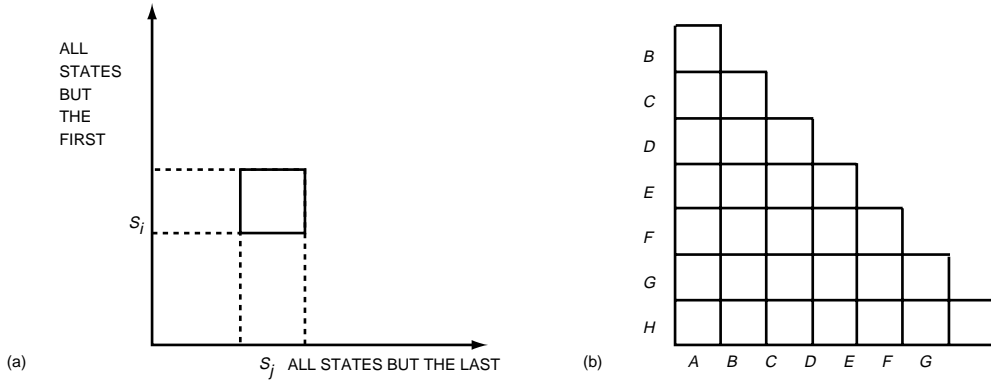

FIGURE 1.85 Implication table format: (a) square for state pair S_i, S_j , (b) implication table format for an eight-state machine.

each remaining possible equivalence to see what pairs can be ruled out. Further sweeps uncover no further nonequivalencies. Consequently, the squares that have not been ruled out represent pairs of equivalent states. The equivalencies are, consequently, $(A, C), (A, G), (A, H), (C, G), (C, H),$ and (G, H) . These equivalencies can be more compactly expressed as the set (A, C, G, H) . This is the same result as obtained using the partition table.

FIGURE 1.86 Implication table development for the machine specified by the state table in Fig. 1.84(a): (a) partial implication table with state pairs Xed out that are not equivalent by virtue of different outputs, (b) partial implication table with the remaining squares having state pair entries, which must be equivalent for that state pair to be equivalent, (c) partial implication table with state pairs /ed out on the first sweep because the next state pairs are not equivalent, (d) implication table after last sweep rules out no additional state pairs.

1.6.20 State Assignment

The number of ways in which the binary code can be assigned to the states increases rapidly with the number of states. Let

N_{SA} = number of ways of assigning states

N_S = number of states

N_{FF} = number of flip-flops required

The number of flip-flops required is related to the number of states by

$$N_{FF} = (\log_2 N_S)_{\text{truncated up}}$$

The number of digits in the binary code assignment is equal to the number of flip-flops N_{FF} . The number of different codes that can be provided is the number that can be assigned to the first state times the number that can be assigned to the second state, and so on down to the number that can be provided to the last state. The number of codes that can be provided to the first state is

$$N_1 = 2^{N_{FF}}$$

Once a code has been assigned to the first state, the choice of codes for the second state is one less,

$$N_2 = N_1 - 1$$

the number of codes available for assigning to the third state is

$$N_3 = N_2 - 1 = N_1 - 2$$

etc. Consequently, the number of different codes that can be assigned to states is

$$N_{SA} = N_1(N_1 - 1)(N_1 - 2) \cdots (N_1 - N_S + 1) = \frac{N_1!}{(N_1 - N_S)!} = \frac{2^{N_{FF}!}}{(2^{N_{FF}} - N_S)!}$$

The individual variable names can be interchanged without changing the circuit. Since there are N_{FF} flip-flops there are $N_{FF}!$ different equivalent ways of assigning codes based on the flip-flop identification numbers. With each of these assignments the particular code digit may be either a 0 or a 1; hence, there are $2^{N_{FF}}$ different codes for each of these permutations. Since these last two factors do not constitute different unique assignments (i.e., represent different hardware), the number of unique assignments is smaller than the number of possible assignments by the factor that is the number of equivalent assignments, $2^{N_{FF}} N_{FF}!$, consequently,

$$N_{UA} = \frac{N_{SA}}{N_{FF}! 2^{N_{FF}}}$$

Table 1.26 shows how the number of flip-flops, the number of possible state assignments, and the number of unique state assignments, are a function of the number of states. The number of unique state assignments increases so rapidly that it is impractical to determine the optimum assignment if the number of states is large. The machine defined by the state table in Fig. 1.87(a) is used to illustrate the effect of code assignment choice. This machine has no equivalent states, as shown by the implication table in Fig. 1.87(b). With seven independent states, three flip-flops are required and, hence, there are 840 unique code assignments. Implementations of the required combinational logic circuits using $J K$ flip-flops for the two code assignments specified in Fig. 1.87(c) are given in Fig. 1.87(d). The gate counts required for these implementations are summarized in Fig. 1.87(e).

TABLE 1.26 State Assignments

N_S	N_{FF}	N_{SA}	N_{UA}
2	1	2	1
3	2	24	3
4	2	24	3

Rule No.	Give logically adjacent assignments to states that:
1	have the same next state for a given input
2	are the same next state of a present state

1.6.21 State Assignment Guidelines

An exhaustive study of all possible implementations is generally impractical; hence, it is desirable to have some guidelines for making a near optimum choice. Complexity is reduced by having realizations with higher order prime implicants. This is provided by codings that have large clusters of minterms. The arrangement of 1s on the K-map are improved by using the logically adjacent assignments rules specified in Table 1.27.

FIGURE 1.87 Comparison of implementations for two code assignments: (a) state table, (b) implication table, (c) selected code assignments, (d) combinational logic circuit implementations, (e) relative complexity of the two implementations.

FIGURE 1.88 Example used to illustrate rules for state assignments: (a) example machine, (b) unique state assignments, (c) unique state assignment K-maps, (d) adjacencies provided by the various orderings, (e) combinational logic circuit implementations, (f) relative complexity of the three implementations.

These are illustrated in Fig. 1.88 with the machine defined by the state table in Fig. 1.88(a). According to rule 1:

- AB should be adjacent since they have the same next state C for $x = 0$.
- AC should be adjacent since they have the same next state D for $x = 1$.

According to rule 2:

- CD should be adjacent since they are the next states of state A.
- there should also be adjacencies AC, BD, and AB.

Since adjacencies AB and AC are called for by both rules, fulfilling them should receive first priority within the constraint of maximizing the number of adjacencies. With four states there are only three unique ways of assigning codes, shown in Fig. 1.88(b).

The K-maps in Fig. 1.88(c) show the three unique assignments for this case. Figure 1.88(e) gives the circuit implementations with D flip-flops and Fig. 1.88(f) gives the relative circuit complexity. Assignment one has the maximum number of adjacencies, the fewest gates, and the fewest connecting wires.

1.6.22 Implication Graph

A flow graph whose nodes represent pairs of states, as specified by the state table, constitutes a tool for selecting good state assignments. The implication graph is similar to the implication table in that it contains the same information in a flow graph form and can be constructed as follows:

- choose a pair of states
- go to the next pair of states for each input and enter as a new node, but omit if the pair is a single state
- repeat until no new pairs can be generated

An illustrative example is given in Fig. 1.89.

TABLE 1.27 Continuation: Implication-Graph-Based State Assignment Guidelines

Rule No.	Give logically adjacent assignments to:
3	state pairs on closed or contiguous subgraphs

An implication graph is complete if it contains all possible pairs. The example in Fig. 1.90 is a complete implication graph. Normally, cases are not complete. A subgraph is part of a complete graph. A closed subgraph is one in which all outgoing arcs for each node within the subgraph terminate on nodes within the subgraph. This is important for state assignments. The example in Fig. 1.89 has no closed subgraphs.

The implication graph should be used to guide the rearrangement of the state table to make:

- logically adjacent states physically adjacent
- the next-state-pair of two current-adjacent states adjacent and to follow rule 3 in the continuation of Table 1.27.

Rule 3 dictates the same choice for the example represented in Fig. 1.89 as rules 1 and 2 do for the same example applied directly to the state table. For other and more complicated examples the various rules may not be in agreement, in which case preference is recommended for rules 1 and 3. In general, the rules should be followed as closely as possible to obtain on an average a more optimum solution than would be obtained on an average by a purely random code assignment choice.

FIGURE 1.89 Example to illustrate an implication graph: (a) state table example, (b) implication graph.

1.6.23 Incompletely Specified Circuits

Incompletely specified circuits may have a combination of unspecified outputs and next states. These unspecified quantities can be treated as *don't cares*. However, the presence of don't cares complicates the process of minimizing the number of states required. With don't cares the concept of **compatible** states replaces that of equivalent states. Two states that are equivalent to a third state are equivalent to each other. However, two states that are compatible with a third state are not necessarily compatible with each other because different choices for the don't cares may be evoked by the different equivalences. As a result the incompletely specified circuits have an added complexity for which merger diagrams are introduced to facilitate treatment. An illustrative example of the incomplete specification is given in Fig. 1.90.

Q^x	0	1
A	A/	C/1
B	B/	A/
C	G/	E/0
D	C/1	C/
E	A/1	C/
F	D/	A/
G	G/	G/

FIGURE 1.90 An incompletely specified circuit.

Incompatible states of an incompletely specified machine are caused by different outputs or by incompatible next states. An incompatible class is a set of mutually incompatible states. A maximal incompatible class is one for which there are no other incompatible states that are incompatible with the states already in the class. The maximal incompatibles can be constructed as illustrated for this example in Fig. 1.91(e). Starting with the rightmost column of the implication table the compatible state pairs are cumulatively listed. Whenever compatible states can be combined in a larger compatible class this is done on the next line. The incompatible sets are given in Fig. 1.91(f).

FIGURE 1.91 Use of implication table to determine compatible states for the example in Fig. 1.90(a): (a) partial implication table with incompatible states caused by different outputs designated by an X, (b) partial implication table with listings of states which must be compatible for the present states to be compatible, (c) partial implication table with first sweep through listings of states with a / to designate incompatibles, (d) implication table for machine after final sweep through listings of states with a \ to designate last found incompatibles, (e) compatibility classes, (f) incompatibility classes.

Determination of the maximal compatible sets is facilitated by a *merger diagram*. The merger diagram is formed by representing the states as dots spaced around a circle as shown in Fig. 1.92(a). A straight line is then drawn between each pair of compatible states. Each maximal set is obtained from the merger diagram by noting those sets of points for which every point in the set is connected to every other point in the set. For the example shown there are five maximal sets: (AEG), (BCG), (CDG), (CEG), and (CFG).

The minimization of an incompletely specified state table is as follows. A set of compatibility classes must be selected that meet the following conditions:

- *Completeness.* All of the states in the original machine must be contained in the set of compatibility classes chosen.
- *Consistency.* The next states must be in some compatibility class within the set, that is, the set of compatibility classes chosen must be closed.
- *Minimality.* Choose the smallest set of compatibility classes that meets the preceding criteria.

FIGURE 1.92 Merger diagram for the machine defined in Fig. 1.90: (a) merger diagram for maximal compatibles, (b) merger diagram for maximal incompatibles.

Each compatibility class corresponds to a state in the reduced machine. Since the selection of the compatibility classes is a trial-and-error process, it is helpful to bound the number of states required S_M in the realization of the minimal-state machine. The upper bound on the number of states is given by

$$S_U = \text{minimum}(N_{MC}, S_O)$$

S_O = number of states in the original machine

N_{MC} = number of sets of maximum compatibles

Since

$$N_{MC} \leq S_O$$

it follows that

$$S_U = N_{MC}$$

The lower bound on the number of states in the minimal circuit is given by

$$S_L = \text{maximum}(N_{M11}, N_{M12}, \dots, N_{M1k}, \dots)$$

N_{M1k} = number of states in k th maximal incompatibles group of the original circuit

For the illustrative sample $S_L = 4$ and $S_U = 5$. The set of maximal compatibles is always complete and consistent but may not be minimal. Search for a minimal set of compatibility classes by examining sets of maximal incompatibles in groups of S_L .

The example defined in Fig. 1.90 has a closure table and reduced state table given in Fig. 1.93(a) and Fig. 1.93(b). When more than one state is listed for the next state it is in essence a restricted don't care in that it does not matter which of the listed states is the next state, whereas a don't care is unrestricted as to which state is the next state.

FIGURE 1.93 Incompletely specified example: (a) closure table, (b) reduced state table.

1.6.24 Algorithmic State Machines

A state machine is a sequential logic circuit. An **algorithmic state machine (ASM)** is a state machine that is designed directly from a hardware algorithm, which is the procedure to be directly implemented in hardware. The procedure consists of two major portions:

- A circuit to process data, that is, produce the output data from the input data
- Another circuit to produce the control signals that initiate the successive steps in the production process

The control logic receives status signals from the processor and external signals that dictate the sequence of control signals produced as shown in Fig. 1.94(a). The objective of this approach is to provide a more logically straightforward and more easily and quickly executable design methodology rather than providing the most optimum circuit with the fewest components.

An algorithmic state machine chart is a specialized form of flow chart, which represents the timing relationships, as well as the sequence of operations and the conditions required for their performance. The ASM chart has three basic elements:

- State box
- Decision box
- Conditional box

These are represented by rectangles and diamonds, both common to conventional flow charts, and boxes with rounded ends, respectively. The state box is represented by labeling it with the state name and

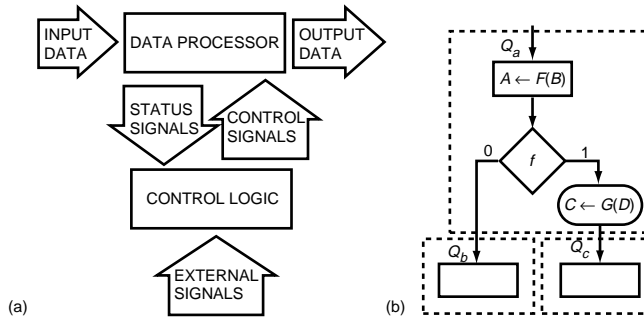

FIGURE 1.94 Algorithmic state machine: (a) hardware algorithm implementation, (b) illustrative ASM chart.

placing the operation that is executed when the machine goes to that state. The decision boxes contain the expression that can have more than one value with a different output for each value. The conditional boxes contain the expression for the operation that is executed if the condition designated by the decision box leading to it is true. The conditional operations are performed when the machine is in the specified state. These elements are illustrated in Fig. 1.94(b). When more than a few storage elements are needed, the previous design procedures get out of hand. The algorithmic state machine is convenient to use for the design of large systems.

1.6.25 Asynchronous Sequential Machines

The basic memory elements, latches, previously introduced are asynchronous sequential machines. Analysis of asynchronous machines with difference equations and timing diagrams rapidly gets out of hand with an increase in complexity. Utilizing the state table, transition table, and excitation table methodology is generally simpler but requires that the system be restricted to the fundamental mode of operation to make the process valid. In the fundamental mode of operation only one input at a time is applied and the system must reach equilibrium before another input is applied. Problems that can occur when not operating in the fundamental mode are described in the discussion of races and cycles.

Transition Tables

Transition tables for asynchronous circuits can convey significant information more quickly by placing circles about the next states that are stable, unstable next states are uncircled. The output and feedback variables have been labeled Q to identify them as state variables. This identifies the transition table for the asynchronous circuit with the transition table of the synchronous circuit. There is usually at least one next state entry that is, the same as the current state in each row. If this were not true then that state would not be stable. The procedure for obtaining a transition table is summarized in Table 1.28.

TABLE 1.28 Procedure for Obtaining an Asynchronous Circuit Transition table

No.	Step
1.	Let Q_k designate the input provided by feedback loop k .
2.	Let Q_k^n designate the output provided by feedback loop k .
3.	Derive the boolean expression for Q_k^n in terms of the inputs.
4.	Construct the K-map for the outputs in terms of the inputs.
5.	Combine the individual K-maps into a composite.
6.	Circle the next state values that are stable.

FIGURE 1.95 Asynchronous sequential circuit example: (a) circuit, (b) output K-maps, (c) transition table.

An example of an asynchronous sequential circuit is shown in Fig. 1.95(a). The K-maps for the outputs are shown in Fig. 1.95(b). The composite K-maps show how the signals change upon passage through the circuit and constitute the transition table shown in Fig. 1.95(c).

Flow Table

In the design process the optimum codes are not known in advance; hence, it is necessary to designate the states by nonnumeric symbols. A flow table, in essence, is a transition table in which the states are designated by letter symbols. Figure 1.96(a) shows a flow table in which the output is included for the case of a two-state circuit with two inputs and one output. The table for this example shows that if the input $x_1 = 0$ the circuit is in state *A* independent of the value of x_2 . If the inputs $x_1 x_2 = 11$ the circuit may be in either state *A* or state *B*. If the inputs changed from 01 to 11 the circuit remains in state *A*, but if the inputs changed from 10 to 11 the circuit remains in state *B*. A change in input, from 00 to 11, is not allowed in the fundamental mode. To illustrate problems that can occur with the nonfundamental mode of operation, consider the circuit that results with the code assignment $A = 0$ and $B = 1$, which gives the transition table, output K-map, and circuit shown in Fig. 1.96(b), Fig. 1.96(c), and Fig. 1.96(d).

Race Conditions

When a change in the input causes two or more variables to change nonsimultaneously, due to unequal delays, one variable reaches its stable state before the others, that is, there is a race between the variables.

FIGURE 1.96 Asynchronous two-state two-input one-output sequential circuit example specified by a flow table: (a) flow table, (b) transition table, (c) output K-map, (d) circuit diagram.

FIGURE 1.97 Race Examples: (a) uncritical, (b) critical.

This may cause state variables to change in an unpredictable manner. Consider the examples shown in Fig. 1.97. If the state changes from 00 to 11 and there are unequal delay times, then the system may go through the intermediate state 01 or 10 depending on whether Q_2 or Q_1 changes first. The race is critical if the final state depends on the order in which the state variables change, otherwise it is noncritical. Critical races must be avoided for reliable operation. Race conditions can be avoided by making binary state assignments in a way that only one state variable can change at a time when a state transition occurs.

Cycles

A cycle is a unique sequence of unstable states. A cycle will keep repeating if it does not end in a stable state. Examples are given in Fig. 1.98.

Stability

The utility of a digital circuit depends on its being able to remain indefinitely in the same state unless driven by an input signal to another state where it remains indefinitely. Figure 1.98(b) illustrates a case where an input signal 1 causes the states to change cyclically through three different states and, hence, is unstable. Figure 1.99 is an example of a two-state two-input that oscillates between 0 and 1 when the both inputs are 1.

FIGURE 1.98 Cycle examples: (a) single transit, (b) unstable.

Race-Free Code Assignments

Race-free code assignments are provided by assigning logically adjacent codes to states between which transitions are made. The procedure for doing this is illustrated by the example in Fig. 1.100(a). Figure 1.100(b) to Figure 1.100(d) show the transitions required from each state and Fig. 1.100(e) shows the composite set of state transitions. A trial code assignment is shown in Fig. 1.100(f). This trial assignment makes A and B adjacent, B and C adjacent, but not A and C .

FIGURE 1.99 Unstable two-state two-input example transition table.

The insertion of an extra row in the flow table of this example, as shown in Fig. 1.101, allows the elimination of critical races by the introduction of **cycles**. This is done by changing an unstable

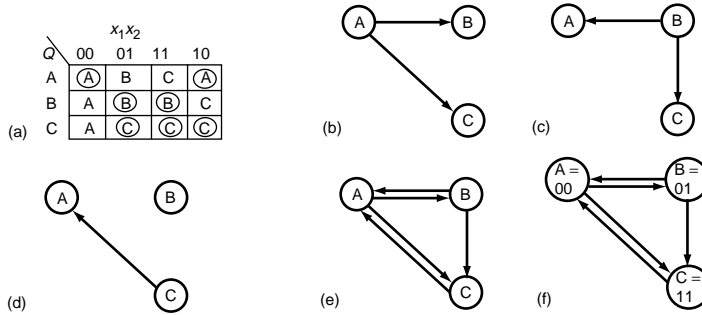

FIGURE 1.100 Example illustrating a method of obtaining race-free assignments: (a) transition table, (b) transition required for row A, (c) transition required for row B, (d) transition required for row C, (e) all transitions required, (f) trial code assignment.

destination state to the added state and then assigning the destination state for the added state to be the original destination state before the added state was introduced. A restriction on the assigned destination states for the added state is that it not be itself in order not to introduce an extra stable state. In Fig. 1.101(a) slashes are used to indicate that the next state may be any state except the current state. Also, in this example the fourth state can be added without increasing the number of binary variables in the state description.

More involved examples may require the introduction of an extra binary variable in the state code in order to provide the extra states needed to introduce the cycles required for elimination of critical races.

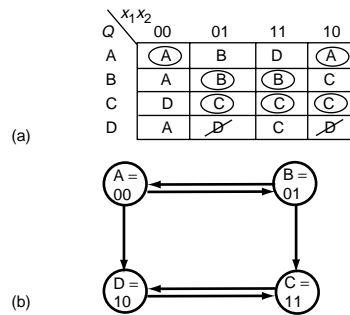

FIGURE 1.101 Modification of the example in Fig. 1.100 giving a race-free assignment: (a) transition table modification, (b) transition diagram.

Defining Terms

Algorithmic state machine (ASM): A sequential logic circuit whose design is directly specified by the algorithm for the task the machine is to accomplish.

Asynchronous: A circuit whose response is directly initiated by the input without depending on a synchronizing signal.

Combinational logic: A logic circuit without memory elements.

Compatible: Two states that can be treated as the same because of the presence of a *don't care*.

Critical race: A race that results in different states depending on the relative delays involved.

Equivalent states: States that produce the same outputs and whose next states are equivalent.

Excitation: Any input to a circuit, but more specifically an input to a storage element.

Excitation table: A table of inputs required to produce a specified set of transitions.

Feedback: An output of a unit connected to the unit's input.

Flip-flop: A two-stage latch in a master-slave configuration.

Implication table: A triangular table having squares identified by state pairs containing information to enable the determination of state equivalency.

Latch: A memory element that does not have immunity to external feedback.

Leading-edge triggered: A device that is activated by the leading edge of a signal.

Master-slave: A two-stage memory element with each stage being a synchronous latch having the synchronizing signal such that the first stage (the master) can accept information when the second stage (the slave) cannot and vice versa.

Mealy model: A model, the outputs of which are functions of the inputs and the states.

Moore model: A model, the outputs of which are functions only of the states.

Noncritical race: A race that always results in the same state.

Partition table: A table that enables the grouping of states into equivalent sets.

Race: When two or more variables may change values at different times due to differences in circuit delays.

Sequential logic: A logic circuit with memory.

Stable: A device, the output or state of which does not change except with an intended excitation.

State: The condition in which a system exists.

State diagram: A figure showing the set of states a system may have and the transitions that can occur between the states and the outputs which are produced.

State table: A tabular display of the same information contained in a state diagram.

Synchronous: A circuit that will not respond to the input without the occurrence of a synchronizing signal.

Trailing-edge triggered: A device that is activated by the trailing edge of a signal.

Transition: The change in a system from one state to another.

Transition table: The tabulation of the state transitions a system has.

Unstable: A device, the output or state of which changes without an intended excitation.

1.7 The Physical Nature of Sound

Floyd E. Toole, E. A. G. Shaw, Gilles A. Daigle and Michel R. Stinson

1.7.1 Introduction¹

Sound is a physical disturbance in the medium through which it is propagated. Although the most common medium is air, sound can travel in any solid, liquid, or gas. In air, sound consists of localized variations in pressure above and below normal atmospheric pressure (*compressions* and *rarefactions*).

Air pressure rises and falls routinely, as environmental weather systems come and go, or with changes in altitude. These fluctuation cycles are very slow, and no perceptible sound results, although it is sometimes evident that the ears are responding in a different way to these *infrasonic* events. At fluctuation frequencies in the range from about 20 cycles per second up to about 20,000 cycles per second the physical phenomenon of sound can be perceived as having pitch or tonal character. This generally is regarded as the *audible* or *audio-frequency range*, and it is the frequencies in this range that are the concern of this chapter. Frequencies above 20,000 cycles per second are classified as *ultrasonic*.

1.7.2 Sound Waves

The essence of sound waves is illustrated in Fig. 1.102, which shows a tube with a piston in one end. Initially, the air within and outside the tube is all at the prevailing atmospheric pressure. When the piston moves quickly inward, it compresses the air in contact with its surface. This energetic compression is rapidly passed on to the adjoining layer of air, and so on, repeatedly. As it delivers its energy to its neighbor, each layer of air returns to its original uncompressed state. A longitudinal sound pulse is moving outward through the air in the tube, causing only a passing disturbance on the way. It is a pulse because there is only an isolated action, and it is longitudinal because the air movement occurs along the axis of sound propagation. The rate at which the pulse propagates is the speed of sound. The pressure rise in the compressed air is proportional to the velocity with which the piston moves, and the perceived loudness of the resulting sound pulse is related to the incremental amplitude of the pressure wave above the ambient atmospheric pressure.

Percussive or impulsive sounds such as these are common, but most sounds do not cease after a single impulsive event. Sound waves that are repetitive at a regular rate are called *periodic*. Many musical sounds are periodic, and they embrace a very wide range of repetitive patterns. The simplest of periodic sounds is a pure tone, similar to the sound of a tuning fork or a whistle. An example is presented when the end of the tube is driven by a loudspeaker reproducing a recording of such a sound (Fig. 1.103). The pattern of displacement vs. time for the loudspeaker diaphragm, shown in Fig. 1.103(b), is called a *sine wave* or *sinusoid*.

If the first diaphragm movement is inward, the first event in the tube is a pressure compression, as seen previously. When the diaphragm changes direction, the adjacent layer of air undergoes a *pressure rarefaction*. These cyclic compressions and rarefactions are repeated, so that the sound wave propagating down the tube has a regularly repeated, periodic form. If the air pressure at all points along the tube were measured at a specific instant, the result would be the graph of air pressure vs. distance shown in Fig. 1.103(c). This reveals a smoothly sinusoidal waveform with a repetition distance along the tube symbolized by λ , the *wavelength* of the periodic sound wave.

If a pressure-measuring device were placed at some point in the tube to record the instantaneous changes in pressure at that point as a function of time, the result would be as shown in Fig. 1.103(d). Clearly, the curve has the same shape as the previous one except that the horizontal axis is time instead of distance. The periodic nature of the waveform is here defined by the time period T , known simply as the *period*

FIGURE 1.102 Generation of a longitudinal sound wave by the rapid movement of a piston in the end of a tube, showing the propagation of the wave pulse at the speed of sound down the length of the tube.

of the sound wave. The inverse of the period, $1/T$, is the *frequency* of the sound wave, describing the number of repetition cycles per second passing a fixed point in space. An ear placed in the path of a sound wave corresponding to the musical tone middle C would be exposed to a frequency of 261.6 cycles per second or, using standard scientific terminology, a frequency of 261.6 Hz. The perceived loudness of the tone would depend on the magnitude of the pressure deviations above and below the ambient air pressure.

FIGURE 1.103 Characteristics of sound waves: (a) a periodic sound wave, a sinusoid in this example, is generated by a loudspeaker placed at the end of a tube. (b) waveform showing the movement of the loudspeaker diaphragm as a function of time: displacement vs. time. (c) waveform showing the instantaneous distribution of pressure along a section of the tube: pressure vs. distance. (d) waveform showing the pressure variation as a function of time at some point along the tube: pressure vs. time.

The parameters discussed so far are all related by the *speed of sound*. Given the speed of sound and the duration of one period, the wavelength can be calculated as

$$\lambda = cT \quad (1.18)$$

where

λ = wavelength

c = speed of sound

T = period

By knowing that the frequency $f = 1/T$, the following useful equation and its variations can be derived:

$$\lambda = \frac{c}{f} \quad f = \frac{c}{\lambda} \quad c = f\lambda \quad (1.19)$$

The speed of sound in air at a room temperature of 22°C (72°F) is 345 m/s (1131 ft/s). At any other ambient temperature, the speed of sound in air is given by the following approximate relationships [1, 2]:

$$c(m/s) = 331.29 + 0.607t(^{\circ}C) \quad (1.20)$$

or

$$c(m/s) = 1051.5 + 1.106t(^{\circ}F) \quad (1.21)$$

where t = ambient temperature.

The relationships between the frequency of a sound wave and its wavelength are essential to understanding many of the fundamental properties of sound and hearing. The graph of Fig. 1.104 is a useful quick reference illustrating the large ranges of distance and time embraced by audible sounds. For example, the tone middle C with a frequency of 261.6 Hz has a wavelength of 1.3 m (4.3 ft) in air at 20°C. In contrast, an organ pedal note at Cl, 32.7 Hz, has a wavelength of 10.5 m (34.5 ft), and the third-harmonic overtone of C8, at 12,558 Hz, has a wavelength of 27.5 mm (1.1 in). The corresponding periods are, respectively, 3.8, 30.6, and 0.08 ms. The contrasts in these dimensions are remarkable, and they result in some interesting and troublesome effects in the realms of perception and audio engineering. For the discussions that follow it is often more helpful to think in terms of wavelengths rather than in frequencies.

Complex Sounds

The simple sine waves used for illustration reveal their periodicity very clearly. Normal sounds, however, are much more complex, being combinations of several such pure tones of different frequencies and perhaps additional transient sound components that punctuate the more sustained elements. For example, speech is a mixture of approximately periodic vowel sounds and staccato consonant sounds. Complex sounds can also be periodic; the repeated wave pattern is just more intricate, as is shown in Fig. 1.105(a). The period identified as T_1 applies to the *fundamental frequency* of the sound wave, the component that normally is related to the characteristic pitch of the sound. Higher-frequency components of the complex wave are also periodic, but because they are typically lower in amplitude, that aspect tends to be disguised in the summation of several such components of different frequency. If, however, the sound wave were analyzed, or broken down into its constituent parts, a different picture emerges: Fig. 1.105(b), (c), and (d). In this example, the analysis shows that the components are all *harmonics*, or whole-number multiples, of the fundamental frequency; the higher-frequency components all have multiples of entire cycles within the period of the fundamental.

To generalize, it can be stated that all *complex periodic waveforms* are combinations of several harmonically related sine waves. The shape of a complex waveform depends upon the relative amplitudes of the various harmonics and the position in time of each individual component with respect to the others. If one of the harmonic components in Fig. 1.105 is shifted slightly in time, the shape of the waveform

FIGURE 1.104 Relationships between wavelength, period, and frequency for sound waves in air.

is changed, although the frequency composition remains the same (Fig. 1.106). Obviously a record of the time locations of the various harmonic components is required to completely describe the complex waveform. This information is noted as the *phase* of the individual components.

Phase

Phase is a notation in which the time of one period of a sine wave is divided into 360° . It is a relative quantity, and although it can be defined with respect to any reference point in a cycle, it is convenient to start (0°) with the upward, or positive-going, zero crossing and to end (360°) at precisely the same point at the beginning of the next cycle (Fig. 1.107). *Phase shift* expresses in degrees the fraction of a period or wavelength by which a single-frequency component is shifted in the time domain. For example, a phase shift of 90° corresponds to a shift of one-fourth period. For different frequencies this translates into different time shifts. Looking at it from the other point of view, if a complex waveform is time-delayed, the various harmonic components will experience different phase shifts, depending on their frequencies.

A special case of phase shift is a *polarity reversal*, an inversion of the waveform, where all frequency components undergo a 180° phase shift. This occurs when, for example, the connections to a loudspeaker are reversed.

Spectra

Translating time-domain information into the frequency domain yields an *amplitude-frequency spectrum* or, as it is commonly called, simply a *spectrum*. Figure 1.108(a) shows the spectrum of the waveform in Fig. 1.104 and Fig. 1.106, in which the height of each line represents the amplitude of that particular component and the position of the line along the frequency axis identifies its frequency. This kind of display is a *line spectrum* because there are sound components at only certain specific frequencies. The phase information is shown in Fig. 1.108(b), where the difference between the two waveforms is revealed in the different *phase-frequency spectra*.

The equivalence of the information presented in the two domains—the waveform in the time domain and the amplitude- and phase-frequency spectra in the frequency domain—is a matter of considerable

FIGURE 1.105 A complex waveform constructed from the sum of three harmonically related sinusoidal components, all of which start at the origin of the time scale with a positive-going zero crossing. Extending the series of odd-harmonic components to include those above the fifth would result in the complex waveform progressively assuming the form of a square wave. (a) complex waveform, the sum of b, c, and d (b) fundamental frequency (c) third harmonic (d) fifth harmonic.

importance. The proofs have been thoroughly worked out by the French mathematician Fourier, and the well-known relationships bear his name. The breaking down of waveforms into their constituent sinusoidal parts is known as *Fourier analysis*. The construction of complex waveshapes from summations of sine waves is called *Fourier synthesis*. *Fourier transformations* permit the conversion of time-domain information into frequency-domain information, and vice versa. These interchangeable descriptions of waveforms form the basis for powerful methods of measurement and, at the present stage, provide a convenient means of understanding audio phenomena. In the examples that follow, the relationships between time-domain and frequency-domain descriptions of waveforms will be noted.

Figure 1.109 illustrates the sound waveform that emerges from the larynx, the buzzing sound that is the basis for vocalized speech sounds. This sound is modified in various ways in its passage down the vocal tract before it emerges from the mouth as speech. The waveform is a series of periodic pulses, corresponding to the pulses of air that are expelled, under lung pressure, from the vibrating vocal cords. The spectrum of this waveform consists of a harmonic series of components, with a fundamental frequency, for this male talker, of 100 Hz. The gently rounded contours of the waveform suggest the absence of strong

FIGURE 1.106 A complex waveform with the same harmonic-component amplitudes as in Fig. 1.105, but with the starting time of the fundamental advanced by one-fourth period: a phase shift of 90° .

high-frequency components, and the amplitude-frequency spectrum confirms it. The *spectrum envelope*, the overall shape delineating the amplitudes of the components of the line spectrum, shows a progressive decline in amplitude as a function of frequency. The amplitudes are described in *decibels*, abbreviated dB. This is the common unit for describing sound-level differences. The rate of this decline is about -12 dB per octave (an *octave* is a 2:1 ratio of frequencies).

FIGURE 1.107 The relationship between the period T and wavelength λ of a sinusoidal waveform and the phase expressed in degrees. Although it is normal to consider each repetitive cycle as an independent 360° , it is sometimes necessary to sum successive cycles starting from a reference point in one of them.

FIGURE 1.108 The amplitude-frequency spectra (a) and the phase-frequency spectra (b) of the complex waveforms shown in Fig. 1.105 and Fig. 1.106. The amplitude spectra are identical for both waveforms, but the phase-frequency spectra show the 90° phase shift of the fundamental component in the waveform of Fig. 1.106. Note that frequency is expressed as a multiple of the fundamental frequency f_1 . The numerals are the harmonic numbers. Only the fundamental f_1 and the third and fifth harmonics (f_3 and f_5) are present.

Increasing the pitch of the voice brings the pulses closer together in time and raises the fundamental frequency. The harmonic-spectrum lines displayed in the frequency domain are then spaced farther apart but still within the overall form of the spectrum envelope, which is defined by the shape of the pulse itself. Reducing the pitch of the voice has the opposite effect, increasing the spacing between pulses and reducing the spacing between the spectral lines under the envelope. Continuing this process to the limiting condition, if it were possible to emit just a single pulse, would be equivalent to an infinitely long period, and the spacing between the spectral lines would vanish. The discontinuous, or *aperiodic*, pulse waveform therefore yields a *continuous* spectrum having the form of the spectrum envelope.

Isolated pulses of sound occur in speech as any of the variations of consonant sounds, and in music as percussive sounds and as transient events punctuating more continuous melodic lines. All these aperiodic sounds exhibit continuous spectra with shapes that are dictated by the waveforms. The leisurely undulations of a bass drum waveform contain predominantly low-frequency energy, just as the more rapid pressure changes in a snare drum waveform require the presence of higher frequencies with their more rapid rates of change. A technical waveform of considerable use in measurements consists of a very brief impulse which has the important feature of containing equal amplitudes of all frequencies within the audio-frequency bandwidth. This is moving toward a limiting condition in which an infinitely short event in the time domain is associated with an infinitely wide amplitude-frequency spectrum.

1.7.3 Dimensions of Sound

The descriptions of sound in the preceding section involved only pressure variation, and while this is the dimension that is most commonly referred to, it is not the only one. Accompanying the pressure changes are temporary movements of the air “particles” as the sound wave passes (in this context a particle is a volume of air that is large enough to contain many molecules while its dimensions are small compared with the wavelength). Other measures of the magnitude of the sound event are the displacement amplitude of the air particles away from their rest positions and the velocity amplitude of the particles during the movement cycle. In the physics of sound, the *particle displacement* and the *particle velocity* are useful

FIGURE 1.109 Characteristics of speech (a) waveforms showing the varying area between vibrating vocal cords and the corresponding airflow during vocalized speech as a function of time (b) the corresponding amplitude-frequency spectrum, showing the 100-Hz fundamental frequency for this male speaker. (From [3]. Used with permission).

concepts, but the difficulty of their measurement limits their practical application. They can, however, help in understanding other concepts.

In a normally propagating sound wave, energy is required to move the air particles; they must be pushed or pulled against the elasticity of the air, causing the incremental rises and falls in pressure. Doubling the displacement doubles the pressure change, and this requires double the force. Because the work done is the product of force times distance and both are doubled, the energy in a sound wave is therefore proportional to the square of the particle displacement amplitude or, in more practical terms, to the square of the sound pressure amplitude.

Sound energy spreads outward from the source in the three dimensions of space, in addition to those of amplitude and time. The energy of such a sound field is usually described in terms of the energy flow through an imaginary surface. The sound energy transmitted per unit of time is called *sound power*. The sound power passing through a unit area of a surface perpendicular to a specified direction is called the *sound intensity*. Because intensity is a measure of energy flow, it also is proportional to the square of the sound pressure amplitude.

The ear responds to a very wide range of sound pressure amplitudes. From the smallest sound that is audible to sounds large enough to cause discomfort, there is a ratio of approximately 1 million in sound pressure amplitude, or 1 trillion (10^{12}) in sound intensity or power. Dealing routinely with such large numbers is impractical, so a logarithmic scale is used. This is based on the *bel*, which represents a ratio of 10:1 in sound intensity or sound power (the power can be acoustical or electrical). More commonly the

TABLE 1.29 Various Power and Amplitude Ratios and Their Decibel Equivalents*

Sound or Electrical Power Ratio	Decibels	Sound Pressure, Voltage, or Current Ratio	Decibels
1	0	1	0
2	3.0	2	6.0
3	4.8	3	9.5
4	6.0	4	12.0
5	7.0	5	14.0
6	7.8	6	15.6
7	8.5	7	16.9
8	9.0	8	18.1
9	9.5	9	19.1
10	10.0	10	20.0
100	20.0	100	40.0
1,000	30.0	1,000	60.0
10,000	40.0	10,000	80.0
100,000	50.0	100,000	100.0
1,000,000	60.0	1,000,000	120.0

* Other values can be calculated precisely by using Equation (1.18) and Equation (1.19) or estimated by using this table and the following rules:

Power ratios that are multiples of 10 are converted into their decibel equivalents by multiplying the appropriate exponent by 10. For example, a power ratio of 1000 is 10^3 , and this translates into $3 \times 10 = 30$ dB. Since power is proportional to the square of amplitude, the exponent of 10 must be doubled to arrive at the decibel equivalent of an amplitude ratio.

Intermediate values can be estimated by combining values in this table by means of the rule that the multiplication of power or amplitude ratios is equivalent to adding level differences in decibels. For example, increasing a sound level 27 dB requires increasing the power by a ratio of 500 (20 dB is a ratio of 100, and 7 dB is a ratio of 5; the product of the ratios is 500). The corresponding increase in sound pressure or electrical signal amplitude is a factor of just over 20 (20 dB is a ratio of 10, and 7 dB falls between 6.0 and 9.5 and is therefore a ratio of something in excess of 2); the calculated value is 22.4. Reversing the process, if the output from a power amplifier is increased from 40 to 800 W, a ratio of 20, the sound pressure level would be expected to increase by 13 dB (a power ratio of 10 is 10 dB, a ratio of 2 is 3 dB, and the sum is 13 dB). The corresponding voltage increase measured at the output of the amplifier would be a factor of between 4 and 5 (by calculation, 10.5).

decibel, one-tenth of a bel, is used. A difference of 10 dB therefore corresponds to a factor-of-10 difference in sound intensity or sound power. Mathematically this can be generalized as

$$\text{Level difference} = \log \frac{P_1}{P_2} \text{ bels} \tag{1.22}$$

or

$$\text{Level difference} = 10 \log \frac{P_1}{P_2} \text{ decibels} \tag{1.23}$$

where P_1 and P_2 are two levels of power.

For ratios of sound pressures (analogous to voltage or current ratios in electrical systems) the squared relationship with power is accommodated by multiplying the logarithm of the ratio of pressures by 2, as follows:

$$\text{Level difference} = 10 \log \frac{P_1^2}{P_2^2} = 20 \log \frac{P_1}{P_2} \text{ dB} \tag{1.24}$$

where P_1 and P_2 are sound pressures.

TABLE 1.30 Typical Sound Pressure Levels and Intensities for Various Sound Sources*

Sound Source	Sound Pressure Level, dB	Intensity W/m ²	Listener Reaction
Jet engine at 10 m	160	10 ³	Immediate damage
	150		
	140		Painful feeling
	130		
SST takeoff at 500 m	120	1	Discomfort

Breathing	10		
	0 [†]	10 ⁻¹²	Inaudible

*The relationships illustrated in this table are necessarily approximate because the conditions of measurement are not defined. Typical levels should, however, be within about 10 dB of the stated values.

[†]0-dB sound pressure level (SPL) represents a reference sound pressure of 0.0002 μ bar, or 0.00002 N/m².

The relationship between decibels and a selection of power and pressure ratios is given in Table 1.29. The footnote to the table describes a simple process for interpolating between these values, an exercise that helps to develop a feel for the meaning of the quantities.

The representation of the relative magnitudes of sound pressures and powers in decibels is important, but there is no indication of the absolute magnitude of either quantity being compared. This limitation is easily overcome by the use of a universally accepted reference level with which others are compared. For convenience the standard reference level is close to the smallest sound that is audible to a person with normal hearing. This defines a scale of *sound pressure level* (SPL), in which 0 dB represents a sound level close to the hearing-threshold level for middle and high frequencies (the most sensitive range). The SPL of a sound therefore describes, in decibels, the relationship between the level of that sound and the reference level. Table 1.30 gives examples of SPLs of some common sounds with the corresponding intensities and an indication of listener reactions. From this table it is clear that the musically useful range of SPLs extend from the level of background noises in quiet surroundings to levels at which listeners begin to experience auditory discomfort and nonauditory sensations of feeling or pain in the ears themselves.

While some sound sources, such as chain saws and power mowers, produce a relatively constant sound output, others, like a 75-piece orchestra, are variable. The sound from such an orchestra might have a *peak factor* of 20 to 30 dB; the momentary, or peak, levels can be this amount higher than the long-term average SPL indicated [4].

The sound power produced by sources gives another perspective on the quantities being described. In spite of some impressively large sounds, a full symphony orchestra produces only about 1 acoustic watt when working through a typical musical passage. On crescendos with percussion, though, the levels can be of the order of 100 W. A bass drum alone can produce about 25 W of acoustic power of peaks. All these levels are dependent on the instruments and how they are played. Maximum sound output from cymbals might be 10 W; from a trombone, 6 W; and from a piano, 0.4 W [5]. By comparison, average speech generates about 25 μ W, and a present-day jet liner at takeoff between 50 and 100 kW. Small gasoline engines produce from 0.001 to 1.0 acoustic watt, and electric home appliances less than 0.01 W [6].

1.8 Principles of Light, Vision, and Photometry

Jerry C. Whitaker

1.8.1 Introduction

Vision results from stimulation of the eye by light and consequent interaction through connecting nerves with the brain.² In physical terms, light constitutes a small section in the range of electromagnetic radiation, extending in wavelength from about 400–700 nm or billionths (10^{-9}) of a meter. (See Fig. 1.110.)

Under ideal conditions, the human visual system can detect:

- Wavelength differences of 1 nm (10 \AA , 1 angstrom unit = 10^{-8} cm)
- Intensity differences of as little as 1%
- Forms subtending an angle at the eye of 1 arc minute, and often smaller objects

Although the range of human vision is small compared with the total energy spectrum, human discrimination—the ability to detect differences in intensity or quality—is excellent.

1.8.2 Sources of Illumination

Light reaching an observer usually has been reflected from some object. The original source of such energy typically is radiation from molecules or atoms resulting from internal (atomic) changes. The exact type of emission is determined by

- The ways in which the atoms or molecules are supplied with energy to replace that which they radiate
- The physical state of the substance, whether solid, liquid, or gaseous

The most common source of radiant energy is the thermal excitation of atoms in the solid or gaseous state.

The Spectrum

When a beam of light traveling in air falls upon a glass surface at an angle, it is *refracted* or bent. The amount of **refraction** depends on the wavelength, its variation with wavelength being known as **dispersion**. Similarly when the beam, traveling in glass, emerges into air, it is refracted (with dispersion). A glass prism provides a refracting system of this type. Because different wavelengths are refracted by different amounts, an incident white beam is split up into several beams corresponding to the many wavelengths contained in the composite white beam. Thus is obtained the spectrum.

If a spectrum is allowed to fall upon a narrow slit arranged parallel to the edge of the prism, a narrow band of wavelengths passes through the slit. Obviously the narrower the slit, the narrower the band of

²Portions of this chapter were adapted from Whitaker, J.C. 2000. *VIDEO Displays*: McGraw-Hill, New York. Used with permission.

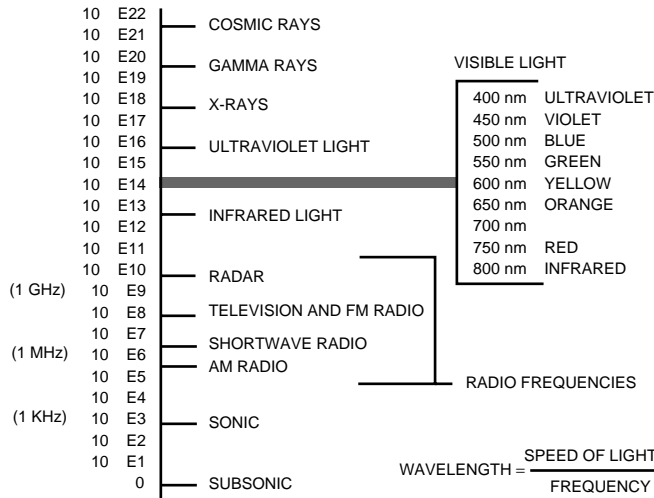

FIGURE 1.110 The electromagnetic spectrum.

wavelengths or the sharper the spectral line. Also, more dispersion in the prism will cause a wider spectrum to be produced, and a narrower spectral line will be obtained for a given slit width.

It should be noted that purples are not included in the list of spectral colors. The purples belong to a special class of colors; they can be produced by mixing the light from two spectral lines, one in the red end of the spectrum, the other in the blue end. Purple (magenta is a more scientific name) is therefore referred to as a *nonspectral color*.

A plot of the power distribution of a source of light is indicative of the watts radiated at each wavelength per nanometer of wavelength. It is usual to refer to such a graph as an **energy distribution curve**.

Individual narrow bands of wavelengths of light are seen as strongly colored elements. Increasingly broader bandwidths retain the appearance of color, but with decreasing purity, as if white light had been added to them. A very broad band extending generally throughout the visible spectrum is perceived as white light. Many white light sources are of this type, such as the familiar tungsten-filament electric light bulb (see Fig. 1.111). Daylight also has a broad band of radiation, as illustrated in Fig. 1.112. The energy distributions shown in Fig. 1.111 and Fig. 1.112 are quite different and, if the corresponding sets of radiation were seen side by side, would be different in appearance. Either one, particularly if seen alone, however, would represent a very acceptable white. A sensation of white light can also be induced by light sources that do not have a uniform energy distribution. Among these is fluorescent lighting, which exhibits sharp peaks of energy through the visible spectrum. Similarly, the light from a monochrome (black-and-white) video cathode ray tube is not uniform within the visible spectrum, generally exhibiting peaks in the yellow and blue regions of the spectrum; yet it appears as an acceptable white (see Fig. 1.113).

1.8.3 Monochrome and Color Vision

The color sensation associated with a light stimulus can be described in terms of three characteristics:

- Hue
- Saturation
- Brightness

The spectrum contains most of the principal hues: red, orange, yellow, green, blue, and violet. Additional hues are obtained from mixtures of red and blue light. These constitute the purple colors. *Saturation* pertains to the strength of the hue. Spectrum colors are highly saturated. White and grays have no hue and,

FIGURE 1.111 The radiating characteristic of tungsten: (trace A) radiant flux from 1 cm² of a blackbody at 3000 K, (trace B) radiant flux from 1 cm² of tungsten at 3000 K, (trace C) radiant flux from 2.27 cm² of tungsten at 3000 K (equal to curve A in the visible region). (Source: Adapted from IES. 1981. *IES Lighting Handbook*. Illuminating Engineering Society of North America, New York.)

therefore, have zero saturation. Pastel colors are of low or intermediate saturation. *Brightness* pertains to the intensity of the stimulation. If a stimulus has high intensity, regardless of its hue, it is said to be bright.

The psychophysical analogs of hue, saturation, and brightness are:

- Dominant wavelength
- Excitation purity
- Luminance

This principle is illustrated in Table 1.31.

FIGURE 1.112 Spectral distribution of solar radiant power density at sea level, showing the ozone, oxygen, and carbon dioxide absorption bands. (Source: Adapted from IES. 1981. *IES Lighting Handbook*. Illuminating Engineering Society of North America, New York.)

FIGURE 1.113 Power distribution of a monochrome video picture tube light source. (Source: Adapted from Fink, D.G. 1952. *Television Engineering*, 2nd ed. McGraw-Hill, New York.)

By means of definitions and standard response functions, which have received international acceptance through the International Commission on Illumination, the dominant wavelength, purity, and luminance of any stimulus of known spectral energy distribution may be determined by simple computations. Although roughly analogous to their psychophysical counterparts, the psychological attributes of hue, saturation, and brightness pertain to observer responses to light stimuli and are not subject to calculation. These sensation characteristics as applied to any given stimulus depend in part on other visual stimuli in the field of view and on the immediately preceding stimulations.

Color sensations arise directly from the action of light on the eye. They are normally associated, however, with objects in the field of view from which the light comes. The objects themselves are therefore said to have color. *Object colors* may be described in terms of their hues and saturations, as is the case for light stimuli. The intensity aspect is usually referred to in terms of lightness, rather than brightness. The psychophysical analogs of lightness are *luminous reflectance* for reflecting objects and *luminous transmittance* for transmitting objects.

At low levels of illumination, objects may differ from one another in their lightness appearances but give rise to no sensation of hue or saturation. All objects appear to be of different shades of gray. Vision at low levels of illumination is called *scotopic vision*, as distinct from *photopic vision*, which takes place at higher levels of illumination. Table 1.32 compares the luminosity values for photopic and scotopic vision.

Only the rods of the retina are involved in scotopic vision; the cones play no part. As the *fovea centralis* is free of rods, scotopic vision takes place outside the fovea. Visual acuity of scotopic vision is low compared with photopic vision.

At high levels of illumination, where cone vision predominates, all vision is color vision. Reproducing systems such as black-and-white photography and monochrome video, however, cannot reproduce all three types of characteristics of colored objects. All images belong to the series of grays, differing only in their relative brightness.

The relative brightness of the reproduced image of any object depends primarily on the luminance of the object as seen by the photographic or video camera. Depending on the camera pickup element or the film, however, the dominant wavelength and purity of the light may also be of consequence. Most films and video pickup elements now in use exhibit sensitivity throughout the visible spectrum and, consequently, marked distortions in luminance as a function of dominant wavelength and purity are not encountered.

Their spectral sensitivities seldom conform exactly to that of the human observer, however, so that some brightness distortions do exist.

Visual Requirements for Video

The objective in any type of visual reproduction system is to present to the viewer a combination of visual stimuli that can be readily interpreted as representing or having close association with a real viewing situation. It is by no means necessary that the light stimuli from the original scene be duplicated. There are certain characteristics in the reproduced image, however, that are necessary and others that are highly desirable. Only a general qualitative discussion of such characteristics will be given here.

In monochrome video, images of objects are distinguished from one another and from their backgrounds as a result of luminance differences. In order that detail in the picture be visible and that objects have clear, sharp edges, it is necessary that the video system be capable of rapid transitions from areas of one luminance level to another. This degree of resolution need not match that possible in the eye itself, but too low an effective **resolution** results in pictures with a fuzzy appearance and lacking fineness of detail.

Luminance range and the transfer characteristic associated with luminance reproduction are likewise of importance in monochrome video. Objects seen as white usually have minimum reflectances of approximately 80%. Black objects have reflectances of approximately 4%. This gives a luminance ratio of 20/1 in the range from white to black. To obtain the total luminance range in a scene, the reflectance range must be multiplied by the illumination range. In outdoor scenes, the illumination ratio between full sunlight and shadow may be as high as 100/1. The full luminance ranges involved with objects in such scenes cannot be reproduced in normal video reproduction equipment. Video systems must be capable of handling illumination ratios of at least 2, however, and ratios as high as 4 or 5 are desirable. This implies a luminance range on the output of the system of at least 40, with possible upper limits as high as 80 or 100.

Monochrome video transmits only luminance information, and the relative luminances of the images should correspond at least roughly to the relative luminances of the original objects. Red objects, for example, should not be reproduced markedly darker than objects of other hues but of the same luminance. Exact luminance reproduction, however, is by no means a necessity. Considerable distortion as a function of hue is acceptable in many applications. Luminance reproduction is probably of primary consequence only if detail in some hues becomes lost.

Images in monochrome video are transmitted one point, or small area, at a time. The complete picture image is repeatedly scanned at frequent intervals. If the frequency of scan is not sufficiently high, the picture appears to flicker. At frequencies above a **critical frequency** no flicker is apparent. The critical frequency changes as a function of luminance, being higher for higher luminance. The basic requirement for monochrome video is that the **field frequency** (the rate at which images are presented) be above the critical frequency for the highest image luminances.

Images of objects in color video are distinguished from one another by luminance differences or by differences in hue or saturation. Exact reproduction in the image of the original scene differences is not necessary or even attainable. Nevertheless, some reasonable correspondence must prevail because the luminance gradation requirements for color are essentially the same as those for monochrome video.

Luminous Considerations in Visual Response

Vision is considered in terms of physical, psychophysical, and psychological quantities. The primary stimulus for vision is radiant energy. The study of this radiant energy in its various manifestations, including the effects on it of reflecting, refracting, and absorbing materials, is a study in physics. The response part of the visual process embodies the sensations and perceptions of seeing. Sensing and perceiving are mental operations and therefore belong to the field of psychology. Evaluation of radiant-energy stimuli in terms of the observer responses they evoke is within the realm of psychophysics. Because observer response sensations can be described only in terms of other sensations, psychophysical specifications of stimuli are made according to sensation equalities or differences.

1.8.4 Photometric Measurements

Evaluation of a radiant-energy stimulus in terms of its brightness-producing capacity is a photometric measurement. An instrument for making such measurements is called a *photometer*. In visual photometers, which must be used in obtaining basic photometric measurements, the two stimuli to be compared are normally directed into small adjacent parts of a viewing field. The stimulus to be evaluated is presented in the *test field*; the stimulus against which it is compared is presented in the *comparison field*. For most high-precision measurements the total size of the combined test and comparison fields is kept small, subtending about 2° at the eye. The area outside these fields is called the *surround*. Although the surround does not enter directly into the measurements, it has adaptation effects on the retina and thus affects the appearances of the test and comparison fields. It also influences the precision of measurement.

1.8.5 Luminosity Curve

A *luminosity curve* is a plot indicative of the relative brightnesses of spectrum colors of different wavelength or frequency. To a normal observer, the brightest part of a spectrum consisting of equal amounts of radiant flux per unit wavelength interval is at about 555 nm. Luminosity curves are therefore commonly normalized to have a value of *unity* at 555 nm. If, at some other wavelength, twice as much radiant flux as at 555 nm is required to obtain brightness equality with radiant flux at 555 nm, the luminosity at this wavelength is 0.5. The luminosity at any wavelength λ is, therefore, defined as the ratio P_{555}/P_λ , where P_λ denotes the amount of radiant flux at the wavelength λ , which is equal in brightness to a radiant flux of P_{555} .

The luminosity function that has been accepted as standard for photopic vision is given in Fig. 1.114. Tabulated values at 10-nm intervals are given in Table 1.32. This function was agreed on by the International Commission on Illumination (CIE) in 1924. It is based on considerable experimental work that was conducted over a number of years. Chief reliance in arriving at this function was based on the step-by-step equality-of-brightness method. Flicker photometry provided additional data.

In the scotopic range of intensities, the luminosity function is somewhat different from that of the photopic range. The two curves are compared in Fig. 1.115. Values are listed in Table 1.32. The two curves are similar in shape, but there is a shift for the scotopic curve of about 40 nm to the shorter wavelengths.

Measurements of luminosity in the scotopic range are usually made by the *threshold-of-vision* method. A single stimulus in a dark surround is used. The stimulus is presented to the observer at each of a number

FIGURE 1.114 The photopic luminosity function. (Source: Adapted from Fink, D.G. 1952. *Television Engineering*, 2nd ed. McGraw-Hill, New York.)

FIGURE 1.115 Scotopic luminosity function (trace A) as compared with photopic luminosity function (trace B). (Source: Adapted from Fink, D.G. 1952. *Television Engineering*, 2nd ed. McGraw-Hill, New York.)

of different intensities, ranging from well below the threshold to intensities sufficiently high to be definitely visible. Determinations are made of the amount of energy, at each chosen wavelength, that is reported visible by the observer a certain percentage of the time, such as 50%. The reciprocal of this amount of energy determines the relative luminosity at the given wavelength. The wavelength plot is normalized to have a maximum value of 1.00 to give the scotopic luminosity function.

In the intensity region between scotopic and photopic vision, called the *Purkinje* or *mesopic region*, the measured luminosity function takes on sets of values intermediate between those obtained for scotopic and photopic vision. Relative luminosities of colors within the mesopic region will therefore vary, depending on the particular intensity level at which the viewing takes place. Reds tend to become darker in approaching scotopic levels; greens and blues tend to become relatively lighter.

Luminance

Brightness is a term used to describe one of the characteristics of appearance of a source of radiant flux or of an object from which radiant flux is being reflected or transmitted. Brightness specifications of two or more sources of radiant flux should be indicative of their actual relative appearances. These appearances will depend in large part on the viewing conditions, including the state of adaptation of the observer's eye.

Luminance, as indicated previously, is a psychophysical analog of brightness. It is subject to physical determination, independent of particular viewing and adaptation conditions. Because it is an analog of brightness, however, it is defined in such a way as to relate as closely as possible to brightness.

The best established measure of the relative brightnesses of different spectral stimuli is the luminosity function. In evaluating the luminance of a source of radiant flux consisting of many wavelengths of light, the amounts of radiant flux at the different wavelengths are weighted by the luminosity function. This converts radiant flux to luminous flux. As used in photometry, the term *luminance* is applied only to extended sources of light, not to point sources. For a given amount (and quality) of radiant flux reaching the eye, brightness will vary inversely with the effective area of the source.

Luminance is described in terms of luminous flux per unit projected area of the source. The greater the concentration of flux in the angle of view of a source, the brighter it appears. Luminance is therefore expressed in terms of amounts of flux per unit solid angle or *steradian*.

In considering the relative luminances of various objects of a scene to be captured and reproduced by a video system, it is convenient to normalize the luminance values so that the white in the region of principal illumination has a relative luminance value of 1.00. The relative luminance of any other object then becomes the ratio of its luminance to that of the white. This white is an object of highly diffusing surface with high and uniform reflectance throughout the visible spectrum. For purposes of computation it may be idealized to have 100% reflectance and perfect diffusion.

Perception of Fine Detail

Detail is seen in an image because of brightness differences between small adjacent areas in a monochrome display or because of brightness, hue, or saturation differences in a color display. Visibility of detail in a picture is important because it determines the extent to which small or distant objects of a scene are visible, and because of its relationship to the **sharpness** appearance of the edges of objects.

Picture definition is probably the most acceptable term for describing the general characteristic of crispness, sharpness, or image-detail visibility in a picture. Picture definition depends on characteristics of the eye, such as visual acuity, and on a variety of characteristics of the picture-image medium, including its resolving power, luminance range, contrast, and image edge gradients.

Visual acuity may be measured in terms of the visual angle subtended by the smallest detail in an object that is visible. The *Landolt ring* is one type of test object frequently employed. The ring, which has a segment cut from it, is shown in any one of four orientations, with the opening at the top or bottom or on the right or left side. The observer identifies the location of this opening. The visual angle subtended by the opening that can be properly located 50% of the time is a measure of visual acuity.

Test-object illuminance, contrast between the test object and its background, time of viewing, and other factors greatly affect visual-acuity measurements. Up to a visual distance of about 20-ft (6-m) acuity is partially a function of distance, because of changes in shape of the eye lens in focusing. Beyond 20 ft it remains relatively constant. Visual acuity is highest for foveal vision, dropping off rapidly for retinal areas outside the fovea.

A black line on a light background is visible if it has a visual angle no greater than $0.5''$. This is not, however, a true measure of visual acuity. For visual-acuity tests of the type described, normal vision, corresponding to a Snellen 20/20 rating, represents an angular discrimination of about $1'$. Separations between adjacent cones in the fovea and resolving power limitations of the eye lens give theoretical visual-acuity values of about this same magnitude.

The extent to which a picture medium, such as a photographic or a video system, can reproduce fine detail is expressed in terms of *resolving power* or *resolution*. Resolution is a measure of the distance between two fine lines in the reproduced image that are visually distinct. The image is examined under the best possible conditions of viewing, including magnification.

Two types of test charts are commonly employed in determining resolving power, either a wedge of radial lines or groups of parallel lines at different pitches for each group. For either type of chart, the spaces between pairs of lines usually are made equal to the line widths. Figure 1.116 shows a test signal electronically generated by a video measuring test set.

Resolution in photography is usually expressed as the maximum number of lines (counting only the black ones or only the white ones) per millimeter that can be distinguished from one another. Measured values of resolving power depend on a number of factors in addition to the photographic material itself. The most important of these typically are:

- Density differences between the black and the white lines of the test chart photographed
- Sharpness of focus of the test-chart image during exposure
- Contrast to which the photographic image is developed
- Composition of the developer

Sharpness of focus depends on the general quality of the focusing lens, image and object distances from the lens, and the part of the projected field in which the image lies. In determining the resolving power

FIGURE 1.116 Test chart for high-definition television applications produced by a signal waveform generator. The electronically produced pattern is used to check resolution, geometry, bandwidth, and color reproduction. (Source: Tektronix.)

of a photographic negative or positive material, a test chart is generally employed that has a high-density difference, such as 3.0, between the black-and-white lines. A high-quality lens is used, the projected field is limited, and focusing is critically adjusted. Under these conditions, ordinary black-and-white photographic materials generally have resolving powers in the range of 30–200 line-pairs/mm. Special photographic materials are available with resolving powers greater than 1000 line-pairs/mm.

Resolution in a video system is expressed in terms of the maximum number of lines, counting both black and white, that are discernible in viewing a test chart. The value of horizontal (vertical lines) or vertical (horizontal lines) resolution is the number of lines equal to the vertical dimension of the raster. Vertical resolution in a well-adjusted system equals the number of scanning lines, roughly 500 in conventional television. In normal broadcasting and reception practice, however, typical values of vertical resolution range from 350–400 lines. The theoretical limiting value for horizontal resolution (R_H) in a 525 line, 30-Hz frame rate system is given by

$$R_H = \frac{2 \times 0.75 \times \Delta f}{30 \times 525}$$

$$R_H = 0.954 \times 10^{-4} \times \Delta f$$

Where Δf is the available bandwidth frequency in Hz. The constants 30 and 525 represent the frame and line frequencies, respectively in the conventional U.S. vision system. A factor of 2 is introduced because in one complete cycle both a black and a white line are obtainable. The factor 0.75 is necessary because of the receiver aspect ratio; the picture height is three-fourths of the picture width. There is an additional reduction of about 15% (not included in the equation) in the theoretical value because of horizontal blanking time during which retrace takes place. A bandwidth of 4.25 MHz—typically that of the conventional terrestrial television system—thus makes possible a maximum resolution of about 345 lines.

Sharpness

The appearance evaluation of a picture image in terms of the edge characteristics of objects is called sharpness. The more clearly defined the line that separates dark areas from lighter ones, the greater the sharpness of the picture. Sharpness is, naturally, related to the transient curve in the image across an edge. The average gradient and the total density difference appear to be the most important characteristics. No physical measure has been devised, however, that in all cases will predict the sharpness (appearance) of an image.

Picture resolution and sharpness are to some extent interrelated but they are by no means perfectly correlated. Pictures ranked according to resolution measures may be rated somewhat differently on the basis of sharpness. Both resolution and sharpness are related to the more general characteristic of picture definition. For pictures in which, under particular viewing conditions, effective resolution is limited by the visual acuity of the eye rather than by picture resolution, sharpness is probably a good indication of picture definition. If visual acuity is not the limiting factor, however, picture definition depends to an appreciable extent on both resolution and sharpness.

1.8.6 Human Visual System

The human visual system (HVS) is powerful and exceeds the performance of artificial visual systems in almost all areas of comparison. Researchers have, therefore, studied the HVS extensively to ascertain the most efficient and effective methods of communicating information to the eye. An important component of this work has been the development of models of how humans see in an effort to improve image processing systems.

1.8.7 A Model for Image Quality

The classic approach to image quality assessment involves the presentation to a group of test subjects visual test material for evaluation and rating. The test material may include side-by-side display comparisons, or a variety of perception-threshold presentations. One common visual comparison technique is called the *pair-comparison* method. A number of observers are asked to view a specified number of images at two or more distances. At each distance, the subjects are asked to rank the order of the images in terms of overall quality, clearness, and personal preference.

An image acquisition, storage, transmission, and display system need not present more visual information to the viewer than the viewer can process. For this reason, image quality assessment is an important element in the development of any new video system. For example, in the development of a video compressing algorithm, the designer needs to know at what compression point impairments are visible to the average viewer.

Evaluation by human subjects, although an important part of this process, is also expensive and time consuming. Numerous efforts have been made to reduce the human visual system and its interaction with a display device to one or more mathematical models. (Some of this research is cited in Grogan (1992), Barten (1992), Daly (1992), Reese (1992), and Martin (1992).) The benefits of this research to design engineers is obvious: more timely feedback on new product offerings. In the development of advanced displays, it is important to evaluate the visual performance of the system well in advance of the expensive fabrication process. Display design software, therefore, is valuable. Because image quality is the primary goal in many display designs, tools that permit the engineer to analyze and emulate the displayed image assist in the design process. Such tools provide early feedback on new display techniques and permit a wider range of prospective products to be evaluated.

After the system or algorithm has successfully passed the minimum criteria established by the model, it can be subjected to human evaluation. The model simulation requires the selection of many interrelated parameters. A series of experiments is typically conducted to improve the model to more closely approximate human visual perception.

Defining Terms

- Brightness:** A term used to describe one of the characteristics of appearance of a source of radiant flux or of an object from which radiant flux is being reflected or transmitted.
- Critical frequency:** The rate of picture presentation, as in a video system or motion picture display, above which the presented image ceases to give the appearance of flickering. The critical frequency changes as a function of luminance, being higher for higher luminance.
- Dispersion:** The variation of refraction as a function of wavelength.
- Energy distribution curve:** A plot of the power distribution of a source of light giving the energy radiated at each wavelength per nanometer of wavelength.
- Field frequency:** The rate at which images in an electronic imaging system are presented. In conventional terrestrial television (National Television Systems Committee (NTSC)), two fields are presented to make up one *frame* (a complete picture).
- Refraction:** The bending of light as it passes from one medium to another, such as from air to glass, at an angle.
- Resolution:** The extent to which an imaging system, such as a photographic or a video system, can reproduce fine detail.
- Sharpness:** The appearance evaluation of a picture image in terms of the edge characteristics of objects contained therein. The more clearly defined the lines separating dark areas from light ones, the greater the sharpness of the picture.

2.1 Circuit Fundamentals

John Choma, Jr. and Stuart K. Burgess

2.1.1 The Electrical Circuit

An **electrical circuit** or *electrical network* is an array of interconnected elements wired so as to be capable of conducting current. The fundamental *two-terminal elements* of an electrical circuit are the **resistor**, the **capacitor**, the **inductor**, the **voltage source**, and the **current source**. The circuit schematic symbols of these elements, together with the algebraic symbols used to denote their respective general values, appear in Fig. 2.1(a) through Fig. 2.1(e).

The value of a resistor is its resistance R , the dimensional of which units are *ohms*. The case of a wire used to interconnect the terminals of two electrical elements corresponds to the special case of a resistor, the resistance of which is ideally zero ohms; that is, $R = 0$. For the capacitor in Fig. 2.1(b), the capacitance C , has units of *farads*, and in Fig. 2.1(c), the value of an inductor is its inductance L , the dimensions of which are *henries*. In the case of the voltage sources depicted in Fig. 2.1(d), a constant, time-invariant source of voltage, or *battery*, is distinguished from a voltage source, the voltage value of which varies with time. The latter type of voltage source is often referred to as a *time-varying signal* or simply, a *signal*. In either case, the value of the battery voltage, E , and the time-varying signal, $v(t)$, is in units of *volts*. Finally, the current source of Fig. 2.1(e) has a value I , the value of which is expressed in *amperes*, which is typically abbreviated to *amps*.

Elements having three, four, or more than four terminals can also appear in practical electrical networks. The discrete component *bipolar junction transistor* (BJT), which is schematically portrayed in Fig. 2.2(a), is an example of a three-terminal element, where the three terminals at issue are the collector, the base, and the emitter. On the other hand, the monolithic *metal-oxide-semiconductor field-effect transistor* (MOSFET) depicted in Fig. 2.2(b) has four terminals: the drain, the gate, the source, and the bulk substrate.

Multiterminal elements appearing in circuits are routinely represented, or *modeled*, by equivalent sub-circuits formed of only interconnected two-terminal elements. Such a representation is always possible, provided that the list of two-terminal elements itemized in Fig. 2.1 is appended by an additional type of two-terminal element known as the **controlled source**, or *dependent generator*. There are four types of controlled sources; two are voltage sources and two are current sources. In Fig. 2.3(a), the dependent generator is a *voltage-controlled voltage source* (VCVS) in that the voltage $v_o(t)$, developed from terminal 3 to terminal 4, is a function of, and is therefore dependent on, the voltage $v_i(t)$ established elsewhere in

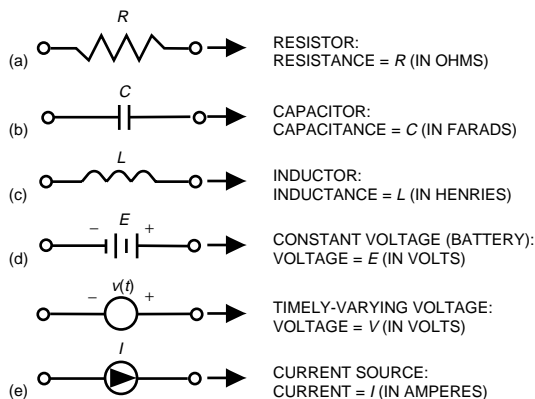

FIGURE 2.1 Circuit schematic symbol and corresponding value notation for: (a) resistor, (b) capacitor, (c) inductor, (d) voltage source, and (e) current source. Note that a constant voltage source, or battery, is distinguished from a voltage source the value of which varies with time.

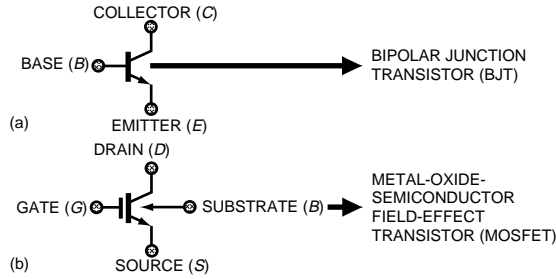

FIGURE 2.2 Circuit schematic symbol for: (a) discrete component bipolar junction transistor (BJT), (b) monolithic metal-oxide-semiconductor field-effect transistor (MOSFET).

the network from terminal 1 to terminal 2. The *controlled voltage* $v_o(t)$, as well as the *controlling voltage* $v_i(t)$, can be constant or time varying. Regardless of the time-domain nature of these two voltages, the value of $v_o(t)$ is not an independent number. Instead, its value is determined by $v_i(t)$ in accordance with a prescribed functional relationship, say,

$$v_o(t) = f[v_i(t)] \tag{2.1}$$

If the function $f(\cdot)$ is linearly related to its argument, then Eq. (2.1) collapses to the form

$$v_o(t) = f_\mu v_i(t) \tag{2.2}$$

where f_μ is a constant, independent of either $v_o(t)$ or $v_i(t)$. When the function on the right-hand side of Eq. (2.1) is linear, the subject VCVS becomes known as a *linear voltage-controlled voltage source*.

The second type of controlled voltage source is *the current-controlled voltage source* (CCVS) depicted in Fig. 2.3(b). In this dependent generator, the controlled voltage $v_o(t)$ developed from terminal 3 to terminal 4 is a function of the *controlling current* $i_i(t)$, flowing in the network between terminals 1 and 2, as indicated. In this case, the generalized functional dependence of $v_o(t)$ on $i_i(t)$ is expressible as

$$v_o(t) = r[i_i(t)] \tag{2.3}$$

which reduces to

$$v_o(t) = r_m i_i(t) \tag{2.4}$$

when $r(\cdot)$ is a linear function of its argument.

The two types of dependent current sources are diagrammed symbolically in Fig. 2.3(c) and Fig. 2.3(d). Figure 2.3(c) depicts a *voltage-controlled current source* (VCCS), for which the controlled current $i_o(t)$ flowing in the electrical path from terminal 3 to terminal 4 is determined by the controlling voltage $v_i(t)$ established across terminals 1 and 2. The controlled current can, therefore, be written as

$$i_o(t) = g[v_i(t)] \tag{2.5}$$

In the *current-controlled current source* (CCCS) of Fig. 2.3(d),

$$i_o(t) = a[i_i(t)] \tag{2.6}$$

where the controlled current $i_o(t)$ flowing from terminal 3 to terminal 4 is a function of the controlling current $i_i(t)$ flowing in the circuit from terminal 1 to terminal 2. As is the case with the two controlled

FIGURE 2.3 Circuit schematic symbol for: (a) voltage-controlled voltage source (VCVS), (b) current-controlled voltage source (CCVS), (c) voltage-controlled current source (VCCS), (d) current-controlled current source (CCCS).

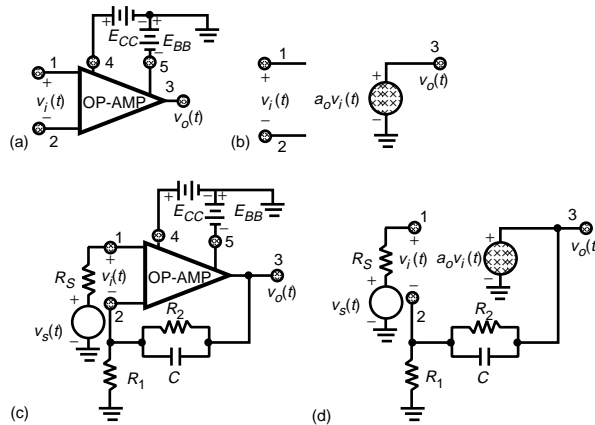

FIGURE 2.4 (a) Circuit schematic symbol for a voltage mode operational amplifier, (b) first order linear model of the op-amp, (c) a voltage amplifier realized with the op-amp functioning as the gain element, (d) equivalent circuit of the voltage amplifier in (c).

voltage sources studied earlier, the preceding two equations collapse to the linear relationships,

$$i_o(t) = g_m v_i(t) \tag{2.7}$$

and

$$i_o(t) = a_\alpha i_i(t) \tag{2.8}$$

when $g(\cdot)$ and $a(\cdot)$, are linear functions of their arguments, respectively.

The immediate implication of the controlled source concept is that the definition for an electrical circuit given at the beginning of this subsection can be revised to read: an electrical circuit or electrical network is an array of *interconnected two-terminal elements* wired in such a way as to be capable of conducting current. Implicit to this revised definition is the understanding that the two-terminal elements allowed in an electrical circuit are the resistor, the capacitor, the inductor, the voltage source, the current source, and any of the four possible types of dependent generators.

In an attempt to reinforce the engineering utility of the foregoing definition, consider the voltage mode *operational amplifier (op-amp)*, whose circuit schematic symbol is shown in Fig. 2.4(a). Observe that the op-amp is a five-terminal element. Two terminals, labeled 1 and 2, are provided to receive input signals that derive either from external signal sources or from the output terminals of subcircuits that feed back a designable fraction of the output signal established between terminal 3 and the system ground. Battery voltages, identified as E_{CC} and E_{BB} in the figure, are applied to the remaining two op-amp terminals (terminals 4 and 5) with respect to ground to *bias* or *activate* the op-amp for its intended application. When E_{CC} and E_{BB} are selected to ensure that the subject operational amplifier behaves as a linear circuit element, the linearized, or small-signal, characteristics of the op-amp in Fig. 2.4(a) can be modeled by the electrical circuit appearing in Fig. 2.4(b). Thus, the voltage amplifier of Fig. 2.4(c), which interconnects two batteries, a signal source voltage, three resistors, a capacitor, and an op-amp, can be represented by the network given in Fig. 2.4(d). Note that the latter configuration uses only two terminal elements, one of which is a voltage-controlled voltage source.

2.1.2 Current and Current Polarity

The concept of an electrical *current* is implicit to the definition of an electrical circuit in that a circuit is said to be an array of two terminal elements that are connected in such a way as to permit the *conduction of current*. Current flow through an element that is capable of current conduction requires that a net nonzero

charge, say, $q(t)$, be transferred over finite time across any cross-sectional area of the element. The current $i(t)$ that actually flows is the time rate of change of this transferred charge; that is,

$$i(t) = \frac{dq(t)}{dt} \tag{2.9}$$

where the MKS unit of charge is the *coulomb*, time t is measured in seconds, and the resultant current is in units of amperes. Note that zero current does not necessarily imply a lack of charge at a given cross section of a conductive element. Rather, zero current implies only that the subject charge is not changing with time; that is, the charge is not moving through the elemental cross section.

Electrical charge can be negative, as in the case of *electrons* transported through a cross section of a conductive element such as aluminum or copper. A single electron has a charge of $-(1.602 \times 10^{-19})$ C. Thus, Eq. (2.9) implies a need to transport an average of (6.242×10^{18}) electrons in 1 s through a cross section of aluminum if the aluminum element is to conduct a constant current of 1 A. Charge can also be positive, as in the case of *holes* transported through a cross section of a semiconductor such as germanium or silicon. To first order, the electrical charge of a hole is the negative of the charge of an electron, which implies that the charge of a hole is $+(1.602 \times 10^{-19})$ C.

A positive charge, $q(t)$, transported from the left of the cross section to the right of the cross section in the element abstracted in Fig. 2.5(a) gives rise to a positive current, $i(t)$, that also flows from left to right across the indicated cross section. Assume that prior to the transport of such charge, the volumes to the left and to the right of the cross section are electrically neutral; that is, these volumes have zero initial net charge. Then, the transport of a positive charge, say, q_o , from the left side to the right side of the element charges the right side to $+q_o$ and the left side to $-q_o$.

Alternatively, suppose a negative charge in the amount of $-q_o$ is transported from the right side of the element to its left side, as suggested in Fig. 2.5(b). Then, the left side charges to $-q_o$ and the right side charges to $+q_o$, which is identical to the electrostatic condition incurred by the transport of a positive charge in the amount of q_o from left- to right-hand sides. Resultantly, the transport of a net negative charge from right to left produces a positive current, $i(t)$, flowing from left to right, just as positive charge transported from left- to right-hand sides induces a current flow from left to right.

Assume, as portrayed in Fig. 2.5(c), that a positive or a negative charge, say, $q_1(t)$, is transported from the left side of the indicated cross section to the right side. Simultaneously, a positive or a negative charge in the amount of $q_2(t)$ is directed through the cross section from right to left. If $i_1(t)$ is the current arising from the transport of the charge $q_1(t)$, and if $i_2(t)$ denotes the current corresponding to the transport of the charge $q_2(t)$, the net effective current $i_e(t)$ flowing from the left side of the cross section to the right side of the cross section is

$$i_e(t) = \frac{d}{dt}[q_1(t) - q_2(t)] = i_1(t) - i_2(t) \tag{2.10}$$

where the charge difference, $(q_1(t) - q_2(t))$, represents the net charge transported from left to right. Observe that if $q_1(t) \equiv q_2(t)$, the net effective current is zero even though conceivably large numbers of charges are transported to and fro across the junction.

FIGURE 2.5 (a) Transport of a positive charge from the left-hand side to the right-hand side of an arbitrary cross section of a conductive element, (b) transport of a negative charge from the right-hand side to the left-hand side of an arbitrary cross section of a conductive element, (c) transport of positive or negative charges from either side to the other side of an arbitrary cross section of a conductive element.

2.1.3 Energy and Voltage

The preceding section highlights the fact that the flow of current through a conductive electrical element mandates that a net charge be transported over finite time across any arbitrary cross section of that element. The electrical effect of this charge transport is a net positive charge induced on one side of the element in question and a net negative charge (equal in magnitude to the aforementioned positive charge) mirrored on the other side of the element. But this ramification conflicts with the observable electrical properties of an element in equilibrium. In particular, an element sitting in free space, without any electrical connection to a source of *energy*, is necessarily in equilibrium in the sense that the net positive charge in any volume of the element is precisely counteracted by an equal amount of charge of opposite sign in said volume. Thus, if none of the elements abstracted in Fig. 2.5 is connected to an external source of energy, it is impossible to achieve the indicated electrical charge differential that materializes across an arbitrary cross section of the element when charge is transferred from one side of the cross section to the other.

The energy commensurate with sustaining current flow through an electrical element derives from the application of a voltage, say, $v(t)$, across the element in question. Equivalently, the application of electrical energy to an element manifests itself as a voltage developed across the terminals of an element to which energy is supplied. The amount of applied voltage $v(t)$ required to sustain the flow of current, $i(t)$, as diagrammed in Fig. 2.6(a), is precisely the voltage required to offset the electrostatic implications of the differential charge induced across the element through which $i(t)$ flows. This is to say that without the connection of the voltage $v(t)$ to the element in Fig. 2.6(a), the element cannot be in equilibrium. With $v(t)$ connected, equilibrium for the entire system comprising element and voltage source is re-established by allowing for the conduction of the current $i(t)$.

Instead of viewing the delivery of energy to an electrical element as a voltage source applied to the element, this energy delivery may be interpreted as the upshot of a current source used to excite the element, as depicted in Fig. 2.6(b). This interpretation follows from the fact that energy must be applied in an amount that effects charge transport at a desired time rate of change. It follows that the application of a current source in the amount of the desired current is necessarily in one-to-one correspondence with the voltage required to offset the charge differential manifested by the charge transport that yields the subject current. To be sure, a voltage source is a physical entity, whereas a current source is not. But the mathematical modeling of energy delivery to an electrical element can be accomplished through either a voltage source or a current source.

In Fig. 2.6, the terminal voltage $v(t)$ corresponding to the applied energy, say, $w(t)$, that is required to transfer an amount of charge $q(t)$ across an arbitrary cross section of the element is

$$v(t) = \frac{dw(t)}{dq(t)} \quad (2.11)$$

where $v(t)$ is in volts when $q(t)$ is in coulombs and $w(t)$ is in joules. Thus, if 1 J of applied energy results in the transport of 1 C of charge through an element, the elemental terminal voltage manifested by the 1 J of applied energy is 1 V.

It should be understood that the derivative on the right-hand side of Eq. (2.11), and thus the terminal voltage demanded of an element that is transporting a certain amount of charge through its cross section, is

FIGURE 2.6 (a) The application of energy in the form of a voltage applied to an element that is made to conduct a specified current, the applied voltage $v(t)$ causes the current $i(t)$ to flow, (b) the application of energy in the form of a current applied to an element that is made to establish a specified terminal voltage, the applied current $i(t)$ causes the voltage $v(t)$ to be developed across the terminals of the electrical element.

a function of the properties of the type of material from which the element undergoing study is fabricated. For example, an insulator, such as paper, air, or silicon dioxide, is incapable of current conduction and, hence, intrinsic charge transport. Thus, $q(t)$ is essentially zero in an insulator and by Eq. (2.11), an infinitely large terminal voltage is mandated for even the smallest possible current. In a conductor, such as aluminum, iron, or copper, large amounts of charge can be transported for very small applied energies. Accordingly, the requisite terminal voltage for even very large currents approaches zero in ideal conductors. The electrical properties of semiconductors, such as germanium, silicon, and gallium arsenide, lie between the extremes of those for an insulator and a conductor. In particular, semiconductor elements behave as insulators when their terminals are subjected to small voltages, whereas progressively larger terminal voltages render the electrical behavior of semiconductors akin to conductors. This conditionally conductive property of a semiconductor explains why semiconductor devices and circuits must be biased to appropriate voltage levels before these devices and circuits can function in accordance with their design requirements.

2.1.4 Power

The foregoing material underscores the fact that the flow of current through a two terminal element requires that charge be transported over time through any cross section of that element or network. In turn, such charge transport requires that energy be supplied to the network, usually through the application of an external voltage source. The time rate of change of this applied energy is the **power** delivered by the external voltage or current source to the network in question. If $p(t)$ denotes this power in watts,

$$p(t) = \frac{dw(t)}{dt} \tag{2.12}$$

where, of course, $w(t)$ is the energy supplied to the network in joules. By rewriting Eq. (2.12) in the form

$$p(t) = \frac{dw(t)}{dq(t)} \frac{dq(t)}{dt} \tag{2.13}$$

and applying Eqs. (2.9) and (2.11), the power supplied to the two terminals of an element or a network becomes the more expedient relationship,

$$p(t) = v(t)i(t) \tag{2.14}$$

Equation (2.14) expresses the power delivered to an element as a simple product of the voltage applied across the terminals of the element and the resultant current conducted by that element. But care must be exercised when applying Eq. (2.14) to practical circuits.

To this end, it is useful to revisit the simple abstraction of Fig. 2.6(a), which is redrawn in slightly modified form in Fig. 2.7. In this circuit, a signal source voltage $v_s(t)$ is applied across the two terminals, terminals 1 and 2, of an element, which responds by conducting a current $i(t)$ from terminal 1 to terminal 2 and developing a corresponding terminal voltage $v(t)$, as shown. If the wires that connect the signal source to the element are ideal zero resistance conductors, the voltage $v(t)$ is identical to $v_s(t)$. Moreover, since the current is manifested by the application of the signal source, which thereby establishes a closed electrical path for current conduction, the element current, $i(t)$, is necessarily the same as the current, $i_s(t)$, that flows through $v_s(t)$.

If attention is focused on only the element in Fig. 2.7, it is natural to presume that the current conducted by the element actually flows from terminal 1 to terminal 2 when, as shown, the voltage

FIGURE 2.7 Circuit used to illustrate power calculations and the associated reference polarity convention.

developed across the element is positive at terminal 1 with respect to terminal 2. This assertion might be rationalized qualitatively by noting that the positive voltage nature at terminal 1 acts to repel positive charges from terminal 1 to terminal 2, where the negative nature of the developed voltage $v(t)$ tends to attract the repulsed positive charges. Similarly, the positive nature of the voltage at terminal 1 serves to attract negative charges from terminal 2, where the negative nature of $v(t)$ tends to repel such negative charges. Since current flows in the direction of transported positive charge and opposite to the direction of transported negative charge, either interpretation gives rise to an elemental current $i(t)$ that flows from terminal 1 to terminal 2. In general, if current is indicated as flowing from the *high* (+) voltage terminal to the *low* (−) voltage terminal of an element, the current conducted by the element and the voltage developed across the element to cause this flow of current are said to be in **associated reference polarity**. When the element current $i(t)$ and the corresponding element voltage $v(t)$, as exploited in the defining power relationship of Eq. (2.14), are in associated reference polarity, the resultantly computed power is a positive number and is said to represent the *power delivered to* the element. In contrast, $v(t)$ and $i(t)$ are said to be in *disassociated reference polarity* when $i(t)$ flows from the low voltage terminal of the element to its high voltage terminal. In this case, the voltage-current product in Eq. (2.14) is a negative number. Rather than stating that the resultant negative power is delivered to the element, it is more meaningful to assert that the computed negative power is a *positive power that is generated by* the element in question.

At first glance, it may appear as though polarity disassociation between element voltage and current variables is an impossible circumstance. Not only is polarity disassociation possible, it is absolutely necessary if electrical circuits are to subscribe to the fundamental principle of *conservation of power*. This principle states that the net power dissipated by a circuit must be identical to the net power supplied to that circuit. A confirmation of this basic principle derives from a further consideration of the topology in Fig. 2.7. The electrical variables, $v(t)$ and $i(t)$, pertinent to the element delineated in this circuit are in associated reference polarity. Accordingly, the power $p_e(t)$ dissipated by this element is positive and given by Eq. (2.14); namely,

$$p_e(t) = v(t)i(t) \quad (2.15)$$

However, the voltage and current variables, $v_s(t)$ and $i_s(t)$, relative to the signal source voltage are in disassociated polarity. It follows that the power $p_s(t)$ *delivered to the signal source* is

$$p_s(t) = -v_s(t)i_s(t) \quad (2.16)$$

Since, as previously stated, $v_s(t) = v(t)$ and $i_s(t) = i(t)$ for the circuit at hand, Eq. (2.16) can be written as

$$p_s(t) = -v(t)i(t) \quad (2.17)$$

The last result implies that the

$$\text{power delivered by the signal source} = +v(t)i(t) \equiv p_e(t) \quad (2.18)$$

that is, the power delivered to the element by the signal source is equal to the power dissipated by the element.

An alternative statement to conservation of power, as applied to the circuit in Fig. 2.7, derives from combining Eq. (2.15) and Eq. (2.17) to arrive at

$$p_s(t) + p_e(t) = 0 \quad (2.19)$$

The foregoing result may be generalized to the case of a circuit comprising an electrical interconnection of N elements, some of which may be voltage and current sources. Let the voltage across the k th element be $v_k(t)$, and let the current flowing through this k th element, in associated reference polarity with $v_k(t)$, be $i_k(t)$. Then, the power, say, $p_k(t)$, delivered to the k th electrical element is $v_k(t)i_k(t)$. By conservation

of power,

$$\sum_{k=1}^N p_k(t) = \sum_{k=1}^N v_k(t)i_k(t) = 0 \tag{2.20}$$

The satisfaction of this expression requires that at least one of the $p_k(t)$ be negative or, equivalently, at least one of the N elements embedded in the circuit at hand must be a source of energy.

2.1.5 Circuit Classifications

It was pointed out earlier that the relationship between the current that is made to flow through an electrical element and the applied energy, and thus voltage, that is required to sustain such current flow is dictated by the material from which the subject element is fabricated. The elemental material and the associated manufacturing methods exploited to realize a particular type of circuit element determine the mathematical nature between the voltage applied across the terminals of the element and the resultant current flowing through the element. To this end, electrical elements and circuits in which they are embedded are generally codified as linear or nonlinear, **active** or **passive**, time varying or time invariant, and **lumped** or **distributed**.

Linear Versus Nonlinear

A *linear two-terminal circuit element* is one for which the voltage developed across, and the current flowing through, are related to one another by a linear algebraic or a linear integrodifferential equation. If the relationship between terminal voltage and corresponding current is nonlinear, the element is said to be *nonlinear*. A linear circuit contains only linear circuit elements, whereas a circuit is said to be nonlinear if at least one of its embedded electrical elements is nonlinear.

All practical circuit elements, and thus all practical electrical networks, are inherently nonlinear. But over suitably restricted ranges of applied voltages and corresponding currents, the volt–ampere characteristics of these elements and networks emulate idealized linear relationships. In the design of an electronic linear signal processor, such as an amplifier, an implicit engineering task is the implementation of biasing subcircuits that constrain the voltages and currents of internal semiconductor elements to ranges that ensure linear elemental behavior over all possible operating conditions.

The voltage–current relationship for the linear resistor offered in Fig. 2.8(a) is

$$v(t) = Ri(t) \tag{2.21}$$

where the voltage $v(t)$ appearing across the terminals of the resistor and the resultant current $i(t)$ conducted by the resistor are in associated reference polarity. The resistance R is independent of either $v(t)$ or $i(t)$. From Eq. (2.14), the dissipated resistor power, which is manifested in the form of heat, is

$$p_r(t) = i^2(t)R = \frac{v^2(t)}{R} \tag{2.22}$$

The linear capacitor and the linear inductor, whose schematic symbols appear, respectively, in Figs. 2.8(b) and 2.8(c), store energy, as opposed to dissipating power. Their volt–ampere equations are the linear relationships,

$$i(t) = C \frac{dv(t)}{dt} \tag{2.23}$$

FIGURE 2.8 Circuit schematic symbol and corresponding voltage and current notation for a: (a) linear resistor, (b) linear capacitor, (c) linear inductor.

for the capacitor, whereas for the inductor in Fig. 2.8(c),

$$v(t) = L \frac{di(t)}{dt} \quad (2.24)$$

Observe from Eqs. (2.23) and (2.14) that the power $p_c(t)$ delivered to the linear capacitor is

$$p_c(t) = v(t)i(t) = Cv(t) \frac{dv(t)}{dt} \quad (2.25)$$

From Eq. (2.12), this power is related to the energy, say, $w_c(t)$, stored in the form of charge deposited on the plates of the capacitor by

$$Cv(t)dv(t) = dw_c(t) \quad (2.26)$$

It follows that the energy delivered to, and hence stored in, the capacitor from time $t = 0$ to time t is

$$w_c(t) = \frac{1}{2}Cv^2(t) \quad (2.27)$$

It should be noted that this stored energy, like the energy associated with a signal source or a battery voltage, is available to supply power to other elements in the network in which the capacitor is embedded. For example, if very little current is conducted by the capacitor in question, Eq. (2.23) implies that the voltage across the capacitor is essentially constant. Recall that an element whose terminal voltage is a constant and in which energy is stored and, therefore, available for use, behaves as a battery.

If the preceding analysis is repeated for the inductor of Fig. 2.8(c), it can be shown that the energy $w_l(t)$ stored in the inductive element from time $t = 0$ to time t is

$$w_l(t) = \frac{1}{2}Li^2(t) \quad (2.28)$$

Whereas an energized capacitor conducting almost zero current functions as a voltage source, an energized inductor supporting almost zero terminal voltage emulates a constant current source.

Active Versus Passive

An electrical element or network is said to be passive if the power delivered to it, defined in accordance with Eq. (2.14), is nonnegative. This definition exploits the requirement that the terminal voltage $v(t)$ and the element current $i(t)$ appearing in Eq. (2.14) be in associated reference polarity. In contrast, an element or network to which the delivered power is negative is said to be active; that is, an active element or network generates power instead of dissipating it.

Conventional two-terminal resistors, capacitors, and inductors are passive elements. It follows that networks formed of interconnected two-terminal resistors, capacitors, and inductors are passive networks. Two-terminal voltage and current sources generally behave as active elements. However, when more than one source of externally applied energy is present in an electrical network, it is possible for one or more of these sources to behave as passive structures. Comments similar to those made in conjunction with two-terminal voltage and current sources apply equally well to each of the four possible dependent generators. Accordingly, multiterminal configurations, whose models exploit dependent sources, can behave as either passive or active networks.

Time Varying Versus Time Invariant

The elements of a circuit are defined electrically by an identifying parameter, such as resistance, capacitance, inductance, and the gain factors associated with dependent voltage or current sources. An element, the identifying parameter of which changes as a function of time is said to be a time-varying element. If said parameter is a constant over time, the element in question is time invariant. A network containing at least one time-varying electrical element is said to be a time-varying network. Otherwise, the network is time-invariant. Excluded from the list of elements whose electrical character establishes the time variance or time

invariance of a considered network are externally applied voltage and current sources. Thus, for example, a network the internal elements of which are exclusively time-invariant resistors, capacitors, inductors, and dependent sources but which is excited by a sinusoidal signal source is nonetheless a time-invariant network.

Although some circuits, and particularly electromechanical networks, are purposely designed to exhibit time-varying volt–ampere characteristics, parametric time variance is generally viewed as a parasitic phenomenon in the majority of practical circuits. Unfortunately, a degree of parametric time variance is unavoidable in even those circuits that are specifically designed to achieve input/output response properties that closely approximate time-invariant characteristics. For example, the best of network elements exhibit a slow aging phenomenon that shifts the values of its intrinsic physical parameters. The upshot of these shifts is electrical circuits the overall performance of which deteriorates with time.

Lumped Versus Distributed

Electrons in conventional conductive elements are not transported instantaneously across elemental cross sections. But their transport velocities are very high. In fact, these velocities approach the speed of light, say, c , which is (3×10^8) m/s or about 982 ft/ μ s. Electrons and holes in semiconductors are transported at somewhat slower speeds, but generally no less than an order of magnitude or so smaller than the speed of light. The time required to transport charge from one terminal of a two-terminal electrical element to its other terminal, compared with the time required to propagate energy uniformly through the element, determines whether an element is lumped or distributed. In particular, if the time required to transport charge through an element is significantly smaller than the time required to propagate the energy through the element that is required to incur such charge transport, the element in question is said to be lumped. On the other hand, if the charge transport time is comparable to the energy propagation time, the element is said to be distributed.

The feature size of an element, in relation to the wavelength of energy propagated through the element, determines whether it should be viewed as a lumped or as a distributed element. If the feature size is significantly smaller than the wavelength of applied energy, the element is lumped; otherwise, it is distributed. Antennas used to capture high-frequency transmissions are excellent examples of distributed circuit elements. Practical resistors, capacitors, and inductors used in most discrete component, hybrid, and integrated circuits are lumped circuit elements.

Defining Terms

Active element: A circuit element that generates power.

Associated reference polarity: A polarity convention that fixes the direction of current flow through a circuit element from the positive voltage side of the element to the negative voltage side of said element.

Capacitor: A two-terminal electrical element that satisfies a prescribed algebraic relationship in the charge–voltage (q – V) plane.

Controlled source: A current or voltage branch element whose value depends on a branch current or voltage determined elsewhere in the network.

Current: The time rate of change of net charge passing through an arbitrary cross section of an electrical element.

Distributed element: A circuit element whose feature size is comparable to, or significantly larger than, the wavelength of applied energy.

Electrical circuit: An array of interconnected elements wired so as to be capable of conducting current.

Inductor: A two-terminal electrical element that satisfies a prescribed algebraic relationship in the flux–current (ϕ – I) plane.

Lumped element: A circuit element whose feature size is significantly smaller than the wavelength of applied energy.

Passive element: A circuit element that dissipates power or *stores* energy.

Power: The time rate of change of energy applied to an electrical element.

Resistor: A two-terminal electrical element that satisfies a prescribed algebraic relationship in the voltage–current (V – I) plane.

Voltage: The energy applied to an element per unit of charge transported through the element.

Further Information

The *Circuits and Devices Magazine*, published by the Institute of Electrical and Electronic Engineers (IEEE), is a good entry level periodical that focuses on applications of the various concepts introduced in this chapter.

The IEEE also publishes two advanced relevant scholarly journals, namely, the *IEEE Transactions on Circuits and Systems, Part I* and the *IEEE Transactions on Circuits and Systems, Part II*.

2.2 Semiconductor Materials

Stuart K. Tewksbury

2.2.1 Introduction

A semiconductor material has a resistivity lying between that of a conductor and that of an insulator. In contrast to the granular materials used for resistors, however, a semiconductor establishes its conduction properties through a complex quantum mechanical behavior within a periodic array of semiconductor atoms, that is, within a crystalline structure. For appropriate atomic elements, the crystalline structure leads to a disallowed energy band between the energy level of electrons bound to the crystal's atoms and the energy level of electrons free to move within the crystalline structure (i.e., not bound to an atom). This energy gap fundamentally impacts the mechanisms through which electrons associated with the crystal's atoms can become free and serve as conduction electrons. The resistivity of a semiconductor is proportional to the free carrier density, and that density can be changed over a wide range by replacing a very small portion (about 1 in 10^6) of the base crystal's atoms with different atomic species (*doping atoms*). The majority carrier density is largely pinned to the net dopant impurity density. By selectively changing the crystalline atoms within small regions of the crystal, a vast number of small regions of the crystal can be given different conductivities. In addition, some dopants establish the electron carrier density (*free electron density*), whereas others establish the *hole* carrier density (holes are the dual of electrons within semiconductors). In this manner, different types of semiconductor (*n* type with much higher electron carrier density than the hole density and *p* type with much higher hole carrier density than the electron carrier density) can be located in small but contacting regions within the crystal.

By applying electric fields appropriately, small regions of the semiconductor can be placed in a state in which all of the carriers (electron and hole) have been expelled by the electric field and that electric field sustained by the exposed dopant ions. This allows electric switching between a conducting state (with a settable resistivity) and a nonconducting state (with conductance vanishing as the carriers vanish).

This combination of localized regions with precisely controlled resistivity (dominated by *electron conduction* or by *hole conduction*) combined with the ability to electronically control the flow of the carriers (electrons and holes) leads to the semiconductors being the foundation for contemporary electronics. This foundation is particularly strong because a wide variety of atomic elements (and mixtures of atomic

elements) can be used to tailor the semiconductor material to specific needs. The dominance of silicon semiconductor material in the electronics area (e.g., the very large-scale integrated (VLSI) digital electronics area) contrasts with the rich variety of semiconductor materials widely used in optoelectronics. In the latter case, the ability to adjust the **bandgap** to desired wavelengths of light has stimulated a vast number of optoelectronic components, based on a variety of technologies. Electronic components also provide a role for nonsilicon semiconductor technologies, particularly for very high bandwidth circuits that can take advantage of the higher speed capabilities of semiconductors using atomic elements similar to those used in optoelectronics. This rich interest in nonsilicon technologies will undoubtedly continue to grow, due to the rapidly advancing applications of optoelectronics, for the simple reason that silicon is not suitable for producing an efficient optical source.

2.2.2 Crystalline Structures

Basic Semiconductor Materials Groups

Most semiconductor materials are crystals created by atomic bonds through which the **valence band** of the atoms are filled with eight electrons through sharing of an electron from each of four nearest neighbor atoms. These materials include semiconductors composed of a single atomic species, with the basic atom having four electrons in its valence band (supplemented by covalent bonds to four neighboring atoms to complete the valence band). These elemental semiconductors, therefore, use atoms from group IV of the atomic chart. Other semiconductor materials are composed of two atoms, one from group N ($N < 4$) and the other from group M ($M > 4$) with $N + M = 8$, filling the valence bands with eight electrons. The major categories of semiconductor material are summarized in the following sections.

Elemental (IV–IV) Semiconductors

Elemental semiconductors consist of crystals composed of only a single atomic element from group IV of the periodic chart, that is, germanium (Ge), silicon (Si), carbon (C), and tin (Sn). Silicon is the most commonly used electronic semiconductor material and is also the most common element on Earth. Table 2.1 summarizes the naturally occurring abundance of some elements used for semiconductors, including nonelemental (compound) semiconductors.

Figure 2.9(a) illustrates the covalent bonding (sharing of outer shell, valence band electrons by two atoms) through which each group IV atom of the crystal is bonded to four neighboring group IV atoms, creating filled outer electron bands of eight electrons.

In addition to crystals composed of only a single group IV atomic species, one can also create semiconductor crystals consisting of two or more atoms, all from group IV. For example, silicon carbide (SiC) has been investigated for high-temperature applications. $\text{Si}_x\text{Ge}_{1-x}$ semiconductors are presently under study to achieve bandgap engineering within the silicon system. In this case, a fraction x ($0 < x < 1$) of the atoms in an otherwise silicon crystal is silicon whereas a fraction $1 - x$ has been replaced by germanium. This ability to replace a single atomic element with a combination of two atomic elements from the same column of the periodic chart appears in the other categories of semiconductor described subsequently (and is particularly important for optoelectronic devices).

TABLE 2.1 Abundance (Fraction of Elements Occurring on Earth) of Common Elements Used for Semiconductors

Element	Abundance
Si	0.28
Ga	1.5×10^{-5}
As	1.8×10^{-6}
Ge	5×10^{-6}
Cd	2×10^{-7}
In	1×10^{-7}

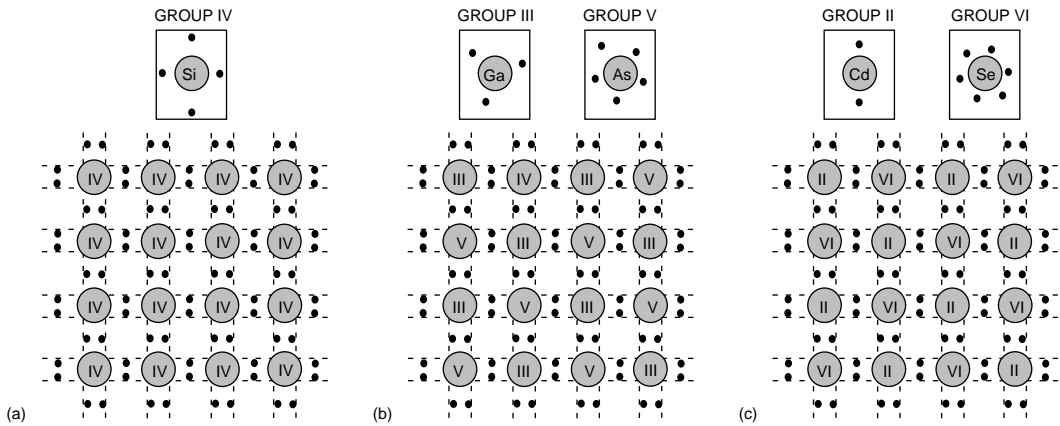

FIGURE 2.9 Bonding arrangements of atoms in semiconductor crystals: (a) elemental semiconductor such as silicon, (b) compound III–V semiconductor such as GaAs, (c) compound II–VI semiconductor such as CdS.

Compound III–V Semiconductors

The III–V semiconductors are prominent (and will gain in importance) for applications of optoelectronics. In addition, III–V semiconductors have a potential for higher speed operation than silicon semiconductors in electronics applications, with particular importance for areas such as wireless communications. The **compound semiconductors** have a crystal lattice constructed from atomic elements in different groups of the periodic chart. The III–V semiconductors are based on an atomic element A from group III and an atomic element B from group V. Each group III atom is bound to four group V atoms, and each group V atom is bound to four group III atoms, giving the general arrangement shown in Fig. 2.9(b). The bonds are produced by sharing of electrons such that each atom has a filled (eight electron) valence band. The bonding is largely covalent, though the shift of valence charge from the group V atoms to the group III atoms induces a component of ionic bonding to the crystal (in contrast to the elemental semiconductors that have purely covalent bonds). Representative III–V compound semiconductors are GaP, GaAs, GaSb, InP, InAs, and InSb.

GaAs is probably the most familiar example of III–V compound semiconductors, used for both high-speed electronics and for optoelectronic devices. Optoelectronics has taken advantage of ternary and quaternary III–V semiconductors to establish optical wavelengths and to achieve a variety of novel device structures. The **ternary semiconductors** have the general form $(A_x, A'_{1-x})B$ (with two group III atoms used to fill the group III atom positions in the lattice) or $A(B_x, B'_{1-x})$ (using two group V atoms in the group V atomic positions in the lattice). The **quaternary semiconductors** use two group III atomic elements and two group V atomic elements, yielding the general form $(A_x, A'_{1-x})(B_y, B'_{1-y})$. In such constructions, $0 \leq x \leq 1$. Such ternary and quaternary versions are important since the mixing factors (x and y) allow the bandgap to be adjusted to lie between the bandgaps of the simple compound crystals with only one type of group III and one type of group V atomic element. The adjustment of wavelength allows the material to be tailored for particular optical wavelengths, since the wavelength λ of light is related to energy (in this case the gap energy E_g) by $\lambda = hc/E_g$, where h is Planck's constant and c is the speed of light. Table 2.2 provides examples of semiconductor laser materials and a representative optical wavelength for each, providing a hint of the vast range of combinations that are available for optoelectronic applications. Table 2.3, on the other hand, illustrates the change in wavelength (here corresponding to color in the visible spectrum) by adjusting the mixture of a ternary semiconductor.

In contrast to single element elemental semiconductors (for which the positioning of each atom on a lattice site is not relevant), III–V semiconductors require very good control of stoichiometry (i.e., the ratio of the two atomic species) during crystal growth. For example, each Ga atom must reside on a Ga (and

TABLE 2.2 Semiconductor Optical Sources and Representative Wavelengths

Material Layers Used	Wavelength, nm
ZnS	454
AlGaInP/GaAs	580
AlGaAs/GaAs	680

AlGaSb/InAsSb/GaSb	3900
PbSnTe/PbTe	6000

not an As) site and vice versa. For these and other reasons, large III–V crystals of high quality are generally more difficult to grow than a large crystal of an elemental semiconductor such as Si.

Compound II–VI Semiconductors

These semiconductors are based on one atomic element from group II and one atomic element from group VI, each type being bonded to four nearest neighbors of the other type, as shown in Fig. 2.9(c). The increased amount of charge from group VI to group II atoms tends to cause the bonding to be more ionic than in the case of III–V semiconductors. II–VI semiconductors can be created in ternary and quaternary forms, much like the III–V semiconductors. Although less common than the III–V semiconductors, the II–VI semiconductors have served the needs of several important applications. Representative II–VI semiconductors are ZnS, ZnSe, and ZnTe (which form in the zinc blende lattice structure discussed subsequently); CdS and CdSe (which can form in either the zinc blende or the wurtzite lattice structure); and CdTe (which forms in the wurtzite lattice structure).

Three-Dimensional Crystal Lattice

The two-dimensional views illustrated in the preceding section provide a simple view of the sharing of valence band electrons and the bonds between atoms. The full three-dimensional lattice structure, however, is considerably more complex than this simple two-dimensional illustration. Fortunately, most semiconductor crystals share a common basic structure, developed as follows.

The crystal structure begins with a cubic arrangement of eight atoms as shown in Fig. 2.10(a). This cubic lattice is extended to a *face-centered cubic* (fcc) lattice, shown in Fig. 2.10(b), by adding an atom to the center of each face of the cube (leading to a lattice with 14 atoms). The *lattice constant* is the side dimension of this cube.

The full lattice structure combines two of these fcc lattices, one lattice interpenetrating the other (i.e., the corner of one cube is positioned within the interior of the other cube, with the faces remaining parallel), as illustrated in Fig. 2.10(c). For the III–V and II–VI semiconductors with this fcc lattice foundation, one fcc lattice is constructed from one type of element (e.g., type III) and the second fcc lattice is constructed from the other type of element (e.g., group V). In the case of ternary and quaternary semiconductors, elements from the same atomic group are placed on the same fcc lattice. All bonds between atoms occur between atoms in different fcc lattices. For example, all Ga atoms in the GaAs crystal are located on

TABLE 2.3 Variation of x to Adjust Wavelength in $\text{GaAs}_x\text{P}_{1-x}$ Semiconductors

FIGURE 2.10 Three-dimensional crystal lattice structure: (a) basic cubic lattice, (b) face-centered cubic (fcc) lattice, (c) two interpenetrating fcc lattices. In this figure, the dashed lines between atoms are not atomic bonds but, instead, are used merely to show the basic outline of the cube.

one of the fcc lattices and are bonded to As atoms, all of which appear on the second fcc lattice. The interatomic distances between neighboring atoms is, therefore, less than the lattice constant. For example, the interatomic spacing of Si atoms is 2.35 Å but the lattice constant of Si is 5.43 Å.

If the two fcc lattices contain elements from different groups of the periodic chart, the overall crystal structure is called the *zinc blende* lattice. In the case of an elemental semiconductor such as silicon, silicon atoms appear in both fcc lattices, and the overall crystal structure is called the *diamond* lattice (carbon crystallizes into a diamond lattice creating true diamonds, and carbon is a group IV element). As in the discussion regarding III–V semiconductors, the bonds between silicon atoms in the silicon crystal extend between fcc sublattices.

Although the common semiconductor materials share this basic diamond/zinc blende lattice structure, some semiconductor crystals are based on a hexagonal close-packed (hcp) lattice. Examples are CdS and CdSe. In this example, all of the Cd atoms are located on one hcp lattice whereas the other atom (S or Se) is located on a second hcp lattice. In the spirit of the diamond and zinc blende lattices, the complete lattice is constructed by interpenetrating these two hcp lattices. The overall crystal structure is called a *wurtzite* lattice. Type IV–VI semiconductors (PbS, PbSe, PbTe, and SnTe) exhibit a narrow bandgap and have been used for infrared detectors. The lattice structure of these example IV–VI semiconductors is the simple cubic lattice (also called an NaCl lattice).

Crystal Directions and Planes

Crystallographic directions and planes are important in both the characteristics and the applications of semiconductor materials since different crystallographic planes can exhibit significantly different physical properties. For example, the surface density of atoms (atoms per square centimeter) can differ substantially on different crystal planes. A standardized notation (the so-called *Miller indices*) is used to define the crystallographic planes and directions normal to those planes.

The general crystal lattice defines a set of unit vectors (\mathbf{a} , \mathbf{b} , and \mathbf{c}) such that an entire crystal can be developed by copying the unit cell of the crystal and duplicating it at integer offsets along the unit vectors, that is, replicating the basis cell at positions $n_a\mathbf{a} + n_b\mathbf{b} + n_c\mathbf{c}$, where n_a , n_b , and n_c are integers. The unit vectors need not be orthogonal in general. For the cubic foundation of the diamond and zinc blende structures, however, the unit vectors are in the orthogonal x , y , and z directions.

Figure 2.11 shows a cubic crystal, with basis vectors in the x , y , and z directions. Superimposed on this lattice are three planes (Fig. 2.11(a), Fig. 2.11(b), and Fig. 2.11(c)). The planes are defined relative to the crystal axes by a set of three integers (h, k, l) where h corresponds to the plane's intercept with the x axis, k corresponds to the plane's intercept with the y axis, and l corresponds to the plane's intercept with the z axis. Since parallel planes are equivalent planes, the intercept integers are reduced to the set of the three smallest integers having the same ratios as the described intercepts. The (100), (010), and (001) planes correspond to the faces of the cube. The (111) plane is tilted with respect to the cube faces, intercepting the x , y , and z axes at 1, 1, and 1, respectively. In the case of a negative axis intercept, the corresponding

FIGURE 2.11 Examples of crystallographic planes within a cubic lattice organized semiconductor crystal: (a) (010) plane, (b) (110) plane, (c) (111) plane.

Miller index is given as an integer and a bar over the integer, for example, $(\bar{1}00)$, that is, similar to the (100) plane but intersecting the x axis at -1 .

Additional notation is used to represent sets of planes with equivalent symmetry and to represent directions. For example, $\{100\}$ represents the set of equivalent planes (100), $(\bar{1}00)$, (010), $(0\bar{1}0)$, (001), and $(00\bar{1})$. The direction normal to the (hkl) plane is designated $[hkl]$. The different planes exhibit different behavior during device fabrication and impact electrical device performance differently. One difference is due to the different reconstructions of the crystal lattice near a surface to minimize energy. Another is the different surface density of atoms on different crystallographic planes. For example, in Si the (100), (110), and (111) planes have surface atom densities (atoms per square centimeter) of 6.78×10^{14} , 9.59×10^{14} , and 7.83×10^{14} , respectively.

2.2.3 Energy Bands and Related Semiconductor Parameters

A semiconductor crystal establishes a periodic arrangement of atoms, leading to a periodic spatial variation of the potential energy throughout the crystal. Since that potential energy varies significantly over interatomic distances, quantum mechanics must be used as the basis for allowed energy levels and other properties related to the semiconductor. Different semiconductor crystals (with their different atomic elements and different interatomic spacings) lead to different characteristics. The periodicity of the potential variations, however, leads to several powerful general results applicable to all semiconductor crystals. Given these general characteristics, the different semiconductor materials exhibit properties related to the variables associated with these general results. A coherent discussion of these quantum mechanical results is beyond the scope of this chapter and, therefore, we take those general results as given.

In the case of materials that are semiconductors, a central result is the energy-momentum functions defining the state of the electronic charge carriers. In addition to the familiar electrons, semiconductors also provide holes (i.e., positively charged particles) that behave similarly to the electrons. Two energy levels are important: one is the energy level (**conduction band**) corresponding to electrons that are not bound to crystal atoms and that can move through the crystal, and the other energy level (valence band) corresponds to holes that can move through the crystal. Between these two energy levels, there is a region of forbidden energies (i.e., energies for which a free carrier cannot exist). The separation between the conduction and valence band minima is called the *energy gap* or bandgap. The energy bands and the energy gap are fundamentally important features of the semiconductor material.

Conduction and Valence Band

In quantum mechanics, a particle is represented by a collection of plane waves ($e^{j(\omega t - \mathbf{k} \cdot \mathbf{x})}$) where the frequency ω is related to the energy E according to $E = \hbar\omega$ and the momentum p is related to the wave vector by $\mathbf{p} = \hbar\mathbf{k}$. In the case of a classical particle with mass m moving in free space, the energy

FIGURE 2.12 General structure of conduction and valence bands.

and momentum are related by $E = p^2/(2m)$ that, using the relationship between momentum and wave vector, can be expressed as $E = (\hbar k)^2/(2m)$. In the case of the semiconductor, we are interested in the energy/momentum relationship for a free electron (or hole) moving in the semiconductor, rather than moving in free space. In general, this $E-k$ relationship will be quite complex, and there will be a multiplicity of $E-k$ states resulting from the quantum mechanical effects. One consequence of the periodicity of the crystal's atom sites is a periodicity in the wave vector k , requiring that we consider only values of k over a limited range (with the $E-k$ relationship periodic in k).

Figure 2.12 illustrates a simple example (not a real case) of a conduction band and a valence band in the energy-momentum plane (i.e., the E vs. k plane). The E vs. k relationship of the conduction band will exhibit a minimum energy value and, under equilibrium conditions, the electrons will favor being in that minimum energy state. Electron energy levels above this minimum (E_c) exist, with a corresponding value of momentum. The E vs. k relationship for the valence band corresponds to the energy-momentum relationship for holes. In this case, the energy values increase in the direction toward the bottom of the page and the minimum valence band energy level E_v is the maximum value in Fig. 2.12. When an electron bound to an atom is provided with sufficient energy to become a free electron, a hole is left behind. Therefore, the energy gap $E_g = E_c - E_v$ represents the minimum energy necessary to generate an electron-hole pair (higher energies will initially produce electrons with energy greater than E_c , but such electrons will generally lose energy and fall into the potential minimum).

The details of the energy bands and the bandgap depend on the detailed quantum mechanical solutions for the semiconductor crystal structure. Changes in that structure (even for a given semiconductor crystal such as Si) can therefore lead to changes in the energy band results. Since the thermal coefficient of expansion of semiconductors is nonzero, the bandgap depends on temperature due to changes in atomic spacing with changing temperature. Changes in pressure also lead to changes in atomic spacing. Though these changes are small, they are observable in the value of the energy gap. Table 2.4 gives the room temperature value of the energy gap E_g for several common semiconductors, along with the rate of change of E_g with temperature (T) and pressure (P) at room temperature.

TABLE 2.4 Variation of Energy Gap with Temperature and Pressure

The temperature dependence, though small, can have a significant impact on carrier densities. A heuristic model of the temperature dependence of E_g is $E_g(T) = E_g(0\text{ K}) - \alpha T^2 / (T + \beta)$. Values for the parameters in this equation are provided in Table 2.5. Between 0 and 1000 K, the values predicted by this equation for the energy gap of GaAs are accurate to about 2×10^{-3} eV.

Direct Gap and Indirect Gap Semiconductors

Figure 2.13 illustrates the energy bands for Ge, Si, and GaAs crystals. In Fig. 2.13(b), for silicon, the valence band has a minimum at a value of k different than that for the conduction band minimum. This is an **indirect gap**, with generation of an electron-hole pair requiring an energy E_g and a change in momentum (i.e., k). For direct recombination of an electron-hole pair, a change in momentum is also required. This requirement for a momentum change (in combination with energy and momentum conservation laws) leads to a requirement that a phonon participate with the carrier pair during a direct recombination process generating a photon. This is a highly unlikely event, rendering silicon ineffective as an optoelectronic source of light. The direct generation process is more readily allowed (with the simultaneous generation of an electron, a hole, and a phonon), allowing silicon and other **direct gap semiconductors** to serve as optical detectors.

In Fig. 2.13(c), for GaAs, the conduction band minimum and the valence band minimum occur at the same value of momentum, corresponding to a direct gap. Since no momentum change is necessary during direct recombination, such recombination proceeds readily, producing a photon with the energy of the initial electron and hole (i.e., a photon energy equal to the bandgap energy). For this reason, direct gap semiconductors are efficient sources of light (and use of different direct gap semiconductors with different E_g provides a means of tailoring the wavelength of the source). The wavelength λ corresponding to the gap energy is $\lambda = hc/E_g$.

TABLE 2.5 Temperature Dependence Parameters for Common Semiconductors

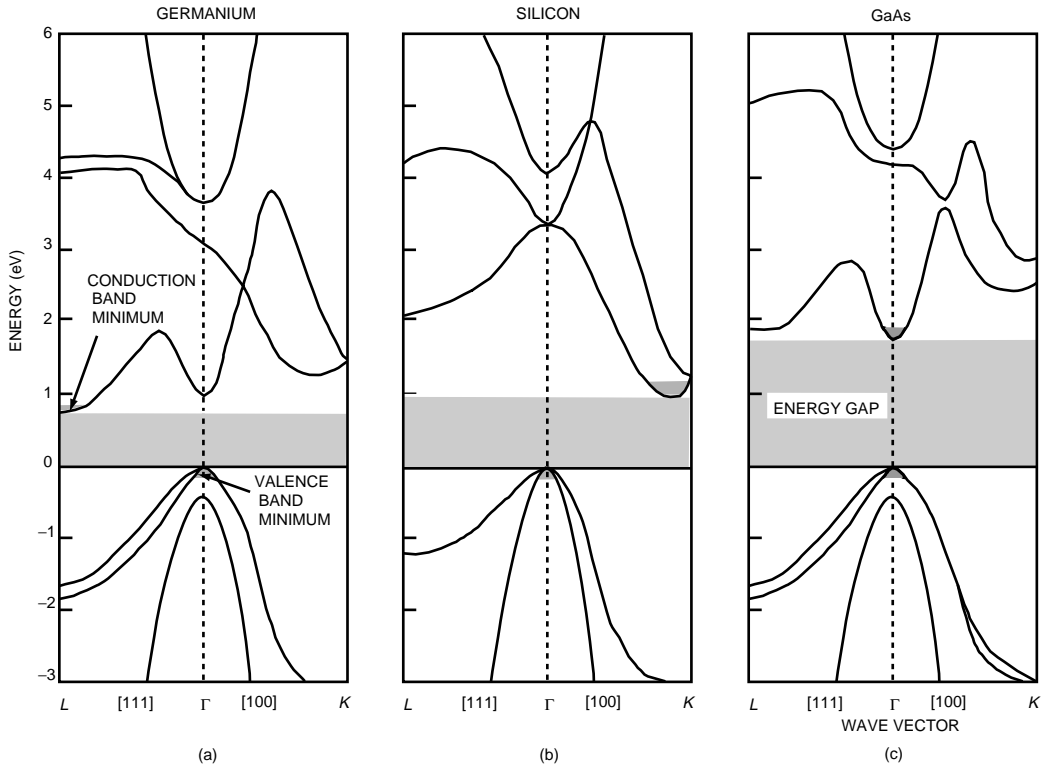

FIGURE 2.13 Conduction and valence bands for (a) Ge, (b) Si, (c) GaAs. (Source: Adapted from Sze, S.M. 1981. *Physics of Semiconductor Devices*, 2nd ed. Wiley Interscience, New York.)

Figure 2.13(c) also illustrates a second conduction band minimum with an indirect gap, but at a higher energy than the minimum associated with the direct gap. The higher conduction band minimum can be populated by electrons (which are in an equilibrium state of higher energy) but the population will decrease as the electrons gain energy sufficient to overcome that upper barrier.

Effective Masses of Carriers

For an electron with energy close to the minimum of the conduction band, the energy vs. momentum relationship along each momentum axis is approximately given by $E(k) = E_0 + a_2(k - k^*)^2 + a_4(k - k^*)^4 + \dots$. Here, $E_0 = E_c$ is the *ground state energy* corresponding to a free electron at rest and k^* is the wave vector at which the conduction band minimum occurs. Only even powers of $k - k^*$ appear in the expansion of $E(k)$ around k^* due to the symmetry of the $E-k$ relationship around $k = k^*$. This approximation holds for sufficiently small increases in E above E_c . For sufficiently small movements away from the minimum (i.e., sufficiently small $k - k^*$), the terms in $k - k^*$ higher than quadratic can be ignored and $E(k) \approx E_0 + a_2k^2$, where we have taken $k^* = 0$. If, instead of a free electron moving in the semiconductor crystal, we had a free electron moving in free space with potential energy E_0 , the energy-momentum relationship would be $E(k) = E_0 + (\hbar k)^2/(2m_0)$, where m_0 is the mass of an electron. By comparison of these results, it is clear that we can relate the curvature coefficient a_2 associated with the parabolic minimum of the conduction band to an **effective mass** m_e^* , that is, $a_2 = (\hbar^2)/(2m_e^*)$ or

$$\frac{1}{m_e^*} = \frac{2}{\hbar^2} \cdot \frac{\partial^2 E_c(k)}{\partial k^2}$$

Similarly for holes, an effective mass m_h^* of the holes can be defined by the curvature of the valence band minimum, that is,

$$\frac{1}{m_h^*} = \frac{2}{\hbar^2} \cdot \frac{\partial^2 E_v(k)}{\partial k^2}$$

Since the energy bands depend on temperature and pressure, the effective masses can also be expected to have such dependencies, though the room temperature and normal pressure value is normally used in device calculations.

This discussion assumes the simplified case of a scalar variable k . In fact, the wave vector \mathbf{k} has three components (k_1, k_2, k_3) , with directions defined by the unit vectors of the underlying crystal. Therefore, there are separate masses for each of these vector components of \mathbf{k} , that is, masses m_1, m_2, m_3 . A scalar mass m^* can be defined using these directional masses, the relationship depending on the details of the directional masses. For cubic crystals (as in the diamond and zinc blende structures), the directions are the usual orthonormal directions and $m^* = (m_1 \cdot m_2 \cdot m_3)^{1/3}$. The three directional masses effectively reduce to two components if two values are equal (e.g., $m_1 = m_2$), as in the case of *longitudinal* and *transverse* effective masses (m_l and m_t , respectively) seen in silicon and several other semiconductors. In this case, $m^* = [(m_t)^2 \cdot m_l]^{1/3}$. If all three values of m_1, m_2, m_3 are equal, then a single value m^* can be used.

An additional complication is seen in the valence band structures in Fig. 2.13. Here, two different $E-k$ valence bands have the same minima. Since their curvatures are different, the two bands correspond to different masses, one corresponding to *heavy holes* with mass m_h and the other to *light holes* with mass m_l . The effective scalar mass in this case is $m^* = (m_h^{3/2} + m_l^{3/2})^{2/3}$. Such light and heavy holes occur in several semiconductors, including Si.

Values of effective mass are given in Tables 2.8 and 2.13.

Intrinsic Carrier Densities

The density of free electrons in the conduction band depends on two functions. One is the density of states $D(E)$ in which electrons can exist and the other is the energy distribution function $F(E, T)$ of free electrons.

The energy distribution function (under thermal equilibrium conditions) is given by the Fermi-Dirac distribution function

$$F(E) = \left[1 + \exp\left(\frac{E - E_f}{k_B T}\right) \right]^{-1}$$

which, in most practical cases, can be approximated by the classical Maxwell-Boltzmann distribution. These distribution functions are general functions, not dependent on the specific semiconductor material.

The density of states $D(E)$, on the other hand, depends on the semiconductor material. A common approximation is

$$D_n(E) = M_c \frac{\sqrt{2}}{\pi^2} \frac{(E - E_c)^{1/2}}{\hbar^3} \frac{(m_e^*)^3}{2}$$

for electrons and

$$D_p(E) = M_v \frac{\sqrt{2}}{\pi^2} \frac{(E_v - E)^{1/2}}{\hbar^3} \frac{(m_h^*)^3}{2}$$

for holes. Here, M_c and M_v are the number of equivalent minima in the conduction band and valence band, respectively. Note that, necessarily, $E \geq E_c$ for free electrons and $E \leq E_v$ for free holes due to the forbidden region between E_c and E_v .

The density n of electrons in the conduction band can be calculated as

$$n = \int_{E=E_c}^{\infty} F(E, T) D(E) dE$$

For Fermi levels significantly (more than a few $k_B T$) below E_c and above E_v , this integration leads to the results

$$n = N_c e^{-(E_c - E_f)/k_B T}$$

and

$$p = N_v e^{-(E_f - E_v)/k_B T}$$

where n and p are the densities of free electrons in the conduction band and of holes in the valence band, respectively. N_c and N_v are *effective densities of states* that vary with temperature (slower than the exponential in the preceding equations), effective mass, and other conditions. Table 2.6 gives values of N_c and N_v for several semiconductors. Approximate expressions for these densities of state are $N_c = 2(2\pi m_e^* k_B T/\hbar^2)^{3/2} M_c$ and $N_v = 2(2\pi m_h^* k_B T/\hbar^2)^{3/2} M_v$. These effective densities of states are fundamental parameters used in evaluating the electrical characteristics of semiconductors. The preceding equations for n and p apply both to **intrinsic semiconductors** (i.e., semiconductors with no impurity dopants) as well as to semiconductors that have been doped with donor and/or acceptor impurities. Changes in the interrelated values of n and p through introduction of dopant impurities can be represented by changes in a single variable, the Fermi level E_f .

The product of n and p is independent of Fermi level and is given by

$$n \cdot p = N_c \cdot N_v e^{-E_g/k_B T}$$

where the energy gap $E_g = E_c - E_v$. Again, this holds for both intrinsic semiconductors and for doped semiconductors. In the case of an intrinsic semiconductor, charge neutrality requires that $n = p \equiv n_i$, where n_i is the *intrinsic carrier concentration* and

$$n_i^2 = N_c \cdot N_v e^{-E_g/k_B T}$$

Since, under thermal equilibrium conditions $np \equiv n_i^2$ (even under impurity doping conditions), knowledge of the density of one of the carrier types (e.g., of p) allows direct determination of the density of the other (e.g., $n = n_i^2/p$). Values of n_i vary considerably among semiconductor materials: $2 \times 10^{-3}/\text{cm}^3$ for CdS, $3.3 \times 10^6/\text{cm}^3$ for GaAs, $0.9 \times 10^{10}/\text{cm}^3$ for Si, $1.9 \times 10^{13}/\text{cm}^3$ for Ge, and 9.1×10^{14} for PbS.

Since there is appreciable temperature dependence in the effective density of states, the equations do not accurately represent the temperature variations in n_i over wide temperature ranges. Using the approximate expressions for N_c and N_v already given,

$$n_i = 2 \left(2\pi k_B T / \hbar^2 \right)^{3/2} \left(m_e^* m_h^* \right)^{3/4} \sqrt{M_c M_v} e^{-E_g / k_B T}$$

exhibiting a $T^{3/2}$ temperature dependence superimposed on the exponential dependence on $1/T$. For example, at 300 K

$$n_i(T) = 1.76 \times 10^{16} T^{3/2} e^{-4550/T} \text{ cm}^{-3} \quad \text{for Ge}$$

and

$$n_i(T) = 3.88 \times 10^{16} T^{3/2} e^{-7000/T} \text{ cm}^{-3} \quad \text{for Si}$$

Substitutional Dopants

An intrinsic semiconductor material contains only the elemental atoms of the basic material (e.g., silicon atoms for Si, gallium and arsenic atoms for GaAs, etc.). The resistivity is quite high for such intrinsic semiconductors and doping is used to establish a controlled lower resistivity material and to establish pn junctions (interface between p -type and n -type regions of the semiconductor). Doping concentrations are generally in the range 10^{14} – $10^{17}/\text{cm}^3$, small relative to the density of atoms in the crystal (e.g., to the density 5×10^{22} atoms/ cm^3 of silicon atoms in Si crystals). Table 2.7 lists a variety of dopants and their energy levels for Si and GaAs.

Figure 2.14(a) illustrates acceptor dopants and donor dopants in silicon. In the case of acceptor dopants, group III elements of the periodic chart are used to substitute for the group IV silicon atoms in the crystal. This acceptor atom has one fewer electron in its outer shell than the silicon atom and readily captures a free electron to provide the missing electron needed to complete the outer shells (eight electrons) provided by the covalent bonds. The acceptor atom, with a captured electron, becomes a negative ion. The electron captured from the outer shell of a neighboring silicon atom leaves behind a hole at that neighboring silicon atom (i.e., generates a free hole when ionized). By using acceptor doping densities N_A substantially greater than n_i , a net hole density $p \gg n_i$ is created. With $np = n_i^2$ a constant, the electron density n decreases as p increases above n_i . The resulting semiconductor material becomes p type. In the case of donor dopants, group V elements are used to substitute for a silicon atom in the crystal. The donor atom has one extra electron in its outer shell, compared to a silicon atom, and that extra electron can leave the donor site and become a free electron. In this case, the donor becomes a positive ion, generating a free electron. By using donor doping densities N_D substantially greater than n_i , a net electron density $n \gg n_i$ is created, and p decreases substantially below n_i to maintain the np product $np = n_i^2$. An n type semiconductor is produced.

TABLE 2.7 Acceptor and Donor Impurities Used in Si and GaAs

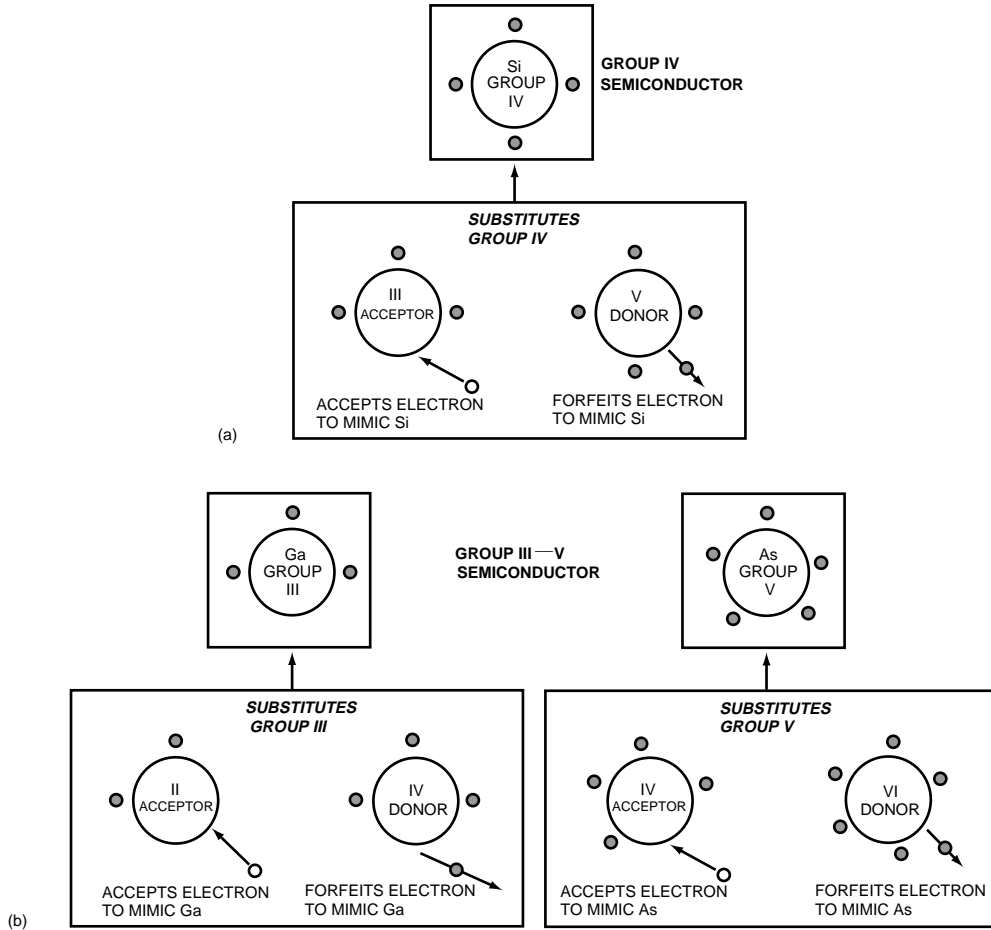

FIGURE 2.14 Substitution of dopant atoms for crystal atoms: (a) IV–IV semiconductors (e.g., silicon), (b) III–V semiconductors (e.g., GaAs).

Figure 2.14(b) illustrates the alternative doping options for a III–V semiconductor (GaAs used as an example). Replacement of a group III element with a group II element renders that group II element an acceptor (one fewer electron). Replacement of a group V element with a group VI element renders that group VI element a donor (one extra electron). Group IV elements such as silicon can also be used for doping. In this case, the group IV element is a donor if it replaces a group III element in the crystal and is an acceptor if it replaces a Group V element in the crystal. Impurities which can serve as either an acceptor or as a donor within a crystal are called **amphoteric impurities**.

Acceptor and donor impurities are most effectively used when the energy required to generate a carrier is small. In the case of small ionization energies (in the crystal lattice), the energy levels associated with the impurities lie within the bandgap close to their respective bands (i.e., donor ionization energies close to the conduction band and acceptor ionization energies close to the valence band). If the difference between the ionization level and the corresponding valence/conduction band is less than about $3k_B T$ (≈ 0.075 eV at 300 K), then the impurities (called **shallow energy level dopants**) are essentially fully ionized at room temperature. The dopants listed in Table 2.7 are such shallow energy dopants. A semiconductor doped with $N_A \gg n_i$ acceptors then has a hole density $p \approx N_A$ and a much smaller electron density $n \approx n_i^2/N_A$. Similarly, a semiconductor doped with $N_D \gg n_i$ donors has an electron density $n \approx N_D$ and a much smaller hole density $p = n_i^2/N_D$. From the results given earlier for carrier concentrations as a function of Fermi level, the Fermi level is readily calculated (given the majority carrier concentration).

Most semiconductors can be selectively made (by doping) either n type or p type, in which case they are called **ambipolar semiconductors**. Some semiconductors can be selectively made only n type or only p type. For example, ZnTe is always p type whereas CdS is always n type. Such semiconductors are called **unipolar semiconductors**.

Dopants with energy levels closer to the center of the energy gap (i.e., the so-called **deep energy level dopants**) serve as electron-hole recombination sites, impacting the minority carrier lifetime and the dominant recombination mechanism in indirect bandgap semiconductors.

2.2.4 Carrier Transport

Currents in semiconductors arise both due to movement of free carriers in the presence of an electric field and due to diffusion of carriers from high, carrier density regions into lower, carrier density regions. Currents due to electric fields are considered first.

In earlier discussions, it was noted that the motion of an electron in a perfect crystal can be represented by a free electron with an effective mass m_e^* somewhat different than the real mass m_e of an electron. In this model, once the effective mass has been determined, the atoms of the perfect crystal can be discarded and the electron viewed as moving within free space. If the crystal is not perfect, however, those deviations from perfection remain after the perfect crystal lattice has been discarded and act as scattering sites within the free space seen by the electron in the crystal.

Substitution of a dopant for an element of the perfect crystal leads to a distortion of the perfect lattice from which electrons can scatter. If that substitutional dopant is ionized, the electric field of that ion adds to the scattering. Impurities located at interstitial sites (i.e., between atoms in the normal lattice sites) also disrupt the perfect crystal and lead to scattering sites. Crystal defects (e.g., a missing atom) disrupt the perfect crystal and appears as a scattering site in the free space seen by the electron. In useful semiconductor crystals, the density of such scattering sites is small relative to the density of silicon atoms. As a result, removal of the silicon atoms through use of the effective mass leaves a somewhat sparsely populated space of scattering sites.

The perfect crystal corresponds to all atomic elements at the lattice positions and not moving, a condition which can occur only at 0 K. At temperatures above absolute zero, the atoms have thermal energy that causes them to move away from their ideal site. As the atom moves away from the nominal, equilibrium site, forces act to return it to that site, establishing the conditions for a classical oscillator problem (with the atom oscillating about its equilibrium location). Such oscillations of an atom can transfer to a neighboring atom (by energy exchange), leading to the oscillation propagating through space. This wavelike disturbance is called a *phonon* and serves as a scattering site (*phonon scattering*, also called *lattice scattering*), which can appear anywhere in the crystal.

Low Field Mobilities

The dominant scattering mechanisms in silicon are ionized impurity scattering and phonon scattering, though other mechanisms such as mentioned previously do contribute. Within this free space contaminated by scattering centers, the free electron moves at a high velocity (the thermal velocity v_{therm}) set by the thermal energy ($k_B T$) of the electron, with $2k_B T/3 = 0.5 m_e^* v_{\text{therm}}^2$ and, therefore, $v_{\text{therm}} = \sqrt{4k_B T/3m_e^*}$. At room temperature in Si, the thermal velocity is about 1.5×10^7 cm/s, substantially higher than most velocities that will be induced by applied electric fields or by diffusion. Thermal velocities depend reciprocally on effective mass, with semiconductors having lower effective masses displaying higher thermal velocities than semiconductors with higher effective masses. At these high thermal velocities, the electron will have an average mean time τ_n between collisions with the scattering centers during which it is moving as a free electron in free space. It is during this period between collisions that an external field acts on the electron, creating a slight displacement of the orbit of the free electron. Upon colliding, the process starts again, producing again a slight displacement in the orbit of the free electron. This displacement divided by the mean free time τ_n between collisions represents the velocity component induced by the external electric field. In the absence of such an electric field, the electron would be scattered in random directions and

TABLE 2.8 Conductivity Effective Masses for Common Semiconductors

	Ge	Si	GaAs
m_e^*	$0.12m_0$	$0.26m_0$	$0.063m_0$
m_h^*	$0.23m_0$	$0.38m_0$	0.53

display no net displacement in time. With the applied electric field, the electron has a net drift in the direction set by the field. For this reason, the induced velocity component is called the *drift velocity* and the thermal velocities can be ignored.

By using the standard force equation $F = eE = m_e^* dv/dt$ with velocity $v = 0$ at time $t = 0$ and with an acceleration time τ_n , the final velocity v_f after time τ_n is then simply $v_f = e\tau_n E/m_e^*$ and, letting $v_{\text{drift}} = v_f/2$, $v_{\text{drift}} = e\tau_n E/(2m_e^*)$. Table 2.8 gives values of the electron and hole effective masses for semiconductors.

The drift velocity v_{drift} in an external field E is seen to vary as $v_{\text{drift}} = \mu_n E$, where the electron's **low field mobility** μ_n is given approximately by $\mu_n \approx e\tau_n/(2m_e^*)$. Similarly, holes are characterized by a low field mobility $\mu_p \approx e\tau_p/(2m_h^*)$, where τ_p is the mean time between collision for holes.

This simplified mobility model yields a mobility that is inversely proportional to the effective mass. The effective electron masses in GaAs and Si are $0.09m_e$ and $0.26m_e$, respectively, suggesting a higher electron mobility in GaAs than in Si (in fact, the electron mobility in GaAs is about three times greater than that in Si). The electron and hole effective masses in Si are 0.26 and $0.38m_e$, respectively, suggesting a higher electron mobility than hole mobility in Si (in Si, $\mu_n \approx 1400 \text{ cm}^2/\text{V} \cdot \text{s}$ and $\mu_p \approx 500 \text{ cm}^2/\text{V} \cdot \text{s}$). The simplified model for μ_n and μ_p is based on the highly simplified model of the scattering conditions encountered by carriers moving with thermal energy. Far more complex analysis is necessary to obtain theoretical values of these mobilities. For this reason, the approximate model should be regarded as a guide to mobility variations among semiconductors and not as a predictive model.

The linear dependence of the mobility μ_n (μ_p) on τ_n (τ_p), suggested by the simplified development given previously, also provides a qualitative understanding of the mobility dependence on impurity doping and on temperature. As noted earlier, phonon scattering and ionized impurity scattering are the dominant mechanisms controlling the scattering of carriers in most semiconductors. At room temperature and for normally used impurity doping concentrations, phonon scattering typically dominates ionized impurity scattering. As the temperature decreases, the thermal energy of the crystal atoms decreases, leading to a decrease in the phonon scattering and an increase in the mean free time between phonon scattering events. The result is a mobility μ_{phonon} that increases with decreasing temperature according to $\mu_{\text{phonon}} \approx B_1 T^{-\alpha}$ where α is typically between 1.6 and 2.8 at 300 K. Table 2.9 gives the room temperature mobility and temperature dependence of mobility at 300 K for Ge, Si, and GaAs. In the case of ionized impurity scattering, the lower temperature leads to a lower thermal velocity, with the electrons passing ionized impurity sites more slowly and suffering a stronger scattering effect. As a result, the mobility μ_{ion} decreases with decreasing temperature. Starting at a sufficiently high temperature that phonon scattering dominates, the overall mobility will initially increase with decreasing temperature until the ionized

TABLE 2.9 Mobility and Temperature Dependence at 300 K

	μ_n	μ_p	μ_n	μ_p	μ_n	μ_p
Mobility, $\text{cm}^{-2}/\text{V} \cdot \text{s}$	3900	1900	1400	470	8000	340
Temperature	$T^{-1.66}$	$T^{-2.33}$	$T^{-2.5}$	$T^{-2.7}$	—	$T^{-2.3}$

Source: Adapted from Wang, S. 1989. *Fundamentals of Semiconductor Theory and Device Physics*. Prentice-Hall, Englewood Cliffs, NJ.

impurity scattering becomes dominant, leading to subsequent decreases in the overall mobility with decreasing temperature.

In Si, Ge, and GaAs, for example, the mobility increases by a factor of roughly 7 at 77 K relative to the value at room temperature, illustrating the dominant role of phonon scattering in these semiconductors under normal doping conditions.

Since scattering probabilities for different mechanisms add to yield the net scattering probability that, in turn, defines the overall mean free time between collisions, mobilities (e.g., phonon scattering mobility and lattice scattering mobility) due to different mechanisms are combined as $\mu^{-1} = \mu_{\text{phonon}}^{-1} + \mu_{\text{ion}}^{-1}$, that is, the smallest mobility dominates.

The mobility due to lattice scattering depends on the density of ionized impurity sites, with higher impurity densities leading to shorter distances between scattering sites and smaller mean free times between collisions. For this reason, the mobility shows a strong dependence on impurity doping levels at temperatures for which such scattering is dominant. As the ionized impurity density increases, the temperature at which the overall mobility becomes dominated by impurity scattering increases. In Si at room temperature, for example, $\mu_e \approx 1400$ and $\mu_p \approx 500$ for dopant concentrations below $\approx 10^{15} \text{ cm}^{-3}$, decreasing to approximately 300 and 100, respectively, for concentrations $> 10^{18} \text{ cm}^{-3}$.

These qualitative statements can be made substantially more quantitative by providing detailed plots of mobility vs. temperature and vs. impurity density for the various semiconductor materials. Examples of such plots are provided in several references (e.g., Tyagi, 1991; Nicollian and Brews, 1982; Shur, 1987; Sze, 1981; Böer, 1990, 1992; Haug, 1975; Wolfe, Holonyak, and Stillman, 1989; Smith, 1978; Howes and Morgan, 1985).

Diffusion results from a gradient in the carrier density. For example, the flux of electrons due to diffusion is given by $F_e = -D_n dn/dx$, with $F_p = -D_p dp/dx$ for holes. The diffusion constants D_n and D_p are related to the mobilities given by $D_n = \mu_n(k_B T/e)\mu_e$ and $D_p = (k_B T/e)\mu_p$, the so-called *Einstein relations*. In particular, the mean time between collisions t_{col} determines both the mobility and the diffusion constant.

Saturated Carrier Velocities

The mobilities discussed previously are called low field mobilities since they apply only for sufficiently small electric fields. The low field mobilities represent the scattering from distortions of the perfect lattice, with the electron gaining energy from the electric field between collisions at such distortion sites. At sufficiently high electric fields, the electron gains sufficient energy to encounter inelastic collisions with the elemental atoms of the perfect crystal. Since the density of such atoms is very high (i.e., compared to the density of scattering sites), this new mechanism dominates the carrier velocity at sufficiently high fields and causes the velocity to become independent of the field (i.e., regardless of the electric field strength, the electron accelerates to a peak velocity at which the inelastic collisions appear and the energy of the electron is lost). The electric field at which velocities become saturated is referred to as the *critical field* E_{cr} . Table 2.10 summarizes the **saturated velocities** and critical fields for electrons and holes in Si. The saturated velocities in GaAs and Ge are about $6 \times 10^6 \text{ cm/s}$, slightly lower than the saturated velocity in Si.

TABLE 2.10 Saturated Velocity and Critical Field for Si at Room Temperature

	Saturated Velocity, cm/s	Critical Electric Field, V/cm
Electrons	1.1×10^7	8×10^3
Holes	9.5×10^6	1.95×10^4

FIGURE 2.15 Velocity vs. electric field for silicon and GaAs semiconductors. (Source: Adapted from Sze, S.M. 1981. *Physics of Semiconductor Devices*, 2nd ed. Wiley Interscience, New York with permission.)

Figure 2.15 shows representative velocity vs. electric field characteristics for electrons in silicon and in GaAs. The linear dependence at small fields illustrates the low field mobility, with GaAs having a larger low field mobility than silicon. The saturated velocities v_{sat} , however, do not exhibit such a large difference between Si and GaAs. Also, the saturated velocities do not exhibit as strong a temperature dependence as the low field mobilities (since the saturated velocities are induced by large electric fields, rather than being perturbations on thermal velocities).

Figure 2.15 also exhibits an interesting feature in the case of GaAs. With increasing electric field, the velocity initially increases beyond the saturated velocity value, falling at higher electric fields to the saturated velocity. This *negative differential mobility* region has been discussed extensively as a potential means of achieving device speeds higher than would be obtained with fully saturated velocities. Table 2.11 summarizes the peak velocities for various semiconductors.

As device dimensions have decreased, the saturated velocities have become a more severe limitation. With critical fields in silicon about 10^4 V/cm, one volt across one micron leads to saturated velocities. Rather than achieving a current proportional to applied voltage (as in the case of the low field mobility condition), currents become largely independent of voltage under saturated velocity conditions. In addition, the emergence of saturated velocities also compromises the speed advantages implied by high mobilities for some semiconductors (e.g., GaAs vs. Si). In particular, although higher low field velocities generally lead to higher device speeds under low field conditions, the saturated velocities give similar speed performance at high electric fields.

FIGURE 2.16 Point defects in semiconductors: (a) Schottky defects, (b) Frenkle defects.

2.2.5 Crystalline Defects

A variety of defects occur in semiconductor crystals, many of which lead to degradations in performance and require careful growth and fabrication conditions to minimize their occurrence. Other defects are relatively benign. This section summarizes several of the defect types.

Point Defects

The point defects correspond to a lattice atom missing from its position. Two distinct cases appear, as shown in Fig. 2.16. *Schottky defects*, shown in Fig. 2.16(a), result when an atom is missing from a lattice site. Typically the atom is assumed to have migrated to the surface (during crystal growth) where it takes a normal position at a surface lattice site. An energy E_s is required to move a lattice atom to the crystal surface, that energy serves as an activation energy for Schottky defects. At temperature T , the equilibrium concentration N_{sd} of Schottky defects is given by $N_{sd} = N_L \exp(-E_{sd}/kT)$, where N_L is the density of lattice atoms, and there is necessarily some nonzero concentration of such defects appearing while the crystal is at the high temperatures seen during growth. The high-temperature defect densities are frozen into the lattice as the crystal cools.

Frenkle defects result when an atom moves away from a lattice site and assumes a position between lattice sites (i.e., takes an interstitial position), as shown in Fig. 2.17(b). The Frenkle defect, therefore, corresponds to a pair of defects, namely, the empty lattice site and the extra interstitially positioned atom. The activation

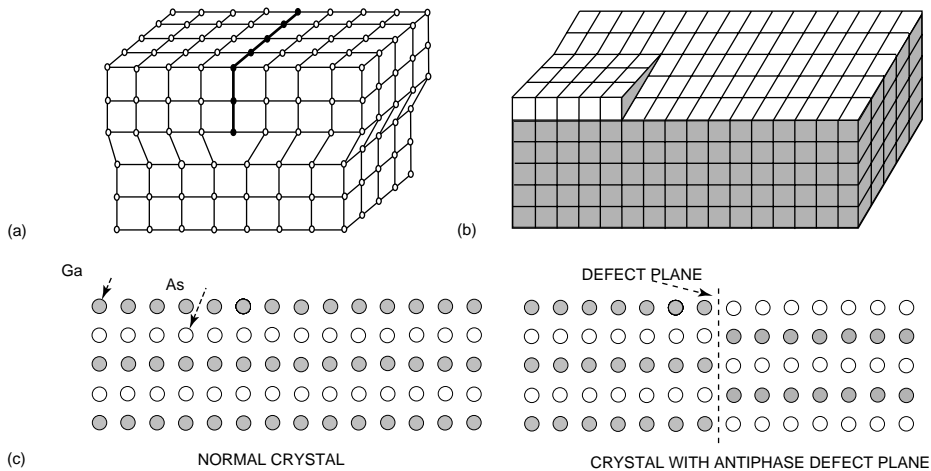

FIGURE 2.17 Line defects: (a) edge dislocation, (b) screw dislocation, (c) antiphase defect.

energy E_{fd} required for formation of this defect pair again establishes a nonzero equilibrium concentration N_{fd} of Frenkle defects given by $N_{fd} = \sqrt{N_L N_I} \exp(-E_{fd}/kT)$. Again, the Frenkle defects tend to form during crystal growth and are frozen into the lattice as the crystal crystallizes.

These point defects significantly impact semiconductor crystals formed mainly through ionic bonding. The covalent bonds of group IV and the largely covalent bonds of group III–V semiconductors, however, are much stronger than ionic bonds, leading to much higher activation energies for point defects and a correspondingly lower defect density in semiconductors with fully or largely covalent bonds. For this reason, the Schottky and Frenkle defects are not of primary importance in the electronic behavior of typical IV–IV and III–V semiconductors.

Line Defects

Three major types of line defects (*edge dislocations*, *screw dislocations*, and *antiphase defects*) are summarized here. The line defects are generally important factors in the electrical behavior of semiconductor devices since their influence (as trapping centers, scattering sites, etc.) extends over distances substantially larger than atomic spacings.

Edge dislocations correspond to an extra plane inserted orthogonal to the growth direction of a crystal, as illustrated in Fig. 2.17(a). The crystalline lattice is disrupted in the region near where the extra plane starts, leaving behind a line of *dangling bonds*, as shown. The dangling bonds can lead to a variety of effects. The atoms at the start of the dislocation are missing a shared electron in their outer band, suggesting that they may act as traps, producing a linear chain of trap sites with interatomic spacings (vastly smaller than normally encountered between intentionally introduced acceptor impurities). In addition to their impact on the electrical performance, such defects can compromise the mechanical strength of the crystal.

Screw dislocations result from an extra plane of atoms appearing at the surface. In this case (Fig. 2.17(b)), the growth process leads to a spiral structure growing vertically (from the edge of the extra plane). The change in lattice structure over an extended region as the crystal grows can introduce a variety of changes in the etching properties of the crystal, degraded junctions, etc. In addition, the dangling bonds act as traps, impacting electrical characteristics.

Antiphase defects occur in compound semiconductors. Figure 2.17(c) illustrates a section of a III–V semiconductor crystal in which the layers of alternating Ga and As atoms on the right side is one layer out of phase relative to the layers on the left side. This phase error leads to bonding defects in the plane joining the two sides, impacting the electrical performance of devices. Such defects require precision engineering of the growth of large diameter crystals to ensure that entire planes form simultaneously.

Stacking Faults and Grain Boundaries

Stacking faults result when an extra, small area plane (platelet) of atoms occurs within the larger crystal. The result is that normal planes are distorted to extend over that platelet (Fig. 2.18(a)). Here, a stack of defects appears above the location of the platelet. Electrical properties are impacted due to traps and other effects.

Grain boundaries appear when two growing microcrystals with different crystallographic orientations merge, leaving a line of defects along the plane separating the two crystalline lattices as shown in Fig. 2.18(b). As illustrated, the region between the two misoriented crystal lattices is filled from each of the lattices, leaving a plane of defects. Grain boundaries present barriers to conduction at the boundary and produce traps and other electrical effects. In the case of polysilicon (small grains of silicon crystal in the polysilicon area), the behavior includes the effect of the silicon crystal seen within the grains as well as the effects of grain boundary regions (i.e., acts as an interconnected network of crystallites).

Unintentional Impurities

Chemicals and environments encountered during crystal growth and during device microfabrication contain small amounts of impurities that can be incorporated into the semiconductor crystal lattice.

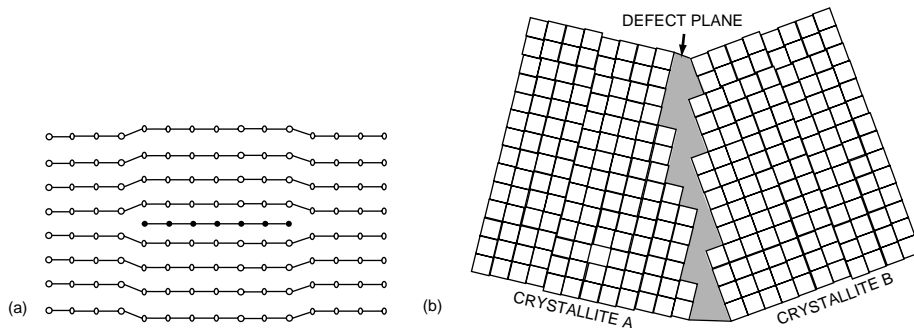

FIGURE 2.18 (a) Stacking faults, (b) grain boundary defects.

Some unintentional impurities replace atoms at lattice sites and are called **substitutional impurities**. Others take positions between lattice sites and are called **interstitial impurities**. Some impurities are benign in the sense of not strongly impacting the behavior of devices. Others are beneficial, improving device performance. Examples include hydrogen, which can compensate dangling bonds and elements that give rise to deep energy trapping levels (i.e., energy levels near the center of the band gap). Such deep level trapping levels are important in indirect gap semiconductors in establishing recombination time constants. In fact, gold was deliberately incorporated in earlier silicon bipolar transistors to increase the recombination rate and achieve faster transistors. Finally, other impurities are detrimental to the device performance.

Optoelectronic devices are often more sensitive to unintentionally occurring impurities. A variety of characteristic trap levels are associated with several of the defects encountered. Table 2.12 summarizes several established trap levels in GaAs, some caused by unintentional impurities and others caused by defects. The strategy for semiconductor material growth and microfabrication is, therefore, a complex strategy, carefully minimizing those unintentional impurities (e.g., sodium in the gate oxides of silicon metal oxide semiconductor (MOS) transistors), selectively adding impurities at appropriate levels to advantage, and maintaining a reasonable strategy regarding unintentional impurities which are benign.

Surface Defects: The Reconstructed Surface

If one imagines slicing a single crystal along a crystallographic plane, a very high density of atomic bonds is broken between the two halves. Such dangling bonds would represent the surface of the crystal, if the crystal structure extended fully to the surface. The atomic lattice and broken bonds implied by the slicing, however, do not represent a minimum energy state for the surface. As a result, there is a reordering of bonds and atomic sites at the surface to achieve a minimum energy structure. The process is called *surface reconstruction* and leads to a substantially different lattice structure at the surface. This surface

TABLE 2.12 Trap States (with Energy E_t) in GaAs

Type	$E_c - E_t$	Name	Type	$E_t - E_v$	Name
Shallow donor	≈ 5.8 meV		Shallow acceptor	≈ 10 meV	
Oxygen donor	0.82 eV	EL2	Tin acceptor	0.17 eV	
Chromium acceptor	0.61 eV	EL1	Copper acceptor	0.42 eV	
Deep acceptor	0.58 eV	EL3	Hole trap	0.71 eV	HB2
Electron trap	0.90 eV	EB3	Hole trap	0.29 eV	HB6

Source: Adapted from Shur, M. 1987. *GaAs Devices and Circuits*. Plenum Press, New York.

reconstruction will be highly sensitive to a variety of conditions, making the surface structure in real semiconductor crystals quite complex. Particularly important are any surface layers (e.g., the native oxide on Si semiconductors) that can incorporate atoms different from the semiconductor's basis atoms. The importance of surfaces is clearly seen in Si MOS transistors, where surface interfaces with low defect densities are now readily achieved. The reconstructed surface can significantly impact electrical properties of several devices. For example, mobilities of carriers moving in the surface region can be substantially reduced compared to bulk mobilities. In addition, MOS devices are sensitive to fixed charge and trap sites that can moderate the voltage appearing at the semiconductor surface relative to the applied gate voltage.

Surface reconstruction is a very complex and detailed topic and is not considered further here. Typically, microfabrication techniques have carefully evolved to achieve high-quality surfaces.

2.2.6 Summary

A rich diversity of semiconductor materials, led by the extraordinarily advanced device technologies for silicon microelectronics and III–V optoelectronics, has been explored for a wide range of applications. Much of the computing, information, and consumer electronics revolutions expected over the next decade will rest of the foundation of these important crystalline materials. As established semiconductor materials such as silicon continue to define the frontier for advanced fabrication of very small devices, new materials are emerging or being reconsidered as possible additional capabilities for higher speed, lower power, and other advantages. This chapter has provided a broad overview of semiconductor materials. Many fine and highly readable books, listed in the references, provide the additional depth which could not be provided in this brief chapter. Tables of various properties are provided throughout the chapter, with much of the relevant information provided in [Table 2.13](#).

Defining Terms

Ambipolar semiconductors: Semiconductors that can be selectively doped to achieve either n type or p type material.

Amphoteric impurities: Doping impurities that may act as either a donor or an acceptor.

Bandgap: Energy difference between the conduction band and the valence band.

Compound semiconductors: Semiconductor crystals composed of two or more atomic elements from different groups of the periodic chart.

Conduction band: Energy level for free electrons at rest in the semiconductor crystal.

Deep energy level impurities: Doping impurities or other impurities whose energy level lies toward the center of the bandgap. Important for carrier recombination in indirect gap semiconductors.

Direct gap semiconductor: Semiconductor whose conduction band minimum and valence band minimum appear at the same wave vector (same momenta); important for optical sources.

Effective mass: Value of carrier mass used to represent motion of a carrier in the semiconductor as though the motion were in free space.

Elemental semiconductors: Semiconductor crystals composed of a single atomic element.

Indirect gap semiconductor: Semiconductor whose conduction band minimum and valence band minimum appear at different wave vectors (different momenta).

Intrinsic semiconductors: Semiconductors with no intentional or nonintentional impurities (dopants).

Low field mobility: Proportionality constant between carrier velocity and electric field.

Quaternary semiconductors: Compound semiconductors with two atomic elements from one group and two atomic elements from a second group of the periodic chart.

Saturated velocities: Maximum carrier velocity induced by electric field (due to onset of inelastic scattering).

Shallow energy level dopants: Doping impurities whose energy level lies very close to the conduction (valence) band for donors (acceptors).

Substitutional impurities: Impurities that replace the crystal's base atom at that base atom's lattice position.

TABLE 2.13 Properties of GaAs and Si Semiconductors at Room Temperature (300 K), CdS and CdSe Both Can Appear in Either Zinc Blende or Wurtzite Lattice Forms

	Lattice	Lattice Constant, Å	Energy Gap, eV	Electron Effective Mass	Hole Effective Mass	Dielectric Constant	Electron Mobility, cm ² /V-s	Hole Mobility, cm ² /V-s

Further Information

The list of references focuses on books that have become popular in the field. The reader is advised to refer to such books for additional detail on semiconductor materials. The Institute for Electrical and Electronics Engineers (IEEE, Piscataway, NJ) publishes several journals that provide information on recent advances in materials and their uses in devices. Examples include the *IEEE Trans. Electron Devices*, the *IEEE Solid State Circuits Journal*, the *IEEE Journal on Quantum Electronics*, and the *IEEE Journal on Lightwave Technology*. The American Physical Society also publishes several journals focusing on semiconductor materials. One providing continuing studies of materials is the *Journal of Applied Physics*. The Optical Society of America (OSA, Washington, DC) publishes *Applied Optics*, a journal covering many practical issues as well as new directions. The Society of Photo-Optical Instrumentation Engineers (SPIE, Bellingham, WA) sponsors a broad range of conferences, with an emphasis on optoelectronic materials but also covering other materials. The SPIE can be contacted directly for a list of its extensive set of conference proceedings.

2.3 Thermal Properties

David F. Besch

2.3.1 Introduction

The rating of an electronic or electrical device depends on the capability of the device to dissipate heat. As miniaturization continues, engineers are more concerned about heat dissipation and the change in properties of the device and its material makeup with respect to temperature.

The following section focuses on heat and its result. Materials may be categorized in a number of different ways. In this chapter, materials will be organized in the general classifications according to their resistivities:

- Insulators
- Semiconductors
- Conductors

It is understood that with this breakdown, some materials will fit naturally into more than one category. Ceramics, for example, are insulators, yet with alloying of various other elements, can be classified as semiconductors, resistors, a form of conductor, and even conductors. Although, in general, the change in resistivity with respect to temperature of a material is of interest to all, the design engineer is more concerned with how much a resistor changes with temperature and if the change drives the circuit parameters out of specification.

2.3.2 Fundamentals of Heat

In the commonly used model for materials, heat is a form of energy associated with the position and motion of the material's molecules, atoms, and ions. The position is analogous with the state of the material and is potential energy, whereas the motion of the molecules, atoms, and ions is kinetic energy. Heat added to a material makes it hotter and vice versa. Heat also can melt a solid into a liquid and convert liquids into gases, both changes of state. Heat energy is measured in calories (cal), British thermal units (Btu), or joules (J). A calorie is the amount of energy required to raise the temperature of one gram (1 g) of water one degree Celsius (1°C) (14.5 to 15.5°C). A Btu is a unit of energy necessary to raise the temperature of one pound (1 lb) of water by one degree Fahrenheit (1°F). A joule is an equivalent amount of energy equal to work done when a force of one newton (1 N) acts through a distance of one meter (1 m). Thus heat energy can be turned into mechanical energy to do work. The relationship among the three measures is: $1 \text{ Btu} = 251.996 \text{ cal} = 1054.8 \text{ J}$.

Temperature

Temperature is a measure of the average kinetic energy of a substance. It can also be considered a relative measure of the difference of the heat content between bodies. Temperature is measured on either the Fahrenheit scale or the Celsius scale. The Fahrenheit scale registers the freezing point of water as 32°F and the boiling point as 212°F . The Celsius scale or centigrade scale (old) registers the freezing point of water as 0°C and the boiling point as 100°C .

The Rankine scale is an absolute temperature scale based on the Fahrenheit scale. The Kelvin scale is an absolute temperature scale based on the Celsius scale. The absolute scales are those in which zero degree corresponds with zero pressure on the hydrogen thermometer. For the definition of temperature just given, zero $^{\circ}\text{R}$ and zero K register zero kinetic energy.

The four scales are related by the following:

$$^{\circ}\text{C} = 5/9(^{\circ}\text{F} - 32)$$

$$^{\circ}\text{F} = 9/5(^{\circ}\text{C}) + 32$$

$$\text{K} = ^{\circ}\text{C} + 273.16$$

$$^{\circ}\text{R} = ^{\circ}\text{F} + 459.69$$

Heat Capacity

Heat capacity is defined as the amount of heat energy required to raise the temperature of one mole or atom of a material by 1°C without changing the state of the material. Thus it is the ratio of the

change in heat energy of a unit mass of a substance to its change in temperature. The heat capacity, often called thermal capacity, is a characteristic of a material and is measured in cal/g per °C or Btu/lb per °F,

$$c_p = \frac{\partial H}{\partial T}$$

Specific Heat

Specific heat is the ratio of the heat capacity of a material to the heat capacity of a reference material, usually water. Since the heat capacity of water is 1 Btu/lb and 1 cal/g, the specific heat is numerically equal to the heat capacity.

Thermal Conductivity

Heat transfers through a material by conduction resulting when the energy of atomic and molecular vibrations is passed to atoms and molecules with lower energy. In addition, energy flows due to free electrons,

$$Q = kA \frac{\partial T}{\partial l}$$

where

- Q = heat flow per unit time
- k = thermal conductivity
- A = area of thermal path
- l = length of thermal path
- T = temperature

The coefficient of thermal conductivity k is temperature sensitive and decreases as the temperature is raised above room temperature.

Thermal Expansion

As heat is added to a substance the kinetic energy of the lattice atoms and molecules increases. This, in turn, causes an expansion of the material that is proportional to the temperature change, over normal temperature ranges. If a material is restrained from expanding or contracting during heating and cooling, internal stress is established in the material.

$$\frac{\partial l}{\partial T} = \beta_L l \quad \text{and} \quad \frac{\partial V}{\partial T} = \beta_V V$$

where

- l = length
- V = volume
- T = temperature
- β_L = coefficient of linear expansion
- β_V = coefficient of volume expansion

Solids

Solids are materials in a state in which the energy of attraction between atoms or molecules is greater than the kinetic energy of the vibrating atoms or molecules. This atomic attraction causes most materials to form into a crystal structure. Noncrystalline solids are called *amorphous*, including glasses, a majority of plastics, and some metals in a semistable state resulting from being cooled rapidly from the liquid state. Amorphous materials lack a long range order.

Crystalline materials will solidify into one of the following geometric patterns:

- Cubic
- Tetragonal

- Orthorhombic
- Monoclinic
- Triclinic
- Hexagonal
- Rhombohedral

Often the properties of a material will be a function of the density and direction of the lattice plane of the crystal.

Some materials will undergo a change of state while still solid. As it is heated, pure iron changes from body centered cubic to face centered cubic at 912°C with a corresponding increase in atomic radius from 0.12 to 0.129 nm due to thermal expansion. Materials that can have two or more distinct types of crystals with the same composition are called *polymorphic*.

Liquids

Liquids are materials in a state in which the energies of the atomic or molecular vibrations are approximately equal to the energy of their attraction. Liquids flow under their own mass. The change from solid to liquid is called *melting*. Materials need a characteristic amount of heat to be melted, called the *heat of fusion*. During melting the atomic crystal experiences a disorder that increases the volume of most materials. A few materials, like water, with **stereospecific** covalent bonds and low packing factors attain a denser structure when they are thermally excited.

Gases

Gases are materials in a state in which the kinetic energies of the atomic and molecular oscillations are much greater than the energy of attraction. For a given pressure, gas expands in proportion to the absolute temperature. For a given volume, the absolute pressure of a gas varies in proportion to the absolute pressure. For a given temperature, the volume of a given weight of gas varies inversely as the absolute pressure. These three facts can be summed up into the Gas law:

$$PV = RT$$

where

P = absolute pressure

V = specific volume

T = absolute temperature

R = universal gas constant t

Materials need a characteristic amount of heat to transform from liquid to solid, called the *heat of vaporization*.

2.3.3 Other Material Properties

Insulators

Insulators are materials with resistivities greater than about $10^7 \Omega \cdot \text{cm}$. Most ceramics, plastics, various oxides, paper, and air are all insulators. Alumina (Al_2O_3) and beryllia (BeO) are ceramics used as substrates and chip carriers. Some ceramics and plastic films serve as the dielectric for capacitors.

Dielectric Constant

A capacitor consists of two conductive plates separated by a dielectric. Capacitance is directly proportional to the dielectric constant of the insulating material. Ceramic compounds doped with barium titanate have

high dielectric constants and are used in capacitors. Plastics, such as mica, polystyrene, polycarbonate, and polyester films also serve as dielectrics for capacitors. Capacitor values are available with both positive and negative changes in value with increased temperature. See the first subsection in [Sec. 2.3.4](#) for a method to calculate the change in capacitor values at different temperatures.

Resistivity

The resistivity of insulators typically decreases with increasing temperature.

Semiconductors

Semiconductors are materials that range in resistivity from approximately 10^{-4} to 10^{+7} $\Omega \cdot \text{cm}$. Silicon (Si), Germanium (Ge), and Gallium Arsenide (GaAs) are typical semiconductors. The resistivity and its inverse, the conductivity, vary over a wide range, due primarily to doping of other elements. The conductivity of intrinsic Si and Ge follows an exponential function of temperature,

$$\sigma = \sigma_0 e^{\frac{E_g}{2kT}}$$

where

σ = conductivity

σ_0 = constant t

E_g = 1.1 eV for Si

k = Boltzmann's constant t

T = temperature $^{\circ}\text{K}$

Thus, the electrical conductivity of Si increases by a factor of 2400 when the temperatures rises from 27 to 200 K.

Conductors

Conductors have resistivity value less than 10^{-4} $\Omega \cdot \text{cm}$ and include metals, metal oxides, and conductive nonmetals. The resistivity of conductors typically increases with increasing temperature as shown in [Fig. 2.19](#)

FIGURE 2.19 Resistivity in a function of temperature.

TABLE 2.14 Characteristics of certain alloys

Sn (%)	Pb (%)	Ag (%)	°C
60	40	—	190
60	38	2	192
10	90	—	302
90	10	—	213
95	5	5	230

Melting Point

Solder is an important material used in electronic systems. The tin-lead solder system is the most used solder compositions. The system's equilibrium diagram shows a typical eutectic at 61.9% Sn. Alloys around the eutectic are useful for general soldering. High Pb content solders have up to 10% Sn and are useful as high-temperature solders. High Sn solders are used in special cases such as in high corrosive environments. Some useful alloys are listed in Table 2.14.

2.3.4 Engineering Data

Graphs of resistivity and dielectric constant vs. temperature are difficult to translate to values of electronic components. The electronic design engineer is more concerned with how much a resistor changes with temperature and if the change drives the circuit parameters out of specification. The following defines the commonly used terms for components related to temperature variation.

Temperature Coefficient of Capacitance

Capacitor values vary with temperature due to the change in the dielectric constant with temperature change. The temperature coefficient of capacitance (TCC) is expressed as this change in capacitance with a change in temperature.

$$\text{TCC} = \frac{1}{C} \frac{\partial C}{\partial T}$$

where

TCC = temperature coefficient of capacitance

C = capacitor value

T = temperature

The TCC is usually expressed in parts per million per degree Celsius (ppm/°C). Values of TCC may be positive, negative, or zero. If the TCC is positive, the capacitor will be marked with a P preceding the numerical value of the TCC. If negative, N will precede the value. Capacitors are marked with NPO if there is no change in value with a change in temperature. For example, a capacitor marked N1500 has a $-1500/1,000,000$ change in value per each degree Celsius change in temperature.

Temperature Coefficient of Resistance

Resistors change in value due to the variation in resistivity with temperature change. The temperature coefficient of resistance (TCR) represents this change. The TCR is usually expressed in parts per million per degree Celsius (ppm/°C).

$$\text{TCR} = \frac{1}{R} \frac{\partial R}{\partial T}$$

TABLE 2.15 TCR values of common resistors

Resistor Type	TCR, ppm/°C		
Carbon composition	+500	to	+2000
Wire wound	+200	to	+500
Thick film	+20	to	+200
Thin film	+20	to	+100
Base diffused	+1500	to	+2000
Emitter diffused	+600		
Ion implanted	±100		

where

TCR = temperature coefficient of resistance

R = resistance value

T = temperature

Values of TCR may be positive, negative, or zero. TCR values for often used resistors are shown in Table 2.15. The last three TCR values refer to resistors imbedded in silicon monolithic integrated circuits.

Temperature Compensation

Temperature compensation refers to the active attempt by the design engineer to improve the performance and stability of an electronic circuit or system by minimizing the effects of temperature change. In addition to utilizing optimum TCC and TCR values of capacitors and resistors, the following components and techniques can also be explored.

- Thermistors
- Circuit design stability analysis
- Thermal analysis

Thermistors

Thermistors are semiconductor resistors that have resistor values that vary over a wide range. They are available with both positive and negative temperature coefficients and are used for temperature measurements and control systems, as well as for temperature compensation. In the latter they are utilized to offset unwanted increases or decreases in resistance due to temperature change.

Circuit Analysis

Analog circuits with semiconductor devices have potential problems with bias stability due to changes in temperature. The current through junction devices is an exponential function as follows:

$$i_D = I_S \left(e^{\frac{qV_D}{nkT}} - 1 \right)$$

where

i_D = junction current

I_S = saturation current

v_D = junction voltage

q = electron charge

n = emission coefficient

k = Boltzmann's constant

T = temperature, in 0 K

Junction diodes and bipolar junction transistor currents have this exponential form. Some biasing circuits have better temperature stability than others. The designer can evaluate a circuit by finding its fractional temperature coefficient,

$$TC_F = \frac{1}{v(T)} \frac{\partial v(T)}{\partial T}$$

where

$v(T)$ = circuit variable

TC_F = temperature coefficient

T = temperature

Commercially available circuit simulation programs are useful for evaluating a given circuit for the result of temperature change. SPICE, for example, will run simulations at any temperature with elaborate models included for all circuit components.

Thermal Analysis

Electronic systems that are small or that dissipate high power are subject to increases in internal temperature. Thermal analysis is a technique in which the designer evaluates the heat transfer from active devices that dissipate power to the ambient.

Defining Terms

Eutectic: Alloy composition with minimum melting temperature at the intersection of two solubility curves.

Stereospecific: Directional covalent bonding between two atoms.

2.4 Resistive Materials

Jan H. Mooij

2.4.1 Introduction

Resistance was defined by Ohm as the ratio between the potential difference between the ends of a conductor and the current flowing through the conductor. The standard unit of resistance is the *Absolute Ohm*, generally denoted Ω . It is defined as the resistance over a conductor that has a potential drop of 1 V when a current of 1 A is flowing through it.

Resistance is by no means a constant. It may depend on voltage or current, as well as temperature, humidity and other parameters. Every device that is not superconducting has a resistance. This is true even for interconnections, which usually have a very low resistance, or insulators where it is extremely high. It is difficult to give a good definition of a resistor. Almost any device may be considered a resistor. Here a resistor may be defined as an electronic device that is primarily meant to provide a specified resistance under specified conditions. This resistance may be constant, it may depend on some external parameter or it can also be adjustable.

This definition is rather vague, which is in accordance with the practical situation. Devices such as heating elements and incandescent lamps are made for other purposes, but under certain circumstances they can be used as a resistor. It is rather easy to measure a resistance, and so sensors based on resistance variations are popular. On the other hand, standard resistors are sometimes used as heating elements or sensors.

The requirements that must be met by resistors are extremely variable. Therefore, many types of resistors exist. A first division may be in:

- **Fixed resistors**, which in first approximation should have a constant resistance, independent of temperature, voltage, etc.
- **Variable resistors**, for which the resistance value can be changed by the user, but must be independent of other outside influences.
- **Nonlinear resistors**, which have been specially designed to depend strongly on a parameter such as temperature or voltage.

2.4.2 Fixed Resistors

By far the largest number of resistors are fixed resistors. Traditional fixed resistors usually are cylindrical with solderable leads. Here several groups may be distinguished.

Wire Wound Resistors

As the name indicates, for wire wound resistors the resistive element consists of a wire. To get sufficient length this wire is wound around a ceramic rod or tube. The ends of the wire are welded or soldered to caps or rings, which are attached to the rod. In turn, these caps or rings are attached to the leads, which may be wires or tags.

Because of the mechanical requirements of winding, in practice all resistive wires are made of metal, usually alloys based on CuNi or NiCr. The useful **resistivity** range in metals is small and, therefore, the resistance can primarily be varied by variation of the length and the diameter of the wire. Restrictions for maximum dimensions limit the resistance range for the standard dimensions and a good **temperature coefficient of resistance (TCR)** to 1–100,000 Ω . A lower value can be reached by using a wire with a low resistivity, but this will result in a higher TCR. Higher values need larger resistors, which can accommodate more wire length.

When insulation is provided with an organic coating the maximum hot spot temperature may not exceed 300°C. Even then a special coating must be used to prevent degradation of the coating. With an enamel coating, higher temperatures up to 450°C may be used.

As a result of the high allowed surface temperature the maximum load of wire wound resistors is relatively high. Their behavior under pulse loads is also good, and they have a low current noise. Because of the windings they tend to have a high inductance. Special resistors are produced in which two layers of wire are wound in opposite directions to minimize the inductance.

Carbon Composition Resistors

The resistive element of carbon composition resistors is a rod that consists of a mixture of carbon powder and organic binder. The outside of the rod is covered with an insulation layer. Wires are introduced into the

ends of the conductive rod. It follows from the dimensions of the rod that the resistivity of the material must be high to get the usual resistance values. Such materials have rather bad stability at elevated temperatures; the TCR is also very negative. They tend to be replaced by film resistors in newer designs. One advantage is their good pulse behavior, especially for single pulses.

Carbon composition resistors are provided in dimensions ranging from 2 to 5 mm diameter. Typically, they have a tolerance of $\pm 20\%$ and a TCR ranging from -500 (low values) to -2000 ppm/ $^{\circ}\text{C}$ (high values).

Film Resistors

Film resistors are made with many different kinds of films, but their basic design is rather constant. A cylindrical ceramic core is covered with a film. Caps that are pressed over this film are used as contacts. To adjust the value of the resistor, a spiral is cut or lasered in the film. During trimming the resistance is measured continuously, and trimming is stopped when the required value has been reached. In this way the initial tolerance of film resistors can be low. Wires are welded to the caps. Insulation and protection against moisture and pollution is provided by an organic coating. Such a coating is very important, as the resistive films can be extremely thin. Such films can easily be damaged by chemical attack, especially under humid conditions.

The marking of film resistors is usually done with a color code. This consists of a number of colored rings around the resistor. For resistors with a tolerance down to $\pm 5\%$ four rings are used: numbers one and two give the first two digits of the resistance value, the third one gives a multiplication factor, and the fourth one indicates the rated tolerance of the resistance value. For resistors with a lower tolerance, five rings are used; here the first three rings give the first three digits of the resistance value. Sometimes an extra ring or dot is used to indicate the TCR of the resistor. The meanings of the different colors are given in Fig. 2.20.

The properties of film resistors are primarily determined by the film. Many resistive materials have been used. They each have their weak and strong points and these determine the suitable applications.

Cracked Carbon Film Resistors

Traditionally cracked carbon film resistors have been used for general purpose applications. The films are made by cracking a hydrocarbon in the absence of oxygen on the rods. The sheet resistance is only partly determined by the thickness of the film. The resistivity of the material can vary strongly, depending on the proportion of amorphous carbon and the amount of contaminants in the film. The TCR usually becomes more negative when the resistivity increases.

FIGURE 2.20 Color code for fixed resistors in accordance with International Electrotechnical Commission (IEC) publication 62.

Carbon film resistors are available over a resistance range from 1 Ω to 10 M Ω . As already stated, their TCR may vary; usually it ranges from -400 ppm/ $^{\circ}$ C for the low values to up to -2000 ppm/ $^{\circ}$ C for very high values. The smallest ones have a length of 3 mm and a maximum diameter of 1.3 mm, with a maximum power rating of 0.25 W. Most resistors are somewhat larger, with a diameter of 1.8 mm. The use of large resistors with a power rating up to 2 W has decreased to a negligible level.

Metal Film Resistors

Metal film resistors are used for many applications. Very low-resistance values can be made with films of nickel phosphorous. Such films can be deposited on ceramic by a chemical process and, therefore, it is relatively cheap to make them very thick. They can have a TCR below ± 50 ppm/ $^{\circ}$ C.

Most other metal films are deposited by physical vapor deposition, usually evaporation or sputtering. Both processes require a high vacuum and are relatively expensive. Sputtering is the most expensive method, but it allows a much better control of the film composition. As a result of mechanization of physical vapor deposition, the deposition price of metal films is now so low that application for general purpose resistors is possible.

Most alloys for metal film resistors are based on nickel-chromium. For lower values, alloys based on copper-nickel also are used. For very high values, a higher resistivity is needed, and some silicides can be used. For resistors with a high-power rating, special alloys or metal oxide films may be employed.

The TCR of metal film resistors is usually better than ± 200 ppm/ $^{\circ}$ C. The stability is very good as long as the maximum working temperature is not exceeded. For most standard resistors this maximum temperature is around 175 $^{\circ}$ C; special alloys may allow temperatures around 300 $^{\circ}$ C. A tolerance of $\pm 5\%$ is standard.

Precision resistors are also made with metal films. Basically these resistors are identical to standard metal film resistors, but special care is taken to improve the TCR, tolerance, and stability. A TCR down to ± 5 ppm/ $^{\circ}$ C and a tolerance better than $\pm 0.02\%$ can be delivered.

Cermet or Metal Glaze Resistors

For most materials a very high sheet resistance can only be obtained by using an extremely thin film. By using a composite material such as a metal glaze, a thick and therefore more stable high ohmic film can be made. Such a film is produced by dipping the ceramic rod in a paste and drying and firing the layer.

As cylindrical resistors cermet or metal glaze resistors are mostly used for high-resistance values and high voltages. The available resistance range is 100 k Ω to 100 M Ω . The standard TCR is ± 200 ppm/K but a TCR better than ± 25 ppm/ $^{\circ}$ C is possible. The stability is good and the current noise acceptable for such high values.

Surface Mounted Device (SMD) Resistors

A large and increasing part of the fixed resistor market is taken by surface mounted device (SMD) resistors. These resistors are mounted directly on the printed circuit board. Electrical contacts are provided at the sides of the resistor.

For most SMD resistors the substrate is a rectangular piece of ceramic, usually alumina. At the upper side conductors are deposited along two edges. The resistive film is deposited between and partly over these electrodes. The resistance value is adjusted by laser trimming. A protective coating is applied over the resistive film. Contacts are made over the edges; these usually extend over the sides of the ceramic and even some distance over the lower side to improve the soldering quality.

For the resistive layer in general purpose resistors thick film technology is normally used. In most cases the contacts are made by dipping a conductive paste. Sometimes evaporated or sputtered contacts are used. To ensure good soldering the contacts are covered with a solder or tin layer. Standard SMD resistors have a tolerance of $\pm 5\%$ and a TCR of 200 ppm/ $^{\circ}$ C. With special thick-film techniques and appropriate contacts, tolerances of $\pm 1\%$ and a TCR of ± 50 ppm/ $^{\circ}$ C can be made.

For precision SMD resistors metal films are used. These films are made of the same alloys as used for cylindrical metal film resistors. Tolerances down to $\pm 0.1\%$ and a TCR of 25 ppm/ $^{\circ}\text{C}$ are available.

The dimensions of SMD resistors are usually given in units of 0.01 in. Most are in the ranges 1206 (3×1.5 mm) to 0603 (1.5×0.75 mm). There is a trend to smaller dimensions, 0402 and even 0201 are available commercially. Larger dimensions (e.g., 1218 size, for 1 W) are provided for applications that require a higher power rating.

Metal electrode facebonding (MELF) resistors are special type of SMD device. Their resistive elements are identical to those of cylindrical film resistors. Instead of wires, they have solderable caps, which are soldered directly on the printed circuit board. Different kinds of resistive films are used, and their properties are comparable to those of similar conventional film resistors.

Resistor Networks

Mounting of resistors is often more expensive than the components themselves. The use of the smallest SMD components is often limited by the difficulty of handling them. The amount of handling and mounting can be reduced by combining a number of resistors with their interconnections to a network on one substrate. This also makes it easier to use smaller resistors.

These networks are mostly made on ceramic or glass substrates. Both thick-film and thin-film technologies may be used. The specifications of these networks are comparable to those of discrete film resistors made with the same technology. Thin films are used when the requirements on tolerance or TCR are high or when very small resistor dimensions are needed. By the use of lithography small devices can be made in thin film. Small dimensions not only save space and weight but they also have advantages when high frequencies are used.

Other components such as capacitors or coils may be integrated in the network. As this requires an extra processing such components are also often mounted on the network, usually as SMDs. The network may also be used to mount integrated circuits and so provide complete circuit blocks.

Resistors on Integrated Circuits

Integrated circuits (IC) themselves may also contain resistors. These resistors are integrated in the IC. It is convenient to make these resistors in the same process steps as the rest of the IC. Therefore, the exact way in which the resistors are made depends on which process is used to produce the IC.

Diffused resistors are used often because they can be formed together with other circuit elements and no extra steps are needed. The available square resistance depends on the doping concentration and the diffusion depth. Further resistance variation can be obtained by using the appropriate number of squares in the design. The square resistances that can be obtained range from 10 to 600 Ω per square, the TCR lies around -1000 ppm/ $^{\circ}\text{C}$. The resistance tolerance is within $\pm 20\%$. With special structures a higher square resistance, up to 3000 Ω per square, can be obtained, but such resistors have a much more negative TCR and their tolerance is higher.

It is possible to use sputtered resistive films with a better TCR on an IC. However, this may lead to contamination of the production line. Therefore, this is only used when it is absolutely necessary.

2.4.3 Variable Resistors

In variable resistors the resistance value can be modified at will, but after adjustment this value must remain constant. The usual way to obtain this is a sliding contact that can move over the surface of the resistive element. The variable resistance can be used as such. In this case two connections are used, one at the start of the resistive element and one connected with the sliding contact.

A variable resistor can also be used as a voltage divider. In this case three connections are used. The total voltage is put over the resistive element; the required voltage is obtained by adjusting the position of the sliding contact. Variable resistors that are used in this way are also called potentiometers.

The resistance increment can be proportional to the displacement of the sliding contact, but also different resistance tracks are possible. The latter are, for instance, used for volume control in audio equipment.

As the sensitivity of the human ear is not linear, a nonlinear track may be better suited. Usually such potentiometers have a low-resistance increment at the start and an ever higher one further on. Therefore, they are sometimes called logarithmic potentiometers. The effect is obtained by varying the **sheet resistivity** and/or the track width over the resistive element in film potentiometers.

Adjustment of variable resistors may be done by turning a knob or by shifting along a line. In the first case, the sliding contact is rotated along an axis and the resistive element is part of a circle. In the second case, a linear resistive element is used. Apart from the mechanics, the technology of both designs is identical. In most cases the one used is a matter of design preference. Another design uses a linear resistive element, but the sliding contact is driven by a spindle that can be rotated. In this way it is easier to achieve small movement of the sliding contact, and so a more precise adjustment can be obtained.

In wire wound variable resistors the resistive element is a wire that is wound around a support. The contact slides over one side of the wires. The wire metals are the same as used for fixed resistors, but care should be taken that no thick oxide layers are present as this may cause a high contact resistance. Wire wound resistors can be made with good tolerance; they also have excellent stability and can have high rated power. They are, therefore, nearly always used when a high-power rating is needed. Their disadvantages include rather bad resolution and high price.

Variable film resistors are made with carbon composition films, usually on a paper laminate substrate, or with metal glaze films on a ceramic substrate. It is complicated to trim these resistive elements. Therefore, the tolerance on the resistance of film variable resistors is usually high, in the order of $\pm 20\%$. For most applications, however, this is no problem.

Carbon composition films have a rather high negative TCR, moderate stability, and sensitivity to humid conditions. Their major advantage is that they are inexpensive.

Metal glaze films are very stable, and their TCR can be much better than carbon composition. Besides being used in professional equipment they are also used in consumer electronics where conductive carbon films are not good enough, such as high-voltage trimmers in television sets. For specific applications, variable resistors may be combined with fixed resistors in a network.

In the usual design, the surface of the resistive element cannot have a protective coating, as this would impede the use of a sliding contact. For use in an aggressive environment special types are made. They depend mostly on hermetic sealing of the whole resistor.

Some variable resistors are only used for trimming circuits during manufacture or repair. They may be replaced by fixed resistors that are trimmed by the customer. Although the components are cheaper, the expensive trimming equipment makes this only attractive in special cases. Other devices are used many times during the operation of the equipment. For the latter types, minimum wear of the resistive element and the wiper is important.

An important property of variable resistors is the contact resistance between the sliding contact and the resistive element because it contributes to the resistance value. In the case of use as a potentiometer, it may be important if a current is flowing through the sliding contact. This may be especially important for volume or balance potentiometers in audio equipment. Here, variations in the contact resistance will give a crackling noise during the movement of the sliding contact. To reduce the contact resistance special sliding contacts are often used, which have multiple contact points or a custom soft contact material.

The *resolution* of the adjustment is the minimum relative resistance adjustment that can be made. For a wire wound variable resistor this is usually determined by the number of windings: each new winding that is contacted causes a step in resistance value or, in the case of use as a potentiometer, a step in potential. If the resistive element is a film, irregularities in the film may determine the resolution, but usually mechanical problems related with slip/stick performance are more important.

2.4.4 Nonlinear Resistors

Nonlinear resistors have a resistance that depends strongly on some external parameter. For any resistor the resistance depends on many parameters, but nonlinear resistors are specially made to show such a dependence. Usually the parameters are voltage or temperature. The major kinds are

- Resistors with a positive temperature coefficient (PTC)
- Resistors with a negative temperature coefficient (NTC)
- Voltage dependent resistors (VDR)

Nonlinear resistors consist of a piece of ceramic material with two metal connections at opposing sides. Usually the device is insulated with some kind of organic coating. The shape and dimensions may vary widely depending on type, manufacturer, and specification. Within each kind of nonlinear resistor special types are available for many specific applications.

There is a growing demand for SMD types of nonlinear resistors.

PTC

Positive temperature coefficient resistors are characterized by a resistance that is only moderately dependent on temperature below a certain temperature, but increases very strongly above that temperature. This increase may be as high as 15% per degree Celsius, and the total increase over some tens of degrees may be several orders of magnitude. A typical example of a resistance/temperature characteristic is given in Fig. 2.21.

The ceramic of PTCs is based on BaTiO₃ with certain additions. Normal grains of ceramic are surrounded by barrier layers of strongly oxidized material. The barrier potential is inversely proportional to the dielectric constant of the crystals. Therefore, the resistance increases sharply when the ferroelectric Curie temperature of the material is exceeded. It is possible to make materials with a specific Curie temperature by variations of the processing conditions. Above a certain temperature the TCR again becomes negative; this means that PTCs can only be used in a limited temperature range. As the barrier layers are thin, their resistance is shunted by a high capacitance. This means that they become strongly frequency dependent above 5 MHz.

Positive temperature coefficients are often used as protective devices in equipment to avoid overheating. By placing the PTC on the hot spot in series with the feeding circuit, overheating leads immediately to a reduction of the current. Protection against overcurrent may be provided by the self-heating of the PTC: when the current becomes too high the PTC limits it to a safe value. Another possibility is to use the PTC as a heating element. As the threshold temperature is approached the current and so the power is reduced, independent of the supply voltage. A PTC can also be used as a temperature sensor.

NTC

Negative temperature coefficient resistors, also called *thermistors*, have a negative temperature dependence in the order of several percent per degree Celsius. They are made from polycrystalline semiconductors, consisting of oxides of chromium, manganese, iron, cobalt, and nickel. The resistance of a NTC resistor can be expressed as

$$R = Ae^{B/T}$$

where *A* and *B* are constants and *T* is the absolute temperature in *K*. *B* depends on the material, it lies between 2000 and 5500 K. This means that around 25°C a temperature change of 1°C gives a resistance change between about 2 and 6%. Most NTCs are specified with the resistance value at 25°C and a constant *B* value between 20 and 85°C.

In measuring an NTC, care should be taken that the dissipated power remains small. When a sufficiently high voltage is applied, so much heat is generated that the resistor temperature increases. This leads to a lower resistance, a higher current, and a further increase of temperature. After some time (from a fraction

FIGURE 2.21 Typical resistance/temperature curve for a PTC resistor.

FIGURE 2.22 Example of a V/i characteristic of a varistor. In the normal operating region a very large change in current only leads to a very small increase of the voltage.

of a second to minutes, depending on the design) an equilibrium is reached. Many applications use this self-heating effect of the NTC. By placing a NTC in series with another device, the start current is reduced. When the NTC heats up, the current gradually increases to its final value.

Other applications include temperature sensing and compensation of the temperature dependence of other devices.

VDR

In VDR resistors (also called varistors) the effective resistance decreases strongly with increasing voltage. The major materials for VDRs are zinc oxide, strontium titanate, and silicon carbide. They consist of many particles with a rectifying action at their contact points. When a certain voltage over a contact is exceeded, the current strongly increases. The number of contacts in series determines the voltage rating, and the number of parallel connections determines the maximum current.

A typical voltage/current curve for a varistor is given in Fig. 2.22. The voltage in the protection zone may vary between some tens of volts to thousands of volts.

ZnO varistors are typically used to suppress voltage surges. Such surges may be generated by lightning, the switching of inductive loads, or electrostatic discharges. The resistor is connected parallel to the load. In normal conditions a negligible current is flowing. When a voltage surge occurs the current through the PTC strongly increases and the surge is suppressed. Another application is in micromotors, where strontium titanate varistors are normally used.

2.4.5 Fundamental Laws of Resistive Elements

The best-known law on resistance is Ohm's law, which states that

$$V = i \times R$$

where

V = voltage over the resistor

i = current

R = resistance

This law actually includes the definition of a resistance. It can also be written as $i = V/R$ or $R = V/i$.

Resistance is a property of a specific conducting element. It depends on the dimensions and the material of the conductor. In most cases the resistance R can be given as

$$R = \rho \times l/A$$

where

- l = length of the conductor
- A = area of cross section
- ρ = resistivity of the material

For resistive films, often the sheet resistivity is used. This is the resistance of a square area on the resistor surface.

Application of the last formula gives

$$R = \rho \times l/t$$

where t is the thickness of the film. This value does not depend on the size of the square, as a greater length is compensated by the greater width.

The standard unit of resistivity is the ohm meter, but the ohm centimeter or the micro-ohm centimeter is also used. Between different materials the ratio between the highest and lowest resistivities at ambient temperature is on the order of 10^{25} . A still higher ratio is found at low temperatures, even when we forget about superconductors, for which the resistivity is essentially zero. The TCR is defined as

$$\frac{1}{R} \times \frac{dR}{dT}$$

It is usually given in parts per million per degree celsius (ppm/°C). In most cases the TCR depends also on temperature. The TCR, therefore, must be specified over a temperature region. Sometimes only the average between 20 and 70°C is given. Other specifications include values for different temperature regions.

Conduction Mechanisms

Electrical conduction is usually separated into two mechanisms. One is metallic conduction, in which the charge carriers in the conduction band are free to move through the lattice at any temperature. Here the number of charge carriers does not depend on temperature, so the temperature dependence is only caused by the variation of the carrier mean free path, that is, the mean distance a charge carrier will travel without being scattered.

In a perfect lattice at absolute zero temperature no scattering of the carriers occurs. At higher temperatures vibrations will disturb the lattice and scattering does occur. This leads to a resistivity that increases with temperature. For most metals this increase is linear at temperatures above approximately 40 K.

In practice, metal lattices are not perfect. Lattice imperfections may include missing atoms, dislocations, and impurities. These imperfections also scatter the charge carriers. It turns out that usually the contributions of thermal vibrations and lattice imperfections can be added up. This is known as Matthiessen's Rule.

Alloying of pure metals increases the amount of disorder in the lattice. Therefore, the resistivity always increases when a pure metal is alloyed, even when the added metal has a lower resistivity in its pure form. At first the resistivity increases linearly with the amount of second metal, but for higher percentages the increase goes slower. A maximum is usually reached around a 50% composition, as higher contents may be considered an alloy of the first metal in the second one.

Quantum mechanics show that the mean free path of the electrons in a metal cannot be smaller than the interatomic distance. For many concentrated alloys of transition metals this limit is approached. Near this limit the resistivity becomes insensitive to a further increase of lattice disorder, and thus the TCR becomes low. It turns out that for these alloys the TCR is approximately zero when the resistivity is around $150 \mu\Omega \cdot \text{cm}$, positive when it is lower and negative when it is higher. Their low TCR makes these alloys useful for fixed resistors.

Ideal semiconductors have no electrical conduction at absolute zero temperature as there are no free charge carriers. At higher temperatures free charge carriers are created by thermal excitation. The electrical

conduction is determined by both the number of charge carriers and their mean free path. The change in carrier density is dominant, and so the TCR of semiconductors is negative.

Because of their strongly negative TCR, ideal semiconductors are not appropriate for fixed resistors as long as only a small part of the charge carriers are in the conduction band. If a large part of the carriers is activated, which may be obtained by heavy doping or a low gap energy, this condition will improve. A special case is graphitic carbon. Here the atoms are arranged in planes. Within the planes the electrical conduction is metallike, but between the planes it is semiconducting.

It is tempting to mix metals and semiconductors to combine their respective positive and negative TCR to achieve a zero TCR. If a simple mixture is made, the conductivity and the TCR are determined by a percolation process. This implies that in a very small composition region the TCR suddenly changes from positive to negative. Therefore, for such materials the reproducibility and the spread of both the resistivity and the TCR are unacceptable.

Useful mixed materials contain thin filaments of conducting material that are incorporated in an insulating matrix. The TCR is almost completely determined by the conductor, but the effective resistivity is very high. The matrix increases the adhesion to the substrate and it may protect the conductor, so such materials have rather good stability. Many cermet or metal glaze materials are based on this principle. Another possibility is the use of grains of a good conductor surrounded by a thin layer of semiconductor. Again the reproducibility is the major problem here.

Maximum Load

The generation of heat is an essential property of any resistance. The power P that is dissipated in a resistor is

$$P = i \times V$$

with i = current and V = voltage. By combination with ohm's law this may also be written as

$$P = i^2 \times R$$

or

$$P = V^2/R$$

The second formula indicates that for a constant current the dissipated power is proportional to the resistance. According to the third formula, for a constant voltage the power is inversely proportional to the resistance.

The dissipated heat will cause an increase in temperature of the resistor and its surroundings. In this way the temperature may become so high that problems occur. Usually the maximum power is determined by either the hottest spot on the resistor or the temperature of the connection between the resistor and the printed circuit. As the latter temperature is usually the lowest one it becomes more important when the temperature of the surroundings increases.

When a part of a resistor becomes too hot a resistance drift occurs. The magnitude of this drift depends on the resistive material and its geometry. The maximum allowed temperature depends also on the specified maximum drift; therefore, for precision resistors a lower temperature is allowed.

The magnitude of the temperature increase is determined by the amount of dissipated energy and the heat resistance to its surroundings. Heat can be dissipated by three processes, transfer to air moving along the resistor, radiation, and conduction.

The heat transfer to air depends on the temperature difference, the surface of the resistor, and the speed and direction of the air flow. Air flow along the resistor may be due to external causes but it can also be caused by natural convection. The air that is heated by the resistor becomes lighter than the surrounding air and, therefore, it tends to rise. The actual formulas for the transfer of heat to air are complicated as they depend strongly on the geometry of the resistor and its surroundings.

The heat transfer by radiation is given by

$$E \times A \times (T_R^4 - T_S^4)$$

Here E is the emission coefficient of the surface, A is the surface area, T_R and T_S are the absolute temperatures of the resistor and its surroundings, respectively. It is clear that the contribution of radiation increases strongly for a higher resistor temperature. The emission coefficient lies between 0 and 1; for organic coatings it has almost the maximum value in the relevant wavelength area.

The equation for heat transfer by conduction is

$$Q = \lambda * A/l$$

Here Q is the heat flow in 1 s, l and A are again the length and the area of the heat conductor, and λ is the heat conduction coefficient. The heat conduction coefficient is much less variable than the electrical conductivity; for solids its value varies around ambient temperature between 1 W/(m · K) for some glasses to 500 W/(m · K) for diamond. Metals generally have a high heat conduction, between 420 W/(m · K) for pure silver to 10 W/(m · K) for some concentrated alloys. For air the heat conduction under standard conditions is so low that it can be neglected relative to convection. Heat conduction is also important for the internal heat flow in the resistor body.

The relative importance of the contributions of the various ways of heat transmission depends on the construction and the geometry of the resistor and its surroundings. Some rules can be given, as most resistors fall into one of two categories.

For small resistors (length up to 5 mm with a maximum surface temperature under 200°C) almost all heat transport occurs by conduction. The area of such resistors is simply too small to dissipate a significant part of the power. This applies for most low-power resistors and all SMD resistors. The nominal rating of such resistors is typically around 0.5 W. In this case the temperature of the resistor depends strongly on the heat resistance of the printed circuit board. Good heat conduction is provided by the connectors on the print. Often in practice the maximum rating is not determined by the hottest spot on the resistor but by the temperature of the soldering spot. It should be realized that the nominal power rating of a resistor is based on a single resistor on a circuit board with a rather good heat conduction. For applications where more resistors are used on one board, a derating may be necessary.

Large resistors that can reach a surface temperature well over 200°C lose most of the produced heat by convection or radiation. In fact, this applies to all normal resistors with a rating over 1 W. For such resistors special measures may be necessary to make sure that the soldering point does not become too hot. Iron wires, with a low-heat conductivity or extra long wires can be used.

Resistors with a very high-power rating cannot be used on a printed circuit board. For these resistors a special mounting must be provided. Of course, it is advisable to keep such resistors away from components that are sensitive to heat. It may also be necessary to provide ventilation slots or a ventilator to dissipate the heat outside the equipment.

Pulse Load

It is well known that a resistor can withstand a higher power than usual when the load is applied for only a short time. Although several mechanisms may determine the maximum allowed power during a pulse, in by far the most cases the maximum temperature turns out to be the limiting factor. Under continuous load a resistor dissipates all energy to its environment. At the start, however, energy also is needed to increase the temperature of the resistor. As the resistor needs time to reach its maximum temperature a lower temperature will be reached when the load is only applied for a short time. Therefore, a higher load can be applied without damage to the resistor.

The maximum allowed pulse power depends on the pulse duration, the repetition frequency, and the properties of the resistor. This dependence may be quite complex, but some general rules always hold. For resistors of a similar type, larger ones always can handle a higher pulse. Also, for a shorter pulse, the allowed pulse power is at least as high as for a longer one. An important rule for repetitive pulses is that

the average power may never exceed the maximum allowed power under continuous load. This rule seems obvious, but is easily forgotten.

Under typical pulse load conditions the dissipation of energy to the environment of the resistor during a pulse can be neglected. Therefore, the rate of temperature increase is determined by the pulse power divided by the effective heat capacity of the resistor. During the pulse this effective heat capacity is not constant. All heat is produced in the resistive element. If the pulse is very short, the heat capacity of the resistive element determines the temperature increase as long as the proportion of the energy that can diffuse to the rest of the resistor is relatively small. Here the temperature is proportional to the pulse time. In this limit good behavior under pulse load can be obtained by using a large heat capacity of the resistive element itself and a resistive material that can withstand high temperatures.

In the course of time, part of the pulse energy diffuses into the rest of the resistor. The thickness of the effective zone d is given by

$$d = \sqrt{\frac{\lambda}{\rho \times C} \times t}$$

where

- λ = heat conductivity of the substrate material
- ρ = density of the material
- C = specific heat capacity of the material
- t = pulse time

All mentioned material properties are those of the material into which the heat is diffusing.

In a first approximation the energy diffusion to the rest of the resistor becomes important when the pulse time is so long that d approaches the thickness of the resistive element. This critical time will vary from around 1 s for large wire wound resistors with 1-mm wires to 10^{-10} s for film resistors with a film thickness of 10 nm. Under this regime the temperature of the resistive element increases with the square root of time.

For even longer times, d becomes on the order of the dimensions of the resistor. In this case also, heat loss to the environment becomes important. Here a gradual transition to continuous load, with a temperature that is independent of time, occurs.

The good pulse behavior of wire wound resistors is primarily based on the relatively large heat capacity of the wires. For pulse behavior, a large wire diameter should be used. As for a given resistance value, a thinner wire also implies a shorter wire; the maximum pulse rating for different wire wound resistors may be quite different.

For thin-film resistors the heat diffusion into the substrate is dominant for all but extremely short pulses. The effective heat capacity is proportional to the surface area; thus, large resistors here also are at an advantage. Breakdown usually occurs at spots where the current density is high, for instance at the end of trimming groove. Irregularities in the film may complicate matters even more. Nevertheless, it is possible to make mathematic models of the pulse behavior of such resistors that accurately predict the maximum allowed pulse power under specified conditions. An example of such a calculated curve is given in [Fig. 2.23](#).

The behavior of resistors with inhomogeneous resistive elements is complicated. The relatively large volume may give a rather good pulse behavior, especially for carbon composition resistors. Very short pulses, however, may reveal the fact that in such materials the actual current carrying part is thin and for such pulses the acceptable pulse energy may be surprisingly small.

Noise

All resistors exhibit *thermal noise*. This depends only on the resistance value; its energy does not depend on current or frequency.

In addition, resistors have *current noise*. This has the character of resistance variations, so that the noise is proportional to the total voltage over the resistor. Its magnitude is different for different resistors. The

FIGURE 2.23 Maximum permissible peak pulse power (P_{\max}) for a 1206 SMD resistor as a function of pulse duration for single pulses and for repetitive pulses with a pulse frequency that is 1000 times the pulse duration.

noise energy drops with frequency. Usually it is inversely proportional to the frequency f but higher powers of f may occur.

The noise energy depends on the number of charge carriers in the resistive element. Resistors with many charge carriers have a low current noise level. Therefore, wire wound resistors are extremely good in this respect. For film resistors, metal films are better than carbon films and metal glaze. Carbon composition resistors have an extremely high noise level. Within one type, low values are better than high ones and big resistors better than small ones.

The specified noise of a resistor always only applies to the current noise. The noise spectrum involves the whole frequency range, but for practical purposes noise is usually specified as measured for a band from 680 to 1680 Hz.

2.4.6 Long-Term Damp Heat

Resistance changes under humid conditions are due to electro-chemical transport of resistive material. In other words, this only happens when liquid water is present in combination with a sufficiently high potential difference. Liquid water may form when the relative humidity is near 100%. When the relative humidity is somewhat below 100%, liquid water may also form when slits or pollution is present. On the other hand, no water will be found on resistors that have a significantly higher temperature than their surroundings.

Humidity problems are almost exclusively found for high-value resistors that are operated far below their power rating. They may combine a sufficiently high voltage with a low heating effect. In addition, film resistors often have very thin films and so even small material transport may cause interruption. This is one reason that thick-film resistors are preferred for very high values.

Frequency Dependence

An ideal resistor has only a resistance, but in practice resistors always also have a capacitance and an inductance component. The simplest equivalent circuit for a practical resistor is given in Fig. 2.24.

As a result, at high frequencies the impedance of low-value resistors increases, whereas for high value resistors it decreases. The changeover usually takes place at nominal resistance values around 100 Ω . An example of the dependence of impedance on frequency is given in Fig. 2.25.

FIGURE 2.24 Simple equivalent circuit for a resistor.

Both the capacitance and the inductance tend to increase with larger dimensions of resistors. The series inductance is high for resistors with a resistive element such as a coil. This is found in most cylindrical film resistors and especially in wire wound resistors. Special types are available with two coils wound in opposite direction to minimize the inductance. Very low inductances and capacitances are found for small rectangular SMD resistors. One should remember that here interactions with the rest of the circuit may be much more important than the impedance of the resistor itself.

FIGURE 2.25 Impedance as a function of frequency for a 1206 SMD resistor.

Defining Terms

Fixed resistor: A resistor that, in first approximation, should have a constant resistance, independent of temperature, voltage, and other operating parameters.

Nonlinear resistor: A resistor with a value that depends strongly on some external parameter such as temperature (thermistor) or voltage (varistor).

Resistivity: The resistance of a cube with specified dimensions made of a given material. Usual units are the $\Omega \cdot \text{m}$ (resistance of a cube with sides of one meter) and the $\Omega \cdot \text{cm}$.

Sheet resistivity: The resistance of a square made of a thin film. This resistance depends only on the film material and the thickness, not on the size of the square.

Temperature coefficient of resistance (TCR): Defined as

$$\frac{1}{R} \times \frac{dR}{dT}$$

It is usually given in parts per million per degree celsius ($\text{ppm}/^\circ\text{C}$).

Variable resistor: A resistor for which the resistance value can be changed by the user, but must be independent of other outside influences.

2.5 Magnetic Materials for Inductive Processes

Martin R. Parker and William E. Webb

2.5.1 Introduction

Inductance is, primarily, a geometrical property of a current-carrying element in an electrical circuit. A circuit element with this property may be termed an inductor. The magnitude and, for that matter, the frequency dependence of inductance, also depend on the material environment of that element. Similar

remarks to these could, of course, be used to define capacitance and, as may be seen throughout this book, inductance and capacitance are invariably intimately related in electronic circuits. One reason is that both are (electrical) energy storage devices in time-varying electronic systems. Capacitance is, however, a measure of the capability of a (potential) circuit element to store charge and, thereby, electric field energy; inductance, by contrast, is a measure of a circuit element's ability to store magnetic field energy. Since magnetic field is derived from current flow, inductance is always associated with current-carrying circuit elements. This dichotomy extends also to the matter of frequency dependence. At zero signal frequency, for example, an (ideal) capacitor has infinite impedance whereas the inductor has zero impedance; at infinite frequency the opposite is true.

The concept of inductance, or, more correctly, **self-inductance** is, perhaps, best illustrated by the archetypal example of the current-carrying conducting coil of N circular turns (Fig. 2.26). When a current I flows through this circuit, as described, a magnetic field is generated inside and around the coil turns, in accordance with Ampere's law, as shown schematically in Fig. 2.26. (A detailed description of these field lines is a nontrivial matter, but is of little importance to the issue in question, which is how much **flux linkage** there is with the coil). Flux linkage Λ is defined by how much of the total **magnetic flux** ϕ threads all of the turns of the coil, multiplied by the total numbers of turns N . Thus, in simple algebraic terms

FIGURE 2.26 A magnetic field produced by a current through a coil. (Adapted from Plonus, M.A. 1978. *Applied Electromagnetics*. McGraw-Hill, New York.)

$$\Lambda = N\phi = N \int \int_A B \cdot dA (\cong NBA)$$

where, because of incomplete linkage by the magnetic flux (Fig. 2.26), in actuality A will typically be slightly less than the cross-sectional area of the coils. The inductance L of this coil is defined as the flux linkage per unit current and is defined as (Plonus, 1978)

$$L = \frac{\Lambda}{I} = \frac{N \left(\int \int_A B \cdot dA \right)}{I} \tag{2.29}$$

The SI unit of inductance is the henry (symbol H) if I is in amperes, Λ in webers, A in square meters, and B in teslas (webers/square meter). The inductance of some current-carrying elements of comparatively simple geometry is described in approximate form next.

2.5.2 Coils

Long Solenoid

The long solenoid is a longer, more tightly wound version of the coil of Fig. 2.26, with a relatively large number of turns (Fig. 2.27). Using Eq. (2.30) and the result that the B -field inside a long solenoid is fairly uniform and given by

$$\frac{\mu_0 NI}{\ell} \tag{2.30}$$

FIGURE 2.27 A short solenoid.

where ℓ is its length, means that the inductance is given by

$$L = \frac{\mu_0 N^2 A}{\ell} \quad (2.31)$$

where $m_0 (= 4\pi \times 10^{-7} \text{ H/m})$ is the **permeability** of free space.

Short Solenoid

Similarly, for a short solenoid of N turns, also of length ℓ and of radius a (Fig. 2.27), it can be shown that

$$B = \frac{\mu_0 N I}{(\ell^2 + 4a^2)^{\frac{1}{2}}} \quad (2.32)$$

Once again, from Eqs. (2.30) and (2.32), it follows that

$$L = \frac{\mu_0 N^2 A}{(\ell^2 + 4a^2)^{\frac{1}{2}}} \quad (2.33)$$

Note that, in the limit of a becoming vanishingly small, the short solenoid takes on the appearance of a long solenoid and Eq. (2.33) reduces to Eq. (2.31).

Flat Coil and Single Loop

In the limit of ℓ approaching zero in Eq. (2.33), we have a flat coil of N turns, radius a , whose inductance is, approximately

$$L = \frac{\mu_0 N^2 a}{2} \quad (2.34)$$

where A (Eq. (2.33)) has been replaced by a . Note that the special case of a single loop is derived from Eq. (2.34), simply by making $N = \ell$, leading to

$$L = \frac{\mu_0 a}{2} \quad (2.35)$$

The Toroid

Another simple classic geometry (Fig. 2.28) is the toroid. This doughnut-shaped winding is a close relative of the long solenoid. Indeed, it may be viewed as a long solenoid whose ends have been joined. Accordingly, the B -field inside the toroid may be given, approximately, by (Eq. 2.31), with the modification that the length ℓ is replaced by $2\pi r$, where r is the (mean) radius of the toroid. A crude approximation for the inductance of the toroid, when r is much greater than radius of the individual windings is, therefore

FIGURE 2.28 A toroid inductor. (Adapted from Irwin, J.D. 1995. *Basic Engineering Circuit Analysis*, 5th ed. Macmillan, NY.)

$$L = \frac{\mu_0 N^2 A}{2\pi r} \quad (2.36)$$

When the dimensions of the windings compare in size with the toroid radius, the simple expression of Eq. (2.36) is inadequate. To illustrate the point, consider the rectangularly cross-sectioned toroid of Fig. 2.29. It is easy to show analytically (Cheng, 1993) that, for this geometry

$$L = \frac{\mu_0 N^2 h (\ell n b / a)}{2} \quad (2.37)$$

FIGURE 2.29 A closely wound toroidal coil. (Adapted from Cheng, D.A. 1993. *Fundamentals of Engineering Electromagnetics*. Addison-Wesley, NY.)

Circuit Description of Self-Inductance

It is a relatively simple matter to describe the voltage drop across a simple self-inductance such as the coil of Fig. 2.30. For a steady-state current I , in the coils, the voltage drop is simply IR , as dictated by Ohm’s Law, where R is the coil resistance. On the other hand, if the current $i(t)$ is time varying, then it follows quite simply from a combination of Faraday’s Law of electromagnetic induction and equations (see, for example, Eqs. (2.29) and (2.31)) for magnetic flux and flux density that the (time-varying) voltage drop v across a self-inductance is

FIGURE 2.30 A circuit illustrating self-inductance. (Adapted from Irwin, J.D. 1995. *Basic Engineering Circuit Analysis*, 5th ed. Macmillan, NY.)

$$v = L \frac{di}{dt} + Ri \tag{2.38}$$

Given that magnetic field energy density is expressible (Plonus, 1978) as

$$w_m = B \cdot H \tag{2.39}$$

it follows that for any of the simple inductive windings described, the total magnetic field energy (that is, the stored energy of any inductor) is

$$W_m = \frac{1}{2} Li^2 \tag{2.40}$$

Note that L may be defined from Eq. (2.40), thus,

$$L = \left(\frac{2W_m}{i^2} \right)^{\frac{1}{2}} \tag{2.40a}$$

2.5.3 Magnetic Materials

All of the preceding described current elements were characterized by air-filled windings. In fact the formulas of Eq. (2.31) are essentially valid (better than 1% accuracy) if the windings encompass any condensed matter other than a magnetic (i.e., ferromagnetic/ferrimagnetic, etc.) material. If, however, any of the described windings are constructed around a **magnetic** material of **permeability** μ , then in each of the formulas of Eqs. (2.31–2.37), μ_0 is replaced by μ . Now, for magnetic materials μ is, typically, much greater than μ_0 . The actual value of μ depends crucially on (1) the current signal frequency and (2) the chemical identity and temperature of the magnetic material comprising the inductive element as well as on the details of its microstructure.

Source: After Plonus, M.A. 1978. *Applied Electromagnetics*. McGraw-Hill, New York.

In inductive devices, one will, typically, find *soft* magnetic materials employed as the core medium. Here, a soft magnetic material is one in which the **relative permeability** μ_r defined as

$$\mu_r = \frac{\mu}{\mu_0} \tag{2.41}$$

is, numerically, $\gg 1$. (See Table 2.16.) For the magnetic materials of Table 2.16 and the like, μ_r is (1) a nonanalytical function of magnetic field intensity (see, for example Fig. 2.31), (2) a complex quantity of the form

$$\mu = \mu' + j\mu'' \tag{2.42}$$

where μ'' is, typically, significant only at high frequencies (see, for example Fig. 2.32) and is a consequence of one or more of the lossy mechanisms outlined in Sec. 2.5.5

2.5.4 Self-Inductance of Wires and Transmission Lines

The concept of inductance is by no means limited to the multitransformed windings of Sec. 2.5.1. Any current-carrying element, even one with the most basic geometry, has at least marginal inductive characteristics. This is, perhaps, best illustrated with the case of a simple, straight copper wire. By integrating the self-(magnetic) field energy density over all internal radial values for a given wire current I (and applying

FIGURE 2.31 Magnetization curve of commercial iron. Permeability is given by the ratio B/H . (Source: Plonus, M.A. 1978. *Applied Electromagnetics*. McGraw-Hill, New York.)

Eq. (2.40a) as a definition for L , it follows that the self-inductance of a wire/unit length, $L' (= L/\ell)$, is

$$L' = \frac{\mu_0}{8\pi} \text{ (H/m)} \quad (2.43)$$

Note that the result is independent of wire radius.

By a similar approach, it can be shown (Plonus, 1978; Cheng, 1993) that the inductance/unit length of a coaxial cable (Fig. 2.33(a)) is

$$L' = \left(\frac{\mu_0}{8\pi}\right) + \left(\frac{\mu_0}{2\pi}\right) \ell n\left(\frac{b}{a}\right) \text{ (H/m)} \quad (2.44)$$

Likewise, a rather more tedious calculation (Plonus, 1978; Cheng, 1993) shows that for the parallel-wire transmission line (Fig. 2.33(b)), the corresponding result is

$$L' = \frac{\mu_0}{\pi} \left(\frac{1}{4} + \ell n\frac{d}{a}\right) \text{ (H/m)} \quad (2.45)$$

Finally, the growth of ultra-high-frequency, large-scale integrated circuitry places ever-increasing importance on parallel strip lines of the type shown in Fig. 2.34(a) and Fig. 2.34(b). It is a rather simple matter (Plonus, 1978) to show that the inductance/unit length for both of these structures is

$$L' = \frac{\mu a}{b} \text{ (H/m)} \quad (2.46)$$

where μ is the permeability of the medium between the strips.

2.5.5 Transformers

A transformer is a device that converts variations in the current in one circuit to variations in the current in one or more other circuits by means of magnetic coupling between two or more coils. In electronic circuits, transformers are used (1) to change the magnitude of an electrical signal, (2) to convert the voltage

FIGURE 2.32 Frequency dependence of the initial permeability of a nanocrystalline NiFeCo/Cu/NiFeCo/FeMn thin film spin valve structure. (Courtesy of B. Pirkle.)

FIGURE 2.33 Characteristics of transmission lines: (a) two views of a coaxial transmission line, (b) a two-wire transmission line. (Source: Cheng, D.A. 1993. *Fundamentals of Engineering Electromagnetics*. Addison-Wesley, New York.)

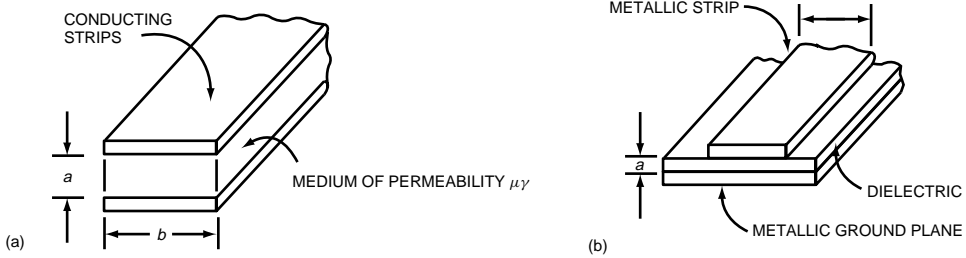

FIGURE 2.34 Parallel stripline techniques. (Source: After Plonus, M.A. 1978. *Applied Electromagnetics*. McGraw-Hill, New York.)

of the AC power line to a level suitable for the power supply, (3) to pass electrical signals between circuits while isolating them from DC, (4) to block DC from devices, such as speakers, whose operation would be adversely affected by large DC currents, (5) to match the impedance of a source to that of a load in order to achieve maximum power transfer and minimize distortion, and (6) used in connection with capacitors they can be part of a resonant circuit to provide narrow-band amplifications.

A transformer consist of two coils placed close together so that most of the magnetic flux generated by a current in one coil passes through the other (Fig. 2.35). To insure that this is the case usually both coils are wound on a common core of magnetic material (see Table 2.16) although, occasionally, transformers intended for high-frequency application have air cores. One coil, the primary, is connected to a time-varying voltage source while the other, the secondary, is connected to a load. The current in the primary creates a time-varying flux in the core. Since this flux also passes through the secondary winding a voltage is generated in the secondary.

FIGURE 2.35 Flux relationships for mutually coupled coils. (Adapted from Irwin, J.D. 1995. *Basic Engineering Circuit Analysis*, 5th ed. Macmillan, New York.)

In general, the voltages V_1 and V_2 in each coil is given in terms of the currents i_1 and i_2

$$\begin{aligned}
 v_1 &= L_{11} \frac{di_1}{dt} + L_{12} \frac{di_2}{dt} \\
 v_2 &= L_{21} \frac{di_1}{dt} + L_{22} \frac{di_2}{dt}
 \end{aligned}
 \tag{2.47}$$

where L_{11} and L_{22} are the self-inductances of the two coils and

$$L_{12} = L_{21} = M
 \tag{2.48}$$

is the **mutual inductance** between the coils.

A useful concept here is that of the ideal transformer; namely, a transformer in which all of the flux from one coil passes through the other and in which there are no internal losses. Not only does the ideal transformer provide a starting point for understanding a real transformer but also in many cases it is an adequate approximation for practical purposes.

From Faraday's Law

$$e_p = N_p \frac{\partial \Phi_p}{\partial t}
 \tag{2.49}$$

and

$$e_s = N_s \frac{\partial \phi_s}{\partial t} \tag{2.50}$$

where e is the voltage across the coil, N is the number of turns, and Φ is the flux through the coil; the subscripts p and s refer to the primary and secondary, respectively. Since for an ideal transformer $\phi_p = \phi_s$, we have

$$\frac{e_s}{e_p} = \frac{N_s}{N_p} = \frac{1}{a} \tag{2.51}$$

where a is the turns ratio. Thus, if the secondary winding has more turns than the primary, the output voltage is greater than the input voltage and the transformer is said to be a *step-up* transformer. Conversely, if the primary has the most turns, the output voltage is lower than the input voltage and we have a *step-down* transformer.

Since the ideal transformer is lossless the input and output power must be the same. Hence, we can write

$$e_p i_p = e_s i_s \tag{2.52}$$

where i_p and i_s are the currents flowing in the primary and secondary, respectively. Eliminating the ratio e_p/e_s from Eqs. (2.51) and (2.52) yields

$$\frac{i_s}{i_p} = \frac{N_p}{N_s} = a \tag{2.53}$$

Clearly, a transformer which increases the voltage decreases the current and vice versa.

A salient point to remember is that the preceding equations apply only to the time-varying components of the voltages and currents. Since static magnetic fields produce no induced voltages, the primary and secondary windings are isolated as far as DC voltages are concerned.

The maximum power transfer theorem states that maximum power is transferred from a source to a load when the internal impedance of the source is equal to the load impedance. In addition, when signals are transmitted over transmission lines it is, in general, necessary that the source and load impedances be matched to the characteristic impedance of the line to avoid reflections and distortion. As mentioned previously transformers are often used to accomplish the necessary impedance matching. The impedance (Z) looking into the primary and secondary terminals of a transformer are

$$Z_p = \frac{e_p}{i_p} \quad \text{and} \quad Z_s = \frac{e_s}{i_s} \tag{2.54}$$

Hence,

$$\frac{Z_s}{Z_p} = \frac{e_s i_p}{i_s e_p} = \frac{1}{a^2} \tag{2.55}$$

that is, the ratio of input to output impedance varies as the square of the turns ratio.

The principle units of magnetic properties relating to transformer design are listed in Table 2.17.

TABLE 2.17 Units

Quantity	Symbol	Unit (S.I.)
Magnetic flux density	B	T (or Wb/m^2)
Magnetic field intensity	H	A/m
Magnetic flux	ϕ	Wb
Magnetic flux linkage	Λ	Wb-turns
Self, mutual inductance	L, M	H
Magnetic permeability	μ	H/m

The polarity of the voltage can be determined by examining the direction in which the coils are wound on the core. For example, consider the transformer shown in Fig. 2.36(a). With the coils wound as shown, a current flowing into the upper terminal of the primary in the direction of the magnetic flux induced in the core can be determined from the right-hand rule to be in the clockwise direction as shown. The current in the secondary will be in the direction that will produce a flux that opposes the flux that induced it. Therefore, the current in the secondary winding is out of the upper terminal. If the direction of either winding is reversed, then the polarity of that coil is also reversed. To indicate the polarity of a transformer dots are placed on the circuit symbol, as shown in Fig. 2.36(b). The manufacturer also sometimes places dots on the case of the transformer. The dot convention states: (1) if current flows into the dotted end of one coil it flows out the dotted end of the other and (2) the polarity of the dotted ends of both coils are the same.

FIGURE 2.36 Voltage polarity of transformers.

If the direction of either winding is reversed, then the polarity of that coil is also reversed. To indicate the polarity of a transformer dots are placed on the circuit symbol, as shown in Fig. 2.36(b). The manufacturer also sometimes places dots on the case of the transformer. The dot convention states: (1) if current flows into the dotted end of one coil it flows out the dotted end of the other and (2) the polarity of the dotted ends of both coils are the same.

Transformer Loss

A real transformer differs from an ideal transformer in two important ways. First, in a real transformer only part of the flux from one coil passes through the other. The part of the flux from the primary that does not pass through the secondary is called the leakage flux. The magnetic coupling between the primary and secondary windings is expressed in terms of the leakage constant (k), which varies between 1 for an ideal transformer and ϕ for two coils that have no magnetic coupling between them. A well-designed ferrite core transformer may have a k very near to 1, whereas the typical value of k for an air core transformer may be as low as 0.5.

In addition to imperfect flux leakage a real transformer has internal power losses that must be considered:

- *Copper loss.* Since the wire from which the coils are core wound has a finite resistance there is a power loss due to ohmic heating of the wire.
- *Eddy current loss.* The time-varying flux not only induces current in the secondary winding of the transformer but also induces circulating currents in the core as well (Fig. 2.37(a) and Fig. 2.37(b)). These eddy currents, as they are called, cause ohmic heating of the core and hence a loss of power. Power transformers normally have laminated cores made of alternate layers of iron and insulating material to coil erupt the flow of the eddy currents and thus reduce the eddy current loss (Fig. 2.37(c)).
- *Hysteresis loss.* Work is also done in rotating the magnetic domains in the core, thus loss is termed hysteresis loss.

FIGURE 2.37 (a) A magnet moving toward a conducting sheet will induce eddy currents as shown; (b) formation of emfs, which cause eddy currents; (c) the reduction of eddy currents by laminating the core. (Source: After Plonus, M.A. 1978. *Applied Electromagnetics*. McGraw-Hill, New York.)

- *Loss due to energy being converted to sound in the core.* This phenomenon, called magnetostriction, is of importance only in very large power transformers. The combination of the eddy current and hysteresis losses is called the *iron loss*.

In addition to these effects, real transformers often have strong capacitance both between the turns of the windings and between the primary and secondary windings. These capacitances may become significant at high frequencies.

Networks containing transformers can be analyzed by introducing an equivalent circuit. Let

- L_p = inductance of the primary winding
- L_s = inductance of the secondary winding
- R_p = inductance of the primary winding
- R_s = inductance of the secondary winding
- Z = the equivalent impedance of the load
- R_0 = hypothetical resistance introduced to account for core losses
- M = mutual inductance between the primary and secondary windings

By definition the mutual inductance is given by

$$M = k\sqrt{L_p L_s} \tag{2.56}$$

We also let

$$L_1 = L_p - aM \tag{2.57}$$

and

$$L_2 = L_s - M/a \tag{2.58}$$

The real transformer of Fig. 2.37(a) can be replaced by the circuit containing an ideal transformer shown in Fig. 2.37(b). It is easily shown that the circuits of Fig. 2.37(a) and Fig. 2.37(b) are described by the same set of loop equations and are, therefore, equivalent. This deviation is beyond the scope of this chapter but can be found in standard circuits texts.

The ideal transformer's only effects are (1) to change the voltage and current by a factor a and ℓ/a , respectively, and (2) to transform the impedances by a factor of a^2 (See Fig. 2.38). We can therefore eliminate the transformer by replacing the secondary voltage and current by scaled quantities i'_1 and i'_2 where

$$i'_s = \frac{i_s}{a} \tag{2.59}$$

$$v_s = av_s \tag{2.60}$$

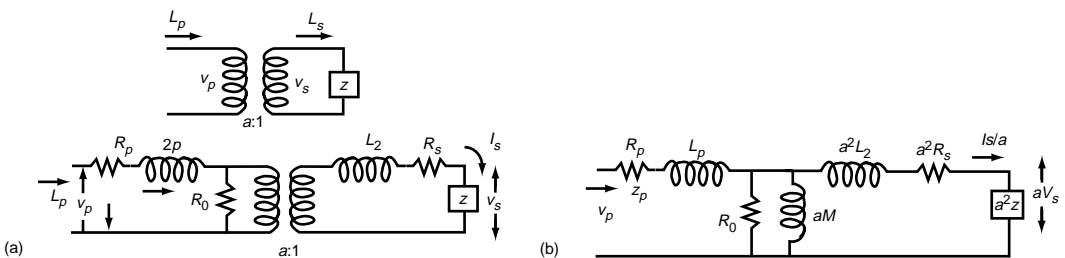

FIGURE 2.38 Transformer characteristics: (a) real transformer, (b) circuit model with ideal transformer.

and by multiply in all impedances on the secondary side of the transformer by a^2 to obtain the network of Fig. 2.37(a). This network can be solved for V'_s and i'_s using standard circuit analysis techniques. Equations (2.59) and (2.60) can then be used to obtain V_s and i_s .

By this procedure it is said that the secondary quantities have been referred to the primary side. It is also possible to refer the primary quantities to the secondary side. In this case the multiplier would be ℓ/a .

Autotransformer

An **autotransformer** consists of a single coil, usually wound on a magnetic core, as shown in Fig. 2.39. The part of the coil common to both input and output sides of the transformer is called the common winding and the rest of the coil is called the series winding. We denote the number of turns on each winding by N_c and N_s , respectively. Usually N_s is much smaller than N_c . Symbols for the various voltages and currents are defined in Fig. 2.39. Either side of the autotransformer can be used as the primary side. If the high-voltage (left-hand) side of the autotransformer in Fig. 2.39 is the primary side it is a step-down transformer, whereas if the low-voltage (right-hand) side is the primary it is a step-up transformer. In the latter case, the direction of all four currents are reversed.

For an ideal autotransformer the relations between the high- and low-side voltages and currents are given by Eq. (2.61), which is valid for both step-up and step-down configurations.

$$\frac{v_L}{v_H} = \frac{I_H}{I_L} = \frac{N_c}{N_c + N_s} \quad (2.61)$$

Autotransformers are frequently wound on a cylindrical core, and the output taken from a movable contact as shown in Fig. 2.40. Such a variable autotransformer could provide a voltage from 0 V to about 10% above the line voltage.

Intermediate-Frequency Transformer

Transformers are often used to couple the intermediate-frequency (IF) stages of a superheterodyne radio. These IF transformers, or *IF-cans* as they are often called, are parallel by capacitors, as shown in Fig. 2.40. Each coil has a moveable ferrite core that may be screwed into or out of the coil changing the inductance of the coil and, hence, the resonant frequency of the tank circuit. The IF transformer will thus pass signals near the resonant frequency. The IF amplifier thus have a very narrow bandwidth.

Baluns

When connecting transmission lines it is frequently necessary to connect a symmetrical line (such as television twin lead) to an asymmetric line (such as coaxial cable). The matching device to accomplish this connection is called a balun. Below 200 MHz, transformers can be used as baluns. Above this frequency, transmission line techniques are usually used. A balun is shown in Fig. 2.41.

FIGURE 2.39 An auto-transformer. Current directions are shown for a step-down autotransformer.

FIGURE 2.40 Variable autotransformer.

FIGURE 2.41 A balun transformer. (Courtesy of Toko.)

Distortion

Transformers can be a major source of distortion in electronic circuits. This distortion arises from two major sources. First, the transformer consists of inductive elements whose impedance is frequency dependent. Transformers, therefore, display harmonic distortion. Second, the magnetization curve of ferromagnetic material (Fig. 2.31) is very nonlinear. This introduces distortion into signals coupled by iron or ferrite core transformers unless the signal level is kept very small.

Defining Terms

Autotransformer: A transformer in which the input and output sides have a common winding.

Flux linkage: Magnetic flux multiplied by the number of turns.

Magnetic flux: Magnetic flux density integrated over cross-sectional area.

Magnetic permeability: Magnetic analog of electrical conductivity, describing the degree to which a magnetic material is capable of sustaining magnetic flux. Defined by ratio of magnetic induction field over magnetic field intensity.

Mutual inductance: The magnetic flux linkage common to two magnetic circuit elements per unit current flowing through the element in question.

Relative permeability: The magnetic permeability of a material divided by the magnetic permeability of free space.

Self-inductance: The magnetic flux linkage per unit current flowing through the circuit element.

2.6.1 Capacitor and Capacitance in Linear Electromagnetic Field

A system of two conducting bodies (which are frequently determined as plates) located in the electro-magnetic field and having equal charges of opposite signs $+Q$ and $-Q$ can be called a **capacitor**. The **capacitance** C of this system is equal to the ratio of the charge Q (here the charge absolute value is taken) to the voltage V (again, the absolute value is important) between the bodies, that is

$$C = \frac{Q}{V} \quad (2.62)$$

Capacitance C depends on the size and shape of the bodies and their mutual location. It is proportional to the dielectric permittivity ϵ of the media where the bodies are located. The capacitance is measured in **farads** (F) if the charge is measured in coulombs (C) and the voltage in volts (V). One farad is a very big unit; the practical capacitors have the capacitances that are measured in micro- (μF , or 10^{-6} F), nano- (nF, or 10^{-9} F), and picofarads (pF, or 10^{-12} F).

The calculation of capacitance requires knowledge of the electrostatic field between the bodies. The following two theorems (Stuart, 1965) are most important in these calculations. The integral of the flux density \mathbf{D} over a closed surface is equal to the charge Q enclosed by the surface (the Gauss theorem), that is

$$\oint \mathbf{D} ds = Q \quad (2.63)$$

This result is valid for linear and nonlinear dielectrics. For a linear and isotropic media $\mathbf{D} = \varepsilon \mathbf{E}$, where \mathbf{E} is the electric field, and this case will be assumed here (unless otherwise specified). The magnitude E of the field is measured in volt per meter, the magnitude D of the flux in coulomb per square meter, and the dielectric permittivity has the dimension of farad per meter. The dielectric permittivity is usually represented as $\varepsilon = \varepsilon_0 K_d$ where ε_0 is the permittivity of air ($\varepsilon_0 = 8.86 \cdot 10^{-12}$ F/m) and K_d is the dielectric constant.

The electric field is defined by an electric potential ϕ . The directional derivative of the potential taken with the minus sign is equal to the component of the electric field in this direction. The voltage V_{AB} between the points A and B , having the potentials ϕ_A and ϕ_B , respectively (the potential is also measured in volts), is equal to

$$V_{AB} = \int_A^B \mathbf{E} d\mathbf{l} = \phi_A - \phi_B \quad (2.64)$$

This result is the second basic relationship. The left hand side of Eq. (2.64) is a line integral. At each point of the line AB we have two vectors: \mathbf{E} defined by the field and $d\mathbf{l}$ that defines the direction of the line at this point.

Let us consider some examples of application of these two basic relationships.

Parallel Plate Capacitor

Assume (Fig. 2.42(a)) that we have two plates of area S each. The plates have the potentials ϕ_A and ϕ_B . The distance d between the plates is small, so that one can neglect the distortions of the electric field along the capacitor perimeter.

The last statement needs some comments. In the general case the parallel plate capacitor has the field that is not uniform (Fig. 2.42(b)). Yet, if the plates are cut so that the inner part has the guard rings, which have also the potentials ϕ_A and ϕ_B , then the inner part will have a uniform electric field (Fig. 2.42(c)). We will assume that Fig. 2.42(a) represents this inner part of Fig. 2.42(c).

Taking a path from the point A to the point B along one of the field lines

$$V_{AB} = \int_A^B \mathbf{E} d\mathbf{l} = E \int_A^B d\mathbf{l} = E d \quad (2.65)$$

if this uniform field has the magnitude E . If one takes a surface (Fig. 2.42(c)) enveloping one of the plates and closely located to it, then

$$Q = \oint \varepsilon \mathbf{E} ds = \varepsilon E S \quad (2.66)$$

FIGURE 2.42 Parallel plate capacitor.

FIGURE 2.43 Characteristics of coaxial cable.

because the field exists inside the capacitor only. From Eqs. (2.65) and (2.66) one immediately obtains that

$$C = \frac{Q}{V} = \frac{Q}{V_{AB}} = \frac{\epsilon S}{d} \tag{2.67}$$

The construction of nearly all practical capacitors can be reduced to this simple two-plate configuration. And when the area S increases (proportionally to the square of the plate diameter), the role of the perimeter (proportional to the first degree of diameter) field becomes smaller, and the guard rings could be omitted.

Coaxial Cable Capacitance

Let us consider a piece of a coaxial cable having the length l . Thus, we are calculating the capacitance of two concentric cylinders, the radius of the inner cylinder being r_1 and the inner radius of the external cylinder being r_2 (Fig. 2.43). The inner cylinder carries a positive charge Q , the dielectric between these two cylinders is characterized by the permittivity ϵ , and the voltage between the cylinders is V .

If the condition $l \gg r_2$ is satisfied, one can neglect the distortions of the electric field near the ends of the coaxial cable and consider that the charge is distributed uniformly, with the linear density $\tau = Q/l$ (τ is measured in coulomb per meter) and the vectors of the electric field \mathbf{E} and the electric flux density \mathbf{D} are directed along the radial lines passing from one cylinder to another. Then one can apply the Gauss theorem to a cylindric surface having the radius r and located between the cylinders. The radial direction of the electric field allows us to neglect the flux through the bottoms S_B and take into consideration the flux through the cylinder side surface S only. Then, for a given r , the electric flux density \mathbf{D} is constant on the side surface and one can write

$$\oint \mathbf{D} ds = \int_S \mathbf{D} ds = \int_S D ds = D \int_S ds = D 2\pi r l = Q\tau l \tag{2.68}$$

From this result one obtains that $D = \tau/(2\pi r)$ and

$$E = \frac{\tau}{2\pi \epsilon r} \tag{2.69}$$

Notice that Eq. (2.69) does not depend on the radius r_1 ; this means that the electric field outside the inner cylinder is the same as the field of a line coinciding with the cylinder axis and carrying the same charge.

The voltage at the cable is

$$V = \int_{r_1}^{r_2} \mathbf{E} dr = \int_{r_1}^{r_2} \frac{\tau}{2\pi \epsilon r} dr = \frac{\tau}{2\pi \epsilon} \ln \frac{r_2}{r_1} \tag{2.70}$$

FIGURE 2.44 The parallel-wire transmission line.

Thus, the capacitance of the cable is equal to

$$C = \frac{2\pi \epsilon l}{\ln(r_2/r_1)} \quad (2.71)$$

The capacitance of tubular capacitors can also be calculated using Eq. (2.71).

Capacitance of a Two-Wire Transmission Line

The cross section of this line is shown in Fig. 2.44. The wires have the charges of opposite signs when a voltage is applied to the line. Again, it is assumed that the length l of wires is much larger than the distance between the wires, that is, $l \gg d$. This allows us to neglect the distortion of electric field near the ends of the transmission line and one can consider that the field is the same in any plane that is perpendicular to the wires axes. Assume also that the line is in air and far enough from ground so that the influence of this conducting ground can be neglected. Let the voltage between the wires be V , the charge at each wire is $Q = \tau l$, where τ is the charge linear density, and each wire has the radius r_0 .

In the coaxial cable the distribution of the electric charge on the inner wire was uniform along the surface of this wire. In the considered case, the charge density on the wires is not uniform; it is higher on the inner parts of the wire surfaces due to attraction force between the charges of opposite sign. Hence, the distance between the electric axes of the wires is less than the distance between their geometrical axes. This difference become smaller when the ratio d/r becomes larger. If $d \gg r$ one can consider that the electric and geometric axes of the wires are coinciding. Then, at the point M the electric field can be found as a result of superposition of the fields from the left and right wires, that is

$$E = \frac{\tau}{2\pi \epsilon_0 r} + \frac{\tau}{2\pi \epsilon_0 (d - r)} \quad (2.72)$$

and the voltage V between the wires can be calculated as

$$V = \int_{M_1}^{M_2} \mathbf{E} \, d\mathbf{r} = \frac{\tau}{2\pi \epsilon_0} \int_{r_0}^{d-r_0} \left(\frac{1}{r} + \frac{1}{d-r} \right) dr = \frac{\tau}{\pi \epsilon_0} \ln \frac{d-r_0}{r_0} \quad (2.73)$$

From Eq. (2.73) one finds that the capacitance of the two-wire line

$$C = \frac{Q}{V} = \frac{\pi \epsilon_0 l}{\ln[(d-r_0)/r_0]} \approx \frac{\pi \epsilon_0 l}{\ln(d/r_0)} \quad (2.74)$$

The capacitance of a wire located at a distance $d/2$ from the ground plane can be obtained using the doubled value given by Eq. (2.74).

2.6.2 Mutual Capacitance

In many technical problems one has to consider an electric field created by a system of some pairs of the bodies with the charges of opposite sign in each pair. The charges of these pairs and the voltages between them are connected by a system of linear equations.

In a system of two capacitors (bodies 1 and 1' and 2 and 2') shown in Fig. 2.45 all four bodies create their common electric field, and the charge of each capacitor depends on both voltages V_1 and V_2 . The field of Fig. 2.45 corresponds to the case when the potential of the body 1 is larger than the potential of the bodies 2 and 2' (with the potential of the body 2 larger than the potential of the body 2'), and the potential of the body 2' is larger than the potential of the body 1'. In this case the charge of one capacitor due to the voltage on another capacitor coincides with the charge created by the voltage on the capacitor itself. Hence, the total charges for the capacitors is

FIGURE 2.45 System of two capacitors.

$$\begin{aligned} Q_1 &= C_{11} V_1 + C_{12} V_2 \\ Q_2 &= C_{21} V_1 + C_{22} V_2 \end{aligned} \tag{2.75}$$

where C_{11} and C_{22} can be called self-capacitances of the first and second capacitor, correspondingly, and C_{12} and C_{21} can be called **mutual capacitances**.

The self-capacitances

$$C_{11} = \left. \frac{Q_1}{V_1} \right|_{V_2=0} \quad \text{and} \quad C_{22} = \left. \frac{Q_2}{V_2} \right|_{V_1=0} \tag{2.76}$$

are determined by all four bodies of the system and is different from the capacitances C_1 and C_2 of each of these capacitors when the other is absent. When one calculates the capacitance C_{11} , the condition $V_2 = 0$ simply means that the plates of another capacitor are connected by a wire, yet under the influence of the first capacitor the plates of this another capacitor obtain equal charges of opposite signs. The self-capitance C_{22} is calculated in a similar way.

The mutual capacitances

$$C_{12} = \left. \frac{Q_1}{V_2} \right|_{V_1=0} \quad \text{and} \quad C_{21} = \left. \frac{Q_2}{V_1} \right|_{V_2=0} \tag{2.77}$$

are determined by the ratios of the charge on the plates of shortened capacitor to the voltage at the plates of another capacitor, when this charge is induced by this voltage.

The mutual capacitance is determined by the geometric configuration of the bodies, their mutual location, and the dielectric permittivity of the media in which the bodies are immersed. Contrary to the self-capacitance, it can be positive or negative. The mutual capacitance is also measured in farads. Also, it is possible to show that

$$C_{12} = C_{21} \tag{2.78}$$

(this property is analogous to the reciprocity condition in passive networks (Scott, 1960)).

In the general case of a system of many capacitors, the charge Q_i of the i th capacitor is determined by all voltages, that is

$$Q_i = C_{ii} V_i + \sum_{i \neq j} C_{ij} V_j \tag{2.79}$$

where C_{ii} is the self-capacitance of the capacitor i (in the presence of other capacitances), and $C_{ij} = C_{ji}$ is the mutual capacitance between the capacitors i and j . This mutual capacitance is equal to the ratio of

the charge on i th capacitor to the voltage on j th capacitor, when all capacitors except the j th are short circuited.

A practical, important system of two mutually coupled capacitors (Kapliansky et al., 1972) is shown in Fig. 2.46. This is the system of two parallel lines of the length l symmetrically located with respect to each other. Let all wires have the same radius r_0 ; the distance between the wires is d_1 in the first line and d_2 in the second one. The lines are located in two parallel planes with the distance d between them. Assume as well that $l \gg r_0, d_1 \gg r_0, d_2 \gg r_0,$ and $d \gg r_0.$

FIGURE 2.46 Capacitively coupled transmission lines.

The charge on the left wire of the first line when it is shortened ($V_1 = 0$) can be found as the difference of the charges induced by the voltage V_2 via the capacitance between the wires 1 and 2 and via the capacitance between the wires 1 and 2'. Using the results of Sec. 2.6.1 one can write that

$$Q_1|_{V_1=0} = \frac{\pi \epsilon_0 l}{2 \ln(a/r_0)} V_2 - \frac{\pi \epsilon_0 l}{2 \ln(b/r_0)} V_2 = \frac{\pi \epsilon_0 l}{2} \frac{\ln(b/a)}{\ln(a/r_0) \ln(b/r_0)} V_2 \tag{2.80}$$

Here $a = (\frac{1}{2})\sqrt{[(d_1 - d_2)^2 + 4d^2]}$ and $b = (\frac{1}{2})\sqrt{[(d_1 + d_2)^2 + 4d^2]}$. Notice also the multiplier of 1/2 in Eq. (2.80) that arises due to the symmetry of the picture: one can assume that wire 2 has the potential $V_1/2$ and wire 2' has the potential $-V_1/2$ with respect to the ground. Thus, one finds that the mutual capacitance is equal to

$$C_{12} = \frac{\pi \epsilon_0 l}{2} \frac{\ln(b/a)}{\ln(a/r_0) \ln(b/r_0)} \tag{2.81}$$

and the self-capacitance of the first line, taking into consideration the presence of the second line, is equal to

$$C_{11} = \frac{\pi \epsilon_0 l}{\ln(d_1/r_0)} + \frac{\pi \epsilon_0 l}{2} \frac{\ln(b/a)}{\ln(a/r_0) \ln(b/r_0)} \tag{2.82}$$

The problem of calculating self-capacitances and mutual capacitances is important, for example, when it is required to determine the level of interference of the transmission line 2 with the communication line 1. This interference can be determined, for example, by the ratio of the charge $C_{12} V_2$ of the mutual capacitance to the charge $C_{11} V_1$ of the self-capacitance.

2.6.3 Energy Stored in the System of Charged Capacitors

Let n conducting bodies be located in a dielectric with permittivity ϵ with the potential of each body ϕ_k and the charge of each body equal to Q_k . It is possible to show (Stuart, 1965) that the energy stored in the electric field of this system is equal to

$$W = \frac{1}{2} \sum_k \phi_k Q_k \tag{2.83}$$

Hence, for one only body this energy will be

$$W = \frac{1}{2} \phi Q = \frac{C \phi^2}{2} = \frac{Q^2}{2C} \tag{2.84}$$

where $C = Q/\phi$ is the body capacitance. For a capacitor, that is the system of two bodies with $Q_1 = Q_2 = Q$ and the voltage $V = \phi_1 - \phi_2$ between the bodies, the energy will be

$$W = \frac{1}{2}\phi_1 Q_1 + \frac{1}{2}\phi_2 Q_2 = \frac{1}{2}Q(\phi_1 - \phi_2) = \frac{QV}{2} = \frac{CV^2}{2} = \frac{Q^2}{2C} \tag{2.85}$$

and it is a quadratic function of the charge Q or the voltage V .

Thus, capacitance can be considered as the concept of energy storage in an electric field. And the particular result (Eq. (2.85)) can be obtained (Stuart, 1965) easily if one accepts Eq. (2.62) as an experimental law of a linear capacitor. It is also known from experiment that work must be done in order to charge the capacitor and, therefore, the capacitor stores energy. This can be calculated as follows. If a current i is flowing into a capacitor with a voltage V across it, then the source is supplying power Vi . Hence, in time dt the energy supplied by the source is $Vi dt$. If there are no resistive elements in the system and the energy is not dissipated, then this energy must be stored in the capacitor. But $i = dQ/dt$, and thus the energy dW is given by VdQ . One also has the law (2.62) relating V and Q and, hence

$$dW = \frac{Q}{C}dQ \tag{2.86}$$

If the initial charge on the capacitor is zero, the final charge is Q , and the final voltage is V , then, indeed

$$W = \int_0^Q \frac{Q}{C}dQ = \frac{1}{2} \frac{Q^2}{C} = \frac{1}{2}CV^2 \tag{2.87}$$

This is the energy of the field created in the space around the capacitor plates.

The energy of two coupled capacitors (four bodies) will be

$$\begin{aligned} W &= \frac{Q_1 V_1}{2} + \frac{Q_2 V_2}{2} = \frac{(C_{11} V_1 + C_{12} V_2) V_1}{2} + \frac{(C_{21} V_1 + C_{22} V_2) V_2}{2} \\ &= \frac{C_{11} V_1^2}{2} + \frac{C_{22} V_2^2}{2} + C_{12} V_1 V_2 \end{aligned} \tag{2.88}$$

Hence, this energy includes the sum of energies stored in each capacitor and the term of mutual energy $C_{12} V_1 V_2$. This last energy can be positive or negative, and the energy of the whole system can be larger or smaller than the sum of the energies stored in each capacitor. Yet, the whole energy of the system will be always positive.

In the same way one can write that for a system of coupled capacitors the stored energy is

$$W = \sum_k \frac{C_k V_k^2}{2} + \sum_{p \neq k} C_{kp} V_k V_p \tag{2.89}$$

and one can show that it is always positive.

2.6.4 Capacitor as a Circuit Component

In an electric circuit the capacitor appears as a two-terminal element described by the following relationship between the current and voltage:

$$i(t) = C \frac{dv(t)}{dt} \tag{2.90}$$

where C is a positive real constant. The result (2.90) follows, of course, from the fact that the capacitor energy is stored as the energy of an electrostatic field and is given by Eq. (2.87). But dealing with an electric circuit one simply defines that if Eq. (2.90) is valid, this circuit element is a capacitor, and C is the capacitance. This element is denoted then as shown in Fig. 2.47(a).

FIGURE 2.47 Charged capacitor and its equivalent circuits in transients.

One can formulate some properties of this element that follow directly from this definition. If t_0 is an instant of time when the voltage on the capacitor is zero, and $p(t) = i(t)v(t)$ is the instant power in the capacitor, then the energy stored in the capacitor is

$$w(t) = \int_{t_0}^t p(t) dt = \int_{t_0}^t C \frac{dv(t)}{dt} v(t) dt = \frac{1}{2} C v^2(t) \tag{2.91}$$

This is the same result (2.87) that was obtained from the capacitor electric field consideration, except that the voltage is considered not as a constant but as a variable. One can see that the constant C is the capacitance and check that it is measured in farads. Indeed, the dimension of this unit, as follows from Eq. (2.90), is $(1 \text{ A/1 V}) 1 \text{ s} = 1 \text{ C/1 V} = 1 \text{ F}$ and coincides with the dimension followed from Eq. (2.62).

For any positive real C

$$\frac{1}{2} C v^2(t) \geq 0 \tag{2.92}$$

and the energy stored in the capacitor in the time interval t_1, t_2 is equal to

$$W = \frac{1}{2} C [v^2(t_2) - v^2(t_1)] \tag{2.93}$$

Hence, if $v(t_2) = v(t_1)$ the energy stored in the capacitor in this time interval is equal to zero for any arbitrary variation of voltage $v(t)$ between t_1 and t_2 . This means that if $v(t_3) > v(t_1)$ (here $t_1 < t_3 < t_2$) then the energy stored in the capacitor in the interval t_1, t_3 will be returned in the circuit during the interval t_3, t_2 ; the capacitor transforms the energy without dissipation. In other words, the energy stored in the capacitor equals zero at all instants when $v(t) = 0$, and in all other instants it is positive. Of course, this energy is stored as the energy of electrostatic field inside the capacitor; the capacitor does not have any stored energy if this electrostatic field is absent. The capacitor is a *definite component*. This means that if $v(t)$ is known the result (2.90) immediately provides the corresponding current $i(t)$. From the other side, if $i(t)$ is given, the voltage $v(t)$ can be found by an integration procedure. Yet, these two cases need some additional remarks (Biorci, 1975) if the relationship (2.90) is considered as a differential relationship that describes the input–output variables of a linear system.

If the voltage $v(t)$ is considered as an input variable, and the current $i(t)$ as an output variable, then in Eq. (2.90) the behavior of the current in a certain time interval is completely determined by the behavior of the voltage in this interval. In this case the solution of the differential equation (2.90) has the forced component only, it is not possible to determine a state variable, and the current is the function that is more impulsive than the voltage (e.g., if the voltage includes a step, the current should include a pulse). Hence,

the particular solution of the differential equation (2.90) coincides in this case with the full solution. The Laplace transform applied to Eq. (2.90) gives the relationship

$$I(s) = CsV(s) \tag{2.94}$$

If the current $i(t)$ is considered as an input variable and $v(t)$ as an output variable, the relationship (2.90) can be rewritten as

$$C \frac{dv(t)}{dt} = i(t) \tag{2.95}$$

In this differential equation the right part does not include any derivatives. In this case the solution, that is, the voltage $v(t)$, should be less impulsive than the current. Yet, the voltage will be known in a given time interval if the value of $v(t)$ is known at the initial point of this interval, and it is not necessary to know any derivatives of $v(t)$ at this instant. The voltage $v(t)$ in this case is called a *state variable*. This assumes that if $i(t)$ is equal to zero for all $t \leq 0$ and that if at $t = 0^-$ the state variable is zero, that is, $v(0^-) = 0$ (the capacitor is initially discharged) the solution of the differential equation (2.95) obtained using the Laplace transform gives the relationship

$$CsV(s) = I(s) \tag{2.96}$$

The relationships (2.94) and (2.96) show that considering the input-output relationships one can introduce two transfer functions, namely, the capacitor impedance

$$Z(s) = \frac{1}{Cs} \tag{2.97}$$

and the capacitor admittance

$$Y(s) = \frac{1}{Z(s)} = sC \tag{2.98}$$

Then in the stationary condition $s \rightarrow 0$ and $Z \rightarrow \infty$, and $Y \rightarrow 0$.

In the sinusoidal regime $s = j\omega = 2\pi f$, where f is the frequency, in hertz, and

$$Z(j\omega) = \frac{1}{j\omega C} = -j \frac{1}{\omega C} \tag{2.99}$$

and

$$Y(j\omega) = j\omega C \tag{2.100}$$

In this case $\dot{V} = (1/j\omega C)\dot{I}$ (here \dot{V} and \dot{I} are phasors) and $\dot{I} = j\omega C \dot{V}$. Thus, in the sinusoidal regime the capacitor is characterized by a reactance

$$X_C = \frac{1}{\omega C} \tag{2.101}$$

measured in ohms, and the current will lead the voltage by 90° .

When one is solving Eq. (2.95) (the input variable is voltage) the particular integral (forced response) coincides with the total response; this is not the case when one is solving Eq. (2.99) (the input variable is current). But even in this case, one can write, as it was in the case of zero initial conditions, that

$$v(t) = \frac{1}{C} \int_{0^-}^t i(t) dt \tag{2.102}$$

for $t \geq 0$. If the current $i(t)$ has a pulse component $Q\delta(t)$ at $t = 0$, then one can divide the integral in two parts (one is from $t = 0^-$ to $t = 0^+$, another from $t = 0^+$ to t) and write

$$v(t) = \left[\frac{1}{C} \int_{0^+}^t i(t) dt \right] \mathbf{1}(t) + \frac{Q}{C} \mathbf{1}(t) \quad (2.103)$$

(here the expression under integral does not include pulse components). Finally, if the capacitor initial condition is different from zero (nonzero state), and $v(0^-) = V_0$ one can write

$$v(t) = \frac{1}{C} \int_{0^-}^t i(t) dt + v(0^-) \quad (2.104)$$

which can be represented in two forms

$$v(t) = \left[\frac{1}{C} \int_{0^-}^t i(t) dt \right] \mathbf{1}(t) + V_0 \mathbf{1}(t) \quad (2.105)$$

and

$$v(t) = \left[\frac{1}{C} \int_{0^-}^t i(t) dt \right] \mathbf{1}(t) + \frac{Q}{C} \mathbf{1}(t) + V_0 \mathbf{1}(t) \quad (2.106)$$

depending on whether $i(t)$ is free of a pulse component at $t = 0$ or includes it.

It is easy to see from these expressions that $v(0^-) = v(0^+)$ excluding the case when $i(t)$ has a pulse component at $t = 0$. This is a formalization of the statement that the capacitor does resist to a change of voltage. If, in a circuit with this capacitor, at an instant $t = 0$ a perturbation occurs that is not able to produce a current pulse, then the capacitor preserves in $t = 0^+$ the voltage that it has at $t = 0^-$.

The Eq. (2.105) assumes that in calculation of transients an initially charged capacitor (Fig. 2.47(a)) can be substituted for by the equivalent circuit shown in Fig. 2.47(b) where the capacitor C is discharged at $t = 0^-$. Thus, the result of voltage variations preceding the instant $t = 0$ is summarized by the voltage $v(0^-) = V_0$. The Eq. (2.106) (much less useful) shows the capacitor equivalent circuit (Fig. 2.47(c)) if it is known *a priori* that the input includes a pulse current that appears at $t = 0$. If one considers the capacitance only at the instant $t = 0^+$, it can be substituted for by a voltage source with the voltage $v(0^-) = V_0$ (Fig. 2.47(d)) or simply by a short circuit (Fig. 2.47(e)) if the capacitor was initially discharged (assuming that there were no pulses in the current at $t = 0$).

Finally, if $v(t)$ is constant, the current $i(t)$ should be permanently zero. Or, it is better to say that if $v(t) = V_0 + v_1(t)$ the capacitor current is the same as if only the component $v_1(t)$ was applied. This particular property is important when the capacitor is used as a coupling element in electronic circuits.

Let us return to the analysis of the sinusoidal regime again. If

$$v(t) = \sqrt{2}V \cos \omega t \quad (2.107)$$

then, as follows from Eq. (2.90)

$$i(t) = -\sqrt{2}\omega CV \sin \omega t = -\sqrt{2}I \sin \omega t \quad (2.108)$$

where $I = V\omega C$, and the instantaneous power is given by

$$p(t) = v(t)i(t) = -2VI \cos \omega t \sin \omega t = -VI \sin 2\omega t \quad (2.109)$$

Hence, the instantaneous power is a sinusoidal variable, the frequency of which is two times larger than the frequency of the current. This power is plotted in Fig. 2.48 (which summarizes the capacitor properties). On the first half-cycle the power is negative, representing a flow of energy from the capacitance to the source. It does not mean that the capacitance can give up energy to the capacitance source before it gets

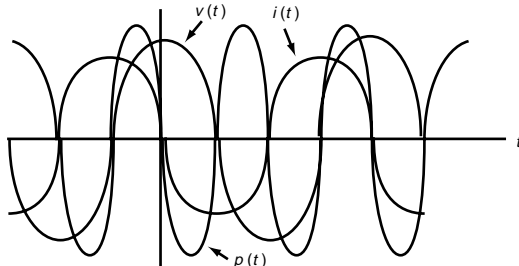

CAPACITOR

FIGURE 2.48 Summary of capacitor properties.

energy from the source. The system in the steady-state condition, and the original energy got into the capacitance during the original transient of the circuit, while the steady-state was being established. Yet, there is a general agreement to consider the instantaneous power in the capacitor with negative sign (Scott, 1960). The average value of this instantaneous power is zero. The active power is usually determined as the average value of the instantaneous power; hence, the capacitor does not have any active power. The instantaneous power in the capacitor is called *instantaneous reactive power* and its maximal value (with negative sign) is called *reactive power* and is denoted by Q . Thus

$$\text{reactive power} = Q = -VI = -\omega CV^2 = -\frac{I^2}{\omega C} = -\frac{V^2}{X_C} = -X_C I^2 \tag{2.110}$$

Again, there is a relationship between the reactive power and the average energy stored in the capacitance. The instantaneous energy is

$$w(t) = C \frac{v^2(t)}{2} = CV^2 \cos^2 \omega t = \frac{CV^2}{2} (1 + \cos 2\omega t) \tag{2.111}$$

and the average value of the energy stored is

$$W = \frac{CV^2}{2} \tag{2.112}$$

It is apparent that for a capacitor

$$Q = -2\omega W \tag{2.113}$$

2.6.5 Series and Parallel Connection of Capacitors

The formulas for series and parallel connection of capacitors can be obtained from the general consideration of series and parallel connection of impedances. For series connection

$$\frac{1}{sC} = \frac{1}{sC_1} + \frac{1}{sC_2} + \cdots + \frac{1}{sC_n} \quad (2.114)$$

where C_1, C_2, \dots, C_n are the capacitances of the capacitors connected in series. Then the equivalent capacitance C can be found as

$$C = \left(\frac{1}{C_1} + \frac{1}{C_2} + \cdots + \frac{1}{C_n} \right)^{-1} \quad (2.115)$$

and is always less than the value of the smallest capacitance. This result can be used when the conditions for using the impedance concept are valid, that is, the capacitors are discharged. The equivalent circuit of the series connection of charged capacitors can be obtained using equivalent circuits shown in [Fig. 2.47](#) and applying Thevenin's theorem (Scott, 1960).

A particular result, namely, the series connection of two capacitors has the equivalent capacitance

$$C = \frac{C_1 C_2}{C_1 + C_2} \quad (2.116)$$

In a similar way one can obtain the equivalent capacitance of parallel connection as

$$C = C_1 + C_2 + \cdots + C_n \quad (2.117)$$

and is always larger than the largest capacitance.

Furthermore, the following two results are useful (for initially discharged capacitors).

- The voltage applied to two capacitors connected in series is divided between these two capacitors inversely proportionally to their capacitance (thus, the larger part of the voltage is on the smaller capacitance).
- The current applied to two capacitors connected in parallel is divided between these two capacitors proportionally to their capacitance (thus, the larger part of the current goes through the larger capacitance).

2.6.6 Construction of Practical Capacitors

The properties of the capacitors that are used as discrete elements of electronic circuits will be described in the following sections (RIFA, 1990/91; Lindquist, 1977). Most of these capacitors are obtained by making contacts with a system of metal plates separated by a dielectric material.

One can divide these capacitors in three broad classes. The first class includes low-loss capacitors with good capacitance stability. These are (in accordance with the dielectric) mica, glass, some ceramic (of low K_d), and low-loss plastic film (polypropylene, polystyrene) capacitors. They are more expensive and should be used for critical precision circuitry (e.g., active and passive telecommunication filters). The second class are capacitors of medium loss and medium stability designed to operate over a wide range of DC and AC voltages. These are paper (oil and wax impregnated), plastic film, and ceramic (medium and high K_d) capacitors. Their DC applications include coupling, decoupling, bypass, smoothing and power separating filters, and energy storage, to mention a few. Their AC applications are no less wide and include motor start, lightning, interference suppression, power line applications (switching and measurement equipment), etc. The third class are aluminum and tantalum electrolytic capacitors providing high capacitance in a tolerable size; however, they do have drawbacks, which are discussed later. For the same rated voltage tantalum capacitors have as much as three times larger capacitance per volume unit as aluminum (for tantalum oxide $K_d = 27.6$, for aluminum oxide $K_d = 8$), they are more reliable and have longer service life.

The electrolytics are designed for DC and polarized voltage applications. Less expensive aluminum capacitors are used in radio and television equipment; more expensive tantalum capacitors are destined for military and harsh environmental applications.

There is a small group of fixed value capacitors (mica, glass, oil, gas and vacuum) designed for high-voltage (up to 35-kV peak), high-current (up to 200 A) transmitter applications. They and variable capacitors are not considered here.

Film and Foil Capacitors

In many cases the capacitor manufacturing process starts by forming one plate using metallization of one side of a flexible dielectric film. A foil (usually aluminum) is used as another plate. The film and foil combination (the nonmetallized film side meets the foil) is rolled on a plastic core with alternate layers slightly offset or extended (Fig. 2.49(a)). The wound roll is then heat treated to harden the film. Then the end disks (tinned copper) are connected. They are soldered to the extended ends of the foil using induction heating. At the metallization foil-ends side they are press fitted using conductive pastes. Subsequently, axial or radial-lead wires (tinned copper or nickel) are welded to the end caps (in some technologies the wires are welded before soldering). Then the capacitor is sealed. It may be dipped in a liquid dielectric, which afterwards dries out (or polymerized) wrapped in a plastic film and end filled, or may be encapsulated in a case or jacket of molded plastic.

FIGURE 2.49 Construction of discrete capacitors.

The variations of this basic process depend on the dielectric film used. For example, in some capacitors two foil layers can be divided by a plain film (polystyrene capacitors) (RIFA, 1990/91) or paper (impregnated with oil); two metallized offsetted films can be used as well (polypropylene capacitors). There are many other sealing procedures as well.

Solid Dielectric Capacitors

The capacitors with brittle dielectric (mica, glass, porcelain) and ceramic capacitors are constructed in stacks (Fig. 2.49(b)).

The dielectric layer is metallized at one side (e.g., a silver electrode is screened on the mica insulators in mica capacitors), then cut into rectangular pieces. The pieces are stacked with an offset of the alternative layers. The end caps are connected using press fitting and conductive pastes. Then the leads are connected and one of the sealing procedures follows.

The dielectric layer for ceramic capacitors is formed by preparing a barium titanate paste that is rolled into a flexible film. The film is covered by conducting ink to form the electrode layer. Then the film is cut, stacked into layers, and the procedure is completed in a manner similar to that already described.

Electrolytic Capacitors

The term *electrolytic capacitor* is applied to any capacitor in which the dielectric layer is formed by an electrolytic method; the capacitor itself does not necessarily contain an electrolyte. The electrolytic capacitors (both aluminum and tantalum) in dry foil form are similar in construction to paper film capacitors. Two foil layers separated by a paper spacer are rolled together. The paper, in this case, is impregnated with electrolyte. The oxygen from the electrolyte forms a thin layer of metal oxide with the anode metal. This metal oxide forms the capacitor dielectric. The capacitor is then hermetically sealed in an aluminum or plastic can. More frequently the metal (thicker) oxide is obtained in a separate process (RIFA, 1990/91) and etching is used to increase the surface area (as much as 300 times that of unetched foil, resulting in higher capacitance in the same volume). The thickness is controlled during the capacitor formation process. The wet form of a tantalum electrolytic capacitor ((Fig. 2.49(c))) includes a porous (to obtain a large active surface) anode slug obtained by pressing of metal tantalum powder with an imbedded tantalum lead. The slug is immersed into electrolyte (e.g., sulfuric acid which is used in most stable capacitors; this electrolyte can leak and corrode the equipment) and the tantalum pentoxide located on the surface of the slug pores forms the capacitor dielectric. The case and electrolyte form the capacitor cathode.

The solid form of tantalum electrolytic capacitors (Lindquist, 1977) differs from the wet version in the electrolyte, which is manganese dioxide (a semiconductor). It also includes a porous anode slug with preformed tantalum pentoxide on the surface and in the pores. Then the slug is covered first by a layer of manganese dioxide (which penetrates into pores in dissolved state), then by graphite and after that by a metal (silver) layer. The last two layers form the capacitor cathode. Then the capacitor is encapsulated. It can be a metal case (the metal layer can be soldered to the case; a nickel negative lead soldered to the silver layer allows to use metal shells backfilled with an epoxy resin) or plastic encasement (molded shells, plastic film, or sleeving).

Integrated Circuit Capacitors

There is a group of capacitors that are adapted to be used in microelectronic circuits. They are called *chip capacitors*. This group includes some ceramic capacitors (due to their small size), tantalum oxide solid capacitors, and tantalum electrolyte solid capacitors. The ceramic and tantalum oxide chips are unencapsulated and are usually fitted with end caps suitable for soldering to a microelectronic circuit board. The beam-leaded tantalum electrolytic chips can be attached by pressure bonding. They have a lower range of values (1 pF–0.027 μ F for temperature compensating ceramic, 100–3000 pF for tantalum oxide, 390 pF–0.47 μ F for general purpose ceramic, and 0.1–10 μ F for tantalum electrolyte) and a lower range of rated voltages (25–200 V for ceramic, 12–50 V for tantalum oxide, and 3–35 V for tantalum electrolyte). Other parameters are the same as for ordinary discrete capacitors.

FIGURE 2.50 Integrated circuit capacitors.

Another group can be found in the microelectronic circuits themselves. These monolayer capacitors appear, first of all, as thin-film tantalum oxide capacitors in some postprocessing technologies of integrated circuits. In this case a tantalum conducting layer is deposited on the top insulating layer of an integrated circuit. Then the bottom capacitor plate is formed using a photo resist-mask-stripping procedure. A dielectric layer covering the bottom plate is formed. In the case of the tantalum bottom plate, this is usually tantalum oxide, which is well controlled by oxidization. Then the top plate (usually aluminum) is deposited.

The plates of the capacitors of integrated circuits (Fig. 2.50(b)) in most modern technologies (Allstot and Black, 1983) are formed by two heavily doped polysilicon layers. The dielectric is usually a thin layer of silicon oxide. The whole capacitor is formed on a layer of thick (field) oxide. The capacitors are temperature stable, their temperature coefficient is about 20 ppm/°C. A detailed comparative evaluation of the different metal oxide semiconductor (MOS) capacitor structures can be found in Allstot and Black (1983).

Other dielectrics, in sensor applications, can be used as well (Boltshauser and Baltes, 1991). Such devices usually incorporate a dielectric with given sensitivity (to humidity, force, etc.) properties. The metallization layer formed on the top of dielectric frequently has a shape providing access of the measured physical variable to the dielectric.

2.6.7 Standard Values and Tolerances of Discrete Capacitors

The first two significant figures (for each of the standard tolerances 5, 10, and 20%) of the standard capacitor values are given in Table 2.18. Capacitors values have bimodal distribution, that is, the values tend to be grouped close to, but within, their tolerance values.

TABLE 2.18 Standard 5, 10, and 20% Capacitor Values

5%	10%	20%	5%	10%	20%
10	10	10	33	33	33
11			36		
12	12		39	39	
13			43		
15	15	15	47	47	47
16			51		
18	18		56	56	
20			62		
22	22	22	68	68	68
24			75		
27	27		82	82	
30			91		

Precision (and more expensive) capacitors having 0.25, 0.5, 0.625, 1, 2, and 3% tolerances (with the values that generally correspond to the 10% values of Table 2.19) are also available. For the capacitors in the small picofarads range, the tolerances can be given as ± 1.5 , ± 1 , ± 0.5 , ± 0.25 , and ± 0.1 pF. Usually low tolerance ranges do not include additional values, the capacitors values simply have tighter distribution. Yet, it is better to check the catalogs; some unpredictable values can be found.

2.6.8 Typical Parameters and Characteristics of Discrete Capacitors

The typical parameters (Lindquist, 1977; Horowitz and Hill, 1989) of the various discrete capacitors are summarized in Table 2.19. Some remarks pertaining to the parameters listed in the table follow.

Voltage Ratings

If the capacitor operating voltage becomes excessive, the electric field E in the dielectric exceeds the breakdown value E_{br} (which is the dielectric characteristic and is in the range 30–300 kV/cm), and the dielectric becomes permanently damaged. In continuous operation, the capacitor should always operate at a voltage that is less than its rated voltage V_R (which, of course, is less than the breakdown voltage V_{br}). Furthermore, this increases the capacitor's reliability and expected lifetime. Most capacitors have standard voltage ratings of 50, 100, 200, 400, and 600 V DC. The tantalum and electrolytic capacitors have ratings of 6, 10, 12, 15, 20, 25, 35, 50, 75, 100 V and higher.

A breakdown usually starts at the plate imperfections, in the points of more dense electric field. Yet, for a chosen technology it is possible to assume that $V_{br} = E_{br}d$ and, hence, is proportional to the dielectric thickness d . To increase the voltage rating of a capacitor, d should be increased. To maintain the same capacitance value $C = \epsilon_0 K_d S/d$, the area must also be increased. One can consider that the capacitor volume increases proportionally to the square of the voltage rating.

The *surge voltage* (or rated peak nonrepetitive voltage) specification of a capacitor determines its ability to withstand high transient voltages induced by a switching or any other disturbances of equipment operation. The allowable (for a limited number of times) surge voltage levels are generally 10% above the rated voltage for electrolytic capacitors (for aluminum capacitors with rated voltage lower than 300 V this figure can be as high as 50% (RIFA, 1990/91)). For ceramic and mica capacitors this voltage is called the *dielectric withstanding voltage* and can be as high as 250% of rated DC voltage.

For electrolytic capacitors the rated *reverse voltage* is specified as well. For aluminum capacitors (un-definite duration) this figure is 1.5 V (usually in the full temperature range). Higher reverse voltages can be applied for very short periods only; this causes some change in capacitance but not capacitor failure. The foil and wet tantalum capacitors have a rated reverse voltage of 3 V at $+85^\circ\text{C}$ and 2 V at $+125^\circ\text{C}$. Solid-electrolyte tantalum electrolytic capacitors can typically withstand a reverse voltage up to 15% of their rated voltage.

Temperature Coefficient

The temperature characteristic of capacitors depends primarily on the temperature dependence of the dielectric constant K_d . A low value of temperature coefficient is obtained for capacitors with dielectrics of low K_d .

Film, mica, glass, porcelain, and paper capacitors have K_d in the range 2–7, aluminum and tantalum electrolytic capacitors have K_d in the range 7–25. The ceramic capacitors are divided in three classes: capacitors with low K_d in the range 25–100, with medium K_d in the range 300–1800, and with high K_d in the range 2500–15,000.

Polycarbonate, polystyrene, polysulfone, teflon, mica, and glass capacitors have the smallest variation with temperature; for the last three types the temperature coefficient (TC) is practically constant in the whole temperature range of their operation.

The temperature behavior of ceramic capacitors depends on the K_d range, and the variation of K_d increases with its value. Yet, the temperature characteristics of ceramic capacitors can be tailored using special additions to the dielectric (barium titanate) and carefully controlled technology. A wide variety

TABLE 2.19 Parameters and Characteristics of Discrete Capacitors

Capacitor Type	Range	Rated Voltage, V_R	TC ppm/°C	Tolerance, $\pm\%$	Insulation Resistance, $M\Omega\mu F$	Dissipation Factor, %	Dielectric Absorption, %	Temperature Range, °C	Comments, Applications	Cost
Polycarbonate	100 pF–30 μF	50–800	± 50	10	5×10^5	0.2	0.1	–55/+125	High quality, small, low TC	High
Polyester/Mylar	1000 pF–50 μF	50–600	+400	10	10^5	0.75	0.3	–55/+125	Good, popular	Medium
Polypropylene	100 pF–50 μF	100–800	–200	10	10^5	0.2	0.1	–55/+105	High quality low absorption	High
Polystyrene	10 pF–2.7 μF	100–600	–100	10	10^6	0.05	0.04	–55/+85	High quality, large, low TC, signal filters	Medium
Polysulfone	1000 pF–1 μF		+80	5	10^5	0.3	0.2	–55/+150	High temperature	High
Parylene	5000 pF–1 μF		± 100	10	10^5	0.1	0.1	–55/+125		High

Thin-film	10 pF–200 pF	6–30	+100	10	10^6	0.01		–55/+125		High
Oil	0.1 μF –20 μF	200–10,000				0.5			High voltage filters, large, long life	
Vacuum	1 pF–1000 pF	2000–3600							Transmitters	

of negative TCs and a few positive TCs are available. The capacitors are marked in accordance with their temperature coefficient; the high-stability types have values ranging from P100 (positive, 100 ppm/°C) to N080 (negative, 80 ppm/°C). The most stable capacitors in this group are denoted as NPO type; they have temperature coefficient (nonspecified) ± 30 ppm/°C. The so-called temperature compensating types (they are frequently used in timing circuits, to compensate the positive temperature coefficient of a resistor) have values in the range from N150 to N750. The TC of high-stability and compensating capacitors is practically constant in the temperature range from -55 to $+125^\circ\text{C}$. Monolithic ceramic capacitors are capable of withstanding and operating at temperatures up to $+260^\circ\text{C}$ when properly designed and manufactured for these applications (ceramic cased capacitors); of course, in this case the temperature coefficient is not constant and the capacitor value itself can drop by as much as 60% (or even more when an additional DC voltage is superimposed).

Tantalum and aluminum capacitors have extremely large variations with temperature. At low temperatures the electrolyte can freeze; at high temperatures it can dry out.

Aluminum capacitors are usually designed for the range from -55 to $+125^\circ\text{C}$ (with the characteristics guaranteed for the range from -40 to $+105^\circ\text{C}$ (RIFA, 1990/91)); at -55°C the capacitance can drop down to 30% of its nominal value; the increase at $+125^\circ\text{C}$ is about 20%.

Tantalum capacitors can be usually designed for the range from -55 to $+200^\circ\text{C}$ (with the characteristics guaranteed for the range from -55 to $+125^\circ\text{C}$); at -55°C the capacitance can drop down to 60% of its nominal value (to 20–30% for large values of capacitance); the increase at $+125^\circ\text{C}$ is also about 20%. The capacitor change is less for devices with higher rated voltage (for example, the change for a capacitor of 150 V is approximately three times less than that of the capacitor of 6-V rated voltage).

Insulation Resistance

Capacitors are not ideal circuit elements. The equivalent circuit of a capacitor (valid from DC up to the low radio frequency range) is shown in Fig. 2.51(a). The shunt resistance R_p (which, in general, is the function of frequency) at DC and low frequencies is referred as the **insulation resistance** of the capacitor. It accounts for dielectric leakage current and dielectric power losses. When the capacitor is charged to $V(0)$ volts and allowed to discharge through itself, the capacitor voltage is

$$v(t) = V(0)[1 - \exp(-t/R_p C)] \quad (2.118)$$

If the time constant $R_p C$ is constant, it can be calculated measuring the voltage $V(0)$ and the voltage $V(T_e)$ that resides on the capacitor when the time T_e has elapsed. Then

$$R_p C = -T_e \ln[1 - V(T_e)/V(0)] \quad (2.119)$$

The time T_e is referred to as the *time of electrification* and is usually chosen to be one (RIFA, 1990/91) or two minutes (Lindquist, 1977). Since for a flat capacitor $C = \epsilon S/d$ and leakage resistance $R_p = \rho d/S$, where ρ is the resistivity of the dielectric, then $R_p C = \rho \epsilon$. Hence, the time constant $R_p C$ is a function of the dielectric properties and depends on the capacitor type only. This allows the use of $R_p C$ (measured in megaohm microfarad or in ohm farad) as a figure of merit (rather than R_p). This figure is referred to as *isolation resistance* in Table 2.19.

FIGURE 2.51 Capacitor equivalent circuits.

FIGURE 2.52 Temperature dependence of the insulation resistance.

The $R_p C$ product decreases (nearly exponentially for many dielectrics) when the temperature increases (Fig. 2.52). It is approximately halved (RIFA, 1990/91) for each $7^{\circ}C$ of temperature rise; the temperature where this decrease starts is different for different dielectrics. The $R_p C$ product also can vary with electrification time (due to dielectric absorption effects) and can increase (up to two orders of magnitude) in subsequent measurements.

In reality the $R_p C$ product depends on the capacitor package as well. For larger capacitor values the decrease with temperature starts earlier. Many manufacturers divide capacitors in groups and also give the R_p value for each group. This is especially valid for electrolytic capacitors; for these capacitors very frequently the rated leakage current I_{RL} is given. This current can be described by an empiric dependence

$$I_{RL} = kCV_R + 4 \tag{2.120}$$

where I_{RL} is in microamperes, V_R is the capacitor rated voltage in volts, C is the capacitance in microfarad, and $0.003 < k < 0.01$. The leakage current is also approximately proportional to temperature.

Dielectric Absorption

Dielectric absorption occurs in all solid dielectric capacitors. If a capacitor is charged for some prolonged period of time, then quickly discharged and allowed to stay open circuited for a certain period of time, a *recovery voltage* can be measured across the capacitor. This recovery voltage is due to residual energy stored in the dielectric that is not released during the original discharge period (the only perfect dielectric from that the whole of the stored energy may be recovered is a perfect vacuum). The dielectric absorption coefficient is determined as

$$DA = \frac{\text{recovery voltage}}{\text{charging voltage}} \tag{2.121}$$

The values listed in Table 2.19 are determined by charging the capacitor for 1 h at the rated voltage, discharging it for 10 s through 5Ω , and measuring the voltage 15 min after the resistor is disconnected. The dielectric absorption coefficient represent the losses in the capacitor that occur at pulse and high-frequency operation.

2.6.9 Capacitor Impedance Characteristic

The capacitor equivalent circuit shown in Fig. 2.51(a) includes, in addition to the insulation resistance R_p (which should represent, in this case, not only leakage but dielectric absorption losses as well), two other parasitic components. The resistance R_s mostly represents the losses in the lead contacts with the caps (and in electrolyte, for electrolytic capacitors). The inductance L represents the inductances of the leads and plates. Both R_s and L are usually small, but the influence of these parasitic components should be taken into consideration in radio frequency applications.

One can find (Lindquist, 1977) from the circuit of Fig. 2.51(a) that the total impedance of the capacitor is equal to

$$Z(s) = R_s + sL + \frac{R_p}{1 + sR_pC} = \frac{L[s^2 + s(1/R_pC + R_s/L) + (1 + R_s/R_p)/LC]}{s + 1/R_pC} \tag{2.122}$$

This impedance has a pole located at $s_p = -1/R_pC$ and two zeros. If the damping factor of the zeros

$$\zeta = \frac{1/R_pC + R_s/L}{2\sqrt{(1 + R_s/R_p)/(LC)}} \approx \frac{R_s}{2\sqrt{L/C}} \tag{2.123}$$

is small (low loss, $\zeta < 1$), the zeros are complex conjugate, having a resonant frequency $\omega_z = \sqrt{[(1 + R_s/R_p)/LC]} \approx 1/\sqrt{LC}$ since $R_s \ll R_p$ in all capacitors. A noticeable resonance effect occurs. The magnitude frequency characteristic for this case is shown in Fig. 2.53(a). If the damping factor is large (high loss, $\zeta > 1$) the zeros are real with values $s_{z1} = -1/R_sC$ and $s_{z2} = -R_s/L$. The magnitude frequency characteristic does not show any resonance (Fig. 2.53(b)). It is clear that the capacitor has a maximum usable frequency range between $1/R_pC$ and $1/\sqrt{LC}$ (low loss) or between $1/R_pC$ and $1/R_sC$ (high loss). The input resistance of the capacitor in the usable range is between R_p and R_s .

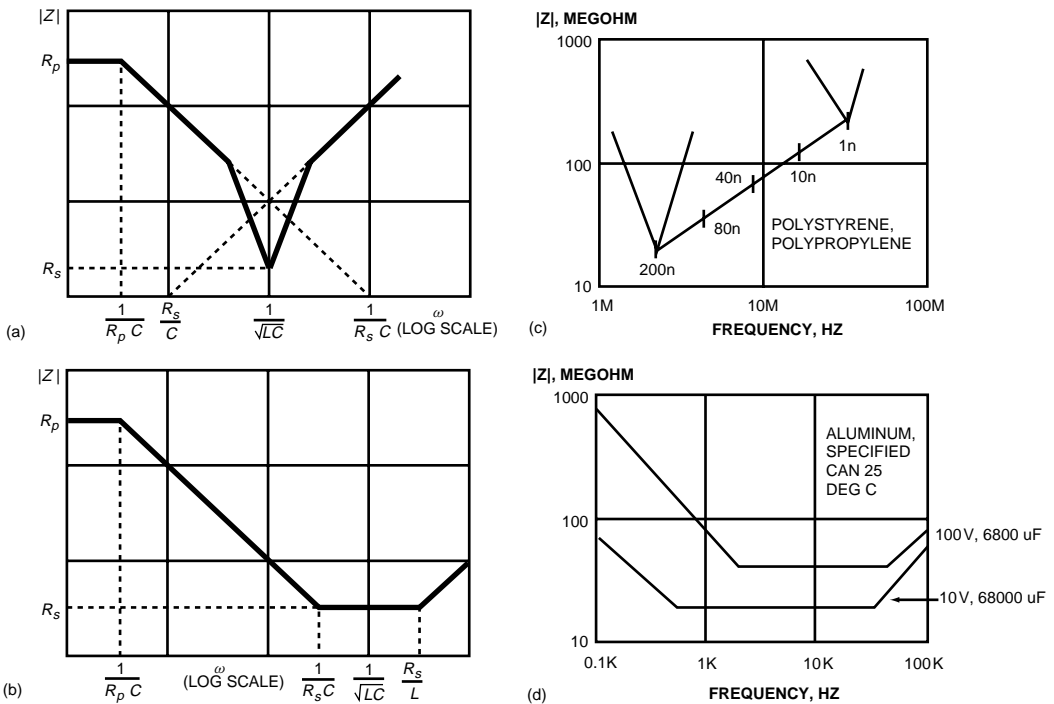

FIGURE 2.53 Capacitor impedance characteristics.

As was mentioned before, both R_p and R_s are functions of frequency, and it would be difficult to describe the capacitor impedance in a wide range of frequencies. Usually, a small part of the magnitude characteristic is given. For precision capacitors one can usually find the characteristics as shown in Fig. 2.53(c) and for the electrolytic capacitances as shown in Fig. 2.53(d). In both cases the characteristics are around the capacitor resonant frequency $\omega_z \approx 1/\sqrt{LC}$.

In this vicinity the equivalent circuit can be simplified. If the condition $\omega^2 R_p C \gg 1$ is satisfied, then

$$Z(j\omega) = R(\omega) + jX(\omega) = R_s + j\omega L + \frac{R_p}{1 + j\omega R_p C}$$

$$\approx R_s + \frac{1}{R_p \omega^2 C^2} + j\left(\omega L - \frac{1}{\omega C}\right) = R_{\text{ESR}} + j(X_L - X_C) \quad (2.124)$$

as it follows from Eq. (2.122). This equation allows us to obtain the parameters of the simplified equivalent circuit of the capacitor (Fig. 2.51(b)), where the effective series resistor $R_{\text{ESR}} = R_s + 1/(R_p \omega^2 C^2)$ represents all of the losses in R_p and R_s . For electrolytic capacitances the inductance L is usually 3–4 nH. For these capacitors R_{ESR} sharply increases at freezing temperatures (RIFA, 1990/91).

2.6.10 Power, Dissipation, and Quality Factors

If the capacitor impedance is represented at AC steady-state operation as

$$Z(j\omega) = R(\omega) + jX(\omega) \quad (2.125)$$

then several figures of merit can be used to describe the losses in the capacitors. The first one is the *power factor* (PF), which is defined as

$$\text{PF} = \frac{\text{power loss}}{\text{apparent power in}} = \frac{I^2 R}{I^2 |Z|} = \frac{R}{|Z|} = \cos \theta \quad (2.126)$$

Two other factors are the **dissipation factor** (DF) defined as

$$\text{DF} = \frac{\text{power loss}}{\text{reactive power stored}} = \frac{I^2 R}{I^2 X} = \frac{R}{X} = \cot \theta = \tan \delta \quad (2.127)$$

and its inverse, the capacitor *quality factor* $Q_C = 1/\text{DF} = X/R = \tan \theta$ (sometimes the DF is determined as the ratio of R_{ESR}/X_C , this approximation is satisfactory in the vicinity of the minimum value of DF magnitude). The DF and PF are essentially equal when the PF is 10% or less. The value δ is called the *angle of losses*.

Substituting $s = j\omega$ in Eq. (2.120) and finding the real and imaginary parts for the impedance $Z(j\omega)$ one can find that

$$\text{DF}(\omega) = \frac{\omega^2 R_s / L + (1 + R_s / R_p) / R_p L C^2}{\omega[\omega^2 - (1/LC - 1/(R_p C)^2)]} \approx \frac{R_s(\omega^2 - 1/R_p R_s C^2)}{\omega(\omega^2 - 1/LC)} \quad (2.128)$$

The magnitude of this frequency-dependent value is shown in Fig. 2.54(a). One can see that, over the maximum useful frequency range of the capacitor, the dissipation factor has a **minimum**. This minimum occurs in the vicinity of $\omega_{\text{min}} = 1/C\sqrt{(R_p R_s)}$ and it has the value of $\text{DF}_{\text{min}} \approx 2\sqrt{(R_s R_p)}$.

The standard measurements of DF are made at the frequency of 1 kHz with a 1V rms voltage applied to the capacitor. This frequency is usually close to $f_{\text{min}} = \omega_{\text{min}}/2\pi$ and the manufacturer frequently provides the plot of dissipation factor in the region of f_{min} (Fig. 2.54(b)) for different groups of capacitors. The dissipation factor at any given frequency is a function of the temperature. Usually, a capacitor is designed in such a way that this function is nearly flat in the industrial range of temperatures with an increase toward the ends of the full temperature range.

FIGURE 2.54 Capacitor dissipation factor.

The frequency dependence of the quality factor Q_C (this figure of merit usually applies to capacitors used in tuned circuits) and its maximal value can be found by inverting the $DF(\omega)$ characteristic. The standard measurements of Q_C for the tuned circuit capacitors are made at the frequency of 1 MHz.

2.6.11 Capacitor Reliability

About one-quarter of the part failures in electronic equipment are capacitor failures. One-half of these failures are caused by improper selection and application. Some typical causes of capacitor failure are: (1) voltage overload, (2) current overload, (3) high temperature, (4) frequency effects, (5) shock and vibration, (6) humidity, and (7) pressure.

Voltage overload produces an excessive electric field in the dielectric that, as was mentioned before, results in the breakdown and permanent damage of the dielectric.

Rapid voltage variations result in current transients. If these currents are of sufficient amplitude and duration, they can permanently damage the dielectric, deform the capacitor, and permanently change the capacitor value. Pulse current limits are commonly expressed in the form of maximal dV/dt in volts per microsecond. The figure is usually given when pulse operation is implied. The values (RIFA, 1990/91) are strongly dependent on the design and dielectric used; thus, for the metallized propylene pulse capacitors the maximal dV/dt can be from 20 to 120 V/ μ s; for the same metallized propylene power capacitors it will be from 100 to 500 V/ μ s; and for metallized paper interference suppressor capacitors this figure can be from 150 to 2000 V/ μ s. For electrolytic capacitors frequently used in power supply rectifiers the figure of rated ripple current (in milliamperes) at operating frequency (usually 100 or 120 Hz) and operating temperature (usually 100°C) is provided. Current overload can also occur when the capacitor operates at high frequencies.

High temperatures and overheating are also common causes of capacitor failure. Excessive temperature accelerates the dielectric aging, makes the plastic film brittle, and can cause cracks in hermetic seals.

Moisture and humidity cause corrosion, reduce the dielectric strength, and lower insulation resistance. Pressure variation, shock, and vibration can cause mechanical damages (seal cracks, etc.) that result in electrical failures. It is interesting to note that for electrolytic capacitors three parameters, namely, capacitance, leakage current, and the equivalent series resistor R_{ESR} are considered as the basic ones, and the failure of the capacitor after a test is established comparing the values of these parameters with the specified ones.

In calculation of capacitor reliability (Lindquist, 1977) it is assumed that capacitors have lifetimes that are exponentially distributed. In this case the distribution is characterized by one parameter only, namely, the mean time to failure (MTTF) τ_0 . The inverse of the MTTF is the failure rate of the component,

TABLE 2.20 Typical Failure Rates for Capacitors

Capacitor Type	Failure Rate (failures/10 ⁶ h)			T _{max} , °C
	Low	Average	High	
Paper/Film	0.0006	0.002	0.66	125
Ceramic (gen. purpose)	0.017	0.11	0.92	150
Ceramic (temp. compensating)	0.0006	0.008	0.41	100
Mica	0.004	0.013	1.0	125
Glass	0.0001	0.0042	0.49	125
Tantalum (gen. purpose)	0.042	0.15	1.7	85
Tantalum (established reliability)	0.0033	0.011	0.35	85
Aluminum (gen. purpose)	0.0096	0.047	1.8	85
Aluminum (established reliability)	0.0072	0.03	0.59	85

$\lambda = 1/\tau_0$. Some typical failure rates are listed in Table 2.20. In capacitors the thermal stress (temperature) and electrical stress (voltage) essentially determine the failure rate. The results in this table are based on voltage stress-temperature combinations: (0.1 V_{max}, 0°C) for low rate, (0.5 V_{max}, T_{max}/2°C) for average rate, and (V_{max}, T_{max}°C) for high rates. The contribution of overvoltage or overheating in each particular case varies from one dielectric to another, the combined stress is an acceptable compromise.

Table 2.20 also provides the so-called basic failure rate λ_0 . To obtain the failure rate that considers the capacitor environmental conditions, the basic rate λ_0 is multiplied by a factor π_E that increases from 1 for the case of nearly zero environmental stress with optimum engineering operation and maintenance to 15 for the case of severe conditions of noise, vibration, and other environmental stresses related to missile launch and space vehicle operation.

The failure rate depends on quality control as well. The failure rate of lower quality capacitors is obtained by multiplying the basic rate λ_0 by a multiplier π_Q . The value of this multiplier increases from 1 for high-quality capacitors to 4 for low-grade ones.

2.6.12 Aging and Radiation Effects

Capacitors exhibit aging effects (Lindquist, 1977) of varying degrees depending on their type. The data must be obtained from the manufacturer.

For frequently used ceramic capacitors the aging consists of a constant decrease of capacitance with time. The change is exponential and is expressed in percentage change per decade of time. The rate of change increases with increase of the dielectric constant K_d (Fig. 2.55). Little aging takes place after 1000 h (about 1.4 month). Usually preaging allowances are made by a manufacturer for the initial aging to maintain shelflife tolerances. Aging also reduces the capacitor insulation resistance.

Radiation gradually deteriorates certain plastic film and ceramic dielectrics (Lindquist, 1977). Organic dielectrics are more susceptible than inorganic dielectrics. Radiation reduces the insulation resistance and decomposes impregnates in paper capacitors. The radiation susceptibility for some capacitors is shown in Fig. 2.56. Glass, mica, and ceramic capacitors are the least susceptible. Film and electrolytic capacitors are average (tantalums are better than aluminums), and paper capacitors are the most susceptible.

FIGURE 2.55 Aging of ceramic capacitors.

FIGURE 2.56 Radiation damage of capacitors.

2.6.13 Nonlinear Dielectrics and Nonlinear Capacitors

The dielectric constant K_d of linear dielectrics does not depend on the electric field E . The electric flux density $D = \epsilon E = \epsilon_0 K_d E$ in such dielectrics is proportional to the field and

$$\epsilon = \frac{D}{E} = \text{const.} \tag{2.129}$$

Most of the dielectrics that have small K_d (1–7) are practically linear, and the dielectrics with high K_d are usually linearized (as in ceramic capacitors). As a result one has linear capacitances. Yet, nonlinear capacitors exist. The charge $Q = g(V)$ residing on this capacitor is a nonlinear function of the voltage V . The current in this case can be described by the equation

$$i(t) = \frac{dQ}{dt} = \frac{dg(v)}{dv} \frac{dv}{dt} = C(v) \frac{dv}{dt} \tag{2.130}$$

If the voltage v includes a bias component V_0 and a slowly changeable control component $V_C(t)$, then

$$i(t) = C[V_0 + V_C(t) + v] \left[\frac{dv}{dt} + \frac{dV_C(t)}{dt} \right] \tag{2.131}$$

If $V_C(t) \ll V_0, v \ll V_C(t)$, and $dv/dt \gg dV_C(t)/dt$, then

$$i(t) = C[V_0 + V_C(t)] \frac{dv}{dt} \tag{2.132}$$

One can see that in this case the capacitor can be controlled. The circuit with this capacitor can be used, for example, in FM oscillators (Clarke and Hess, 1971).

Nonlinear capacitors are realized as special hyper-abrupt p - n junctions. The devices are generally known as *varicaps* or *varactors*.

Defining Terms

Capacitance: Equal to the ratio $C = Q/V$ of the charge Q to the voltage V between two aforementioned conducting bodies.

Capacitor: A system of two conducting bodies located in the electromagnetic field and having equal charges $+Q$ and $-Q$ of opposite signs.

Dielectric absorption: Equal to the ratio of recovery voltage (the voltage which appears at the quickly discharged capacitor if it is allowed to stay open-circuited for one hour) to the initial charging voltage.

Dissipation factor: Equal to the ratio of power loss to the reactive power stored when a sinusoidal voltage is applied to the capacitor.

Farad: The measurement unit of capacitance; this is a very big unit, practical capacitors have the capacitances that are measured in nano-, micro-, and picofarads.

Insulation resistance: Equal to the time constant of the discharge of the initially charged capacitor when the capacitor is discharged through itself.

Mutual capacitance: Equal to the ratio of the charge on the plates of i th capacitor to the voltage at the plates of another j th capacitor, when this charge is induced by this voltage and when all capacitors except j th are short circuited.

2.7 Properties of Materials

James F. Shackelford

2.7.1 Introduction

The term *materials science and engineering* refers to that branch of engineering dealing with the processing, selection, and evaluation of solid-state materials (Shackelford, 1996). As such, this is a highly interdisciplinary field. This chapter reflects the fact that engineers outside of the specialized field of materials science and engineering largely need guidance in the selection of materials for their specific applications. A comprehensive source of property data for engineering materials is available in *The CRC Materials Science and Engineering Handbook* (Shackelford, Alexander, and Park, 1994). This brief chapter will be devoted to defining key terms associated with the properties of engineering materials and providing representative tables of such properties. Because the underlying principle of the fundamental understanding of solid-state materials is the fact that atomic- or microscopic-scale structure is responsible for the nature of materials properties, we shall begin with a discussion of structure. This will be followed by a discussion of the importance of specifying the chemical composition of commercial materials. These discussions will be followed by the definition of the main categories of materials properties.

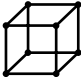

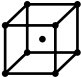

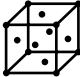

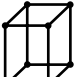

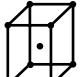

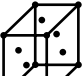

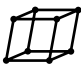

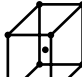

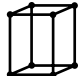

2.7.2 Structure

A central tenet of materials science is that the behavior of materials (represented by their **properties**) is determined by their structure on the atomic and microscopic scales (Shackelford, 1996). Perhaps the most fundamental aspect of the structure–property relationship is to appreciate the basic skeletal arrangement of atoms in **crystalline** solids. Table 2.21 illustrates the fundamental possibilities, known as the 14 **Bravais lattices**. All crystalline structures of real materials can be produced by decorating the unit cell patterns of Table 2.21 with one or more atoms and repetitively stacking the unit cell structure through three-dimensional space.

2.7.3 Composition

The properties of commercially available materials are determined by chemical composition as well as structure (Shackelford, 1996). As a result, extensive numbering systems have been developed to label materials, especially metal **alloys**. Table 2.22 gives an example for gray cast irons.

2.7.4 Physical Properties

Among the most basic and practical characteristics of engineering materials are their physical properties. Table 2.23 gives the **density** of a wide range of materials in units of mega gram per cubic meter (= gram per cubic centimeter), whereas Table 2.24 gives the **melting points** for several common metals and ceramics.

2.7.5 Mechanical Properties

Central to the selection of materials for structural applications is their behavior in response to mechanical loads. A wide variety of mechanical properties are available to help guide materials selection (Shackelford, Alexander, and Park, 1994). The most basic of the mechanical properties are defined in terms of the **engineering stress** and the **engineering strain**. The engineering stress σ is defined as

$$\sigma = \frac{P}{A_0} \tag{2.133}$$

where P is the load on the sample with an original (zero stress) cross-sectional area A_0 . The engineering strain ε is defined as

$$\varepsilon = \frac{[l - l_0]}{l_0} = \frac{\Delta l}{l_0} \quad (2.134)$$

where l is the sample length at a given load and l_0 is the original (zero stress) length. The maximum engineering stress that can be withstood by the material during its load history is termed the *ultimate tensile strength*, or simply **tensile strength** (TS). An example of the tensile strength for selected wrought (meaning worked, as opposed to cast) aluminum alloys is given in Table 2.25. The stiffness of a material is indicated by the linear relationship between engineering stress and engineering strain for relatively small levels of load application. The **modulus of elasticity** E , also known as **Young's modulus**, is given by the ratio

$$E = \frac{\sigma}{\varepsilon} \quad (2.135)$$

Table 2.26 gives values of Young's modulus for selected compositions of glass materials. The ductility of a material is indicated by the percent elongation at failure ($= 100 \times \epsilon_{\text{failure}}$), representing the general ability of the material to be plastically (i.e., permanently) deformed. The percent elongation at failure for selected polymers is given in Table 2.27.

2.7.6 Thermal Properties

Many applications of engineering materials depend on their response to a thermal environment. The **thermal conductivity** *k* is defined by **Fourier's law**

$$k = \frac{-\left[\frac{dQ}{dt}\right]}{\left[A\left(\frac{dT}{dx}\right)\right]} \tag{2.136}$$

^aEstimated.^b10–260°C. (Source: Data from ASM, 1984. *ASM Metals Reference Book*, 2nd ed., p. 172. American Society for Metals, Metals Park, OH.)

where dQ/dt is the rate of heat transfer across an area A due to a temperature gradient dT/dx . It is also important to note that the dimensions of a material, in general, increases with temperature. Increases in temperature lead to greater thermal vibration of the atoms and an increase in average separation distance of adjacent atoms. The **linear coefficient of thermal expansion** α is given by

$$\alpha = \frac{dl}{ldT} \quad (2.137)$$

with α having units of millimeter per millimeter degree Celsius. Examples of thermal conductivity and thermal expansion coefficient for alloy cast irons are given in Table 2.28.

2.7.7 Chemical Properties

A wide variety of data is available to characterize the nature of the reaction between engineering materials and their chemical environments (Shackelford, Alexander, and Park, 1994). Perhaps no such data are more fundamental and practical than the **electromotive force series** of metals shown in Table 2.29. The voltage associated with various half-cell reactions in standard aqueous environments are arranged in order, with

TABLE 2.29 Electromotive Force Series of Metals

the materials associated with more anodic reactions tending to be corroded in the presence of a metal associated with a more cathodic reaction.

2.7.8 Electrical and Optical Properties

To this point, we have concentrated on various properties dealing largely with the structural applications of engineering materials. In many cases the electromagnetic nature of the materials may determine their engineering applications. Perhaps the most fundamental relationship in this regard is **Ohm's law**, which states that the magnitude of current flow I through a circuit with a given resistance R and voltage V is related by

$$V = IR \tag{2.138}$$

where V is in units of volts, I is in amperes, and R is in ohms. The resistance value depends on the specific sample geometry. In general, R increases with sample length l and decreases with sample area A . As a result, the property more characteristic of a given material and independent of its geometry is **resistivity** ρ defined as

$$\rho = \frac{[RA]}{l} \tag{2.139}$$

The units for resistivity are ohm meter ($\Omega \cdot m$). Table 2.30 gives the values of electrical resistivity for various materials, indicating that metals typically have low resistivities (and correspondingly high electrical conductivities) and ceramics and polymers typically have high resistivities (and correspondingly low conductivities).

An important aspect of the electromagnetic nature of materials is their optical properties. Among the most fundamental optical characteristics of a light transmitting material is the **index of refraction** n defined as

$$n = \frac{v_{vac}}{v} \tag{2.140}$$

where v_{vac} is the speed of light in vacuum (essentially equal to that in air) and v is the speed of light in a transparent material. The index of refraction for a variety of polymers is given in Table 2.31.

TABLE 2.30 Electrical Resistivity of Selected Materials

Metal (Alloy Cast Iron)	$\rho, \Omega \cdot m$	Ceramic	$\rho, \Omega \cdot m$	Polymer	$\rho, \Omega \cdot m$
Low-C white cast iron	$0.53 \cdot 10^{-6}$	Al_2O_3	$>10^{13}$	ABS	$2-4 \cdot 10^{13}$
Martensitic Ni-Cr iron	$0.80 \cdot 10^{-6}$	B_4C	$0.3-0.8 \cdot 10^{-2}$	Acrylic	$>10^{13}$
High-Si iron	$0.50 \cdot 10^{-6}$	BN	$1.7 \cdot 10^{11}$	HDPE	$>10^{15}$
High-Ni iron	$1.4-1.7 \cdot 10^{-6}$	BeO	$>10^{15}$	Nylon 6/6	$10^{12}-10^{13}$
Ni-Cr-Si iron	$1.5-1.7 \cdot 10^{-6}$	MgO	$1.3 \cdot 10^{13}$	Phenolic	10^7-10^{11}
High-Al iron	$2.4 \cdot 10^{-6}$	SiC	$1-1 \cdot 10^{10}$	Polyacetal	10^{13}
Medium-Si ductile iron	$0.58-0.87 \cdot 10^{-6}$	Si_3N_4	10^{11}	Polypropylene	$>10^{15}$
High-Ni (20%) ductile iron	$1.02 \cdot 10^{-6}$	SiO_2	10^{16}	PTFE	$>10^{16}$

2.7.9 Additional Data

The following, more detailed tabular data are reprinted from: Dorf, R.C. 1993. *The Electrical Engineering Handbook*. CRC Press, Boca Raton, FL, pp. 2527–2544.

Electrical Resistivity

Electrical Resistivity of Pure Metals

The first part of this table gives the electrical resistivity, in units of $10^{-8} \Omega \cdot \text{m}$, for 28 common metallic elements as a function of temperature. The data refer to polycrystalline samples. The number of significant figures indicates the accuracy of the values. However, at low temperatures (especially below 50 K) the electrical resistivity is extremely sensitive to sample purity. Thus the low-temperature values refer to samples of specified purity and treatment.

The second part of the table gives resistivity values in the neighborhood of room temperature for other metallic elements that have not been studied over an extended temperature range.

Electrical Resistivity of Selected Alloy Cast Irons

Description	Electrical Resistivity, $\mu\Omega \cdot \text{m}$
Abrasion-resistant white irons	
Low-C white iron	0.53
Martensitic nickel–chromium iron	0.80
Corrosion-resistant irons	
High-silicon iron	0.50
High-chromium iron	
High-nickel gray iron	1.0 ^a
High-nickel ductile iron	1.0 ^a
Heat-resistant gray irons	
Medium-silicon iron	
High-chromium iron	
High-nickel iron	1.4–1.7
Nickel-chromium–silicon iron	1.5–1.7
High-aluminum iron	2.4
Heat-resistant ductile irons	
Medium-silicon ductile iron	0.58–0.87
High-nickel ductile (20 Ni)	1.02
High-nickel ductile (23 Ni)	1.0 ^a

^aEstimated. (Source: Data from 1984. *ASM Metals Reference Book*, 2nd ed. American Society for Metals, Metals Park, OH.)

Resistivity of Selected Ceramics (Listed by Ceramic)

Ceramic	Resistivity, $\Omega \cdot \text{cm}$
Borides	
Chromium diboride (CrB_2)	21×10^{-6}
Hafnium diboride (HfB_2)	$10\text{--}12 \times 10^{-6}$ at room temp.
Tantalum diboride (TaB_2)	68×10^{-6}
Titanium diboride (TiB_2) (polycrystalline)	
85% dense	$26.5\text{--}28.4 \times 10^{-6}$ at room temp.
85% dense	9.0×10^{-6} at room temp.
100% dense, extrapolated values	$8.7\text{--}14.1 \times 10^{-6}$ at room temp. 3.7×10^{-6} at liquid air temp.
Titanium diboride (TiB_2) (monocrystalline)	
Crystal length 5 cm, 39 and 59 deg. orientation with respect to growth axis	$6.6 \pm 0.2 \times 10^{-6}$ at room temp.
Crystal length 1.5 cm, 16.5 and 90 deg. orientation with respect to growth axis	$6.7 \pm 0.2 \times 10^{-6}$ at room temp.
Zirconium diboride (ZrB_2)	9.2×10^{-6} at 20°C 1.8×10^{-6} at liquid air temp.
Carbides: boron carbide (B_4C)	0.3–0.8

Dielectric Constants

Dielectric Constants of Solids: Temperatures in the Range $17\text{--}22^\circ\text{C}$

Material	Frequency (Hz)	Dielectric Constant	Material	Frequency (Hz)	Dielectric Constant
Acetamide	4×10^8	4.0	Phenanthrene	4×10^8	2.80
Acetanilide	—	2.9	Phenol (10°C)	4×10^8	4.3
Acetic acid (2°C)	4×10^8	4.1	Phosphorus, red	10^8	4.1
Aluminum oleate	4×10^8	2.40	Phosphorus, yellow	10^8	3.6
Ammonium bromide	10^8	7.1	Potassium aluminum sulfate	10^6	3.8
Ammonium chloride	10^8	7.0	Potassium carbonate (15°C)	10^8	5.6
Antimony trichloride	10^8	5.34	Potassium chlorate	6×10^7	5.1
Apatite \perp optic axis	3×10^8	9.50	Potassium chloride	10^4	5.03
Apatite \parallel optic axis	3×10^8	7.41	Potassium chromate	6×10^7	7.3
Asphalt	$<3 \times 10^6$	2.68	Potassium iodide	6×10^7	5.6
Barium chloride (anhyd.)	6×10^7	11.4	Potassium nitrate	6×10^7	5.0
Barium chloride ($2\text{H}_2\text{O}$)	6×10^7	9.4	Potassium sulfate	6×10^7	5.9
Barium nitrate	6×10^7	5.9	Quartz \perp optic axis	3×10^7	4.34
Barium sulfate (15°C)	10^8	11.4	Quartz \parallel optic axis	3×10^7	4.27
Beryl \perp optic axis	10^4	7.02	Resorcinol	4×10^8	3.2
Beryl \parallel optic axis	10^4	6.08	Ruby \perp optic axis	10^4	13.27
Calcite \perp optic axis	10^4	8.5	Ruby \parallel optic axis	10^4	11.28
Calcite \parallel optic axis	10^4	8.0	Rutile \perp optic axis	10^8	86
Calcium carbonate	10^6	6.14	Rutile \parallel optic axis	10^8	170
Calcium fluoride	10^4	7.36	Selenium	10^8	6.6
Calcium sulfate ($2\text{H}_2\text{O}$)	10^4	5.66	Silver bromide	10^6	12.2
Cassiterite \perp optic axis	10^{12}	23.4	Silver chloride	10^6	11.2
Cassiterite \parallel optic axis	10^{12}	24	Silver cyanide	10^6	5.6
<i>d</i> -Cocaine	5×10^8	3.10	Smithsonite \perp optic axis	10^{12}	9.3
Cupric oleate	4×10^8	2.80	Smithsonite \parallel optic axis	10^{10}	9.4
Cupric oxide (15°C)	10^8	18.1	Sodium carbonate (anhyd.)	6×10^7	8.4
Cupric sulfate (anhyd.)	6×10^7	10.3			
Cupric sulfate ($5\text{H}_2\text{O}$)	6×10^7	7.8			
Diamond	10^8	5.5			
Diphenylmethane	4×10^8	2.7			

(Continued)

Dielectric Constants of Solids: Temperatures in the Range 17–22°C (Continued)

Material	Frequency (Hz)	Dielectric constant	Material	Frequency (Hz)	Dielectric Constant
Dolomite \perp optic axis	10^8	8.0			
Dolomite \parallel optic axis	10^8	6.8	Sodium carbonate (10H ₂ O)	6×10^7	5.3
Ferrous oxide (15°C)	10^8	14.2	Sodium chloride	10^4	6.12
Iodine	10^8	4	Sodium nitrate	—	5.2
Lead acetate	10^6	2.6	Sodium oleate	4×10^8	2.75
Lead carbonate (15°C)	10^8	18.6	Sodium perchlorate	6×10^7	5.4
Lead chloride	10^6	4.2	Sucrose (mean)	3×10^8	3.32
Lead monoxide (15°C)	10^8	25.9	Sulfur (mean)	—	4.0
Lead nitrate	6×10^7	37.7	Thallium chloride	10^6	46.9
Lead oleate	4×10^8	3.27	<i>p</i> -Toluidine	4×10^8	3.0
Lead sulfate	10^6	14.3	Tourmaline \perp optic axis	10^4	7.10
Lead sulfide (15°)	10^6	17.9	Tourmaline \parallel optic axis	10^4	6.3
Malachite (mean)	10^{12}	7.2	Urea	4×10^8	3.5
Mercuric chloride	10^6	3.2	Zircon \perp, \parallel	10^8	12
Mercurous chloride	10^6	9.4			
Naphthalene	4×10^8	2.52			

Dielectric Constants of Ceramics

Material	Dielectric Constant, 10^6 Hz	Dielectric Strength V/mil	Volume Resistivity $\Omega \cdot \text{cm}$ (23°C)	Loss Factor ^a
Alumina	4.5–8.4	40–160	10^{11} – 10^{14}	0.0002–0.01
Corderite	4.5–5.4	40–250	10^{12} – 10^{14}	0.004–0.012
Forsterite	6.2	240	10^{14}	0.0004
Porcelain (dry process)	6.0–8.0	40–240	10^{12} – 10^{14}	0.0003–0.02
Porcelain (wet process)	6.0–7.0	90–400	10^{12} – 10^{14}	0.006–0.01
Porcelain, zircon	7.1–10.5	250–400	10^{13} – 10^{15}	0.0002–0.008
Steatite	5.5–7.5	200–400	10^{13} – 10^{15}	0.0002–0.004
Titanates (Ba, Sr, Ca, Mg, and Pb)	15–12.000	50–300	10^8 – 10^{15}	0.0001–0.02
Titanium dioxide	14–110	100–210	10^{13} – 10^{18}	0.0002–0.005

^aPower factor \times dielectric constant equals loss factor.

Dielectric Constants of Glasses

Type	Dielectric Constant at 100 MHz (20°C)	Volume Resistivity (350°C M $\Omega \cdot \text{cm}$)	Loss Factor ^a

Part A. Data on Valence Bands of Semiconductors (Room Temperature)

Substance	Band Curvature Effective Mass (expressed as fraction of free electron mass)				Energy Separation of Split-Off Band, eV	Measured (light) Hole Mobility cm ² /V · s
	Heavy Holes	Light Holes	Split-off Band Holes			
Semiconductors with Valence Band Maximum at the Center of the Brillouin Zone ("F")						
Si	0.52	0.16	0.25		0.044	500
Ge	0.34	0.043	0.08		0.3	1820
Sn	0.3					2400
AlAs						
AlSb	0.4				0.7	550
GaP					0.13	100
GaAs	0.8	0.12	0.20		0.34	400
GaSb	0.23	0.06			0.7	1400
InP					0.21	150
InAs	0.41	0.025	0.083		0.43	460
InSb	0.4	0.015			0.85	750
CbTe	0.35					50
HgTe	0.5					350
Semiconductors with Multiple Valence Band Maxima						
Substance	Number of Equivalent Valleys and Direction	Band Curvature Effective Masses			Anisotropy, $K = m_L/m_T$	Measured (light) Hole Mobility, cm ² /V · s
		Longitudinal m_L	Transverse m_T			
PbSe	4 "L" [111]	0.095	0.047		2.0	1,500
PbTe	4 "L" [111]	0.27	0.02		10	750
Bi ₂ Te ₃	6	0.207	~0.045		4.5	515

Part B. Data on conduction Bands of Semiconductors (Room Temperature Data)

Single Valley Semiconductors					
Substance	Energy Gap, eV	Effective Mass (m_0)	Mobility $\text{cm}^2/\text{V} \cdot \text{s}$	Comments	
GaAs	1.35	0.067	8500	3 (or 6?) equivalent [100] valleys 0.36 eV above this maximum with a mobility of ~ 50	
InP	1.27	0.067	5000	3 (or 6?) equivalent [100] valleys 0.4 eV above this minimum	
InAs	0.36	0.022	33,000	Equivalent valleys ~ 1.0 eV above this minimum	
InSb	0.165	0.014	78,000		
CdTe	1.44	0.11	1000	4 (or 8?) equivalent [111] valleys 0.51 eV above this minimum	

Multivalley Semiconductors					
Substance	Energy Gap	Number of Equivalent Valleys and Direction	Band Curvature Effective Mass		Anisotropy $K = m_L/m_T$
			Longitudinal m_L	Transverse m_T	
Si	1.107	6 in [100] Δ	0.90	0.192	4.7
Ge	0.67	4 in [111] at L	1.588	0.0815	19.5
GaSb	0.67	as Ge (?)	~ 1.0	~ 0.2	~ 5
PbSe	0.26	4 in [111] at L	0.085	0.05	1.7
PbTe	0.25	4 in [111] at L	0.21	0.029	5.5
Bi_2Te_3	0.13	6			~ 0.05

Resistivity of Semiconducting Minerals

Mineral	$\rho, \Omega \cdot \text{m}$	Mineral	$\rho, \Omega \cdot \text{m}$
Diamond (C)	2.7	Gersdorffite, NiAsS	1 to 160×10^{-6}
Sulfides		Glaucodote, (Co, Fe)AsS	5 to 100×10^{-6}
Argentite, Ag_2S	1.5 to 2.0×10^{-3}	Antimonide	
Bismuthinite, Bi_2S_3	3 to 570	Dyscrasite, Ag_3Sb	0.12 to 1.2×10^{-6}
Bornite, $\text{Fe}_2\text{S}_3 \cdot n\text{Cu}_2\text{S}$	1.6 to 6000×10^{-6}	Arsenides	
Chalcocite, Cu_2S	80 to 100×10^{-6}	Allemonite, SbAs_2	70 to 60,000
Chalcopyrite, $\text{Fe}_2\text{S}_3 \cdot \text{Cu}_2\text{S}$	150 to 9000×10^{-6}	Lollingite, FeAs_2	2 to 270×10^{-6}
Covellite, CuS	0.30 to 83×10^{-6}	Nicollite, NiAs	0.1 to 2×10^{-6}
Galena, PbS	6.8×10^{-6} to 9.0×10^{-2}	Skutterudite, CoAs_3	1 to 400×10^{-6}
Haverite, MnS_2	10 to 20	Smaltite, CoAs_2	1 to 12×10^{-6}
Marcasite, FeS_2	1 to 150×10^{-3}	Tellurides	
Metacinnabarite, 4HgS	2×10^{-6} to 1×10^{-3}	Altaite, PbTe	20 to 200×10^{-6}
Millerite, NiS	2 to 4×10^{-7}	Calavarite, AuTe_2	6 to 12×10^{-6}
Molybdenite, MoS_2	0.12 to 7.5	Coloradoite, HgTe	4 to 100×10^{-6}
Pentlandite, $(\text{Fe, Ni})_9\text{S}_8$	1 to 11×10^{-6}	Hessite, Ag_2Te	4 to 100×10^{-6}
Pyrrhotite, Fe_7S_8	2 to 160×10^{-6}	Nagyagite, $\text{Pb}_6\text{Au}(\text{S, Te})_{14}$	20 to 80×10^{-6}
Pyrite, FeS_2	1.2 to 600×10^{-3}	Sylvanite, AgAuTe_4	4 to 20×10^{-6}
Sphalerite, ZnS	2.7×10^{-3} to 1.2×10^4	Oxides	
Antimony-sulfur compounds		Braunite, Mn_2O_3	0.16 to 1.0
Berthierite, FeSb_2S_4	0.0083 to 2.0	Cassiterite, SnO_2	4.5×10^{-4} to 10,000
Boulangerite, $\text{Pb}_5\text{Sb}_4\text{S}_{11}$	2×10^3 to 4×10^4	Cuprite, Cu_2O	10 to 50
Cylindrite, $\text{Pb}_3\text{Sn}_4\text{Sb}_2\text{S}_{14}$	2.5 to 60	Hollandite, $(\text{Ba, Na, K})\text{Mn}_8\text{O}_{16}$	2 to 100×10^{-3}
Franckeite, $\text{Pb}_5\text{Sn}_3\text{Sb}_2\text{S}_{14}$	1.2 to 4	Ilmenite, FeTiO_3	0.001 to 4
Hauchecornite, $\text{Ni}_9(\text{Bi, Sb})_2\text{S}_8$	1 to 83×10^{-6}	Magnetite, Fe_3O_4	52×10^{-6}
Jamesonite, $\text{Pb}_4\text{FeSb}_6\text{S}_{14}$	0.020 to 0.15	Manganite, $\text{MnO} \cdot \text{OH}$	0.018 to 0.5
Tetrahedrite, Cu_3SbS_3	0.30 to 30,000	Melaconite, CuO	6000

(Continued)

Resistivity of Semiconducting Minerals (Continued)

Mineral	$\rho, \Omega \cdot \text{m}$	Mineral	$\rho, \Omega \cdot \text{m}$
Arsenic-sulfur compounds		Psilomelane, $\text{KMnO} \cdot \text{MnO}_2 \cdot n\text{H}_2\text{O}$	0.04 to 6000
Arsenopyrite, FeAsS	20 to 300×10^{-6}	Pyrolusite, MnO_2	0.007 to 30
Cobaltite, CoAsS	6.5 to 130×10^{-3}	Rutile, TiO_2	29 to 910
Enargite, Cu_3AsS_4	0.2 to 40×10^{-3}	Uraninite, UO	1.5 to 200

^a θ_N = Néel temperature, determined from susceptibility maxima or from the disappearance of magnetic scattering.

^b θ_P = a constant in the Curie-Weiss law written in the form $\chi_A = C_A/(T + \theta_P)$, which is valid for antiferromagnetic material for $T > \theta_N$.

^c $(P_A)_{\text{eff}}$ = effective moment per atom, derived from the atomic Curie constant $C_A = (P_A)_{\text{eff}}^2 (N^2/3R)$ and expressed in units of the Bohr magneton, $\mu_B = 0.9273 \times 10^{-20}$ erg G⁻¹.

^d P_A = magnetic moment per atom, obtained from neutron diffraction measurements in the ordered state.

Properties of Magnetic Alloys: Saturation Constants and Curie Points of Ferromagnetic Elements

Element	σ_s^a (20°C)	M_s^b (20°C)	σ_s (0 K)	n_B^c	Curie point, °C
Fe	218.0	1,714	221.9	2.219	770
Co	161	1,422	162.5	1.715	1,131
Ni	54.39	484.1	57.50	0.604	358
Gd	0	0	253.5	7.12	16

^a σ_s = saturation magnetic moment/gram.

^b M_s = saturation magnetic moment/cm³, in cgs units.

^c n_B = magnetic moment per atom in Bohr magnetons.

^bHR, hot rolled or froged; CR, cold rolled or drawn; M, machined; G, must be ground; P, punched; C, cast; Sn, sintered.

^cH, hard; B, brittle; S, strong; D, ductile; M, malleable; W, weak.

^dValue given is intrinsic H_c .

Resistance of Wires

The following table gives the approximate resistance of various metallic conductors. The values have been computed from the resistivities at 20°C, except as otherwise stated, and for the dimensions of wire indicated. Owing to differences in purity in the case of elements and of composition in alloys, the values can be considered only as approximations.

The following dimensions have been adopted in the computation.

			Diameter			Diameter		
			mils			mils		
B. & S.			1 mil =			1 mil =

Defining Terms

Alloy: Metal composed of more than one element.

Bravais lattice: One of the 14 possible arrangements of points in three-dimensional space.

Crystalline: Having constituent atoms stacked together in a regular, repeating pattern.

Density: Mass per unit volume.

Electromotive force series: Systematic listing of half-cell reaction voltages.

Engineering strain: Increase in sample length at a given load divided by the original (stress-free) length.

Engineering stress: Load on a sample divided by the original (stress-free) area.

Fourier's law: Relationship between rate of heat transfer and temperature gradient.

Index of refraction: Ratio of speed of light in vacuum to that in a transparent material.

Linear coefficient of thermal expansion: Material parameter indicating dimensional change as a function of increasing temperature.

Melting point: Temperature of transformation from solid to liquid upon heating.

Ohm's law: Relationship between voltage, current, and resistance in an electrical circuit.

Property: Observable characteristic of a material.

Resistivity: Electrical resistance normalized for sample geometry.

Tensile strength: Maximum engineering stress during a tensile test.

Thermal conductivity: Proportionality constant in Fourier's law.

Young's modulus (modulus of elasticity): Ratio of engineering stress to engineering strain for relatively small levels of load application.

2.8 International Standards and Constants¹

2.8.1 International System of Units (SI)

The International System of units (SI) was adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960. It is a coherent system of units built from seven *SI base units*, one for each of the seven dimensionally independent base quantities: they are the meter, kilogram, second, ampere, kelvin, mole, and candela, for the dimensions length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity, respectively. The definitions of the SI base units are given subsequently. The *SI derived units* are expressed as products of powers of the base units, analogous to the corresponding relations between physical quantities but with numerical factors equal to unity.

In the International System there is only one SI unit for each physical quantity. This is either the appropriate SI base unit itself or the appropriate SI derived unit. However, any of the approved decimal prefixes, called *SI prefixes*, may be used to construct decimal multiples or submultiples of SI units.

It is recommended that only SI units be used in science and technology (with SI prefixes where appropriate). Where there are special reasons for making an exception to this rule, it is recommended always to define the units used in terms of SI units. This section is based on information supplied by IUPAC.

Definitions of SI Base Units

Meter: The meter is the length of path traveled by light in vacuum during a time interval of $1/299\,792\,458$ of a second (17th CGPM, 1983).

Kilogram: The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram (3rd CGPM, 1901).

Second: The second is the duration of $9\,192\,631\,770$ periods of the radiation corresponding the transition between the two hyperfine levels of the ground state of the cesium-133 atom (13th CGPM, 1967).

Ampere: The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length (9th CGPM, 1948).

Kelvin: The kelvin, unit of thermodynamic temperature, is the fraction $1/273.16$ of the thermodynamic temperature of the triple point of water (13th CGPM, 1967).

Mole: The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12. When the mole is used, the elementary entities must

¹Material herein was reprinted from the following sources:

Lide, D.R., ed. 1992. *CRC Handbook of Chemistry and Physics*, 76th ed. CRC Press, Boca Raton, FL: International System of Units (SI), symbols and terminology for physical and chemical quantities, classification of electromagnetic radiation.

Zwillinger, D., ed. 1996. *CRC Standard Mathematical Tables and Formulae*, 30th ed. CRC Press, Boca Raton, FL: Greek alphabet, physical constants.

be specified and may be atoms, molecules, ions, electrons, or other particles, or specified groups of such particles (14th CGPM, 1971).

Examples of the use of the mole:

- 1 mol of H₂ contains about 6.022×10^{23} H₂ molecules, or 12.044×10^{23} H atoms
- 1 mol of HgCl has a mass of 236.04 g
- 1 mol of Hg₂Cl₂ has a mass of 472.08 g
- 1 mol of Hg₂²⁺ has a mass of 401.18 g and a charge of 192.97 kC
- 1 mol of Fe_{0.91}S has a mass of 82.88 g
- 1 mol of e⁻ has a mass of 548.60 μg and a charge of -96.49 kC
- 1 mol of photons whose frequency is 10¹⁴ Hz has energy of about 39.90 kJ

Candela: The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of (1/683) watt per steradian (16th CGPM, 1979).

Names and Symbols for the SI Base Units

Physical Quantity	Name of SI Unit	Symbol for SI Unit
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

SI Derived Units with Special Names and Symbols

Physical Quantity	Name of SI Unit	Symbol for SI Unit	Expression in Terms of SI Base Units
Frequency ^a	hertz	Hz	s ⁻¹
Force	newton	N	m kg s ⁻²
Pressure, stress	pascal	Pa	N m ⁻² = m ⁻¹ kg s ⁻²
Energy, work, heat	joule	J	N m = m ² kg s ⁻²
Power, radiant flux	watt	W	J s ⁻¹ = m ² kg s ⁻³
Electric charge	coulomb	C	A s
Electric potential, electromotive force	volt	V	J C ⁻¹ = m ² kg s ⁻³ A ⁻¹
Electric resistance	ohm	Ω	V A ⁻¹ = m ² kg s ⁻³ A ⁻²
Electric conductance	siemens	S	Ω ⁻¹ = m ⁻² kg ⁻¹ s ³ A ²
Electric capacitance	farad	F	C V ⁻¹ = m ⁻² kg ⁻¹ s ⁴ A ²
Magnetic flux density	tesla	T	V s m ⁻² = kg s ⁻² A ⁻¹
Magnetic flux	weber	Wb	V s = m ² kg s ⁻² A ⁻¹
Inductance	henry	H	V A ⁻¹ s = m ² kg s ⁻² A ⁻²
Celsius temperature ^b	degree Celsius	°C	K
Luminous flux	lumen	lm	cd sr
Illuminance	lux	lx	cd sr m ⁻²
Activity (radioactive)	becquerel	Bq	s ⁻¹
Absorbed dose (of radiation)	gray	Gy	J kg ⁻¹ = m ² s ⁻²
Dose equivalent (dose equivalent index)	sievert	Sv	J kg ⁻¹ = m ² s ⁻²
Plane angle	radian	rad	1 = m m ⁻¹
Solid angle	steradian	sr	1 = m ² m ⁻²

^aFor radial (circular) frequency and for angular velocity the unit rad s⁻¹, or simply s⁻¹, should be used, and this may not be simplified to Hz. The unit Hz should be used only for frequency in the sense of cycles per second.

^bThe Celsius temperature θ is defined by the equation:

$$\theta / ^\circ\text{C} = T / \text{K} - 273.15$$

The SI unit of Celsius temperature interval is the degree Celsius, °C, which is equal to the kelvin, K. °C should be treated as a single symbol, with no space between the ° sign and the letter C. (The symbol °K and the symbol °, should no longer be used.)

Units in Use Together with the SI

These units are not part of the SI, but it is recognized that they will continue to be used in appropriate contexts. SI prefixes may be attached to some of these units, such as milliliter, ml; millibar, mbar; megaelectronvolt, MeV; kilotonne, ktonne.

Physical Quantity	Name of Unit	Symbol for Unit	Value in SI Units
Time	minute	min	60 s
Time	hour	h	3600 s
Time	day	d	86 400 s
Plane angle	degree	°	($\pi/180$) rad
Plane angle	minute	'	($\pi/10\ 800$) rad
Plane angle	second	"	($\pi/648\ 000$) rad
Length	ångström ^a	Å	10^{-10} m
Area	barn	b	10^{-28} m ²
Volume	litre	l, L	dm ³ = 10^{-3} m ³
Mass	tonne	t	Mg = 10^3 kg
Pressure	bar ^a	bar	10^5 Pa = 10^5 N m ⁻²
Energy	electronvolt ^b	eV (= $e \times V$)	$\approx 1.60218 \times 10^{-19}$ J
Mass	unified atomic mass unit ^{b,c}	u (= $m_a(^{12}\text{C})/12$)	$\approx 1.66054 \times 10^{-27}$ kg

^aThe ångström and the bar are approved by CIPM for temporary use with SI units, until CIPM makes a further recommendation. However, they should not be introduced where they are not used at present.

^bThe values of these units in terms of the corresponding SI units are not exact, since they depend on the values of the physical constants e (for the electronvolt) and N_A (for the unified atomic mass unit), which are determined by experiment.

^cThe unified atomic mass unit is also sometimes called the dalton, with symbol Da, although the name and symbol have not been approved by CGPM.

Greek Alphabet

2.8.2 Physical Constants

General

Equatorial radius of the Earth = 6378.388 km = 3963.34 miles (statute).

Polar radius of the Earth, 6356.912 km = 3949.99 miles (statute).

1 degree of latitude at 40° = 69 miles.

1 international nautical mile = 1.15078 miles (statute) = 1852 m = 6076.115 ft.

Mean density of the Earth = 5.522 g/cm³ = 344.7 lb/ft³

Constant of gravitation (6.673 ± 0.003) $\times 10^{-8}$ /cm³gm⁻¹s⁻².

Acceleration due to gravity at sea level, latitude 45° = 980.6194 cm/s² = 32.1726 ft/s².

Length of seconds pendulum at sea level, latitude 45° = 99.3575 cm = 39.1171 in.

- 1 knot (international) = 101.269 ft/min = 1.6878 ft/s = 1.1508 miles (statute)/h.
- 1 micron = 10^{-4} cm.
- 1 ångstrom = 10^{-8} cm.
- Mass of hydrogen atom = $(1.67339 \pm 0.0031) \times 10^{-24}$ g.
- Density of mercury at 0°C = 13.5955 g/ml.
- Density of water at 3.98°C = 1.000000 g/ml.
- Density, maximum, of water, at 3.98°C = 0.999973 g/cm³.
- Density of dry air at 0°C, 760 mm = 1.2929 g/l.
- Velocity of sound in dry air at 0°C = 331.36 m/s = 1087.1 ft/s.
- Velocity of light in vacuum = $(2.997925 \pm 0.000002) \times 10^{10}$ cm/s.
- Heat of fusion of water 0°C = 79.71 cal/g.
- Heat of vaporization of water 100°C = 539.55 cal/g.
- Electrochemical equivalent of silver 0.001118 g/s international amp.
- Absolute wavelength of red cadmium light in air at 15°C, 760 mm pressure = 6438.4696 Å.
- Wavelength of orange-red line of krypton 86 = 6057.802 Å.

3.1 Crystal Oscillators

Jeffrey P. Tate and Patricia F. Mead

3.1.1 Introduction

Crystal oscillators were first developed in the early 1920s and have found wide spread application in radio and television communications. Today, these oscillators remain popular in precision **frequency** applications including timing device circuits and radio frequency filters. The oscillators are typically described as *voltage controlled oscillators* (VCXOs) or *oven controlled oscillators* (OCXOs). These devices offer frequency precision and stability over large temperature ranges, exhibiting stability tolerances better than $\pm 0.005\%$ for sources with over 100-MHz oscillation.

3.1.2 Piezoelectric Effect

Basic Physical Principles

Materials that are used for crystal oscillator applications exhibit the **piezoelectric** effect. This phenomenon produces an electric field within a material when a mechanical force is applied. Conversely, if an electrical drive signal is applied to the crystal, a mechanical vibration results. If the driving signal is periodic in nature, then the resulting vibration will also be periodic. Very accurate electric signal frequencies can be produced by certain materials with the appropriate shape, electrode geometry, and ambient conditions. For this reason, crystal **resonators** are used in applications such as television, cellular radio communications, and electronic test equipment where accurate synthesis of signal frequencies is required throughout.

The relationship between the electric field, electric displacement, electric polarization, and mechanical stress and strain is given by what are called *constitutive relations*. The electrical quantities are related in the following manner:

$$D = \epsilon_0 E + P$$

where D is the electrical displacement, E is the electric field and P is the electric polarization. The term ϵ_0 is the free-space permittivity. The polarization depends on the applied electric field. In a piezoelectric material an electric polarization can also result from an applied stress or strain. This is called the *direct piezoelectric effect*. Therefore the polarization is proportional to the stress (T) or strain (S) that is

$$P = dT \quad \text{or} \quad P = eS$$

In the converse piezoelectric effect, the stress or strain forces are generated by the electric field applied to the crystal. Thus, we have

$$S = dE \quad \text{or} \quad T = eE$$

The constants of proportionality d and e are called piezoelectric stress and strain coefficients. The stress and strain forces are represented by matrix quantities, and the coefficients are tensor quantities. A tensor mathematically represents the fact that the polarization can depend on the stress or strain in more than one direction. This is also true for the relationship between the stress or strain and the electric field. Many other physical properties in crystals also exhibit this nature, which is called *anisotropy*. Thus when a property is anisotropic, its value depends on the direction of orientation in the crystal. For the direct piezoelectric effect, the total polarization effect is the sum of these two contributions, an applied electric field and applied mechanical force. Based on the relationship between the electric displacement and the electric polarization it is then possible to write equations that relate the displacement D to the applied stress or strain. Electric displacement is the quantity that is preferred in experiment and engineering.

Excitation of Wave Modes in Crystals

A variety of electric polarization effects can be produced in piezoelectric crystals by squeezing, bending, shearing, or torsion forces. Conversely, a variety of simple and coupled mechanical vibrations can be produced by applied electric fields. When an electric field is applied, the orientation of the field results in different mechanical vibrations or elastic wave motions in the crystal. These motions are called **modes**, and they depend on the placement of the electrodes. The electrode shape and the shape and cut of the crystal also affects the mode spectrum. Some shapes considered include thick plates, thin plates, and narrow bars. Plates can be square, rectangular, or circular in cross section. In Fig. 3.1 an example of a bar with different electrode placements for exciting longitudinal vibrations is shown. In case of Fig. 3.1(a) the electric field is acting along the bar thickness and in case of Fig. 3.1(b) the electric field is perpendicular to the bar thickness. Another example is a flexing mode in a narrow bar. In this case the electric field is transverse to the bar thickness and parallel to its bending axis. It is possible to generate both even and odd flexing modes. Mechanical bending of the bar conversely produces opposing electric fields and currents. Other mechanical vibrations that are possible include torsional, face-shear, and thickness-shear modes.

FIGURE 3.1 Arrangement of electrodes on a narrow bar for excitation of longitudinal vibrations: (a) electrodes on planes perpendicular to axis X3, (b) electrodes on planes perpendicular to axis X1. (From Zelenka, J. 1986. *Piezoelectric Resonators and Their Application*, Chap. 3. Elsevier, Amsterdam.)

A description of the propagation of elastic wave modes in piezoelectric resonators requires the use of continuum mechanics and the Maxwell equations for the electromagnetic field. When a driving electric field is applied to a crystal, the frequency of the field determines the amplitude of the elastic wave vibration. Conversely, a harmonically applied stress/strain determines what electrical signal frequencies are produced. The maximum vibration amplitude occurs when the frequency of the driving electrical signal coincides with a mechanical resonance of the crystal.

3.1.3 Crystal Resonators

Resonant Frequency and Loss Mechanisms

The resonant frequency of the crystal depends on the physical properties and dimensions of the crystal. For applications requiring precision frequency control these properties and dimensions must be very stable. When stability is an issue, compensation techniques may be required to achieve the desired frequency control. Crystal resonators are typically plates with finite dimensions. The mechanical resonant frequencies for these bounded crystal plates are not easy to obtain through exact calculation. For circular and rectangular plates three-dimensional vibrations are possible, but they are difficult to model exactly. Approximations, however, are used to describe the complex modes of vibration in these systems. Methods for employing these approximations are discussed in detail in Zelenka (1986).

Another important concern for piezoelectric resonator applications is the amount of energy lost due to internal damping forces. A system capable of resonant oscillations will have, associated with it, a figure of merit called the material quality **factor Q**. The quality factor relates the energy stored to the energy dissipated per cycle. Mechanical losses can arise from intrinsic mechanisms such as thermal phonons (lattice vibrations) or defects in crystals. As the temperature increases, the thermal phonon population increases and the intrinsic phonon loss will also increase. The presence of this loss causes the stress and strain to differ in phase angle. A measure of this deviation is the relationship

$$\tan \delta = \frac{1}{Q}$$

where δ is the phase deviation between stress and strain and Q is the material quality factor. For crystals used in precision frequency control applications the value of the quality factor will be very high, indicating that the losses are minimal. Values of Q from 10^5 to 10^7 are typical.

Some of the potential sources of loss in piezo-electronic crystals include defect centers (e.g., Al-OH⁻, Al-Na⁺, Al-Li⁺, and Al-hole centers) and the liberation of interstitial alkali ions. An example of the measured loss of an **AT-cut** crystal resonator is shown in Fig. 3.2 where the two curves indicate the acoustic loss before and after the application of hydrogen sweeping. This sweeping process uses an electric field to

FIGURE 3.2 Acoustic loss vs temperature spectrum of an AT-cut resonator in the as-grown state (dashed curve) and hydrogen sweeping (solid curve). (After Halliburton, L.E. et al. 1985. In *Precision Frequency Control Vol. 1*, eds. E. Gerber and A. Ballato, Chap. 1. Academic Press, Orlando, FL.)

sweep out interstitial cation impurities such as hydrogen from the crystal. Significant loss peaks are present when the crystal is used prior to the sweeping procedure.

Another important parameter for piezoelectronic systems is the electrochemical coupling coefficient κ , which is given by the formula

$$k = \sqrt{\frac{W_p}{W_e}}$$

where W_p is the stored elastic energy and W_e is the stored electric energy. For crystals used in oscillator applications the value for κ is quite low. For an AT-cut quartz plate the value is about 0.0001. A low value for the coupling coefficient means that the electrical and mechanical systems are loosely coupled. If the crystal has a high Q factor, however, the presence of a small driving signal is sufficient to generate a response that maintains the excitation.

Calculation of Resonant Frequency

The resonant frequency of the quartz crystal is largely influenced by the shape of the cavity resonator which is composed of the piezoelectric quartz material. A quartz crystal resonator does not behave as a one-dimensional system; however, the basic principles behind three-dimensional resonance calculations are described in a one-dimensional picture. The equation describing free vibration in a one-dimensional system is

$$\frac{\partial^2 \Psi(x, t)}{\partial t^2} = \frac{v^2 \partial^2 \Psi(x, t)}{\partial x^2}$$

where v is the speed at which a vibrational disturbance can propagate through the medium and $\Psi(x, t)$ describes the displacement of a point in the material.

If we assume that the wave function Ψ may be factored into a product of independent functions of time t and position x , and if we apply the boundary conditions

$$\Psi(x, 0) = \Psi(0, t) = \Psi(L, t) = 0$$

it may be shown that

$$\Psi(x, t) = A_n \sin \left[\frac{n\pi vt}{L} \right] \sin \left[\frac{n\pi x}{L} \right]$$

From this expression we may readily recognize the resonant frequencies

$$f_n = \frac{nv}{2L}$$

The fundamental frequency occurs for $f_1 = v/2L$, and the second harmonic occurs for $f_2 = v/L$.

TABLE 3.1 Elastic Coefficients of Alpha Quartz

Sources: See Bechmann, R. 1958. *Phys. Rev.* 110(5): 1060; Mason, W.P. 1950. *Piezoelectric Crystals and Their Applications to Ultrasonics*, p. 84. Van Nostrand Reinhold, New York, NY.

Extending to the three-dimensional case, we find for a body of width w , length l , and thickness e , the fundamental frequencies are expressed as

$$f_{nmp} = \frac{v}{2} \left[\left(\frac{n}{e} \right)^2 + \left(\frac{m}{l} \right)^2 + \left(\frac{p}{w} \right)^2 \right]^{\frac{1}{2}}$$

but if the thickness is much less than the length or width of the system, the expression reduces to the one-dimensional expression with $f_n = nv/2L$. Further, the velocity of propagation in quartz crystals is determined from the direction of vibration through the elastic coefficients c_{ij} . Substituting an explicit expression for velocity into the resonant frequency expression, we find for an X-cut and Y-cut crystal,

$$f_{nx} = n/2e \sqrt{\frac{c_{11}}{\rho}}$$

$$f_{ny} = n/2e \sqrt{\frac{c_{66}}{\rho}}$$

where ρ is mass density. Values for the elastic coefficients of **alpha quartz** is given in Table 3.1.

The mode structure discussed previously has been developed assuming rectangular-shaped electrodes. Most high-frequency resonators, however, use flat or spherical circular electrode shapes. The electrode shapes affect the boundary conditions for the mode vibrations, and the resulting resonant frequencies must now be described by mathematical functions that are able to satisfy those boundary conditions. For example, with flat circular electrodes, Bessel functions are used to describe the resonant mode behavior. Spherical contoured plates are also routinely applied to resonator designs.

Oscillation of Overtones and Spurious Modes

Under normal conditions, the fundamental frequency oscillates in the quartz resonator. However, the characteristics of the external network can be utilized to promote oscillation in a higher order *overtone* mode. The exact overtone frequency is typically not an exact harmonic of the fundamental frequency. However, the overtone is normally close to a harmonic value. The external circuit is tuned to a frequency near the desired overtone frequency.

Spurious modes are inharmonic modes that may also appear in the vibrational spectrum of the quartz resonator. The spurious modes usually occur in high-resistance modes, and they generally occur at frequencies that are higher than the desired oscillation frequency. The occurrence of spurious modes is increased for crystals operating in an overtone mode as shown in Fig. 3.3.

FIGURE 3.3 Overtone and spurious frequency response of a quartz crystal. (Source: Frerking, M.E. 1978. *Crystal Oscillator Design and Temperature Compensation*, Chap. 4. Van Nostrand Reinhold, New York, NY.)

Resonator Cut Types

Control of the resonant frequency response of crystal oscillators is also influenced by a variety of crystal cavity configurations. These configurations also influence the coefficients that determine the sensitivity of the resonant frequency to temperature changes or applied stress fields. Additionally, the application of the crystal electrodes also affects these coefficients.

Quartz crystals have a trigonal symmetry so that physical features repeat every 120° . A diagram showing the natural faces of a quartz crystal is shown in Fig. 3.4. The structure shows 6 m-faces, which are parallel to the z axis. The cap faces include two r-faces, called *minor rhomb* faces; an R-face, called the *major rhomb* face; and the rarely occurring s- and x-faces. Note that the crystals shown in Fig. 3.4 are also mirror images of each other. Quartz crystals occur in one or the other of the varieties shown. These are called left quartz (Fig. 3.4(a)) and right quartz (Fig. 3.4(b)). Also, the two varieties shown are found both in naturally occurring and cultured (man-made) quartz.

X-, Y-, and Z-Cuts

The convention for making an X-cut is simply to saw the quartz crystal along a plane that is parallel to the X axis. For a Y-cut, the crystal is sawed in a plane that is parallel to the Y axis. Finally, for a Z-cut, the crystal is sawed in a plane that is parallel to the Z axis.

FIGURE 3.4 Face geometry of quartz crystal: (a) left quartz, (b) right quartz. (Source: Bottom, V. 1982. *Introduction to Quartz Crystal Unit Design*. Van Nostrand Reinhold, New York, NY.)

AT- and BT-Cuts

Circuit parameter values of the crystal are largely influenced by the angle at which the quartz is cut from the raw quartz slab (precut form). One of the most popular cuts is the AT-cut, which typically is operated in a thickness shear mode between 1 and 200 MHz. Also, above ~25 MHz, the AT-cut quartz crystal typically operates in an overtone mode. The AT-cut is usually made from a Y-bar, which simply indicates that the maximum dimension of the crystal is in the Y direction. Also, the actual cut is defined as a cut with angle, $\theta = 35^{\circ}15'$ with respect to the z axis. Another popular cut is the **BT-cut**; this is a cut made at an angle of -49° with respect to the z axis. The BT-cut crystals are usually Y-cut also, and the BT-cut crystals are more likely to be applied in an overtone mode, although fundamental mode oscillation is also common.

CT- and DT-Cuts

CT-cuts and DT-cuts represent a family of cuts where the centerpoint of the electrode face is placed at a mechanical node. The modes created by the CT or DT family of cuts are two-dimensional face shear modes. The two dimensional vibration is achieved by supporting the structure at the position of the node, so that movement is then restricted. The most significant feature of the CT- and DT-cuts lies in the fact that they are achieved by rotating the Y-cut about the X axis into two positions at which the temperature dependence of the face shear modes are virtually independent of temperature. Crystals with these cuts are largely used in the frequency range of 100–1000 kHz.

Compensational Cut Formations

The resonant frequency of the quartz cavity has been observed to be highly dependent on several environmental factors, including temperature and external or internal stresses applied to the quartz material. These factors can result in frequency sensitivities on the order of 100 ppm in some cases. This type of sensitivity would make precision frequency control applications extremely difficult without the use of fairly sophisticated control networks that would stabilize temperature and isolate the quartz oscillator from external vibration noise. Fortunately, however, a variety of crystal cuts have been discovered that result in a much lower sensitivity to temperature and stress effects. The stress compensated SC-cut (EerNisse, 1975) is described in [Sec. 3.1.7](#).

Much of the important theoretical development involving compensation cuts for quartz crystals has been done by EerNisse (1975, 1976). EerNisse has been able to show that the frequency-stress coefficient is determined by the Φ cut angle, and the first-order frequency-temperature coefficient is determined almost entirely by the θ -cut angle. Several standard cut types, such as the thermal-transient-compensated (TTC-) cut (Klusters et al., 1977), TS-cut (Holland, 1964), and SC-cut all refer to double rotated cuts with $\theta \sim 34^{\circ}$ and $\Phi \sim 22^{\circ}$. A similar cut is the IT-cut by Bottom and Ives (1951). The IT-cut has $\theta = 34^{\circ}17'$ and $\Phi = 19^{\circ}06'$. The frequency-temperature coefficient is zero for the IT-cut.

3.1.4 Equivalent Circuit of a Quartz Resonator

The discussion of this section follows the development presented by Frerking (1978). Because of the piezoelectric effect, the quartz resonator behaves physically as a vibrating object when driven by a periodic electric signal near a resonant frequency of the cavity. This resonant behavior may be characterized by equivalent electrical characteristics that may then be used to accurately determine the response and performance of the electromechanical system.

Dye and Butterworth (1926) developed the equivalent lump electrical network that describes an electrostatic signal driving a mechanically vibrating system (electromechanical transducers). The equivalent electric network that models the piezoresonator was later developed by Van Dyke (1928), Butterworth, and others, and is shown in Fig. 3.5. In the equivalent network, the circuit parameters

FIGURE 3.5 Equivalent network of piezoelectric resonator.

TABLE 3.2 Typical Equivalent Circuit Parameter Values for Quartz Crystals

Parameter	200 kHz		30 MHz	90 MHz
	Fundamental	2 MHz	3rd o/tone	5th o/tone
R_1	2 k Ω	100 Ω	20 Ω	40 Ω
L_1	27 H	520 mH	11 mH	6 mH
C_1	0.024 pF	0.012 pF	0.0026 pF	0.0005 pF
C_0	9 pF	4 pF	6 pF	4 pF
Q	18×10^3	18×10^3	18×10^3	18×10^3

R_i , L_i , and C_i represent parameters associated with the quartz crystal, whereas C_0 represents the shunt capacitance of the resonator electrodes in parallel with the container that packages the crystal.

The inductance L_i is associated with the mass of the quartz slab, and the capacitance C_i is associated with the stiffness of the slab. Finally, the resistance R_i is determined by the loss processes associated with the operation of the crystal. Each of the equivalent parameters can be measured using standard network measurement techniques (see Sec. 3.1.6). Table 3.2 lists typical parameter values.

Application of an electric field across the electrodes of the crystal results in both face and thickness shear waves developing within the crystal resonator. For a Y-cut crystal where the thickness of the cut is along the Y-direction, face shear modes occur in the XZ plane, whereas thickness shear modes develop in the XY plane.

The vibration is enhanced for electric signals near a resonant frequency of the resonator. Low-frequency resonances tend to occur in the face shear modes, whereas high-frequency resonances occur in thickness shear modes. In either case, when the applied electric signal is near a resonant frequency, the energy required to maintain the vibrational motion is very small.

Nonresonant Behavior

If the applied electric signal is not near a resonant frequency of the resonator, the quartz crystal behaves as a parallel plate capacitor with capacitance

$$C_0 = \frac{ke_0A}{d}$$

where A is the electrode area, d is the thickness of the quartz slab, and k is the relative dielectric constant of the resonator material. Because of the anisotropic nature of quartz crystals, the value of k varies with the direction of the applied electric signal. Finally, the impedance of the nonresonant quartz crystal device is described by

$$Z_0 = \frac{j}{\omega C_0}$$

where ω is the angular frequency of the applied electric signal.

Resonant Behavior

The characteristic series combination impedance of the quartz slab may be expressed as

$$Z_i = R_i + j \left[\omega L_i - \frac{1}{\omega C_i} \right]$$

The equivalent slab impedance of the total parallel network is determined by calculating the parallel combination of Z_0 and Z_i , which may be defined as Z_p . At resonance, Z_p is purely resistive, and this condition is satisfied for

$$\omega = \sqrt{\left(\frac{1}{L_i C_i} + \frac{1}{2L_i C_0} - R_i^2 \frac{1}{2L_i^2} \right) \pm \left(\frac{1}{2L_i C_0} - \frac{R_i^2}{2L_i^2} \right)}$$

with

$$\left(\frac{1}{2L_i C_0} - \frac{R_i^2}{2L_i^2}\right)^2 \gg \frac{R_i^2}{L_i^3 C_i}$$

These two frequencies correspond to the series resonance f_s (obtained using the minus sign) and the parallel resonance f_a .

The series resonance is given by

$$f_s = \frac{1}{2\pi} \sqrt{\left(\frac{1}{L_i C_i}\right)}$$

and when $C_i/C_0 \ll 1$, the parallel resonance (also known as the *antiresonance*) is given by

$$f_a = f_s \left[1 + \frac{C_i}{2C_0}\right]$$

The crystal is normally operated at frequencies located between the series resonance and the parallel or so-called antiresonance frequencies. This defines a useful bandwidth for the crystal relative to the series resonance and may be expressed as

$$\Delta f = f_s \frac{C_i}{2C_0}$$

For the preceding expressions, the quartz resonator is not connected to an external driving network. The effect of the external network can be accounted for by a load capacitance C_L in parallel with C_0 . In the presence of an external load capacitance C_L , the antiresonance frequency of the loaded quartz resonator is expressed as

$$f_L = f_s \left[1 + \frac{C_i}{2(C_0 + C_L)}\right]$$

and the frequency shift away from the series resonant frequency is

$$\Delta f_L = \frac{C_i}{2(C_0 + C_L)}$$

3.1.5 Experimental Determination of the Crystal Oscillator Parameters

Determination of Resonant Frequency

The discussions of the first two subsections of [Sec. 3.1.5](#) follow the derivation of Zelenka (1986). The circuit for measurement of the resonant frequency is shown in Fig. 3.6. This is a passive π network that is also useful for obtaining equivalent circuit parameters, such as dynamic capacitance, crystal resistance, and inductance. The measurement of resonant frequency requires a signal generator at the input and a voltmeter or phase meter connected to the output. The resonant frequency can be measured under two distinct circuit conditions: at the minimum resonator impedance (f_{im}) or at zero resonator reactance (f_{ir}).

The first condition is observed when the output voltage of the π network is a maximum. The second condition occurs when the phase shift between the input and output voltages is zero. This case requires the use of a phase meter for the measurement. For the i th resonance, the two frequencies are equal to

FIGURE 3.6 Passive π network for measurement of equivalent circuit parameters. (From Zelenka, J. 1986. *Piezoelectric Resonators and Their Applications*, Chap. 5. Elsevier, Amsterdam.)

the series resonant frequency defined previously if the resonator losses are negligible (i.e., resonator resistance R_i is close to zero). If the losses cannot be neglected, then more complex formulas that relate the measured frequencies to the series resonant frequency are required. They are given as

$$f_{im} = f_{is} \left[1 - \frac{r_i}{Q_i^2} + \frac{1}{2} \left(r_i^3 + \frac{3r_i^2}{4} \right) \frac{1}{Q_i^4} + \dots \right]$$

and

$$f_{ir} = f_{is} \left[1 + \frac{r_i}{Q_i^2} + \frac{1}{2} \left(r_i^3 + \frac{3r_i^2}{4} \right) \frac{1}{Q_i^4} + \dots \right]$$

where r_i is the ratio C_0/C_i and Q_i is the quality factor (for the i th resonator mode).

Measurement of the Equivalent Circuit Parameters

The dynamic capacitance of the resonator C_i is determined by measuring two frequency detunings. The different detunings result from connection of two different external capacitances C_{s1} and C_{s2} in series with the resonator. The measurement method is described in detail by Zelenka (1986). If the resonator Q factor satisfies the inequality

$$Q_i > 20\sqrt{r_i}$$

then the magnitude of the dynamic capacitance is same for both f_{im} and f_{ir} resonant frequencies. If this condition is not satisfied, then the capacitance differs for the two cases. In situations where applications are not as demanding, the dynamic capacitance can be obtained from the expression

$$C_i = \frac{2\Delta f_i}{f_{is}} (C_0 + C_{si})$$

where Δf_i is the detuning that results when the capacitor C_{s1} is connected. This formulation is less accurate because the parasitic capacitances included in C_0 are not canceled out. The magnitude of these spurious capacitance effects cannot always be determined with sufficient accuracy.

Once the resonant frequency and the dynamic capacitance are determined, the inductance L_i is found using a measurement of the phase shift between the input and output voltages of the π network. The resistance R_i is given for the crystal of the resonator. The phase shift is given by

$$\tan \phi = \frac{X_i}{R_i + R}$$

where X_i is the i th-mode resonator reactance and R is the output resistance of the π network. For a series resonant circuit the reactance is

$$X_i = \omega L_i + \frac{1}{\omega C_i} \simeq 2\Delta\omega L_i$$

where $\Delta\omega$ is the frequency difference or shift between the operating frequency and the series resonant value for the i th mode resonance. The frequency shift can be related to the phase shift by

$$\tan \phi = \frac{\Delta f}{f_{is}} 2Q_{\text{eff}}$$

$$Q_{\text{eff}} = \frac{\omega_{is} L_i}{R_i + R}$$

A measurement of the phase shift and the determination of the frequency ratio $\Delta f/f_{is}$ allows us to calculate Q_{eff} . Using a value of R_i provided for the crystal of interest, the L_i can be obtained. The value of the resonator resistance R_{ir} at series resonance can also be determined by measuring the input and

output voltages at resonance (V_{1r} , V_{2r}) and when the crystal resonator is short-circuited (V_1 , V_2) using the formula

$$R_{ir} = R \left(\frac{V_2 V_{1r}}{V_1 V_{2r}} - 1 \right)$$

The expression that relates R_{ir} to R_i is

$$R_{ir} = R_i \left[1 + \frac{C_0^2}{C_i^2 Q_i^2} \right]$$

which can be used to obtain R_i if the resistance data for a specific resonator are not available.

Crystal Quality Factor

It is possible to determine the electrical quality factor of the crystal resonator indirectly using the equivalent circuit parameters and the formula

$$Q_i = \frac{1}{2\pi f_{is} R_i C_i}$$

The infrared quality factor or *material* Q can be obtained with a measurement of the extinction coefficient α . A detailed discussion of the theory behind this measurement is provided in an article by Brice (1985). An approximation to the extinction coefficient called α_v is obtained for several wave numbers of interest (wave number is reciprocal of wavelength). The value of Q is then calculated from the formula

$$Q = \frac{C10^5}{\alpha_v^*}$$

where C is a constant that depends on wave number. Typical wave numbers are 3410, 3500, and 3585 cm^{-1} . Values of Q have been extensively determined using this formulation with statistical deviation on the order of 10%, when Q is in the range $0.3 < Q \times 10^{-6} < 3.0$.

3.1.6 Piezoelectric Materials

Piezoelectric materials that have found significant application in frequency control applications include quartz, lithium niobate, lithium tantalate, bismuth germanium oxide, aluminum phosphate (berlinite), and langasite. These materials have been covered extensively in the literature, which includes the reference texts by Zelenka (1986), Gerber and Ballato (1985, Vol. 1), and Bottom (1982) and many journal publications (Ballato and Gualtieri, 1995; Wall and Vig, 1994; Brice, 1985). Quartz is most commonly used for crystal resonator applications and the subject is covered in great detail in many of these works. Materials have undergone considerable changes over the last two decades in terms of the quality and types of materials available. An extensive summary of the material properties such as elastic and piezoelectric coefficients for some representative samples are given in the text by Zelenka (1987) and also the work edited by Gerber and Ballato (1985).

Defects and Impurities

As discussed in Sec. 3.1.3 the presence of defects and impurities can promote loss in piezoelectric crystals. Defects are divided into two main groups, *point* and *extended defects*. The point defects include the aluminum-related centers as well as oxygen-vacancy centers. Aluminum ions can easily substitute for silicon in quartz; however, charge compensation is required. Aluminum has a +3 charge whereas the silicon valence is +4. An additional positive charge is required that can be supplied by H^+ , Li^+ , Na^+ , or holes at interstitial sites in the crystal lattice. Iron-related defects are also possible since iron is also a trivalent (+3) ion.

Oxygen-vacancy centers, which are also called E' centers, are also possible. These centers have been extensively studied in quartz crystals and can take several forms. These point defects have not yet been

FIGURE 3.7 Correspondence between etch tunnels and X-ray topographic region in +X region: (a) Optical photograph, (b) X-ray topograph. (From Halliburton, L.E. et al. 1985 in *Precision Frequency Control Vol. 1*, eds. E. Gerber and A. Ballato, Chap. 1. Academic Press, Orlando, FL.)

observed to cause acoustic loss peaks in quartz. An example of an oxygen-vacancy center is the E'_1 center that is formed when an oxygen vacancy traps an unpaired electron.

In quartz materials grown from seed crystals, the dominant impurity near the seed is molecular H_2O . This gives way to OH^- as you move away from the seed. It is the presence of such water molecules that is primarily responsible for the hydrolytic weakening in quartz.

Extended defects such as dislocations and fault surfaces can also arise in piezoelectric crystals. These defects have been studied extensively using a number of experimental techniques. One type of extended defect, called an *etch tunnel*, is shown in Fig. 3.7. It is believed that the growth of such tunnels depends on the control of the initial seed–crystal interface and maintenance of a uniform growth rate. It is also possible that interstitial action impurities such as those mentioned previously are involved in etch tunnel formation.

Piezoelectric Ceramic and Polymers

Some ceramic and polymer materials also display piezoelectric properties. For ceramics these include polycrystal line materials based on solid solutions of $Pb(Zr, Ti)O_3$. The ratio of zirconium and titanium constituents help to determine the crystal symmetry structure that results after heating and then cooling of the samples. Modern piezoelectric ceramics are referred to as PZT ceramics. Other materials such as barium, strontium, calcium, and/or trivalent rare earth elements can be added to the ceramics in small quantities to modify the piezoelectric properties.

Polymers that exhibit the piezoelectric effect include polyvinyl chloride, polyvinyl fluoride, and difluor polyethylene. These polymers acquire their properties through technological processing. The thin plastic foil samples are exposed to strong electric fields and then cooled to room temperature. This process results in a polarization of the material.

Motional Time Constant

Ballato and Gualtieri (1994) employ an intrinsic parameter $\tau_1^{(m)}$ (the **motional time constant**) to make comparisons between different piezoelectric materials. This constant is inversely proportional to the product of frequency and quality factor for the m th resonator mode. It is possible to define the motional time

TABLE 3.3 Motional Time Constants and Characteristic Lengths for Some Piezoelectric Bulk Resonators

Type/Cut	N_0 , m/s	Q ($\times 10^3$)	τ_1 ($\times 10^{-15}$ s)	k^2 , %	L_0 , nm
Quartz (AT)	1,661		11.8	0.77	39.24

Source: See Ballato, J.G. and Gualtieri, J.G. 1994. Advances in high-Q piezoelectric resonator materials and devices. *IEEE Trans. on Ultrasonics, Ferroelectrics, and Frequency Control* 41(6): 834–844.

constant in several ways. One of these definitions is based on the equivalent circuit model. In this case the quality factor is the electrical quality factor. It is also believed that the motional time constant can be related to the material properties directly, for example, by relating it to the ratio of viscosity and the elastic stiffness. In Table 3.3, the motional time constant for a variety of materials used in bulk resonator applications is shown. Other parameters included in the table are quality factor Q , characteristic length L_0 , square of the piezoelectric coupling coefficient k^2 , and a frequency constant N_0 . The motional time constant is inversely proportional to the maximum operating frequency for a given material and overtone. The relationship between L_0 , N_0 , and operating frequency is given by the formula from Ballato and Gualtieri (1994) as

$$f = N_0(L_0 T^2)^{-\frac{1}{3}}$$

where T is the resonator thickness and f is the operating frequency at the maximum overtone.

3.1.7 Temperature and Stress Compensation Techniques and Aging Effects

Thermal Properties of Crystal Resonators

The property that most directly affects the performance of a crystal resonator is the thermal expansion of the crystal. This can result in shifts in the resonant frequency due to stresses occurring in the crystal and at the crystal–electrode interfaces. The temperature characteristics of the elastic constants are important to the frequency–temperature characteristic. These constants also depends in part on the cut of the crystal. An example is the common AT-cut for quartz that has a limiting frequency stability of $\pm 0.002\%$ over the range from -55 to $+105^\circ\text{C}$. This stability limit can be further improved by reducing the operating temperature range. For applications requiring more enhanced stability performance, methods of temperature control or compensation can be employed.

The general relationship between frequency and temperature for crystal resonators is given by

$$f = A_1(t - t_0) + A_2(t - t_0)^2 + A_3(t - t_0)^3$$

where t_0 is the room temperature and t is the operating temperature, and A_1 , A_2 , and A_3 are constants. This relationship accounts for the resonator dimensions, size, and thickness of the electrodes and the electrode material. Another important factor in frequency–temperature stability is the overtone order of the operating frequency. It has been shown experimentally with AT-cut resonators that the frequency–temperature characteristic can be minimized for higher overtone operation (e.g., the third overtone).

FIGURE 3.8 Frequency vs. temperature characteristics for a typical temperature compensated crystal oscillator. (From Frerking, M.E. 1978. *Crystal Oscillator Design and Temperature Compensation*, Chap. 4. Van Nostrand Reinhold, New York)

Temperature Control and Compensation and Aging

An oven is typically used for the purpose of controlling temperature. Crystal resonators reside inside the oven with the oscillator control circuitry either internal or external to the oven. When the circuitry is externally connected, stabilities in frequency of ± 5 parts in 10^7 are possible. For internal circuitry, stabilities of several parts per billion have been obtained in proportionally controlled ovens. Improved frequency-temperature stability can also be obtained with two-stage ovens. Usage of ovens is limited, however, by the disadvantages that arise such as required warmup time, high-power consumption, large volume, and reduced component reliability when frequent on/off cycling of the oven occurs.

Compensation for temperature-related frequency shifts can be accomplished by connecting a reactance (e.g., a variable voltage capacitor called a varactor) in series with the resonator. The effect of this reactance is to pull the frequency to cancel the effect of frequency drift caused by temperature changes. An example of a frequency vs. temperature characteristic both before and after compensation is shown in Fig. 3.8. Notice that the general form for the characteristic before compensation follows the cubic variation given earlier in this section.

Several techniques for temperature compensation are possible. They include analog temperature compensation, hybrid analog-digital compensation, and digital temperature compensation. For analog compensation a varactor is controlled by a voltage divider network that contains both thermistors and resistors to control the compensation. Stability values are in the range from 0.5 to 10 ppm. The lowest value requires that individual components in the voltage divider network be adjusted under controlled temperature conditions. This is difficult over large temperature ranges for analog networks because of the tight component value tolerances required and because of interactions between different analog segments. Analog networks can be segmented to increase the independence of the component adjustments required to improve stability.

These problems can be alleviated with the use of some form of hybrid or digital compensation. In this scheme, the crystal oscillator is connected to a varactor in series as in the analog case. This capacitor provides the coarse compensation (about ± 4 parts in 10^7). The fine compensation is provided by the digital network to further improve the stability. The hybrid analog-digital method is then capable of producing stability values of ± 5 parts in 10^8 over the range -40 to $+80^\circ\text{C}$. For a detailed discussion of these temperature compensation techniques see Frerking (1978).

Stress Compensation

Stress compensation is employed to stabilize the crystal resonator frequency against shifts caused by mechanical stresses. These result from temperature changes or from electrode changes, due to differences in the expansion coefficients that can occur over time. The frequency variations are caused by alteration of the crystal elastic coefficients with stress bias. The method developed for stress compensation is a special

crystal cut called the *stress-compensated* or SC-cut. This cut was developed to obtain a resonator, the frequency of which would be independent of the mentioned stresses. It was determined that a cut at angles near $\phi = 22.5^\circ$ and $\theta = 34.5^\circ$ on a doubly rotated quartz plate would be free of frequency shifts caused by stress bias in the plane of the plate. This cut was theoretically predicted by EerNisse, who named it.

The SC-cut has some advantages over the more common AT- and BT-cuts. These include a flatter frequency-temperature response, especially at the turning points, and less susceptibility to aging due to changes in the mounting stresses. The lower sensitivity to frequency changes means that the SC-cut resonators can be frequency-temperature tested more rapidly than their AT- and BT-cut counterparts. A disadvantage of the SC-cut is that it is sensitive to air damping and must be operated in a vacuum environment to obtain optimum Q factors. The frequency-temperature curve is also roughly 70° higher for the SC-cut over the more common AT-cut, which could also be a disadvantage in some applications.

Aging Effects

Aging in crystal oscillators generally refers to any change over time that affects the frequency characteristics of the oscillator or the physical parameters that describe the device, for example, motional time constant and equivalent circuit parameters. Some factors that influence aging include surface deterioration, surface contamination, electrode composition, and environmental conditions.

Deterioration on the surface contributes to strain in the crystal, and this type of strain can impact the operating frequency of the oscillator. More important, the surface strain is extremely sensitive to humidity and temperature early in the life of the crystal. One method of combating this surface degradation mechanism is to etch away the strained surface layers. HF or NH_4F_2 can be used to remove the strained surface layers. The surface is etched until the change in operating frequency increases only linearly as the etch time is increased. The initial slope of the frequency change vs. etch time curve is exponential. Once the strained surface layers have been removed, however, the slope becomes linear.

Another surface issue is contamination from foreign materials. The presence of foreign substances loads the oscillator with an additional mass, and this can be reflected in the equivalent circuit parameters. The contaminants can be introduced during unclean fabrication processes, or from out gassing of other materials after the device has been packaged or from contaminants in the environment during storage. The contamination process is often increased in higher temperature environments and temperature cycling leads to stability problems for the device.

Aging problems associated with the device electrode include delamination, leading to increased resistance or corrosion effects. Typical electrode materials include gold, silver, and aluminum. Of these, silver is the most popular material. Because of silver oxidation processes, however, the electrode mass can significantly affect the operational frequency. Reactions typically involve either oxygen or other elements that may be classified as halides. Occasionally, silver electrodes are exposed to iodine to produce a layer of silver iodide. Silver iodide is a largely inactive compound that protects against further increases in the corrosion process. Alternatively, gold is largely inactive and easy to deposit, so that a gold electrode may not require additional coating materials. On the other hand, gold only loosely binds with the quartz substrate so that a layer of chromium is often added to provide a surface for adhesion to gold. Without the chrome layer, delaminations may develop at the gold-quartz interface. Aluminum is a popular electrode material for high-speed operations. Aluminum, however, is highly reactive with oxygen. The growth of aluminum oxide layers is usually very slow, and after a layer thickness of ~ 50 Å has been reached, the growth is reduced to near zero. Unfortunately, the reaction rate is not strongly influenced by temperature so that accelerated procedures involving high-temperature operations are largely ineffective. One technique to combat this aging effect is anodic oxidation. This process leaves a thick oxide layer on the electrode, but the growth rate is proportional to the electrode voltage. The process can, therefore, be accelerated to an acceptable time frame. Additional discussion of aging effects is presented Bottom (1982).

Defining Terms

Alpha quartz: The crystalline form of SiO_2 at temperatures below 573° .

AT-cut: A quartz plate cut from Y-bar quartz at an angle 35° with respect to the z axis.

BT-cut: A quartz plate cut from Y-bar quartz at an angle -49° with respect to the z axis.

Crystal: A solid material composed of atoms, ions, or molecules that are arranged in a structured three-dimensional pattern.

Frequency: A measure of the number of cycles repeated per second.

Mode: An allowed oscillating frequency.

Motional time constant: A material parameter that is inversely proportional to product of the frequency and Q -factor for a particular mode.

Piezoelectric: A material effect whereby an applied electric field produces a mechanical strain, and an applied mechanical strain produces an electric field.

Q -factor: A figure of merit that represents that ratio of stored to dissipated energy per cycle.

Resonator: A cavity or chamber which has been cut to permit oscillation at a particular frequency.

3.2 Surface Acoustic Wave (SAW) Devices

Ardie D. Walser

3.2.1 Introduction

Acousto-optic modulators control the transmission of light by local changes in the index of refraction of the transmission medium. This modulation or change occurs by means of a traveling sound wave that induces a stress-related modification of the local index. The sound wave can be transverse (*coplanar device*), longitudinal (*colinear*), or a combination of both as in the case of a *surface acoustic wave* (SAW).

Optical wave diffraction can be produced by either bulk acoustic waves traveling in the volume of the material, or by surface acoustic waves propagating on the surface of the medium (that is, in the form of a planar waveguide). The penetration depth of the surface acoustic wave is within one acoustic wavelength (Λ) of the surface. The energy of the surface acoustic field is concentrated in the same spatial region as **optical waveguides**, making SAW devices well suited for integrated optic applications.

Whether bulk or surface acoustic waves are used, two fundamentally different types of optical modulations are possible. The type of modulation is dictated by the interaction length L of the optical beam with the acoustic wave, where L is approximately the width of the acoustic wave front (or acoustic beam spot size). In the Raman–Nath type modulator the optical beam transverses the acoustic beam, and the interaction length of the optical path (i.e., the width of the acoustic wave) is so short that the optical waves only undergo a phase grating diffraction, producing many interference peaks in the far field.

Increasing the interaction length by widening the acoustic beam causes the optical waves to undergo multiple diffractions before leaving the acoustic field. This is similar to the diffraction of X rays by atomic planes observed by Bragg. In such a situation the optical beam is incident at a specific angle (i.e., Bragg angle) to the acoustically induced index grating displaying only one intense diffraction lobe in the far-field pattern.

3.2.2 Photoelastic Effect

A material's optical index of refraction is coupled to its mechanical strain via the **photoelastic effect**, traditionally expressed by a fourth-rank tensor, \mathbf{p}_{ijkl}

$$\Delta\boldsymbol{\eta}_{ij} = \Delta\left(\frac{1}{n^2}\right)_{ij} = \mathbf{p}_{ijkl}\mathbf{S}_{kl} \tag{3.1}$$

where $\Delta\boldsymbol{\eta}_{ij}$ (or $\Delta(1/n^2)_{ij}$) is the change in the optical impermeability tensor and \mathbf{S}_{kl} is the strain tensor, defined as

$$\mathbf{S}_{kl}(r) = \frac{1}{2} \left[\frac{\partial u_k(r)}{\partial x_l} + \frac{\partial u_l(r)}{\partial x_k} \right] \tag{3.2}$$

where u_k characterizes the mechanical displacement along the direction x_l , of an arbitrary point $P(x_1, x_2, x_3)$ in the body of a uniform elastic solid under stress. The variables \mathbf{p}_{ijkl} form the strain-optic tensor. For a crystal in the presence of a strain field the index ellipsoid is given by

$$(\boldsymbol{\eta}_{ij} + \mathbf{p}_{ijkl}\mathbf{S}_{kl})x_i x_j = 1 \tag{3.3}$$

Exploiting the symmetry of the optical impermeability tensor $\boldsymbol{\eta}_{ij}$, the strain tensor \mathbf{S}_{kl} and the strain-optic tensor \mathbf{p}_{ijkl} , contracted indices can be used to abbreviate the notation. The equation for the change in the optical impermeability tensor then becomes

$$\Delta\left(\frac{1}{n^2}\right) = \mathbf{p}_{ij} \mathbf{S}_j i j, \quad i, j = 1, 2, \dots, 6 \tag{3.4}$$

where S_j are the strain components. The strain field alters the orientation and dimensions of the index ellipsoid. This change is dependent on the applied strain field and the strain optic coefficients \mathbf{p}_{ijkl} . Only the orientation or form of the strain-optic coefficients \mathbf{p}_{ijkl} can be derived from the symmetry of the material, which is usually of crystalline form. Point group symmetry determines which of the 36 coefficients are zero, as well as the relationships that may exist between nonzero coefficients. For a more comprehensive analysis of photoelastic tensors, refer to Nye (1957).

An acoustic wave can produce a strain causing a change in the index of refraction via the photoelastic effect (Dixon, 1967). It has been shown (Pinnow, 1970) that the change in the index of refraction is related to the acoustic power P_a by the expression

$$\Delta n = \sqrt{\frac{n^6 p^2 P_a}{2\rho v^3 A}} \tag{3.5}$$

TABLE 3.4 Common Materials Used in Acousto-optic Interactions

Material	λ , μm	n	ρ , g/cm^2	ν $(10^3)/\text{s}$	M , (10^{-15})

where n is the index of refraction in the unstrain medium, p the appropriate element of the photoelastic tensor, P_a the acoustic power in watts, ρ the mass density, ν the acoustic velocity, and A the cross-sectional area that the acoustic wave travels through. This expression is commonly written as

$$\Delta n = \sqrt{\frac{MP_a}{2A}} \quad (3.6)$$

where M is defined by

$$M = \frac{n^6 p^2}{\rho \nu^3} \quad (3.7)$$

the acousto-optic figure of merit. M represents the relative magnitude of the index change produced by an elastic wave of constant power, it is therefore a convenient figure for comparing various acousto-optic materials. The value of M depends on the material and its orientation. Values of M for some common acousto-optic materials are shown in Table 3.4.

3.2.3 Acousto-Optic Effect

We will establish the basic principles that govern the behavior of all acousto-optic devices whether of bulk or waveguide (SAW) construction. An acousto-optic modulator is composed of an acoustic medium (such as water, glass, lithium niobate, rutile, etc.) and a transducer. The transducer converts electrical signals into sound waves propagating in the acoustic medium with an acoustic frequency spectrum that is limited by the bandwidth of the transducer that matches the electrical excitation. The sound wave causes a perturbation in the index of refraction of the material, setting up a refractive index grating of the form

$$n(\mathbf{r}, t) = n + \text{Re}[\Delta n \exp\{j(\Omega t - \mathbf{K} \cdot \mathbf{r})\}] \quad (3.8)$$

which has a grating period Λ equal to the sound wavelength in the material, and moves along the direction of the sound wave with a velocity

$$\nu = \frac{\Omega}{|\mathbf{K}|} = \frac{\Omega}{2\pi} \Lambda \quad (3.9)$$

equal to the sound velocity in the material. Since the velocity of light ($c = 3 \times 10^8$ m/s) is approximately five orders of magnitude greater than the velocity of sound (several times 10^3 m/s) the index grating can be viewed as stationary.

For clarity and ease of calculation we shall examine the scattering of an electromagnetic wave by an acoustical wave in an isotropic medium. Consider an acoustic wave that is launched from the bottom of

a cell containing an isotropic fluid (water, etc.). A periodic strain distribution is established inducing a traveling index grating in the medium.

Raman–Nath Diffraction

When the cell is thin (Fig. 3.9) and the acoustic wave is weak, the optical beam direction change is very small on transmission through the cell. For Raman–Nath type diffraction, the interaction length must be so short that multiple diffractions do not take place. This condition occurs when

$$L \ll \frac{\Lambda^2}{\lambda} \tag{3.10}$$

is satisfied, where λ is the optical wavelength within the material. Equation (3.10) establishes a relationship between the interaction length L and the acoustic wavelength Λ . The phase change of the emerging optical beam after passing through the acoustic wave is

$$\Delta\varphi = \frac{\Delta n 2\pi L}{\lambda} \sin\left(\frac{2\pi y}{\Lambda}\right) \tag{3.11a}$$

and using Eq. (3.6)

$$\Delta\varphi = \frac{2\pi}{\lambda} \sqrt{\frac{MPL}{2a}} \sin\left(\frac{2\pi y}{\Lambda}\right) \tag{3.11b}$$

where Δn is the index change caused by the sound wave, and A equals L multiplied by the thickness of the acoustic beam a . The spatial component ($\sin(2\pi y/\Lambda)$) adds a corrugated structure to the phase front of the transmitted optical beam. The index variation produced by the acoustic wave can be considered a phase diffraction grating, in which the transmitted light reflects off the grating into many orders (Fig. 3.9). The angle θ of the direction of a maximum of the emergent wave is given by

$$\sin\theta - \sin\theta_0 = m\frac{\lambda}{\Lambda}, \quad m = 0, \pm 1, \pm 2, \dots \tag{3.12}$$

where θ_0 is the angle of incidence, Λ is the wavelength of the acoustic wave, and m is an integer representing the order of a diffraction maxima. For normal incidence ($\theta_0 = \pi/2$) Eq. (3.12) becomes

$$\sin\theta = m\frac{\lambda}{\Lambda}, \quad m = 0, \pm 1, \pm 2, \dots \tag{3.13}$$

Hence, for Raman–Nath diffraction several discrete peaks are observed in the emerging optical beam. The intensity of these orders are given by (Hammer, 1982)

$$\begin{aligned} \frac{I}{I_0} &= \frac{1}{2} [J_m(\Delta\varphi')]^2, \quad |m| > 0 \\ \frac{I}{I_0} &= [J_0(\Delta\varphi)]^2, \quad m = 0 \end{aligned} \tag{3.14}$$

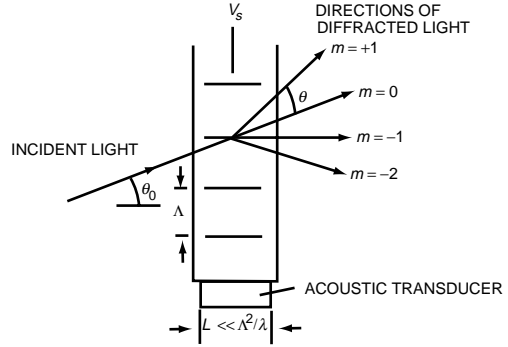

FIGURE 3.9 An acousto-optic deflector in the Raman–Nath regime ($L \ll \Lambda^2/\lambda$), where the cell can be considered a phase grating spatially modulating the emerging beam.

Where the J are the ordinary Bessel functions, I_0 is the intensity of the optical beam that is transmitted when the acoustic wave is absent, and $\Delta\varphi$ is the maximum value of $\Delta\varphi$ written as

$$\Delta\varphi' = \frac{2\pi L}{\lambda} \Delta n = \frac{2\pi}{\lambda} \sqrt{\frac{MPL}{2a}} \tag{3.15}$$

The Raman–Nath output is usually taken to be the zeroth-order mode. The modulation index equals the fraction of the light diffracted out of the zeroth-order and is expressed as

$$\frac{[I_0 - I(m = 0)]}{I_0} = 1 - [J_0(\Delta\varphi')]^2 \tag{3.16}$$

In general, the Raman–Nath modulator has a smaller modulation index than that of a comparable Bragg modulator, which is a primary reason for why the Raman–Nath modulator is not as popular as the Bragg type.

Bragg Diffraction

When the interaction length between the optical and acoustic beams are relatively long, so that multiple diffraction can occur, as is the case for thick cells, Bragg type diffraction takes place. The relation expressing this condition is given by

$$L \geq \frac{\Lambda^2}{\lambda} \tag{3.17}$$

where L is the interaction length and Λ is the acoustic wavelength defined earlier. The cell can be interpreted as a stack of reflectors spaced by the wavelength of the acoustic wave (Fig. 3.10). This is analogous to the treatment of X-ray diffraction by layers of atoms in a lattice, first studied by Bragg. When the path difference between rays reflected from adjacent layers equals an integral multiple of the optical wavelength (Fig. 3.11), the rays reflected from each layer interfere constructively and the total reflected light intensity displays a peak. The Bragg diffraction condition is

$$2\Lambda \sin \theta = \frac{\lambda}{n} \tag{3.18}$$

with n equal to the index of refraction of the medium and θ the angle of incidence. For a modulator, generally the zeroth-order beam is taken as the output. The modulation depth is then given as

$$\frac{I_0 - I}{I_0} = \sin^2 \left(\frac{\Delta\varphi'}{2} \right) = \sin^2 \left[\frac{\pi}{\lambda} \sqrt{\frac{MPL}{2a}} \right] \tag{3.19}$$

FIGURE 3.10 An acousto-optic deflector that is in the Bragg regime ($L \gg \Lambda^2/\lambda$); the cell can be viewed as a stack of reflecting layers with a period equal to the acoustic wavelength (Λ).

where I_0 is the transmitted intensity when the acoustic wave is not present, I is the zeroth-order intensity in the presence of the acoustic beam, and $\Delta\phi'$ is the maximum phase shift of the optical beam produced by the acoustic wave.

The Bragg diffraction condition shown in Eq. (3.18) is the result of assuming that the traveling acoustic wave is stationary relative to the optical beam. The motion of the acoustic wave can be accounted for by considering the Doppler shift undergone by an optical beam reflecting from a mirror moving at the velocity of sound v at an angle that satisfies the Bragg condition. The Doppler frequency shift of a wave reflected from a moving surface (such as the wave front of a traveling sound wave) is

$$\Delta\omega = 2\omega \frac{v_{\parallel}}{c/n} \tag{3.20}$$

where $\Delta\omega$ is the optical frequency and v_{\parallel} is the projection of the surface velocity vector along the optical wave propagation direction. We can see from Fig. 3.12 that $v_{\parallel} = v \sin \theta$ substituting it into Eq. (3.20)

$$\Delta\omega = 2\omega \frac{v \sin \theta}{c/n} \tag{3.21}$$

Using the expression for the Bragg diffraction, Eq. (18) condition we can write

$$\Delta\Omega = \frac{2\pi v}{\Lambda} = \Omega \tag{3.22}$$

where the frequency of the reflected optical wave is up shifted by Ω (Fig. 3.11). If the direction of propagation of the sound wave were reversed, then the optical wave would be down shifted by Ω .

Particle Description of Acousto-Optic Interactions

Taking advantage of the dual particle-wave nature of light and of sound we can deduce many of the features of the diffraction of light by sound. In accordance with the quantum theory of light, an optical wave of angular frequency ω can be described as a stream of particles (photons), each of energy $\hbar\omega$ and momentum $\hbar k$. Similarly, an acoustic wave of angular frequency Ω can be thought of as made up of particles (phonons) with momentum $\hbar K$ and energy $\hbar\Omega$. The diffraction of light by an acoustic wave can be described as a

FIGURE 3.11 The reflections of an incident optical beam from two adjacent crests (separated by the acoustic wavelength Λ) of an acoustical wave moving with the velocity v_s . The reflections from the two crests will interfere constructively only if the optical path difference $AO + OB$ equals an optical wavelength, thus, satisfying the Bragg condition ($2L \sin \theta = \lambda/n$).

FIGURE 3.12 (a) Wavevector diagram of an incident optical beam (k) being scattered by an acoustic beam (K) into a diffracted beam (k'); (b) the vectorial description of the conservation of momentum that is used to derive the Bragg condition for the diffraction of an optical beam by an acoustic wave front.

series of single collisions each involving the destruction or annihilation of an incident photon at ω and one phonon and the simultaneous creation of a new diffracted photon at a frequency ω' , which propagates in the scattered beam direction (Fig. 3.12).

The conservation of momentum dictates that the total momentum $\hbar(k + K)$ of the colliding particles equal the momentum $\hbar k'$ of the scattered photon, hence

$$k' = k + K \quad (3.23)$$

The conservation of energy requires that

$$\omega' = \omega + \Omega \quad (3.24)$$

the Doppler shift formula, where the diffracted optical waves frequency shift is equal to the sound frequency. The conservation of momentum condition is an alternate expression of Bragg's condition (Fig. 3.12). To demonstrate this, consider Fig. 3.11 where the value of the sound frequency Ω is much less than that of the incident optical frequency ω . We can express this condition as follows

$$\omega \gg \Omega \quad (3.25)$$

From Eq. (3.24) and Eq. (3.25) we have

$$\omega' \approx \omega, \quad \text{and} \quad k' \approx k \quad (3.26)$$

Therefore, the magnitudes of the incident and diffracted optical wavevectors are equal, and the magnitude of the acoustic wavevector is

$$K = 2k \sin \theta \quad (3.27)$$

the Bragg condition.

3.2.4 Devices and Applications

The use of acousto-optic interaction offers the possibility of manipulating laser light at high speeds since the use of mechanical moving parts is not involved. Advances in the acousto-optic device applications stem from the availability of lasers, which produce intense, coherent light; from the development of efficient broadband transducers, which generate elastic waves up to the microwave frequencies; and from the discovery of materials with excellent elastic and optical properties. The **acousto-optic effect** can be used to build beam deflectors, light modulators, tunable filters, signal processors, and spectral analyzers.

Our discussion on the acousto-optic effect applies to both bulk and thin-film materials. In this section we will study devices using SAW. The SAW device is lighter and more compact, and for a given acoustic energy its diffraction efficiency is greater than that of corresponding bulk-effect devices.

SAW Construction

An interdigital transducer deposited on the surface of a piezoelectric substrate (i.e., lithium niobate) launches a surface acoustic wave (Fig. 3.13). The interdigital transducer has a comblike structure that establishes an alternating electric field whose polarity is spatially alternating. This alternation produces an electrically induced strain in the medium via the piezoelectric effect that excites an acoustic wave. The acoustic wave modulates the index of refraction of the medium that diffracts the optical beam. Note that this diffraction effect is not only due to the modification of the index of refraction, but also to the physical deformation of the medium produced by the acoustic wave.

Transducer

For a SAW waveguide modulator, an interdigitated, single periodic pattern of metal fingers are deposited directly onto the waveguide surface, as shown in (Fig. 3.14), where the transducer has a design

FIGURE 3.13 Waveguide acousto-optic Bragg modulator. The incident guided optical wave is deflected through an angle of 2θ by a surface acoustc wave (SAW) launched by an interdigital transducer.

constant referred to as the *aspect ratio* L/Λ . The interdigital transducer (IDT) launches a SAW in the direction normal to the finger pattern. Frequencies up to 1 GHz are possible using photolithographic techniques for this simple patterning. When designing a SAW waveguide modulator, wide bandwidth and high diffraction efficiency (which implies low acoustic driver power) are desired attributes. By decreasing the interactive length (acoustic aperture) L of a modulator, a larger bandwidth can be achieved. However, this would be at the expense of the diffraction efficiency as can be seen in Eq. (3.19). To satisfy both conflicting conditions more elaborate transducer designs have been employed. Wide bandwidths have been accomplished by such schemes as the following

FIGURE 3.14 The standard interdigital transducer for SAW excitation, where the aspect ratio or relative aperture (L/Λ) is a design parameter.

- The *multiple tilted-array transducer* (Lee, Kim, and Tsai, 1979), where an array of standard IDTs with staggered center frequencies are tilted toward each other in order to satisfy the Bragg condition at each frequency (Fig. 3.15).
- The *Phase-array transducer* (Nguyen and Tsai, 1977) that consists of several IDT segments with one period displacement (phase difference) between adjacent segments, using frequency control SAW beam steering (Fig. 3.16).

FIGURE 3.15 Multiperiodic transducer in a tilted array for increased bandwidth. The array of simple transducers have staggered center frequencies and are tilted toward each other in order to satisfy the Bragg condition at each center frequency. This increases the acoustic aperture and the frequency range of the transducer.

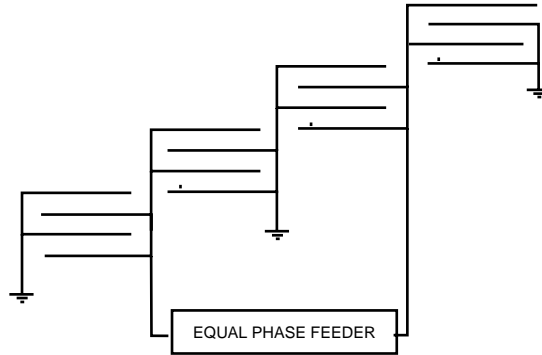

FIGURE 3.16 A phase-array transducer. By placing a variable phase shift of the RF signal between the individual transducers, a scanning acoustic wave front is generated, producing a wide aperture acoustic beam that tracks the Bragg condition over a large frequency bandwidth.

- The *tilted-finger chirped transducer* (Joseph and Chen, 1979), which broadens the excitation bandwidth by the chirp in the electrode period (Fig. 3.17). The interdigitated spacing is gradually changed along the length of the transducer in the direction of the SAW propagation.

Beam Deflectors and Switches (Bragg Type)

A number of light modulators using the acousto-optic effect can be fabricated. Both amplitude and frequency modulation can be achieved. The modulator can operate in either the Raman–Nath regime or the Bragg regime. However, the Raman–Nath modulators are limited to low frequency and have limited bandwidth. This is due to the short interaction length permitted by the criterion $L \ll \Lambda^2/\lambda$. Even at the maximum allowable interaction length L , for high RF (small Λ), excessive acoustic power would have to be used, causing Raman–Nath modulators to be impractical. We will concentrate on devices that operate in the Bragg regime, since these types of devices have wide bandwidth and can operate at high modulation frequencies.

The intensity of the diffracted beam of a Bragg cell is proportional to the amplitude of the acoustic wave. Modulating the amplitude of the acoustic wave causes a corresponding modulation on the diffracted optical beam. This device can be used as a linear light modulator (Fig. 3.18).

Increasing the amplitude of the acoustic wave eventually causes saturation to occur and almost complete diffraction of the optical beam is achieved. The modulator now behaves like an optical switch. By turning the acoustic wave on and off, the reflected optical beam is turned on and off and the transmitted optical beam is turned off and on (Fig. 3.19).

FIGURE 3.17 Tilted-finger chirped transducer.

FIGURE 3.18 The intensity of the diffracted optical beam is proportional to the amplitude of the acoustic wave, hence the device is an acousto-optic modulator.

Important Parameters of SAW Devices

Next we shall define some of the important parameters that describe the characteristics of Bragg type acousto-optic devices.

Deflection Angle

An acousto-optic Bragg diffraction occurs only when the incident beam is at the Bragg angle θ_B with respect to the acoustic wave. Using the Bragg condition

$$K = 2k \sin \theta_B \tag{3.28}$$

we can write

$$\theta_B = \sin^{-1} \frac{\lambda}{2n\Lambda} = \sin^{-1} \frac{\lambda f}{2nv} \tag{3.29}$$

where λ and n are the wavelength and effective index of the optical guided wave, respectively and Λ , f , and v are the SAW wavelength, frequency, and phase velocity, respectively. In practice the Bragg angle is

FIGURE 3.19 Increasing the power of the acoustic wave will eventually cause saturation, where total diffraction occurs and the modulator performs as an acousto-optic switch. Turning the sound on causes the optical beam to deflect, and turning the sound off allows the optical beam to pass unperturbed.

small so we can write

$$2\theta_B = \frac{\lambda}{n\Lambda} = \frac{\lambda f}{nv} \quad (3.30)$$

Thus, the deflection angle $2\theta_B$ is approximately proportional to the SAW frequency, which is the basic principle of operation of an acousto-optic beam deflector.

Diffraction Efficiency

The diffraction efficiency (the fraction of incident light energy diffracted) at the Bragg condition for SAW-propagation width L and SAW intensity I_a can be written as

$$\eta = \frac{I_{\text{diffracted}}}{I_{\text{incident}}} = \sin^2 \left(\frac{\pi L}{\lambda \sqrt{2} \cos \theta_B} \sqrt{M I_a} \right) \quad (3.31)$$

The acoustic intensity I_a required for total conversion of the incident light is given by

$$I_a = \frac{\lambda^2 \cos^2 \theta_B}{2ML^2} \quad (3.32)$$

Noting that a SAW is localized in a layer of thickness nearly equal to the acoustic wavelength Λ , the power per unit area averaged in this layer (intensity I_a) can be approximated by $P_a/\Lambda L$. Using this relation with Eq. (3.32) the acoustic power required, P_a , is

$$P_a = \Lambda L I_a = \frac{\lambda^2 \cos^2 \theta_B}{2M} \left(\frac{\Lambda}{L} \right) \quad (3.33)$$

It is desirable according to Eq. (3.33) to have a small aspect ratio (Λ/L) for efficient operation of a modulator. In the low diffraction efficiency region ($n < 0.5$, low acoustic power levels) Eq. (3.31) can be written as

$$\eta = \frac{I_{\text{diffracted}}}{I_{\text{incident}}} = \frac{\pi^2}{2\lambda^2 \cos^2 \theta_B} \left(\frac{L}{\Lambda} \right) M P_a \quad (3.34)$$

or using $I_a = P_a/\Lambda L$

$$\eta = \frac{I_{\text{diffracted}}}{I_{\text{incident}}} = \frac{\pi^2}{2\lambda^2 \cos^2 \theta_B} \left(\frac{L}{\Lambda} \right) M P_a \quad (3.35)$$

Thus, if the acoustic power is modulated, so is the diffracted light beam intensity. The SAW power P_a is the RF power that is fed to the SAW transducer multiplied by the conversion efficiency of the transducer. The interdigital transducer often used to produce SAW propagation is a bidirectional device. The maximum theoretical efficiency for SAW excitation directed toward the interaction region is -3 dB, which is approached in practice.

Bandwidth

The bandwidth of a Bragg acousto-optic modulator is limited by both the excitation bandwidth of the transducer and the bandwidth of the acousto-optic interaction. In practice, the aspect ratio (or relative aperture) L/Λ of the interdigital transducer electrodes are designed to match the radiation resistance to the RF source impedance at the center frequency. By using an optimum number of interdigital finger pairs N_{opt} , the excitation bandwidth is maximized. For an optimum finger pair number N_{opt} the relative SAW excitation bandwidth $2\Delta f_T/f$ is given by

$$\frac{2\Delta f_T}{f} \approx \frac{1}{N_{\text{opt}}} \quad (3.36)$$

The interaction bandwidth $2\Delta f_{AO}/f$ is determined by the angular selectivity ($2\Delta\theta_i$) of a Bragg diffraction. The SAW transducer is oriented such that the direction of propagation of the acoustical and optical waves satisfy the Bragg condition at the center frequency. A change in the frequency dictates a corresponding change in the Bragg angle θ_B and a deviation from the Bragg condition. This, in turn, causes a decrease in the diffraction efficiency through the angular selectivity of the acousto-optic grating. From Eq. (3.30) we have

$$\frac{\Delta f_{AO}}{f} = \frac{2\Delta\theta_b nv}{\lambda f} \tag{3.37}$$

Using

$$2\Delta\theta_i \approx \frac{5}{QL} \approx \frac{\Lambda}{L} \tag{3.38}$$

the expression for the angular selectivity (a parameter associated with the decline in the diffraction efficiency due to angular deviation from the Bragg condition) where Q is the magnitude acoustic wave vector $2\pi/\Lambda$, we can write Eq. (3.37) as

$$\frac{2\Delta f_{AO}}{f} = \frac{10nv}{\lambda 2\pi f} \left(\frac{\Lambda}{L} \right) \tag{3.39}$$

Note that the interaction bandwidth is inversely proportional to the acoustic frequency f and proportional to the acoustic wavelength Λ for a given aspect ratio L/Λ . The smaller value of $2\Delta f_{AO}/f$ and $2\Delta f_T/f$ determines the overall bandwidth of the Bragg cell. At low frequencies the SAW excitation bandwidth limits the overall bandwidth. At high frequencies the SAW is limited by the interaction bandwidth.

The modulation bandwidth Δf of an acousto-optic modulator is determined primarily by the angular spread of the optical beam. The finite angular distribution of the wave vector allows the Bragg diffraction to occur over a finite range of acoustic frequencies. By differentiating Eq. (3.30), the expression for the bandwidth is

$$\Delta f = \frac{2nv}{\lambda} \Delta\theta_B \tag{3.40}$$

Response Speed

The SAW transit time over the interaction region determines the Bragg cells response speed τ . Where D represents the guide wave width (or the interaction region) the response time is written as

$$\tau = \frac{D}{v} \tag{3.41}$$

To insure that the input and output guided waves spatially overlap the SAW propagation width L , width D must satisfy the following condition:

$$D > 2L \tan \theta_B \approx \frac{\lambda L}{n\Lambda} \tag{3.42}$$

This relationship places a lower limit on D , where one might seek to reduce it in order to increase the response time of the Bragg cell.

Time Bandwidth Product

The time bandwidth product is a nondimensional parameter defined as the product of the bandwidth $2\Delta f$ and the SAW transit time τ . For a Bragg cell not only is size of the absolute deflection important but so is the number of resolvable spots. For a guided wave with a width D the beam divergence angle is

$$2\delta\theta = 0.88\lambda/nD \tag{3.43}$$

due to diffraction. Using Eq. (3.40) and Eq. (3.41) the number N of resolvable spots can be written

$$N = \frac{\Delta\theta_b}{\delta\theta} = \frac{D}{0.88v} (2\Delta f) \approx \tau 2\Delta f \tag{3.44}$$

FIGURE 3.20 Schematic drawing of a guided-wave acousto-optic Bragg deflector, using two tilted surface acoustic waves.

Surface Acoustic Wave Beam Deflectors

The use of LiNbO_3 thin-film waveguides for Bragg interactions between surface acoustic waves and optical guided waves have been demonstrated (Kuhn et al., 1970). Since the diffraction efficiency η depends on the acoustic intensity I_a , with the confinement of the acoustic power near the surface (around Λ), only a low modulation or switching power is needed to alter the guided optical wave. Shown in Fig. 3.20 is an experimental setup in which both the surface wave and optical beam are guided in the waveguide. Transducer 1 and transducer 2 diffract the incident beam into two different diffraction optical beams that are spatially displaced. Multiple tilted transducers are very effective because they permit the Bragg condition to be satisfied over a large acoustic aperture (interaction length) and over a wide frequency range.

Acousto-Optic Tunable Filters (AOTF)

Spectral tunable filters can be fabricated exploiting the acousto-optic interaction. In general tunable filters employ codirectional (large-angle) acousto-optic interaction; however, a small angle scheme can be used. In either case a strong diffraction (or reflection) of the incident optical wave occurs only when the Bragg condition is satisfied. If the incident optical beam contains several frequencies (or consists of multiple spectral components), only the optical frequency that satisfies the Bragg condition at a given acoustic frequency will be diffracted. Therefore, by varying the acoustic frequency, the frequency of the diffracted optical beam can also be varied.

Illustrated in Fig. 3.21 is an acousto-optic tunable filter in the noncollinear geometry. These filters offer advantages such as the freedom of choosing propagation directions for various applications and the

FIGURE 3.21 Schematic of a TeO_2 noncollinear acousto-optic tunable filter.

FIGURE 3.22 Schematic for a standing wave surface acoustic wave optical modulator (SWSAWOM) for optical frequency shifting.

freedom of choosing the operation acoustic frequency for a given crystal. A TeO_2 noncollinear acousto-optic tunable filter was constructed that could tune from 7000 to 4500 Å by changing the acoustic frequency from 100 to 180 MHz (Chang, 1970).

Acousto-Optic Frequency Shifter

As stated earlier the frequency shifting effect of an acousto-optic device is usually considered negligible when the device is used as a modulator or beam shifter. In certain applications, however, this small shift in frequency can be useful. Illustrated in Fig. 3.22, is a standing wave surface acoustic wave optical modulator (SWSAWOM) that can produce frequency shifts of an optical carrier wave that are large enough to permit frequency multiplexing of a number of information signal channels onto one optical beam (Ih et al., 1988). In this device a Ti diffused waveguide is formed in a LiNbO_3 substrate, where the output of a semiconductor laser is butt coupled into the waveguide. The guided optical beam is then collimated by a **geodesic lens** before passing through a SWSAWOM. The SWSAWOM consists of two transducers each generating a SAW in opposite directions, producing an upward and downward frequency shift of the optical waves. Thus the diffracted optical beam has frequency components at $f_o + f_m$ and $f_o - f_m$, where f_m is the RF signal at which the transducers are driven. The diffracted optical beam is focused into a square-law detector by a second geodesic lens. The two spectral components of the optical beam beat together to produce a modulated subcarrier frequency of $f_c = 2f_m$. Several of these units could be constructed, each with its own particular information impressed upon its unique subcarrier frequency f_{ci} . The signals can be sorted out at the receiver via microwave filters.

The applications of SAW devices are numerous, their implementation as deflectors, tunable filters, and frequency shifters, as described, are just a few of their possible uses. Other important device applications are time multiplexer, pulse compression of chirped signal, correlators, spectrum analyzer, and isolators.

Defining Terms

Acousto-optic effect: Mechanical strain produced in a material by the passage of an acoustic wave, causing a change in the index of refraction in the material via the photoelastic effect.

Geodesic lens: A lens composed of circularly symmetric aspherical depressions (or dimples) in the surface of a thin-film waveguide. In this type of lens, light waves are confined in the waveguide and follow the longer curved path through the lens region. Waves propagating near the center of the lens travel a longer path than waves near the edge, modifying the wave front so that focusing can occur.

Optical waveguides: Optical waveguides confine, guide, and provide a propagation path for light. For integrated optical applications the geometry of the device is usually planar with a rectangular slab structure. The device contains a thin-film layer with an index of refraction (n_g) within which the light propagates. The confinement of the optical wave is based on the principle of total internal reflection, which requires that the thin film be sandwiched between an upper and lower layer with indices of refraction n_u and n_c , respectively, of values less than n_g .

Photoelastic effect: Mechanical strain in a solid causes a change in the index of refraction that can affect the phase of a light wave traveling in the strain medium. This is called the photoelastic effect.

3.3 Electromechanical Devices

C. Sankaran

3.3.1 Introduction

Electricity has long been recognized as a force with unlimited potential. Uncontrolled, electricity can perform no useful function, but can cause serious damage to property and personnel. Electromechanical devices allow us to control and harness the vast potential of electricity. While discussing electromechanical equipment, electricity and magnetism must be given equal status. Most electromechanical devices require interaction between electricity and magnetism to perform the required task. Because of the interdependency of electricity and magnetism, knowledge of the basic relationship between the two is vital to understand how electromechanical devices operate. The following laws emphasize the relationship between the two physical properties.

3.3.2 Ampere's Law

The law states that the **magnetic field intensity** around a closed magnetic circuit is equal to the total current linkage of the electromagnetic circuit,

$$\oint H dL = Ni,$$

where H is the magnetic field intensity, N the number of turns in the electrical winding, and dL is an elementary length of the magnetic circuit. In Fig. 3.23, $L = 2\pi R$ is the mean length of the toroid magnetic circuit. From Ampere's law, $HL = Ni$. The field intensity $H(\text{A/m}) = Ni/L$.

FIGURE 3.23 Ampere's law.

The magnetic field intensity is responsible for producing a magnetic **flux** ϕ in the magnetic medium. The **flux density** or the amount of flux lines per unit area of cross section of the magnetic medium is given by $B = \mu H$, where μ is known as the absolute permeability of the magnetic medium. Also, $\mu = \mu_0 \mu_r$, where μ_0 is the permeability of free space equal to $4\pi \cdot 10^{-7} \text{ Wb/A/m}$ and μ_r is the **relative permeability** of the magnetic medium. Permeability is the measure of ease with which a magnetic medium is made to carry magnetic flux. The higher the permeability, the smaller is the magnetizing force necessary to produce a given quantity of flux.

3.3.3 Faraday's Law

The law states that a time-varying magnetic flux field induces a voltage in a single conductor given by $e = -d\phi/dt$ where $d\phi/dt$ is the rate of change of flux with time and e is the induced voltage in the conductor. The negative sign indicates that the direction of the induced voltage is in a direction that would oppose the direction of the changing field. If N number of conductors are subjected to the changing magnetic field, then $e = -Nd\phi/dt$. This equation states that if the expression for the flux with respect to time is known, then the expression for the induced voltage is obtained by differentiating ϕ with respect to time.

3.3.4 Generator and Motor Laws

A voltage is induced in a conductor situated in a magnetic field if the conductor is moved across the flux field so as to create relative motion between the conductor and the flux lines. Generators utilize this principle for generating electricity. The induced voltage in a conductor of length L m, moving across a magnetic field of density B T with a velocity of V m/s is given by $e = BLV \sin \theta$, where θ is the relative

FIGURE 3.24 (a) Generator action, (b) motor action.

angle between the direction of the flux lines and direction of movement of the conductor. This expression is basic to generation of voltages in a generator. It is to be noted that if the conductors move perpendicular to the field, $\sin \theta = 1.0$, and maximum voltage is induced in the conductor. If the conductor moves parallel to the direction of the flux, $\theta = 0$ and zero voltage is induced in the conductor.

If a conductor of length L m, carrying I A is placed in a magnetic field of density B , due to interaction between the current and the magnetic field, a force is exerted on the conductor. The force is given by F (N) = $BLI \sin \psi$, where ψ is the angle between the direction of the flux and the axis of the conductor.

3.3.5 Fleming's Right-Hand (Generator) and Left-Hand (Motor) Rules

The directions of the magnetic field, the direction of movement of the conductor, and the direction of the induced voltage during generator action are governed by Fleming's right-hand rule. The rule states, with the index finger, middle finger, and the thumb of the right hand oriented at right angle to each other, if the index finger and the thumb represent the directions of the flux lines and the direction of movement of the conductor, the middle finger points in the direction of the induced voltage. Figure 3.24(a) illustrates Fleming's right-hand generator rule.

The direction of the magnetic field, the direction of the current, and the direction of motion experienced by a conductor during motor action are governed by Fleming's left-hand rule. The rule states, with the index finger, the middle finger and the thumb of the left hand placed at right angles to each other, if the index finger and the middle finger, represent the direction of the flux lines and the direction of the current in a conductor, the thumb points in the direction of movement of the conductor. Figure 3.24(b) illustrates the left-hand motor rule.

3.3.6 Switch Mechanisms and Relays

Switches are devices that are used to make or break an electrical circuit. Switches are classified into manually operated and electrically operated types. Electrically operated switches are usually larger and rated to interrupt large magnitudes of currents. During interruption of current in an electrical circuit, arcs are produced. The temperature of arcs can exceed 5000°C . If the arc is not rapidly extinguished, substantial contact erosion would occur. This would shorten the life of the switch considerably. To withstand high-temperatures and the mechanical forces associated with contact operation, the contacts in large switches are made of high-temperature, high-strength alloys of copper and silver. Periodic inspection and cleaning of the contacts must be part of maintenance of the switches. Irregularities associated with arcing and pitting and carbon deposits must be cleaned using a fine steel wool pad. Push buttons and toggle switches are usually low-current

devices, rated 10 A or less used in low-energy electrical control or power circuits rated less than 600 V. These are classified into maintained contact or momentary contact devices depending on if the change in contact status is to be momentary or maintained for the circuit to operate. These devices are provided with a *make* and a *break* rating. Since arcing accompanies current disruption, the break ratings of these devices are lower than the make ratings. Normally, push buttons and relays are tested for number of operations exceeding 100,000 and perhaps as high as one million. These devices are sometimes provided with DC ratings. DC ratings are lower than AC ratings since current interruptions are more difficult to accomplish for direct currents due to the absence of zero crossover points of the current, which facilitate current interruption.

Power disconnect switches are used in high-energy electrical power systems for opening and closing electrical circuits rated up to 4000 A at 480 V. Smaller disconnect switches are manually operated, whereas larger switches use spring charged mechanisms to achieve fast contact operation. Arc chutes and arc chambers are provided in the power switches to divide, divert, and extinguish the arc. Maintenance procedures of power disconnect switches must include examination and cleaning of the arc chutes.

Relays are electromechanical devices that open or close an electrical circuit in response to a signal, which may be voltage, current, power, frequency, speed, temperature, pressure, flow, level, or any other physical phenomenon. Electromagnetic relays operate by the forces due to magnetic fields on an armature. Electromagnetic relays consist of an operating coil located on an electromagnet in which an armature is free to slide. When a current is circulated in the coil, a magnetic field is produced in the core of the electromagnet. The action of the magnetic field on the armature causes the armature to slide, which is the actuating action in a relay. Although it takes only a few milliamps of current to keep a relay sealed in, several amperes may be needed to initiate the movement of the armature. An important consideration for application of relays in control circuits is the selection of control transformers, which supply the relays. Excessive voltage drop in the transformer windings during initial relay operation could cause the relay to not operate. Solid-state relays are more versatile and operate within a broader voltage range. Some solid-state relays may be used for AC or DC operation. Solid-state relays are also more easily integrated into process controller schemes due to their versatility.

3.3.7 Fuses

Fuses are electrothermal devices that are used to interrupt current flow through an electrical circuit if the heating effect of the current exceeds the thermal rating of the fusible element within the fuse. As current flows through the fuse element, heat, which is proportional to the square of the current, is produced. If the current exceeds the rating of the fuse, then the heat generated by the current melts the fusible element thereby interrupting the current flow. Fuses have unique current/time (I/T) characteristics based on their design. Fast acting fuses clear the overload condition in less time than time-lag fuses. Figure 3.25 shows typical melt times of a family of time-lag fuses. Selection of fuses must be based on the thermal withstand capabilities of the load being protected. Fuse coordination is a term that refers to a fuse application process, which assigns priorities to the order in which fuses must open while protecting an electrical system. It is always preferred that the fuse immediately upstream of the protected circuit open first in case of overcurrents and the fuse nearest to the source should be the last device to open. This selectivity is required to maintain power to rest of the electrical system in case of abnormal conditions in one circuit.

Current limiting fuses are designed to open an electrical circuit before the current waveform can reach its first peak. Figure 3.26 compares energy levels that would be absorbed by the faulted circuit with and without the current limiting fuse. Without fault current limiting, considerable damage to equipment would occur. Dual-element fuses are designed to withstand transient currents, which may be present during motor starting or transformer turn on. Dual-element fuses have time-delay characteristics, which allow them to withstand short durations of current surges. These fuses are provided with a short-circuit element and an overload, element. The overload element operates under prolonged overloads, whereas the short circuit element acts to open the circuit in case of short circuits.

Fuses are classified according to their voltage and current ratings and according to their ability to interrupt fault currents. The interrupting rating of fuses varies according to their design. Failure to provide

FIGURE 3.25 Average total clearing time-current characteristic curves.

fuses with adequate interrupting ratings can result in considerable damage to equipment and possible injury to personnel.

3.3.8 Circuit Breakers

Circuit breakers are electromechanical devices used for the interruption of electrical currents due to overloads or short circuits. Most circuit breakers are thermal magnetic devices. The thermal element in a circuit breaker is a bimetal strip, which is heated by the current. The deflection of the bimetal strip due to overloads causes the breaker to trip. The bimetal strip provides inverse time trip protection as the amount

FIGURE 3.26 Current limiting fuse action.

of heat produced in the strip is proportional to the product of the square of the current and time (I^2t). Protection during short circuit conditions is provided by a magnetic element, which is actuated by the large currents that are generated during a short circuit. Typical operating characteristics of a thermal magnetic circuit breaker is shown in Fig. 3.27. Conventional thermal magnetic circuit breakers are being replaced by electronic circuit breakers. These breakers incorporate circuitry to sense the current and operate the circuit breaker in accordance with its design algorithm. These breakers incorporate potentiometer adjustments to change the overcurrent protection levels and operating time. In addition, changing the rating of the circuit breaker is readily accomplished by changing the rating plug provided on the breaker. Electronic circuit breakers also provide effective protection against ground faults. Ground fault occurs when an energized electrical wire contacts a grounded metal structure. Depending on the impedance of the ground fault, the fault currents may not be high enough to cause a conventional thermal magnetic circuit breaker to open. The electronic circuit breakers have special circuitry to detect low current ground faults. Figure 3.28 shows typical adjustments available on an electronic circuit breaker.

Circuit breakers are rated according to their voltage, current, and symmetrical current interrupting ratings. It is vital that the ratings of the breaker match the requirements of the circuit being protected.

3.3.9 Indicating Devices

Indicating devices are used to detect and measure electrical parameters such as voltage, current, frequency, real and reactive power, power factor, and energy. Most indicating devices use the principle of interaction between magnetic fields for their operation. In a moving coil meter, the coil carrying the signal to be measured is placed across the open poles of a permanent magnet iron core. The interaction between the permanent magnet field and the field due to the signal causes a rotating torque proportional to the signal. Since reversal of current in the coil produces opposite torque, moving coil indicators are only used to measure DC signals. Iron vane-type instruments have two iron vanes, which are magnetized by the coil carrying the signal. The two vanes are magnetized to opposite polarities producing a repulsive torque, which is proportional to square of the signal. Iron vane instruments can be used to measure DC or AC signals. Dynamometer-type instruments are used to measure power. These contain two field coils and a moving coil, which is suspended in the resultant field of the field coils. The field coils carry the voltage signal and the moving coil carries the current signal. The torque produced is proportional to the product of the voltage and the current and the phase angle between the two.

FIGURE 3.27 Operating characteristics of thermal magnetic circuit breaker.

FIGURE 3.28 Front panel adjustment on an electronic circuit breaker.

Rectifier-type instruments rectify the AC signal to DC for detection in a moving coil instrument. Since the moving coil instrument produces deflection proportional to the average value of the signal, the meter readings are scaled by 1.11 to indicate RMS values of the measured AC signal. However, if the AC signal contains substantial waveform distortion due to harmonics, large errors are introduced in the measurement.

Thermocouple-type instruments measure the temperature produced when a precision resistor is heated by the signal. The electrical current produced by the thermocouple is used in a moving coil instrument to measure the signal. Since the heat produced in a resistance is proportional to the RMS value of the signal, accuracy is maintained while measuring waveforms containing high-frequency components.

Energy is the product of voltage, current, powerfactor and time. Induction-disc-type instruments are used to measure energy consumed in an electrical circuit. The induction-disc instrument contains a metal disc made of aluminum or copper alloy, which is supported on bearings in a permanent magnet core and exposed to magnetic fields produced by the voltage and current. The torque developed by the induction disc is proportional to the resultant magnetic field induced in the induction disc by the voltage and the current and the cosine of the phase angle between the two. The magnet frame contains a compensating winding for power factor calibration. The watt-hour indicator is calibrated to indicate 1 kWh for a designed number of revolutions of the disc. At present, digital instruments have largely replaced the analog-type indicating devices. The digital instruments employ high sampling frequency rates to reconstruct the waveform and use frequency transformation techniques to ascertain its effective value and waveform characteristics.

Defining Terms

Flux: Lines of magnetism that circulate in a magnetic medium when a magnetizing force is applied, measured in weber; $1 \text{ Wb} = 10^8$ lines of flux.

Flux density: Lines of magnetic flux per unit area, measured in tesla; $1 \text{ T} = 1 \text{ Wb/m}^2$.

Magnetic field intensity: Magnetizing force per unit length of the magnetic circuit, measured in ampere turns per meter.

Relative permeability: Ease of magnetization of a magnetic medium compared with free air. This is a dimensionless quantity.

3.4 Aural Pickup Devices

Roy W. Rising

3.4.1 Introduction

When you say the word audio to most people, two things come to mind: microphones and loudspeakers. These two most visible portions of any audio system are just a small part of the chain of equipment that makes audio for a radio or television station, production facility, public address/intercommunication system, or any other communications network function.

The selection of equipment for a professional audio environment is a critical part of facility planning. Good planning can make the difference between a system that is capable of handling whatever jobs may arise and one that serves as a barrier to getting projects done. Every part of the audio chain is important. There are no insignificant links. Key elements of an audio facility include:

- Source origination equipment, including microphones, tape recorders and disk-based systems
- Audio control and mixing equipment
- Distribution and buffer amplifiers
- Patch bay systems
- Audio equalization and special effects equipment

3.4.2 Aural Pickup Devices

Every electronic system has a starting point. For audio, that point usually is a microphone. Advancements in recording technology have, however, given operators a multitude of options with regard to programming. The source origination equipment available for a well-equipped audio system ranges from traditional microphones to recorders of various types including digital tape and disk-based recording and playback systems. Technology has given audio programmers a new menu of sources.

Microphone Types

Microphones are transducers. No matter how large or small, elaborate or simple, expensive or economical a microphone might be, it has only one basic function: to convert acoustical energy to electrical energy. With this fundamental in mind, you might wonder why microphones exist in such a wide array of sizes, shapes, frequency-response characteristics, and element types. The answer is that although the basic function of all microphones is the same, they have to work in many different applications and under various conditions. Choosing the right microphone for a particular job might seem easy, but it is a decision that deserves considerable thought. Just as no two production situations are alike, the microphone requirements also are varied.

Microphone manufacturers try to offer a selection of products to match any application. With a good working knowledge of the various designs, choosing the right microphone for the job becomes an easier task. The learning process begins with a look at some of the microphones commonly in use today.

Microphone types can be roughly divided into two basic classes: those intended for professional applications, such as broadcast stations and recording studios, and those designed for industrial applications, such as communications equipment and special purpose audio pickup where faithful audio reproduction is not the primary concern.

Professional Microphones

A wide variety of microphones is available for professional applications. The requirements of the professional audio/video industry have led to the development of products intended for specialized applications. In general, three basic classes of microphone elements are used by professionals: dynamic, condenser, and ribbon types.

Apart from the basic microphone elements, professional users also have a number of product classes from which to choose. The selection includes:

- Stand mounted or handheld
- Tiny clip-on
- Shotgun
- Wireless
- Parabolic
- Line level

Each has its place in the professional sound recorder's bag of technical tricks.

Dynamic Microphones

Dynamic microphones are the real workhorses of the professional world. They are rugged and reliable, not particularly temperamental, and they do not require a powered impedance-conversion circuit (as condenser types do). Dynamic microphones also provide excellent sound quality, some matching the detail and precision of the finest, most expensive condensers.

The basic mechanical design of a dynamic microphone is shown in [Fig. 3.29](#). The dynamic transducer consists of a lightweight, bobbinless coil (the **voice coil**) attached to a rigid aluminum or mylar dome diaphragm and suspended in the gap between the poles of a permanent magnet. When sound waves move the diaphragm, the coil produces an output voltage. The cartridge is shock mounted in the case, which normally includes a foam filter screen for dirt and breath pop protection. Some products

include a non-moving *hum bucking* winding whose inverted output phase cancels magnetically induced hum.

The source impedance of a dynamic microphone is mostly resistive, so that the output is not substantially affected by electrical loading. These microphones are capable of wide dynamic range with low noise and minimal distortion. Dynamic microphones can be readily designed for unidirectional or omnidirectional response patterns.

Although dynamic microphones can be made fairly small and lightweight, performance tends to suffer as the size is decreased. For this reason, condenser-type transducers have taken over the clip-on body microphone market. These devices, however, are easily damaged by moisture.

Condenser Microphones

Condenser types have become popular for good reasons. They can be small and lightweight, and they can deliver accurate sound reproduction. In the world of microphones there are tradeoffs. To get the advantages of a condenser microphone you have to put up with some disadvantages. These include the following:

- The need to power an impedance-converting circuit
- A high degree of sensitivity to wind noise
- A dynamic range that is limited by the impedance converter
- The need for shielding against RF and electromagnetic interference

Condenser microphones also are more sensitive to humidity and physical shock than dynamic types.

The transducer element of a condenser microphone consists of a lightweight metal or metalized plastic diaphragm located very near a metal backplate. This forms a capacitor, as shown in Fig. 3.30. When sound waves strike the diaphragm, they cause a change in spacing between it and the backplate, varying the capacitance. With the application of a DC bias, the capacitance variations are translated into variations in electrical voltage. Extremely small capacitance gives condenser microphones a high impedance, making it necessary to add an active circuit that converts the element impedance to a lower value compatible with established standards.

A polarizing voltage of between 9 and 48 V DC is applied to the diaphragm by an external power supply. This often is built into the audio mixing console and fed as a phantom current through the microphone cable. Figure 3.31 shows the circuit for delivering standard 48 V DC **phantom power**. Some microphones do not work correctly at voltages below 36 V DC.

Because the diaphragm of a condenser microphone is not loaded down with the mass of a voice coil, it can respond quickly and accurately to incident sound. Condensers generally have excellent audio characteristics, making them a good choice for professional audio applications. Photomicrographs of condenser diaphragms at work have revealed why these microphones have varying personalities. Instead of the expected resonating drum head appearance, the surface may look like crinkled aluminum foil (L. Burroughs, 1969; personal communication). This results in uneven high-frequency response sometimes

FIGURE 3.29 Basic construction of a dynamic microphone.

FIGURE 3.30 Mechanical construction of a condenser microphone.

FIGURE 3.31 Typical circuit for 48-VDC phantom power.

called peakiness. Manufacturers’ graphs usually average this unevenness as a rise in the presence range, about 6–10 kHz.

Another type of condenser microphone is the **electret** (more accurately called an **electret-biased** condenser microphone). In this case, the condenser’s DC bias is supplied by an electret material, rather than a battery or power supply. The electret material, generally a fluorocarbon polymer, can be a part of the diaphragm or the backplate. Its electrostatic charge lasts almost indefinitely. A well-designed electret capsule retains its charge and sensitivity for 100 years or so. After more than 30 years of use, the sensitivity may drop by no more than 3 dB.

Electrets still require an impedance converter. It normally is housed within the microphone case, powered by either an internal battery or external phantom power. The amplifier, usually a field-effect transistor (FET) stage with high-input impedance, buffers the capsule from standard preamp input impedances that otherwise would resemble a short-circuit.

Electrets are most common as tiny clip-on microphones. The extremely small diaphragm in these units eliminates most of the physical shortcomings found in large diaphragm microphones. They provide very high accuracy, approaching the theoretically perfect point pickup. Electrets are available for both professional sound recording and laboratory applications.

Ribbon Microphones

Ribbon devices are not nearly as common as condenser and dynamic microphones, largely because of their reputation for fragility. However, they do provide good frequency response, excellent sound quality, and low handling noise.

The construction of a typical ribbon microphone is shown in Fig. 3.32. Basically, the ribbon microphone produces an output signal the same way as the dynamic microphone: a conductor moves in a magnetic field inducing a voltage. Instead of a voice coil, the ribbon microphone uses a thin corrugated strip of aluminum foil suspended between the poles of a permanent magnet. The ribbon, which may be as thin as 0.001 in, acts like a 1/2-turn coil and also serves as the diaphragm.

The output voltage of the ribbon diaphragm is very small, and the impedance is very low. Therefore, ribbon microphones include a transformer to boost the signal voltage. The highly inductive source impedance of ribbon microphones is sensitive to loading. The nominal (named) input impedance of a microphone preamp usually is 150 Ω. The actual

FIGURE 3.32 Basic construction of a ribbon microphone.

value should be 2000 Ω or greater. Although seldom required because of the ribbon microphone's low-output level, passive input attenuators must be used with caution. Loading below 2000 Ω will compromise frequency response.

A ribbon microphone responds to the particle velocity of the atmosphere. Dynamic and condenser microphones react to variations in atmospheric pressure. Pressure and velocity always are 90° out of phase, and so it is not possible to phase ribbon microphones with condensers and dynamics.

Ribbon microphones provide excellent sonic characteristics, good transient response, and low self-noise.

Commercial/Industrial Microphones

Microphones intended for applications outside of video production, radio, and music recording or performance are built for a different set of operational needs than those in the professional audio industry. The primary requirements of microphones for commercial and industrial users are ruggedness and intelligibility under adverse conditions. Sonic purity is less important.

Microphones in this group include hand-held noise-canceling units for mobile communications and industrial plant operations, handset and headset-boom microphones for intercom and order wire circuits, and public address microphones. Each user group has its own particular set of needs, met through variations on a few basic designs.

Carbon Microphones

Carbon microphones are low cost, rugged, reliable, and produce a high-output signal. They are used by the millions in telephone handsets. However, their output signal is inconsistent, somewhat distorted, and useful only over a limited frequency range.

The carbon microphone consists of a metal diaphragm, a fixed backplate, and carbon granules sandwiched in between (see Fig. 3.33). When sound waves move the diaphragm they alter the pressure on the granules, changing the resistance between diaphragm and backplate. Like a condenser microphone, this modulates an externally supplied voltage. The output of the carbon button is balanced by a transformer also serving to block DC from the preamplifier input.

Piezoelectric Microphones

Piezoelectric devices (also known as **crystal** or **ceramic** microphones) provide fairly broad frequency response and high output, especially at low frequencies. They generally are inexpensive and reliable, finding

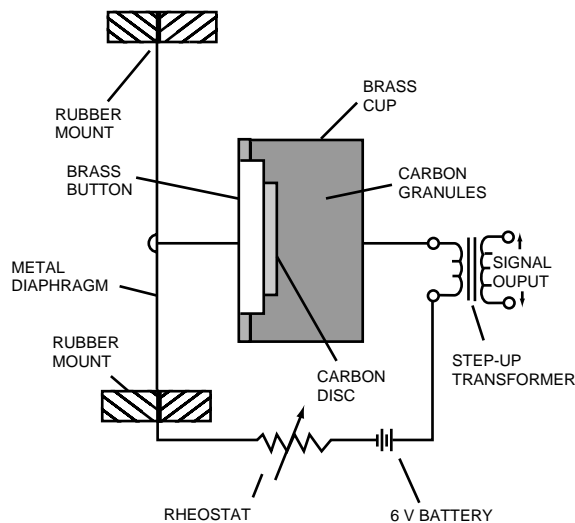

FIGURE 3.33 Construction and external electrical elements of a carbon microphone.

applications in communication microphones and some sound measurement devices. The main disadvantages of piezoelectric microphones are high-output impedance, which makes them susceptible to electrical noise, and sensitivity to mechanical vibration.

Figure 3.34 shows the basic construction of a piezoelectric microphone. The equivalent circuit is that of a capacitor in series with a voltage generator. When mechanically stressed, the element generates a voltage across its opposing surfaces. One end of the piezoelectric element is attached to the center of a diaphragm (usually made of aluminum foil) and the other end of the element is clamped to the microphone frame. When sound energy strikes the diaphragm, it vibrates the crystal, deforming it slightly. In response, the crystal generates a voltage proportional to this bending, delivering an electrical representation of the sound.

FIGURE 3.34 Mechanical layout of a piezoelectric microphone.

Controlled Magnetic Microphones

A controlled magnetic microphone consists of a strip of magnetically permeable material suspended in a coil of wire, with one end placed between the poles of a permanent magnet. The center of the diaphragm is attached to the suspended end of the armature. Movement of the armature in the magnet's gap induces a voltage in the surrounding coil. The voltage is proportionate to the armature swing and constitutes the output signal. Electrically the transducer is equivalent to a voltage generator in series with a resistor and an inductor. Controlled magnetic microphones are also known as magnetic, variable-reluctance, moving-armature, or balanced-armature devices, depending on the manufacturer.

Controlled magnetic microphones commonly are used for communications and paging because of their sensitivity, ruggedness, and dependability.

3.4.3 Directional Patterns

Every microphone type has a specific directional or polar pattern. That is, each microphone responds in a specific way to sounds arriving from different directions. The polar pattern describes graphically the directionality of a given microphone. Although many different polar patterns are possible, the most common are **omnidirectional**, **bidirectional**, and varieties of **unidirectional**. Some products provide selection among these patterns and a few offer intermediate choices as well. An omnidirectional microphone responds uniformly to sound arriving from any direction. A unidirectional microphone is most sensitive to sounds arriving at the front of the microphone; it is less sensitive to sounds coming from other directions. Bidirectional microphones are most sensitive to sounds on either side of the pickup element. The pickup pattern for a bidirectional microphone is a figure eight.

The main disadvantages of an omnidirectional microphone, as compared with a unidirectional, are lack of rejection of background sounds or noise and a susceptibility to feedback in sound-reinforcement applications.

Omnidirectional microphones are widely used in broadcast and other professional applications for several reasons. First, it is difficult to make a unidirectional microphone very small. As a result, most on-camera clip-on microphones are omnidirectional. This does not create much of a problem, however, because most broadcast environments where body microphones are employed can be controlled to minimize background noise and other extraneous sounds. Also, a body microphone can be located closer to the mouth than a boom microphone at the edge of the frame.

FIGURE 3.35 Typical cardioid polar pattern, plotted at six discrete frequencies. The graphics plot the output in decibels as a function of the microphone's angle relative to the sound source.

Many of the microphones used by radio and television reporters are omnidirectional because it is often desirable to pick up some ambient sounds in the field to add to the broadcast's sense of liveness. Another plus is the omnidirectional microphone's ability to pick up room ambiance and natural reverberation to alleviate the aural flatness a unidirectional microphone might produce.

There are many applications, however, where a unidirectional pickup pattern is desirable. The most obvious is sound reinforcement, where the need to avoid feedback is a primary concern. By reducing the pickup of extraneous sounds, a unidirectional microphone makes available more overall system gain.

The most common form of unidirectional microphone is the **cardioid** type, whose polar pattern is graphically depicted as heart shaped (see Fig. 3.35). The area at the bottom of the heart corresponds to the on-axis front of the microphone, the area of greatest sensitivity. The notch at the top of the heart corresponds to the back of the microphone, the area of least receptivity (referred to as the null). By contrast, the omnidirectional microphone's polar pattern is (ideally) depicted as a circle.

Special Pattern Microphones

Other varieties of unidirectional microphones include the **supercardioid**, **hypercardioid**, and ultradirectional types such as the line/gradient **shotgun** microphone. Supercardioid and hypercardioid microphones are variations of the bidirectional pattern. The front lobe is enlarged as the back lobe is reduced. The null points are moved from the sides toward the rear of the pattern. The supercardioid polar pattern is shown in Fig. 3.36. Also note the variation in polar response for the four frequencies shown.

Hypercardioid microphones offer somewhat greater rejection of off-axis sound, but usually at the expense of frequency response and/or polar pattern smoothness. A few units do provide uniform frequency response from all directions, but sometimes the truth they tell about ambient conditions is less desirable. Lack of polar pattern smoothness can be a hazard in live performance foldback systems. An unexpected off-axis lobe may be pointed at a nearby high-level loudspeaker. Some foldback applications have demonstrated higher gain before feedback using omnidirectional microphones with extremely smooth polar frequency response.

The line/gradient shotgun microphone is a special type of ultradirectional design. The shotgun offers an extremely tight polar response pattern sometimes referred to as club shaped. However, most shotguns come

FIGURE 3.36 Typical supercardioid polar pattern, plotted at four discrete frequencies. Note the nulls that appear at the sides of the microphone, rather than at the back.

with a dizzying array of unpredictable side lobes. For interior applications, these often result in deteriorated quality because of reflection off the walls and other hard surfaces. Outdoors, shotgun microphones seem to reach farther than other directional microphones. In truth, they simply reject background noise better. Keep in mind that microphones do not reach; sound travels. The shotgun can pick out sounds at a distance, while ignoring ambient noise. Because the shotgun has a narrow working angle, the microphones must be kept on axis while in use. This is in contrast to the wider acceptance of other directional microphones, the null of which sometimes can be directed toward a problem source without losing the intended source. Generally speaking, the longer the body, the more directional a shotgun microphone will be.

New shotgun designs feature a combination of cartridge tuning and interference tube tuning to achieve smoother frequency response and polar patterns. Compromises in the tuning factors dictate what the microphone sounds like, and how it behaves.

Stereo Pickup Techniques

Stereo microphones contain dual elements. A front facing cardioid or super cardioid picks up the direct monophonic signal. A side-facing figure eight element captures the stereo space surrounding the microphone. Internal addition and subtraction of the two signals yields left and right information. Known as *mid-side* (MS) microphones, these systems also offer direct output from the elements for recording and subsequent processing into left and right signals with adjustable stereo spatiality. Some products provide built-in left/right selection of mono, partial stereo, and full stereo.

Frequency Response

The frequency response of a microphone describes the sensitivity of the device as a function of frequency. The **range of response** defines the highest and lowest frequencies the microphone can successfully reproduce. The shape of a microphone’s response curve indicates how it responds within this range. [Figure 3.37](#) shows a typical microphone frequency-response plot.

Frequency response often is affected by the polar pattern of the microphone. As mentioned previously, the frequency response may vary depending on the direction of the sound source and the distance from the sound source to the microphone. Most directional microphones exhibit proximity effect, an unnatural

FIGURE 3.37 A typical frequency-response plot for a microphone used in stage and general sound-reinforcement work. Note the high-end presence peak and low-end rolloff.

boost of low frequencies when placed less than 1 m from the source. In addition, some microphones have built-in equalization controls that can alter their frequency response.

The ideal frequency range for a microphone may be 16 Hz–20 kHz with ruler-flat response and no peakiness or other colorations. Sound from such a microphone can be adjusted by careful use of filters and equalizers for specific results. In practice, the best frequency response for a given microphone depends on the application and the personal taste of the user. For precise, accurate, lifelike studio recording, a microphone with flat response usually is desirable. For most sound reinforcement applications and other voice-oriented uses, a presence boost in the upper midrange and rolloff on the low end adds clarity and intelligibility. Many handheld microphones used for field reporting and interviews have response tailored for voice intelligibility. The range from 150 Hz to 12 kHz is effective for this purpose.

3.4.4 Selecting Microphone Types

The handheld microphone, probably the most popular type of microphone, is available in many shapes and sizes. Manufactured in both directional and nondirectional versions, the handheld microphone provides wide frequency response, low handling noise, and a wide choice of characteristic sounds. Because adequate space is available, a shock-mount system is incorporated into most professional handheld microphones. Just holding a microphone or dragging the cable across a floor can cause low-frequency noise to be transmitted to the cartridge. A shock-mount system minimizes such noise.

The clip-on body microphone also is in high demand today. Its small size and wide frequency response offer professional users what appears to be the best of all worlds. Small size translates into minimum visual distraction on-camera or before an audience. Wide frequency response assures good audio quality. There are other points to consider, however, before a clip-on microphone is chosen for an application.

The smallest clip-ons available are omnidirectional. This makes the talent's job more comfortable because staying on-microphone is easier. Directional clip-ons are available, but they have performance tradeoffs. The most obvious is size. To make a microphone directional, a back entry must be added to the housing so that sound can reach the back of the capsule. The distance from the back port to the element determines the wave length above which (hence, the frequency below which) the pattern becomes omnidirectional. This translates into a larger housing for the microphone capsule. Although not as large as a handheld microphone, an effective unidirectional clip-on must be noticeably larger than its omnidirectional counterpart. To keep the size under control, shock mounting of the directional capsule may be compromised. This results in a microphone that exhibits more handling noise than a comparable omnidirectional microphone.

Windscreens for clip-on microphones usually are needed for outdoor use. Even a soft breeze can cause damage to the audio track. The culprit is turbulence, caused by wind hitting the grille or case of the microphone. The sharper the edges, the greater the turbulence. A good windscreen helps to break up the flow of air around the microphone and reduce turbulence. Windscreens work best when fitted loosely around the grille of any microphone. A windscreen that has been jammed down on a microphone serves only to close off part of the normal acoustic path from the sound source to the diaphragm. The end result is attenuated high-frequency response and reduced wind protection.

The task of applying a microphone to a sound source engages an interesting process of elimination. If the source may be expected to be constant within defined limits, the selection range may be narrowed. If the unexpected must be anticipated, however, more generic specifications should be considered.

Defining Terms

Bidirectional pattern: A microphone pickup pattern resembling a figure eight, in which the device is most sensitive to sounds on either side of the pickup element.

Cardioid pattern: A microphone pickup pattern whose polar plot is graphically depicted as heart shaped.

Electret (or electret-biased) microphone: A variation on the basic condenser microphone in which the DC bias is supplied by an electret material, rather than a battery or power supply.

Phantom power: The practice of powering the element of a condenser microphone via a low-value current on the microphone cable.

Range of responses: The highest and lowest frequencies that a microphone can successfully reproduce.

Voice coil: The bobbinless coil transducer element of a dynamic microphone.

3.5 Aural Reproduction Devices

Michael Starling

3.5.1 Introduction

The most frequently employed aural reproduction device is the loudspeaker. Loudspeakers are *electromechano-acoustic* transducers that transform electrical energy into acoustic energy, through the mechanical coupling of a diaphragm to the air mass. Aural reproduction design consists of a series of resonance, damping, matching, and energy transfer tradeoffs.

Many acousticians believe that the loudspeaker is the single most critical component in the recording and playback chain. Even the most subtle, and sometimes nonquantifiable nonlinearity of the loudspeaker system can seriously color sound quality. The physics of the electromechanoacoustic process presents a seemingly infinite number of opportunities for reproduction error. Moreover, these anomalies are further complicated by radically differing effects when reproduced stereophonically.

Various techniques and approaches have been devised to deal with the distortions and errors that accumulate through each stage of the reproducing system. These anomalies are best understood by reducing the elements of electromechanoacoustic transduction to core principles.

3.5.2 Sound Theory

Wavelength and frequency are related inversely as illustrated by $\lambda = v/f$, where the wavelength (in meters or feet) is equal to the velocity (meters or feet per second)/frequency in hertz. Velocity at sea level and 25°C is 1130 f/s or 339 m/s. Temperature and other effects on velocity will be shown later, but can be assumed to be minimal under normal indoor conditions. See Fig. 3.38 (Eargle, 1994, 5) to determine the wavelength for any given frequency.

Point Source Radiation

The inverse square law states that sound field intensity drops roughly 6 dB for each doubling of distance in *spherical space*. This is shown by

$$L_p \text{ (measuring point)} = L_p \text{ (reference point)} + 20 \log D_r / D_m$$

Spherical space is an ideal, often referred to as *free space* and limited in practice to elevated sound sources in outdoor settings and in the characteristics of anechoic chambers.

As noted by D. Davis and C. Davis (1987), the sound intensity drops by only 3 dB per doubling of distance in cylindrical space. This occurs when encountering an infinite line source, such as can be approached by

FIGURE 3.38 Frequency and wavelength in air. (Source: Eargle, J.M. 1994. *Electroacoustical Reference Data*, p. 5. Van Nostrand Reinhold, New York.)

FIGURE 3.39 Attenuation with distance from plane and line sources in a free field. (Source: Eargle, J.M. 1994. *Electroacoustical Reference Data*. Van Nostrand Reinhold, New York.)

the ambient noise of race cars evenly spread. Beyond a distance of roughly one-third of the length of the line source, however, the loss will approach 6 dB per doubling of distance. This is illustrated by Fig. 3.39 (Eargle, 1994, 9).

One example of an effort to simulate a point source radiator is shown in Fig. 3.40. (Tremaine 1973, 1111).

By connecting the voice coils 180° out of phase and perforating the diaphragms, the internal air resistance is minimized, and the surrounding air mass is modulated coherently. Such speaker systems have been installed by hanging them from ceilings. The lack of ideal free space and infinite line sources in most settings is readily apparent. Free field inverse square losses can be calculated using the nomograph in Fig. 3.41 (Eargle, 1994, 7).

FIGURE 3.40 Simulated spherical loud-speaker. The housing is perforated with many small holes. The voice coils are connected 180° out of phase. (Source: Tremaine, H.M. 1973. *Audio Cyclopedia*, 2nd ed., p. 111. Howard Sams.)

Plane Source Radiation in an Infinite Baffle

Plane source radiation loss patterns are predicted based on the length of the sides of the plane radiator. The plane radiator is assumed to present a uniform emanated wave with the surface of the radiating piston vibrating in phase at all points.

No discernible loss is noted until a distance of roughly one-third of the length of the shorter side of the plane radiator is reached. Once a distance from the plane radiator is reached that is roughly one-third of the distance of the shorter side, the sound field falls off at roughly 3 dB per doubling of distance. Once a distance that is roughly one-third of the length of the longer side of the plane radiator is reached, the attenuation approaches 6 dB per doubling of distance.

The actual distances are given as A/π and B/π . When the ratio of the sides is within two or three of each other, the three rate of loss regions are difficult to discern. However, once A and B are in a ratio of six or higher, the three regions become more apparent. See Fig. 3.42 (Eargle, 1994, 9).

FIGURE 3.41 Inverse square losses in a free field. (From Eargle, J.M. 1994. *Electroacoustical Reference Data*, p. 7. Van Nostrand Reinhold, New York.)

FIGURE 3.42 Attenuation with distance from plane and line sources in a free field. (Source: Eargle, J.M. 1994. *Electroacoustical Reference Data*, p. 9. Van Nostrand Reinhold, New York.)

Diffraction Around Solid Objects

The environmental setting of the reproducing system greatly affects objective (measurable by test instruments) and subjective (discernible to trained listeners) frequency response and imaging location. Comb filtering is especially apparent when studying the diffraction patterns where sound waves from planal sources impinge the object. Not unexpectedly, objects with minimal sharp transitions produce the least serious off-axis colorations.

Note that spherical objects produce the most uniform frequency response. Also note that where $\theta = 150^\circ$ the most serious diffraction occurs. For the cylinder and cube this angle places a very sharp transition between the point of radiation and the measuring point at 0° . Since a variety of objects are found in most listening areas, even in recording studios, very careful design of the ambient monitoring environment is essential to transparent sound reproduction. See Fig. 3.43 (Eargle, 1994, 29).

Reflection

Reflection occurs whenever a sound wave hits an object that is larger than $1/4$ wavelength. Reflections from large objects often impairs speech intelligibility. However, reflections with short time delays can be very beneficial because they can be designed to constructively combine with the incident sound to produce an apparently much louder sound (see the **Haas effect**, discussed subsequently). For reflections occurring beyond 50 ms, however, loss of intelligibility can result. Diffuse reverberation combines to impair intelligibility once the direct-to-noise ratio falls below 10–15 dBA. An ideal direct signal-to-noise ratio for maximum intelligibility is considered 25 dBA.

With any significant reflection, where reverberation time exceeds 1.5 s, the intelligibility of speech is severely affected. Because syllables typically occur some 3–4 times per second, the effect of reverberant overhang is considerably less under 1.5 s. Peutz is credited with charting the relationship of the loss of consonants and concluded that a 15% loss was the maximum tolerable by most listeners. It has been noted that for large indoor areas, such as sports arenas, a single central reproducing sound cluster is more favorable than several loudspeakers groups due to the increased reverberant field caused by the dispersed arrays. Moreover, the remaining problem of sound coverage in areas not within the field of the main cluster (walkways, galleries, and under balconies) is solved by low-level distributed systems, with time delays synchronized to that of the main cluster.

FIGURE 3.43 Diffraction of sound by a cylinder, a cube, and a sphere. (Source: Eargle, J.M. 1994. *Electroacoustical Reference Data*, p. 29. Van Nostrand Reinhold, New York.)

Refraction

Refraction occurs whenever sound passes between different transmission media. This commonly occurs when sound passes between layers of air of differing temperature. The velocity of sound increases with increasing temperature, and differing wind velocities encountered at different elevations can also cause sound bending. D. Davis and C. Davis (1987) have noted that the effect of temperature differences is particularly apparent over frozen surfaces on a sunny day. This is because the warmer air above the surface of the cold surface travels faster than the cooler air below, thus bending the sound wave back toward the ground and resulting in tremendous transmission range. See Fig. 3.44 and Fig. 3.45 (D. Davis and C. Davis, 1987, 151).

FIGURE 3.44 Effect of temperature differences between the ground and the air on the propagation of sound. (Source: Davis, D. and Davis, C. 1987. *Sound System Engineering*, 2nd ed., p. 151. Howard Sams.)

FIGURE 3.45 Effect of temperature differences between the ground and the air on the propagation of sound. (Source: Davis, D. and Davis, C. 1987. *Sound System Engineering*, 2nd ed., p. 151. Howard Sams.)

Absorption

Absorption is the inverse of reflection. When a sound wave strikes any large object (greater than 1/4 wavelength) part of the wave is reflected and part is absorbed. For a given material the absorption coefficient is expressed as the ratio of absorbed sound to reflected sound. Thus, the absorption coefficient is a number between 0 and 1 and directly describes the percentage of absorbed sound (0.25 absorption coefficient is equal to 25% absorbed sound).

Atmospheric absorption is a form of sound energy dissipation caused by the combined action of the viscosity and heat conduction of the air and the relaxed vibrations due to rotational energy effects of air molecules. Vibrational energy is affected by the presence of water molecules in the air.

3.5.3 Environmental Effects on Sound Reproduction

Other environmental effects also affect aural reproducing systems and must be considered by careful designers.

Humidity

The greater air density of higher humidities actually improves (lessens) the normally increased attenuation of higher audio frequencies. At 20% relative humidity the atmospheric absorption begins to deviate from the absorption rate of 80% humidity above 3 kHz. At a distance of 40 m (131 ft) the 10-kHz frequency absorption is 10 dB greater with only 20% relative humidity. This factor is important for large outdoor sound reinforcement settings. See Fig. 3.46 (Eargle, 1994, 15).

Temperature

Because the wavelength of radiated sound is fundamental to interactions in the ambient field, factors also affecting the velocity of the sound are important. As we have seen, velocity is a product of wavelength and frequency. $\lambda = c/f$, where c is the velocity of sound in feet per second or meters per second, f is the frequency of sound in hertz and λ is the wavelength in feet or meters. To calculate velocity at a specific temperature, $c = 20.6\sqrt{273 + ^\circ\text{C}}$. Thus, the velocity of sound varies between 340.36 m/s at 0°C and 355.61 m/s at 25°C.

Doppler Effect

The classic frequency shift of a moving sound source that approaches or recedes from the listener is also an important component of reproducing systems. The compression and expansion of wavelength has been shown by D. Davis and C. Davis (1987) for a car or train passing the listener at 60 mi/h. The shift of a 1000-Hz tone shifts from 1184 to 928 Hz. This effect is also at work due to the low-frequency excursion of a loudspeaker diaphragm while simultaneously reproducing a high-frequency signal. Calculation of

FIGURE 3.46 Atmospheric absorption due to inverse square losses and relative humidity. (Source: Eargle, J.M. 1994. *Electroacoustical Reference Data*, p. 15. Van Nostrand Reinhold, New York.)

Doppler shift is illustrated by

$$F = \frac{V \pm V_L}{V \pm V_s} F_s$$

where

- F = frequency heard
- V = velocity of sound
- V_L = velocity of the listener
- V_s = velocity of the source
- F_s = frequency of the sound source

3.5.4 Characteristics of Human Hearing

Equal Loudness Contours

As early as 1933, Fletcher and Munson demonstrated that human hearing was subject to diminished response, particularly to lower frequencies, at lower sound pressure levels. This effect is commonly compensated for by the familiar loudness buttons on most consumer amplifiers. See Fig. 3.47 (Borwick, 1994, 2).

3.5.4.1 High-Frequency Acuity and Aging

High-frequency response generally diminishes with age, and this loss usually affects men more than women. D. Davis and C. Davis (1987) recommend that design engineers should not compensate for the hearing loss. They state three compelling reasons:

- Young people with normal hearing will be annoyed.
- Older people who have made mental compensations for the gradual onset of the loss would also be annoyed.

FIGURE 3.47 Equal loudness contours for human hearing in free-field listening conditions. (Source: Ford. 1994. Principles of sound radiation. In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed. p. 2. Focal.)

FIGURE 3.48 Effect of loudspeaker sound path differences on signal arrival times and intelligibility. (Source: Mapp. 1994. Sound reinforcement and public address. In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 355. Focal.)

- Available high-frequency drivers would produce noticeably increased distortion due to the high-frequency boost.

Since spoken word intelligibility is dependent on accurate consonant perception, designers of specialized systems, such as hearing aids or radio reading services for the elderly, should make appropriate system compensations.

Haas Effect

The effect of time delays between direct and reflected sounds can cause apparent spatial shifts in the sound source and also affect loudness and intelligibility. These effects were documented by Haas in 1951. As shown by Mapp, reflections can result in the listening phenomena illustrated in Fig. 3.48 (Borwick, 1994, 355).

Delays of as little as a few milliseconds are what constitutes location information in the integration abilities of humans. Two synchronized sound sources placed before a listener, as is standard with stereo loudspeakers, appear to shift from being at the midpoint location to emanating toward the first in time source until delayed by 20–30 ms. Once the delay exceeds 20–30 ms the sources will diverge and be clearly discernible as two separately emanating sounds.

Haas’ work was primarily concerned with the effect of delayed sound from a common source. He noted that with up to 20–30 ms of delay, the delayed sound would be masked and listeners would detect only a single louder direct sound source. See Fig. 3.49 (Borwick, 1994, 356).

FIGURE 3.49 Haas effect curve. (Source: Mapp. 1994. Sound reinforcement and public address. In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 356. Focal.)

3.5.5 Elements of Aural Transduction Systems

Horn Systems

Horn loudspeakers may be viewed as an impedance matching device that mechanically couples the diaphragm to the air mass at the mouth of the horn. Horn-type loudspeakers were the first loudspeakers, and to this day their efficiency is unmatched by other loudspeaker types. Typical horn efficiency is between 25 and 50%, compared to less than 5% efficiency for most direct radiating loudspeakers. Any system employing only a horn is known as a *projector type* system.

Over the course of many years of experimentation with various rates of flare, it was discovered that the exponential and hypex flares produced the highest throat resistances, and also the flattest response. A hypex flare is a hybrid between a hyperbolic and exponential flare. See Fig. 3.50 (Tremaine, 1973, 1099).

FIGURE 3.50 Comparison of the different rates of flare used in the design of loudspeaker horns. (Source: Tremaine, H.M. 1973. *Audio Cyclopedia*, 2nd ed., p. 1099. Howard Sams.)

The impedance and frequency response of various horn flares is shown in Fig. 3.51 (Borwick, 1994, 18).

Lower frequency response of horn radiators generally falls off at 6 dB/octave, provided that throat impedance is resistive (above the horn cutoff frequency). High-frequency response is limited by the mass reactance of the moving system, but can be extended several octaves by designing the cavity volume to resonate with the mass of the diaphragm at a frequency above cutoff impedance of the moving system and reflected throat resistance. The response above this resonance point falls off at 12 dB/octave.

FIGURE 3.51 The acoustic impedance at the throats of infinitely long exponential, hyperbolic, conical and parabolic horns (after Dinsdale and Olson). (Source: Ford, 1994. In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 18. Focal.)

A special problem at high frequencies, when the diaphragm radius approaches one-quarter wavelength, results in a lack of phase coherence between the radiating edge and the center of the diaphragm. Response irregularities result, but are often compensated for by use of a phasing plug. The plug is fitted between the diaphragm and throat and presents several identical air paths between these two elements. This results in a constant phase delay across the diaphragm and smoothes the response irregularities at the higher frequencies. See Fig. 3.52 (Borwick, 1994, 96).

An unusual side effect of horn radiator efficiency and directional air mass coupling is that air overload can be encountered in horn systems above 120 dB. At these levels the air itself becomes nonlinear. The most troubling obstacle in large high-output systems are the harmonic distortions due to the compression volume being less than the volume displaced during rarefaction. See Fig. 3.53 (Tremaine, 1973, 1093).

For optimum efficiency, Kelly has recommended that the diaphragm area must be larger than the throat area. He notes that for a given distortion level, the power output is directly proportional to the area of the throat entrance port. See Fig. 3.54 (Borwick, 1994, 99).

Direct Radiators

Direct radiators are the most widely employed form of loudspeaker design. These are speakers in which a diaphragm is directly coupled to the air mass and radiates directly into the listening area. Although

FIGURE 3.52 Phasing plug with 50-mm diaphragm and 20-mm throat. (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 96. Focal.)

FIGURE 3.53 (a) During compression the diaphragm moves forward, (b) during rarefaction the diaphragm moves backward. (From Tremaine, H.M. 1973. *Audio Cyclopaedia*, 2nd ed., p. 1093. Howard Sams.)

direct radiator loudspeakers were first discussed by Lord Rayleigh in 1877, Chester Rice and E.W. Kellogg are credited with the construction of the first direct radiator dynamic loudspeaker in 1925. Six years later, in 1931, Frederick, of Bell Telephone Laboratories, demonstrated a two-way system. Innumerable improvements on these developments have followed over the ensuing decades, yet the fundamental designs are still fully recognizable.

FIGURE 3.54 Percentage second harmonic distortion as a function of power at horn throat, with the ratio of the frequency f to the cutoff frequency f_c . (From Kelly. 1994. In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 99. Focal.)

Despite their common usage, direct radiators achieve their modern success through the accumulated improvement of many decades of experience with such diverse problems as voice coil heat buildup, diaphragm nodes, enclosure types, and the complications of multiple radiator/crossover networks.

The objective of these interrelated tasks is illusory: to recreate for the listener the original incident sound field with a flat direct frequency response and a flat reverberant field. As noted by Colloms (1991): “[N]early all box-type direct radiator loudspeakers have the opposite characteristic to that which is required. For most loudspeakers their power response reduces with frequency, worsened by the natural increase in room absorption with increasing frequency.”

The obstacles to successful direct radiator systems cross diverse branches of physics and continue to provide fertile ground for radical design departures as new approaches to old problems are documented before professional societies.

Figure 3.55 provides a cross sectional view of the basic dynamic loudspeaker direct radiator (Tremaine, 1973, 1079, and 1080).

FIGURE 3.55 Cross-sectional construction view of a dynamic loudspeaker. Item A is the frame or basket, supporting a diaphragm B, with a voice coil C attached to the apex of the diaphragm. The outer edges of the diaphragm are supported by a flexible edge D. The voice coil consists of several turns of small copper or aluminum wire, centered over a central pole piece E in a magnetic structure F built in the form of the letter E. The voice-coil assembly is centered over the pole piece by means of spider G. The magnetic lines of flux are indicated by the dotted lines H. The central pole piece E becomes the south pole of the magnetic field and the outer edges of the magnetic structure are the north pole of the magnetic field. (From Tremaine, H.M. 1973. *Audio Cyclopedia*, 2nd ed., pp. 1079, 1080. Howard Sams.)

Voice Coil

The voice coil is the heart of modern loudspeakers. In its simplest form the voice coil is a coil of wire, through which electrical waves are applied, suspended within a fixed magnetic field, and directly coupled to a movable diaphragm. It is the physical movement of the voice coil due to the interaction of its magnetic current flow and the magnetic field surrounding the coil that causes the diaphragm to vibrate in response to the applied audio waves and thereby produce sound.

Temperature Rise

The voice coil itself is inherently nonlinear due to heat buildup that occurs over prolonged activity, especially at higher volume levels. Power handling of early loudspeakers was largely limited by the paper formers then in use. Those voice coils could only tolerate a temperature rise to about 100°C, which limited a typical 10-in diaphragm unit to about 35 W of continuous input power. Modern formers using a polyamide (Nomex) or polyimide (Kapton) can operate with up to 350° temperature rises.

Temperature rise immunity is critical since an increased input power raises both temperature and resistance. It has been generally noted that for a rise of 250°C resistance of the coil doubled, similar to the *apparent power* handling capacity of the loudspeaker. In reality, of course, the operative coupling force of the loudspeaker is proportional to current only and under these conditions the overall efficiency of the system is halved. See Fig. 3.56 (Borwick, 1994, 74).

Gap Placement and Dimensional Configuration

For maximum efficiency, maximizing the magnetic field flux across the voice coil requires the smallest coil to pole piece gap dimension possible based on peak voice coil excursion and power dissipation. As a practical matter this gap must be increased somewhat to compensate for dimensional expansion as operating temperature increases.

For a nominal 50-mm voice coil operating at 250°C gap clearance must be increased by 0.4 mm.

FIGURE 3.56 Voice-coil temperature vs. input power. (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 74. Focal.)

Three basic voice coil/magnetic gap ratios are in common use: overhanging, short coil, and equal coil and gap. See Fig. 3.57. (Borwick, 1994, 76). The equal gap ratio is the most cost-effective configuration. Distortion due to asymmetry of the leakage flux is minimal, provided the top plate thickness of the magnetic assembly is four times greater than the peak voice coil displacement. This requirement is readily met and is the most commonly employed method in small excursion midrange and high-frequency systems.

FIGURE 3.57 The three basic voice-coil/magnet gap configurations: (a) overhanging coil, (b) short coil, (c) equal-length coil and gap. (Source: In *Loudspeaker and Headphone Handbook*, 1994. ed. J. Borwick, 2nd ed., p. 76. Focal.)

The oversized voice coil configuration is best for wide excursion units, such as subwoofers and other high-power, low-frequency systems. The main disadvantage of this configuration is that considerable distortion results from any asymmetry in the flux leakage between the compression and rarefaction swing. This flux leakage distortion is best minimized by the oversized top plate assembly, but is also the most costly.

Flux distribution and distortion are additionally affected by whether the effective center pole of the voice coil is flush or extended above the top plate of the magnetic structure. The most cost-effective manufacturing places the units flush but results in asymmetrical flux leakage. By lengthening the center pole of the voice coil above the top plate of the magnetic structure, more symmetrical flux leakage is achieved and second harmonic distortion is dramatically decreased.

The Magnetic Structure

The earliest dynamic loudspeakers employed an electrodynamic design whereby the field coil was energized by a DC current. When the field coil was energized the audio frequency signal applied to the voice coil caused the voice coil to swing inward or outward depending on the instantaneous polarity. Modern designs have dispensed with the mechanical offset this required and now rely exclusively on permanent-magnet systems for the loudspeaker’s fixed field.

From the earliest designs of carbon steel with magnetic flux (B) and magnetic force (H) products of about 1.6 kJ/m³, Alnico was developed by 1934 (cobalt-iron-nickel-aluminum-copper) with a BH product of

12.8 kJ/m³. Fully columnar magnets, heated above the Curie point (1200°C), cooled in a strong unidirectional flux field resulted in anisotropic magnets with a BH maximum of 60 kJ/m³. However, during the 1970s the world supply of cobalt was destabilized due to mining problems. Earlier work based on using nonmetallic ferrite cores to reduce eddy currents was accelerated. Ferrite cores are still far more economical, but require much greater volume to achieve flux densities approaching that of Alnico cores.

Operating temperature of the magnet has a substantial effect on voice coil assembly performance. Modernly, **ferrofluids** (generally MOFe₂O₃) are commonly employed in the gap between the voice coil and the magnet surface. The fluid is held in intimate contact with the magnetic assembly surface and the voice coil itself. Over short throw applications the ferrofluid is directionally secure and can even be stabilized for low-frequency high-excursion systems by proper venting of the dust cap.

The ferrofluid results in greatly improved heat transfer, which allows the voice coil assembly to handle much greater transient peaks. Temperature recovery is substantially improved. A peak of 8 W above nominal program for 1 min would cause the voice coil to rise from 80° to 100°C with the return to nominal operating temperature in 10 s. Without ferrofluid treatment the voice coil would rise to 213°C.

Also note that the normally resulting increase in mechanical damping is generally transparent, even at low signal levels, due to the well-stabilized magnetic moment of the ferrofluid itself. See Fig. 3.58 (Borwick, 1994, 92).

In many direct radiators a centering spider connects between the voice coil and basket frame or magnet as a means of stabilizing the coil's position relative to the pole piece. A second spider is sometimes employed for greater ruggedness, but with a commensurate effect on mechanical complexity of the voice coil/magnet motor and, thus, on frequency response and efficiency. Modern spiders are generally constructed of impregnated cloth for rigidity. The term spider evolved from the first 15-in loudspeaker developed by RCA which used heavy threads to center the voice coil. Unlike modern spiders these early true spider systems required frequent recentring.

FIGURE 3.58 Schematic showing ferrofluid in the magnet gap. (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 92. Focal.)

Diaphragm

The acoustic impedance of the diaphragm varies with factors such as material construction, baffle design, surface compliance, suspension damping, applied frequency, and even operating temperature and humidity. Traditional cone diaphragms were made of paper construction. Modern musical instrument loudspeakers still employ paper felted cones due to high stiffness-to-mass and ruggedness. Polypropylene is popular for consumer applications, but generally is limited to applications below 7 kHz.

Although heat buildup and physical distortion of the voice coil are a central reproducing system design problem, the diaphragm itself is perhaps the most challenging hurdle simply because the physical dimensions required to move any appreciable air volume deviate significantly from the ideal uniform piston in which all radiating mechanical parts vibrate with the same phase, magnitude, and velocity.

Direct radiator systems frequently exhibit nonlinearities due to the flexure nodes caused by standing waves across the diaphragmatic surface. To minimize flexure nodes a given diaphragm should be designed to cover no more than one decade (e.g., 20–200 Hz, 200 Hz–2 kHz, and 2–20 kHz). Many proprietary techniques are employed by various manufacturers that seek to achieve maximum stiffness and minimum mass of the diaphragm. Specific formulations of pulp, slurry, binders, and coefficient additives are often closely guarded trade secrets.

Hybrid techniques such as corrugating the cone with secondary suction and coating can achieve successful decoupling at higher frequencies, thereby minimizing **node flexure**. Nonetheless, some degree of node flexure is evident in most direct radiators. Extreme examples are shown in Fig. 3.59 (Borwick, 1994, 49) that illustrate the deleterious effects of such uniform piston breakup.

FIGURE 3.59 Nodal patterns of the cone. (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 49. Focal.)

Most full-range designs employ a curvilinear cross sectional design following exponential or hyperbolic law. This improves the diaphragm's resistance to resonance above the piston band limit where the wavelength is equal to the diaphragm's diameter. Straight sided designs are usually employed only where extra mass for long excursions are required.

Multiradiating Systems

To address the response and radiation limitations of single diaphragm systems a variety of unique *multiradiating* approaches has evolved. The *whizzer* was among the earliest modifications designed to extend frequency response by providing a parasitic secondary short diaphragm extrusion attached just outside the cone-former junction. See Fig. 3.60 (Tremain, 1973, 1090).

Where a large radiation angle is required to cover a wide listening area, the task cannot be accomplished by a single direct radiator. And where low distortion for a wide variety of program types is required, the task cannot be accomplished by a single direct radiator.

In accomplishing an extended smooth frequency response, two-way and three-way loudspeaker systems are the norm, with each diaphragmatic radiator being suited for a specific portion of the audio frequency spectrum. To prevent distortion due to unintended power leakage reaching a radiator designed for a different range of the spectrum electrical crossover networks are required ahead of the electromotive assemblies.

Because usable filter designs do not have an infinite rolloff at crossover, careful overlap design is essential. This requires smooth response for each drive unit across the transition region as well as precision design to match the complex impedance characteristics of the target driver and present a stable impedance to the source amplifier.

Two categories of crossover networks are employed, high level and low level. High-level crossover networks feed the target drivers through passive components. The primary practical advantage of the low-level crossover is that matching to the complex driver unit load impedance is handled by separate power amplifiers rather than the network itself. The cost implications for low-level crossover systems are obvious and are commonly found only in high-performance applications. See Fig. 3.61 (Borwick, 1994, 198).

FIGURE 3.60 Electrovoice dynamic speaker unit with a whizzer attached to diaphragm to increase the midrange and high-frequency response. (Source: Tremain, H.M. 1973. *Audio Cyclopedia*, 2nd ed., p. 1090. Howard Sams.)

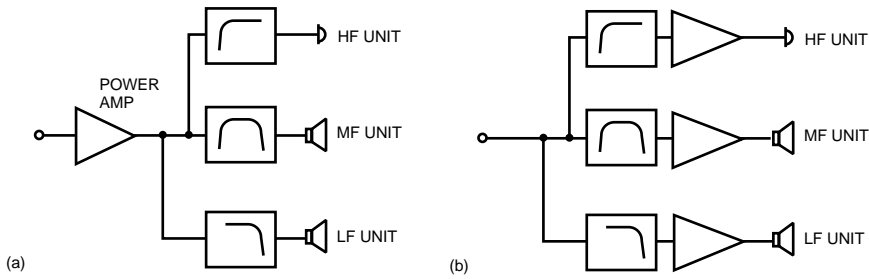

FIGURE 3.61 Crossover network with high level filters (a), and low-level filters (b). (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 198. Focal.)

Modern crossover design for high-level systems requires matching the complex electroacoustic response of the driver to one of the commonly executable filter section types. This desired filter shape is referred to as the *target function*. These target filter functions are commonly based on first order Butterworth derivations, including Linkwitz–Riley cascades. The phase-delay characteristics of crossover networks are especially problematic and frequently result in sharply irregular polar plots for the multidriver systems. See Fig. 3.62 (Borwick, 1994, 210). The Linkwitz–Riley target shapes are especially desirable due to their in-phase relationship. The reference axis of the drive units is not altered with this crossover target shape.

Reference axis plots are especially important to multidriver units. By knowing the polar response of the multidriver system, proper vertical mounting of the frequency-dependent radiators can be determined. Depending on anticipated listener location, the reference axis can be vertically aimed by use of sloping or stepped baffles, as well as by inverting typical driver layout. See Fig. 3.63 (Borwick, 1994, 213).

Enclosures

At an early date open baffle systems were realized to result in unwanted reinforcement and cancellation effects due to radiation interference between the front and rear diaphragm surface. To the ensuing box type enclosure, a vent was quickly added, although it was originally envisioned as a mere pressure equalizer. Later work showed that careful vent design could appreciably improve low-frequency response of the radiating system. Yet, in addition to improved low-frequency response, the vented box affects higher frequencies due to a variety of mechanical and acoustic resonances and diffraction.

In 1957 Olson of RCA laboratories showed that the measured frequency response of direct radiating loudspeakers was demonstrably affected by the type of enclosure in which it was mounted. The unmistakable conclusion of these experiments was that shapes which avoided sharp transitions provided significantly flatter response. In fact, the response was close to ideal only for spherical enclosures. The truncated pyramidal shapes also presented little opportunity for response coloration as shown by the graphs in Fig. 3.64 (Eargle, 1994, 31).

FIGURE 3.62 Vertical polar characteristic at crossover frequency; two-way system with unit target functions; third-order Butterworth. (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 210. Focal.)

FIGURE 3.63 Two-way system: methods for varying the direction of the reference axis. (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 213. Focal.)

The theoretical infinite baffle has numerous advantages over real-world designs. There are no baffled edges to cause diffraction and no enclosure to generate undesirable resonances. Moreover, with the forward plane completely isolated from the rear radiation, a solid angle of dipole radiation is produced. Although the finite baffle (open baffle) shares the figure-8 radiation of the infinite baffle, directivity will be induced as the plane surface approaches one wavelength.

The enclosed box, although the nearest practical embodiment of the infinite baffle, produces deleterious resonance, and diffraction and distorted radiation angle effects.

It is the vented enclosure, sometimes referred to as a *bass reflex* or *ported* box that couples rear radiation over a narrow range of low frequencies to direct radiation. The aperture forms a Helmholtz resonator coupling the air in the vent to the compliance of the air in the box. Various varieties of vents involving multiple chambers, transmission line, and bandpass designs are employed depending on specific frequencies to be reinforced. The dimension, shape, position, and air flow of the vent requires careful consideration. In general the minimum area and diameter is illustrated by (as shown in Borwick (1994, 274)):

$$S_v \geq 0.8 f_B V_D$$

and

$$d_v \geq \sqrt{f_B V_D}$$

where

S_v = area of the vent

d_v = diameter of a circular vent

V_D = peak displacement volume of the driver

f_B = resonant frequency of the vented enclosure

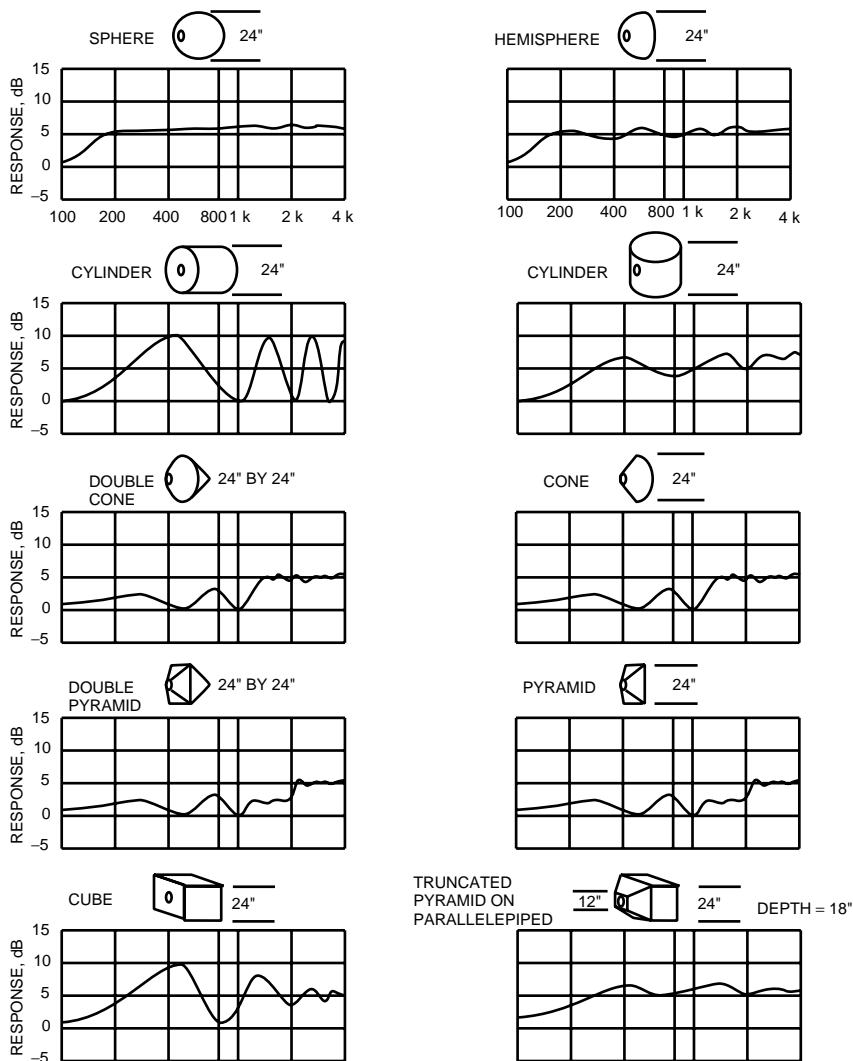

FIGURE 3.64 Response curves showing diffraction by 10 objects of different shape. (Source: Eargle, J.M. 1994. *Electroacoustical Reference Data*, p. 31. Van Nostrand Reinhold, New York.)

The cabinet itself will vibrate and reradiate into the sound field to some extent for most enclosure types. In general, the more dense the enclosure material, the less susceptible the unit will be to reradiation. Nonetheless, some modern loudspeakers employ aluminum, synthetic resins, and even foamed plastic for enclosure construction. Various techniques such as bracing, damping, and layered enclosure construction can be employed with good success in suppressing cabinet radiation.

It is imperative that corner and edge joints be fully rigid and secure. Since the 1970s virtually all wooden cabinet designs employ an all-glued joint construction with cabinet access via the bass unit mounting hole. This construction has substantially enhanced low-frequency reinforcement.

3.5.6 Unique Approaches to Loudspeaker Design and Assessment

Despite the near ubiquity of direct radiators, the foregoing discussion illustrates a host of mechanical and electrical obstacles unique to this design class. Unique approaches to moving the air mass for sound reproduction have attempted to overcome such difficulties.

FIGURE 3.65 Electrostatic or capacitor type loudspeaker. (Source: Tremaine, H.M. 1973. *Audio Cyclopedia*, 2nd ed. Howard Sams.)

Electrostatic Design

The electrostatic loudspeaker is essentially a charged capacitor of considerable plate size, which produces sound waves by the application of audio frequency voltages. Electrostatic loudspeakers appeared as early as the 1930s but it was not until the 1950s that commercially successful units were produced.

The electrostatic loudspeaker is said to operate more linearly than typical cone type radiators. Thus, it is claimed that the electrostatic loudspeaker operates as a true uniform piston across all points of the radiating surface. Because of its large surface area relative to the air mass the electrostatic loudspeaker is said to be essentially *massless* compared to direct radiating designs.

Despite these advantages, electrostatic loudspeakers are generally used only by a dedicated group of high-performance aficionados. Production costs are an order of magnitude greater than for comparable cone type systems and electrostatic units possess a number of significant limitations, including low efficiency, strict volume limitations, and even electric shock hazards due to the high operating charges present on the diaphragm. See Fig. 3.65 (Tremaine, 1973, 1085) for an illustration of basic electrostatic construction.

Ionic Design

The ideal radiator would be truly massless and employ no moving parts. Such a device was produced for a short time and was known as the ionophone. The operation depended on a small quartz tube, open at one end with the other connected to a Kanthal electrode. The electrode is connected to a radio frequency oscillator of high-voltage output causing ionic discharge to occur in the air within the quartz tube. See Fig. 3.66 (Borwick, 1994, 37).

By amplitude modulating the RF oscillator at an audio frequency, the glow discharge in the tube varies accordingly. Pressure waves are set up within the tube at the audio modulating frequency, and by connecting the open end of the tube to the throat of an exponential horn fairly high sound pressure levels near 100 SPL can be generated. Nonetheless, overall efficiency is low due to the substantial voltages required to produce ionic discharge, and the horn coupling places strict limits on low-frequency response.

Despite the theoretical promise of electrostatic and ionic design approaches, the direct radiators, due primarily to the good success and low cost of modern construction continue to remain the most commonly used among all reproducing systems, even for the most demanding professional requirements.

Loudspeaker Assessments

Most loudspeaker manufacturers periodically engage in various forms of subjective loudspeaker assessments. Such subjective assessments can produce statistically significant results that are extremely difficult, if not impossible, to quantify using objective testing techniques. Since subjective tests involve relatively expensive testing devices (humans, usually on the clock) such tests are infrequently employed. Because of

FIGURE 3.66 Detail of the ionophone assembly with the output circuit of the oscillator. (Source: In *Loudspeaker and Headphone Handbook*, ed. J. Borwick, 2nd ed., p. 37. Focal.)

the many variables inherent in subjective testing, as well as the costs required to produce a scientifically valid study, increasing attention has been paid to such methodology in recent years.

So called *double blind* testing, employing A/B/X methodology has been particularly successful in producing verifiable results of listener preferences and discernment. The reference, source, and random sampling of either is used under A/B/X testing to achieve good correlation in statistical validity. Commonly utilized analysis of variance (ANOVA) is frequently employed, and the test administrators are blind to the testing material, the specific parameter under test, and often, even the subjects.

Of course many variables will affect subjective tests and the International Electrotechnical Commission (IEC) has produced a recommended listening room configuration for conducting tests on loudspeakers. See Fig. 3.67 (Toole).

Not surprisingly listeners exhibit biases related to hearing ability, and to a lesser extent, age. Broadband sensitivity is apparently the most important factor in the reliability of most test subjects evaluating loudspeaker systems. It is estimated that approximately 60% of the population possess acceptable broadband sensitivity to be reliable test subjects. It has been noted that stereo assessments tend to obscure slightly the discernment of typical listeners. Monophonic tests of the same loudspeaker systems revealed a more heightened sensitivity to colorations than when listeners heard the systems in stereo.

A sample listener rating grid is shown in Fig. 3.68, as utilized by the Communications Research Centre in Ottawa during evaluations of proposed digital radio broadcast systems.

3.5.7 Headphones and Earphones

Several unique factors render headphone and earphone design even more complex than loudspeaker systems. Most specialized communications headphones rely on restricted frequency response tailored to maximize speech intelligibility. This discussion will cover the more common issues associated with high-fidelity headphone reproduction.

A fundamental problem of binaural listening is known as *in-head localization* (IHL) and is apparently due to the lack of a dispersed wavefront striking the aural cavity. Other problems such as bone conduction (BC), the frequency response and resonance challenges of small aperture assemblies, variable leakage

FIGURE 3.67 A plain view of the listening room of the IEC recommended configuration. In monophonic tests, loudspeakers can be located at positions 3, 4, 5, and 6, with listeners at positions 1, 3, and 5. In stereophonic tests, loudspeakers are located at positions B and D, and listeners at positions 2 and 5. (Source: Toole, F.E. Loudspeaker measurements and their relationship to listener preferences. *JAES* 34 (Pts 1 and 2).)

effects, the *cone of confusion*, the *occlusion effect*, the *missing 6-dB effect*, and even factors such as cushion compliance add additional complexity to headphone design.

In-Head Localization

Headphones, unlike ambient listening conditions, offer a consistent and stable aural environment, do not normally affect others in the vicinity, and offer excellent sound quality at a far lower price than comparable loudspeaker systems. In-head localization is perhaps the greatest single obstacle to ubiquitous use of headphone systems.

It is the lack of frontal spatial localization that most vexes headphone designers. Substantial progress has been made at improving not only median plane front and rear cues, but also elevation information can now be added to headphone listening. Through much study it has been determined that specific spectral bands hold the key to significant location information. Two directional bands are associated with front localization, 260–550 Hz and 2.5–6 kHz. Rear localization is achieved by boosting 700 Hz–1.8 kHz and 10–13 kHz. Upward elevation localization is achieved by boosting 7–10 kHz. Additional cues have been successfully added to replicate the dynamic mechanism of head movements by synchronously varying interaural time delays (ITD) and interaural amplitude delays (IAD). Directional shifts of up to 60° have been reported using these simple techniques, yet full frontal localization remains elusive.

FIGURE 3.68 Image of the 5-grade impairment scale.

One interesting experiment reported by Poldy involved making a binaural recording using the listener’s own head for placement of the electret microphones in the ear canals. This process was repeated for other listeners. When playing the recordings back using symmetrical headphones each listener easily recognized his own recording and heard the sounds in front. The recordings made in other person’s ears were elevated or in-head localized. Thus, although progress is being made in this area, each listener’s unique interaural cues to frontal localization may provide an insurmountable challenge to solving this long standing problem. Real-time signal processing power may eventually lead to more specific, and certainly more costly, results.

Related to the problem of missing frontal information is the so-called cone of confusion which describes the ambiguity of lateral localization when extreme left or right information is reproduced in the headphone assembly. See Fig. 3.69.

FIGURE 3.69 The cone of confusion for a spherical head model.

Small Aperture Assemblies

Basic headphone designs are based on circumaural, supra-aural, closed, and open. In circumaural construction the headphone surrounds the ear, for supra-aural design the headphones rests on the ear. In general, the closed and circumaural designs have better low-frequency response, which is largely controlled

by leakage. The open headphone design is best illustrated by the isodynamic headphone, which uses an acoustically permeable membrane. While background noise is added to the reproduced sound, low-frequency response is good and in-head localization is minimized.

Moving coil transducers are the most commonly encountered design class but, as with loudspeakers, membrane resonances must be carefully minimized through damping strategies. Cushion compliance and cup resonances must also be factored into high-fidelity designs.

Bone Conduction and the Occlusion Effect

Low-frequency bone conduction has been cited as the missing link in understanding headphone reproduction phenomena, especially frontal localization. Bone conduction is generally masked some 50 dB below *acoustic conduction* (AC) and is not generally considered to have any verifiable effect on localization. Amplification of bone conduction resulting from ear occlusion (via a headphone, for example) occurs up to approximately 2 kHz. This can be readily demonstrated by plugging the ears while humming a low sweep tone. Clenching the jaw and relaxing it will vary the amplification experienced. Sound pressure level shifts due to occlusion have been reported as high as 40 dB at 150 Hz.

The Missing 6 dB Effect

At frequencies below 300 Hz listeners have consistently required an additional 6–10 dB in SPL to judge sounds in headphones as being equally as loud as sounds generated by loudspeakers. Various explanations have been proffered for this phenomena, including the observation that sounds that emanate from a larger sound source may be perceived as being louder. Of growing concern is the increased SPL levels required by headphone users to achieve loudness comparable to ambient listening. These levels may more frequently pass the danger thresholds prescribed to avoid permanent hearing loss.

Defining Terms

Ferrofluid: Iron based solution employed in voice coil/pole piece gap improving magnetic flux and power handling capacity.

Flexure nodes: Standing wave patterns in loudspeaker membrane caused by applied energy.

Haas effect (law of the first wavefront): The first sound heard will mask subsequent short delay arriving sounds, the combination appearing as a louder source.

Piston: Ideal loudspeaker radiating diaphragm with all segments of the diaphragm moving uniformly.

4.1 Coaxial Transmission Lines

Jerry C. Whitaker

4.1.1 Introduction

The components that connect, interface, transfer, and filter RF energy within a given system or between systems are critical elements in the operation of vacuum tube devices. Such hardware, usually passive, determines to a large extent the overall performance of the RF generator. To optimize the performance of power vacuum devices, it is first necessary to understand and optimize the components upon which the tube depends.

The mechanical and electrical characteristics of the transmission line, waveguide, and associated hardware that carry power from a power source (usually a transmitter) to the load (usually an antenna) are critical to proper operation of any RF system. Mechanical considerations determine the ability of the components to withstand temperature extremes, lightning, rain, and wind, that is, they determine the overall reliability of the system.

Skin Effect

The effective resistance offered by a given conductor to radio frequencies is considerably higher than the ohmic resistance measured with direct current. This is because of an action known as the *skin effect*, which

causes the currents to be concentrated in certain parts of the conductor and leaves the remainder of the cross-section to contribute little or nothing toward carrying the applied current.

When a conductor carries an alternating current, a magnetic field is produced that surrounds the wire. This field continually expands and contracts as the ac wave increases from zero to its maximum positive value and back to zero, then through its negative half-cycle. The changing magnetic lines of force cutting the conductor induce a voltage in the conductor in a direction that tends to retard the normal flow of current in the wire. This effect is more pronounced at the center of the conductor. Thus, current within the conductor tends to flow more easily toward the surface of the wire. The higher the frequency, the greater the tendency for current to flow at the surface. The depth of current flow d is a function of frequency and is determined from the following equation:

$$d = \frac{2.6}{\sqrt{\mu f}} \quad (4.1)$$

where d is the depth of current in mils, μ is the permeability (copper = 1, steel = 300), and f is the frequency of signal in MHz. It can be calculated that at a frequency of 100 kHz, current flow penetrates a conductor by 8 mils. At 1 MHz, the skin effect causes current to travel in only the top 2.6 mils in copper, and even less in almost all other conductors. Therefore, the series impedance of conductors at high frequencies is significantly higher than at low frequencies. Figure 4.1 shows the distribution of current in a radial conductor.

When a circuit is operating at high frequencies, the skin effect causes the current to be redistributed over the conductor cross-section in such a way as to make most of the current flow where it is encircled by the smallest number of flux lines. This general principle controls the distribution of current, regardless of the shape of the conductor involved. With a flat-strip conductor, the current flows primarily along the edges, where it is surrounded by the smallest amount of flux.

FIGURE 4.1 Skin effect on an isolated round conductor carrying a moderately high frequency signal.

4.1.2 Coaxial Transmission Line

Two types of coaxial transmission line are in common use today: rigid line and corrugated (semiflexible) line. Rigid coaxial cable is constructed of heavy-wall copper tubes with Teflon or ceramic spacers. (Teflon™ is a registered trademark of DuPont.) Rigid line provides electrical performance approaching an ideal transmission line, including

- High power-handling capability
- Low loss
- Low VSWR (voltage standing wave ratio)

Rigid transmission line is, however, expensive to purchase and install.

The primary alternative to rigid coax is semiflexible transmission line made of corrugated outer and inner conductor tubes with a spiral polyethylene (or Teflon) insulator. The internal construction of a semiflexible line is shown in Fig. 4.2. Semiflexible line has four primary benefits:

- It is manufactured in a continuous length, rather than the 20-foot sections typically used for rigid line.

FIGURE 4.2 Semiflexible coaxial cable: (a) section of cable showing the basic construction, and (b) cable with various terminations. (Courtesy of Andrew Corporation, Orland Park, IL.)

- Because of the corrugated construction, the line can be shaped as required for routing from the transmitter to the antenna.
- The corrugated construction permits differential expansion of the outer and inner conductors.
- Each size of line has a minimum bending radius. For most installations, the flexible nature of corrugated line permits the use of a single piece of cable from the transmitter to the antenna, with no elbows or other transition elements. This speeds installation and provides for a more reliable system.

Electrical Parameters

A signal traveling in free space is unimpeded; it has a free-space velocity equal to the speed of light. In a transmission line, capacitance and inductance slow the signal as it propagates along the line. The degree to which the signal is slowed is represented as a percentage of the free-space velocity. This quantity is called the relative velocity of propagation and is described by

$$V_p = \frac{1}{\sqrt{LC}} \quad (4.2)$$

where L is the inductance in henrys per foot, C is the capacitance in farads per foot, and

$$V_r = \frac{V_p}{c} \times 100\% \quad (4.3)$$

where V_p is the velocity of propagation, c is 9.842×10^8 feet per second (free-space velocity), and V_r is the velocity of propagation as a percentage of free-space velocity.

Transverse Electromagnetic Mode

The principal mode of propagation in a coaxial line is the *transverse electromagnetic mode* (TEM). This mode will not propagate in a waveguide, and that is why coaxial lines can propagate a broad band of frequencies efficiently. The cutoff frequency for a coaxial transmission line is determined by the line dimensions. Above cutoff, modes other than TEM can exist and the transmission properties are no longer defined. The cutoff frequency is equivalent to

$$F_c = \frac{7.50 \times V_r}{D_i D_o} \quad (4.4)$$

where F_c is the cutoff frequency in gigahertz, V_r is the velocity (percent), D_i is the inner diameter of outer conductor in inches, and D_o is the outer diameter of inner conductor in inches.

At dc, current in a conductor flows with uniform density over the cross-section of the conductor. At high frequencies, the current is displaced to the conductor surface. The effective cross-section of the conductor decreases and the conductor resistance increases because of the skin effect.

Center conductors are made from copper-clad aluminum or high-purity copper and can be solid, hollow tubular, or corrugated tubular. Solid center conductors are found on semiflexible cable with $1/2$ -inch or smaller diameter. Tubular conductors are found in $7/8$ -inch or larger-diameter cables. Although the tubular center conductor is used primarily to maintain flexibility, it can also be used to pressurize an antenna through the feeder.

Dielectric

Coaxial lines use two types of dielectric construction to isolate the inner conductor from the outer conductor. The first is an air dielectric, with the inner conductor supported by a dielectric spacer and the remaining volume filled with air or nitrogen gas. The spacer, which may be constructed of spiral or discrete rings, typically is made of Teflon or polyethylene. Air-dielectric cable offers lower attenuation and higher average power ratings than foam-filled cable but requires pressurization to prevent moisture entry.

Foam-dielectric cables are ideal for use as feeders with antennas that do not require pressurization. The center conductor is completely surrounded by foam-dielectric material, resulting in a high dielectric breakdown level. The dielectric materials are polyethylene-based formulations that contain antioxidants to reduce dielectric deterioration at high temperatures.

Impedance

The expression *transmission line impedance* applied to a point on a transmission line signifies the vector ratio of line voltage to line current at that particular point. This is the impedance that would be obtained if the transmission line were cut at the point in question, and the impedance looking toward the receiver were measured.

Because the voltage and current distribution on a line are such that the current tends to be small when the voltage is large (and vice versa), as shown in Fig. 4.3, the impedance will, in general, be oscillatory in the same manner as the voltage (large when the voltage is high and small when the voltage is low). Thus, in the case of a short-circuited receiver, the impedance will be high at distances from the receiving end that are odd multiples of $1/4$ -wavelength, and will be low at distances that are even multiples of $1/4$ -wavelength.

The extent to which the impedance fluctuates with distance depends on the *standing wave ratio* (ratio of reflected to incident waves), being less as the reflected wave is proportionally smaller than the incident wave. In the particular case where the load impedance equals the characteristic impedance, the impedance of the transmission line is equal to the characteristic impedance at all points along the line.

FIGURE 4.3 Magnitude and power factor of line impedance with increasing distance from the load for the case of a short-circuited receiver and a line with moderate attenuation: (a) voltage distribution, (b) impedance magnitude, and (c) impedance phase.

The *power factor* of the impedance of a transmission line varies according to the standing waves present. When the load impedance equals the characteristic impedance, there is no reflected wave and the power factor of the impedance is equal to the power factor of the characteristic impedance. At radio frequencies, the power factor under these conditions is accordingly resistive. However, when a reflected wave is present, the power factor is unity (resistive) only at the points on the line where the voltage passes through a maximum or a minimum. At other points the power factor will be reactive, alternating from leading to lagging at intervals of $\frac{1}{4}$ -wavelength. When the line is short-circuited at the receiver, or when it has a resistive load less than the characteristic impedance so that the voltage distribution is of the short-circuit type, the power factor is inductive for lengths corresponding to less than the distance to the first voltage maximum. Thereafter, it alternates between capacitive and inductive at intervals of $\frac{1}{4}$ -wavelength. Similarly, with an open-circuited receiver or with a resistive load greater than the characteristic impedance so that the voltage distribution is of the open-circuit type, the power factor is capacitive for lengths corresponding to less than the distance to the first voltage minimum. Thereafter, the power factor alternates between capacitive and inductive at intervals of $\frac{1}{4}$ -wavelength, as in the short-circuited case.

Resonant Characteristics

A transmission line can be used to perform the functions of a resonant circuit. For example, if the line is short-circuited at the receiver, at frequencies in the vicinity of a frequency at which the line is an odd number of $\frac{1}{4}$ -wavelengths long, the impedance will be high and will vary with frequency in the vicinity of resonance. This characteristic is similar in nature to a conventional parallel resonant circuit. The difference is that with the transmission line, there are a number of resonant frequencies, one for each of the infinite number of frequencies that make the line an odd number of $\frac{1}{4}$ -wavelengths long. At VHF, the parallel impedance at resonance and the circuit Q obtainable are far higher than can be realized with lumped circuits. Behavior corresponding to that of a series resonant circuit can be obtained from a transmission line that is an odd number of $\frac{1}{4}$ -wavelengths long and open-circuited at the receiver.

Transmission lines can also be used to provide low-loss inductances or capacitances if the proper combination of length, frequency, and termination is employed. Thus, a line short-circuited at the receiver will offer an inductive reactance when less than $\frac{1}{4}$ -wavelength, and a capacitive reactance when between $\frac{1}{4}$ - and $\frac{1}{2}$ -wavelength. With an open-circuited receiver, the conditions for inductive and capacitive reactances are reversed.

4.1.3 Electrical Considerations

VSWR (voltage standing wave ratio), attenuation, and power-handling capability are key electrical factors in the application of coaxial cable. High VSWR can cause power loss, voltage breakdown, and thermal degradation of the line. High attenuation means less power delivered to the antenna, higher power consumption at the transmitter, and increased heating of the transmission line itself.

VSWR is a common measure of the quality of a coaxial cable. High VSWR indicates nonuniformities in the cable that can be caused by one or more of the following conditions:

- Variations in the dielectric core diameter
- Variations in the outer conductor
- Poor concentricity of the inner conductor
- Nonhomogeneous or periodic dielectric core

Although each of these conditions may contribute only a small reflection, they can add up to a measurable VSWR at a particular frequency.

Rigid transmission line is typically available in a standard length of 20 ft, and in alternative lengths of 19.5 and 19.75 ft. The shorter lines are used to avoid VSWR buildup caused by discontinuities resulting from the physical spacing between line section joints. If the section length selected and the operating frequency have a $\frac{1}{2}$ -wave correlation, the connector junction discontinuities will add. This effect is known as flange buildup. The result can be excessive VSWR. The *critical frequency* at which a $\frac{1}{2}$ -wave relationship exists

TABLE 4.1 Representative Specifications for Various Types of Flexible Air-Dielectric Coaxial Cable

Cable Size (in.)	Maximum Frequency (MHz)	Velocity (%)	Peak Power 1 MHz (kW)	Average Power		Attenuation ^a	
				100 MHz (kW)	1 MHz (kW)	100 MHz (dB)	1 MHz (dB)
1 ⁵ / ₈	2.7	92.1	145	145	14.4	0.020	0.207
3	1.64	93.3	320	320	37	0.013	0.14
4	1.22	92	490	490	56	0.010	0.113
5	0.96	93.1	765	765	73	0.007	0.079

^aAttenuation specified in dB/100 ft.

is given by

$$F_{cr} = \frac{490.4 \times n}{L} \tag{4.5}$$

where F_{cr} is the critical frequency, n is any integer, and L is the transmission line length in feet. For most applications, the critical frequency for a chosen line length should not fall closer than ± 2 MHz of the passband at the operating frequency.

Attenuation is related to the construction of the cable itself and varies with frequency, product dimensions, and dielectric constant. Larger-diameter cable exhibits lower attenuation than smaller-diameter cable of similar construction when operated at the same frequency. It follows, therefore, that larger-diameter cables should be used for long runs.

Air-dielectric coax exhibits less attenuation than comparable-sized foam-dielectric cable. The attenuation characteristic of a given cable is also affected by standing waves present on the line resulting from an impedance mismatch. Table 4.1 shows a representative sampling of semiflexible coaxial cable specifications for a variety of line sizes.

4.1.4 Coaxial Cable Ratings

Selection of a type and size of transmission line is determined by a number of parameters, including power-handling capability, attenuation, and phase stability.

Power Rating

Both peak and average power ratings are required to fully describe the capabilities of a transmission line. In most applications, the peak power rating limits the low frequency or pulse energy, and the average power rating limits high-frequency applications, as shown in Fig. 4.4. Peak power ratings are usually

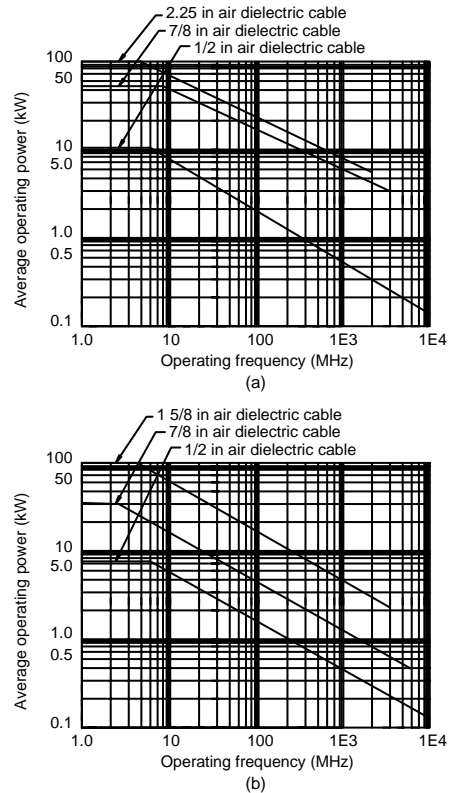

FIGURE 4.4 Power rating data for a variety of coaxial transmission lines: (a) 50 Ω line, and (b) 75 Ω line.

stated for the following conditions:

- VSWR = 1.0
- Zero modulation
- One atmosphere of absolute dry air pressure at sea level

The peak power rating of a selected cable must be greater than the following expression, in addition to satisfying the average-power-handling criteria:

$$E_{pk} > P_t \times (1 + M)^2 \times \text{VSWR} \tag{4.6}$$

where E_{pk} is the cable peak power rating in kilowatts, P_t is the transmitter power in kilowatts, M is the amplitude modulation percentage expressed decimally (100% = 1.0), and VSWR is the voltage standing wave ratio. From this equation, it can be seen that 100% amplitude modulation will increase the peak power in the transmission line by a factor of 4. Furthermore, the peak power in the transmission line increases directly with VSWR.

The peak power rating is limited by the voltage breakdown potential between the inner and outer conductors of the line. The breakdown point is independent of frequency. It varies, however, with the line pressure (for an air-dielectric cable) and the type of pressurizing gas.

The average power rating of a transmission line is limited by the safe, long-term operating temperature of the inner conductor and the dielectric. Excessive temperatures on the inner conductor will cause the dielectric material to soften, leading to mechanical instability inside the line.

The primary purpose of pressurization of an air-dielectric cable is to prevent the ingress of moisture. Moisture, if allowed to accumulate in the line, can increase attenuation and reduce the breakdown voltage between the inner and outer conductors. Pressurization with high-density gases can be used to increase both the average power and the peak power ratings of a transmission line. For a given line pressure, the increased power rating is more significant for peak power than for average power. High-density gases used for such applications include Freon 116 and sulfur hexafluoride. Figure 4.5 illustrates the effects of pressurization on cable power rating.

An adequate safety factor is necessary for peak and average power ratings. Most transmission lines are tested at two or more times their rated peak power before shipment to the customer. This safety factor is intended as a provision for transmitter transients, lightning-induced effects, and high-voltage excursions resulting from unforeseen operating conditions.

FIGURE 4.5 Effects of transmission line pressurization on peak power rating. Note that P' = rating of the line at the increased pressure and P = rating of the line at atmospheric pressure.

TABLE 4.2 Electrical Characteristics of Common RF Connectors

Connector Type	DC Test Voltage (kV)	Peak Power (kW)
SMA	1.0	1.2
BNC, TNC	1.5	2.8
N, UHF	2.0	4.9
GR	3.0	11
HN, 7/16	4.0	20
LC	5.0	31
7/8 EIA, F Flange	6.0	44
1 5/8 EIA	11.0	150
3 1/8 EIA	19.0	4

Connector Effects

Foam-dielectric cables typically have a greater dielectric strength than air-dielectric cables of similar size. For this reason, foam cables would be expected to exhibit higher peak power ratings than air lines. Higher values, however, usually cannot be realized in practice because the connectors commonly used for foam cables have air spaces at the cable/connector interface that limit the allowable RF voltage to “air cable” values.

The peak-power-handling capability of a transmission line is the smaller of the values for the cable and the connectors attached to it. Table 4.2 lists the peak power ratings of several common RF connectors at standard conditions.

Attenuation

The attenuation characteristics of a transmission line vary as a function of the operating frequency and the size of the line itself. The relationships are shown in Fig. 4.6.

The efficiency of a transmission line dictates how much power output from the transmitter actually reaches the antenna. Efficiency is determined by the length of the line and the attenuation per unit length.

The attenuation of a coaxial transmission line is defined by

$$\alpha = 10 \times \log \left\{ \frac{P_1}{P_2} \right\} \tag{4.7}$$

where α is the attenuation in decibels per 100 m, P_1 is the input power into a 100-m line terminated with the nominal value of its characteristic impedance, and P_2 is the power measured at the end of the line. Stated in terms of efficiency (E , percent),

$$E = 100 \times \left\{ \frac{P_o}{P_i} \right\} \tag{4.8}$$

where P_i is the power delivered to the input of the transmission line and P_o is the power delivered to the antenna. The relationship between efficiency and loss in decibels (insertion loss) is illustrated in Fig. 4.7.

FIGURE 4.6 Attenuation characteristics for a selection of coaxial cables: (a) 50 Ω line, and (b) 75 Ω line.

Manufacturer-supplied attenuation curves are typically guaranteed to within approximately $\pm 5\%$. The values given usually are rated at 24°C (75°F) ambient temperature. Attenuation increases slightly with higher temperature or applied power. The effects of ambient temperature on attenuation are illustrated in Fig. 4.8.

Loss in connectors is negligible, except for small (SMA and BNC) connectors at frequencies of several gigahertz and higher. Small connectors used at high frequencies typically add 0.1 dB of loss per connector.

When a transmission line is attached to a load such as an antenna, the VSWR of the load increases the total transmission loss of the system. This effect is small under conditions of low VSWR. Figure 4.9 illustrates the interdependence of these two elements.

Phase Stability

A coaxial cable expands as the temperature of the cable increases, causing the electrical length of the line to increase as well. This factor results in phase changes that are a function of operating temperature. The phase relationship can be described by

$$\theta = 3.66 \times 10^{-7} \times P \times L \times T \times F \quad (4.9)$$

where θ is the phase change in degrees, P is the phase-temperature coefficient of the cable, L is the length of coax in feet, T is the temperature range (minimum-to-maximum operating temperature), and F is the frequency in MHz. Phase changes that are a function of temperature are important in systems utilizing multiple transmission lines, such as a directional array fed from a single phasing source. To maintain proper operating parameters, the phase changes of the cables must be minimized. Specially designed coaxial cables that offer low-phase-temperature characteristics are available. Two types of coax are commonly used for this purpose: (1) phase-stabilized cables, which have undergone extensive temperature cycling until such time as they exhibit their minimum phase-temperature coefficient, and (2) phase-compensated cables, in which changes in the electrical length have been minimized through adjustment of the mechanical properties of the dielectric and inner/outer conductors.

Mechanical Parameters

Corrugated copper cables are designed to withstand bending with no change in properties. Low-density foam- and air-dielectric cables generally have a minimum bending radius of ten times the cable diameter. Super flexible versions provide a smaller allowable bending radius.

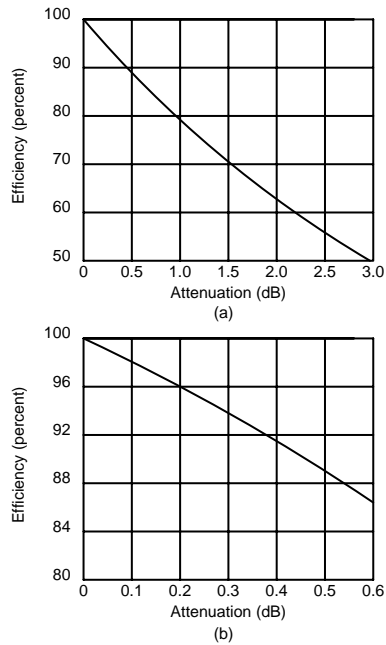

FIGURE 4.7 Conversion chart showing the relationship between decibel loss and efficiency of a transmission line: (a) high-loss line, and (b) low-loss line.

FIGURE 4.8 The variation of coaxial cable attenuation as a function of ambient temperature.

Rigid transmission lines will not tolerate bending. Instead, transition elements (elbows) of various sizes are used. Individual sections of rigid line are secured by multiple bolts around the circumference of a coupling flange.

When a large cable must be used to meet attenuation requirements, short lengths of a smaller cable (jumpers or pigtailed) can be used on either end for ease of installation in low-power systems. The trade-off is slightly higher attenuation and some additional cost.

The *tensile strength* of a cable is defined as the axial load that may be applied to the line with no more than 0.2% permanent deformation after the load is released. When divided by the weight per foot of cable, this gives an indication of the maximum length of cable that is self-supporting and therefore can be readily installed on a tower with a single hoisting grip. This consideration usually applies only to long runs of corrugated line; rigid line is installed one section at a time.

The *crush strength* of a cable is defined as the maximum force per linear inch that can be applied by a flat plate without causing more than a 5% deformation of the cable diameter. Crush strength is a good indicator of the ruggedness of a cable and its ability to withstand rough handling during installation.

Cable jacketing affords mechanical protection during installation and service. Semiflexible cables typically are supplied with a jacket consisting of low-density polyethylene blended with 3% carbon black for protection from the sun's ultraviolet rays, which can degrade plastics over time. This approach has proved to be effective, yielding a life expectancy of more than 20 years. Rigid transmission line has no covering over the outer conductor.

For indoor applications, where fire-retardant properties are required, cables can be supplied with a fire-retardant jacket, usually listed by Underwriters Laboratories. Note that under the provisions of the National Electrical Code, outside plant cables such as standard black polyethylene-jacketed coaxial line may be run as far as 50 ft inside a building with no additional protection. The line can also be placed in conduit for longer runs.

Low-density foam cable is designed to prevent water from traveling along its length, should it enter through damage to the connector or the cable sheath. This is accomplished by mechanically locking the outer conductor to the foam dielectric by annular corrugations. Annular or ring corrugations, unlike helical or screw-thread-type corrugations, provide a water block at each corrugation. Closed-cell polyethylene dielectric foam is bonded to the inner conductor, completing the moisture seal.

A coaxial cable line is only as good as the connectors used to tie it together. The connector interface must provide a weatherproof bond with the cable to prevent water from penetrating the connection. This is ensured by the use of O-ring seals. The cable connector interface must also provide a good electrical bond that does not introduce a mismatch and increase VSWR. Good electrical contact between the connector and the cable ensures that proper RF shielding is maintained.

4.2 Waveguide

Kenneth R. Demarest

4.2.1 Waveguide Modes

Any structure that guides electromagnetic waves can be considered a **waveguide**. Most often, however, this term refers to closed metal cylinders that maintain the same cross-sectional dimensions over long distances. Such a structure is shown in Fig. 4.10, which consists of a metal cylinder filled with a dielectric. When filled with low-loss dielectrics (such as air), waveguides typically exhibit lower losses than transmission lines, which makes them useful for transporting RF energy over relatively long distances. They are most often used for frequencies ranging from 1 to 150 GHz.

Every type of waveguide has an infinite number of distinct electromagnetic field configurations that can exist inside it. Each of these configurations is called a **waveguide mode**. The characteristics of these modes depend upon the cross-sectional dimensions of the conducting cylinder, the type of dielectric material inside the waveguide, and the frequency of operation.

Waveguide modes are typically classed according to the nature of the electric and magnetic field components E_z and H_z . These components are called the longitudinal components of the fields. Several types of modes are possible in waveguides.

- *TE modes*. Transverse-electric modes, sometimes called H modes. These modes have $E_z = 0$ at all points within the waveguide, which means that the electric field vector is always perpendicular (i.e., transverse) to the waveguide axis. These modes are always possible in waveguides with uniform dielectrics.
- *TM modes*. Transverse-magnetic modes, sometimes called E modes. These modes have $H_z = 0$ at all points within the waveguide, which means that the magnetic field vector is perpendicular to the waveguide axis. Like TE modes, they are always possible in waveguides with uniform dielectrics.

FIGURE 4.10 A uniform waveguide with arbitrary cross section.

- *EH modes.* EH modes are hybrid modes in which neither E_z nor H_z are zero, but the characteristics of the transverse fields are controlled more by E_z than H_z . These modes are often possible in waveguides with inhomogeneous dielectrics.
- *HE modes.* HE modes are hybrid modes in which neither E_z nor H_z are zero, but the characteristics of the transverse fields are controlled more by H_z than E_z . Like EH modes, these modes are often possible in waveguide with inhomogeneous dielectrics.
- *TEM modes.* Transverse-electromagnetic modes, often called transmission line modes. These modes can exist only when a second conductor exists within the waveguide, such as a center conductor on a coaxial cable. Because these modes cannot exist in single, closed conductor structures, they are not waveguide modes.

Waveguide modes are most easily determined by first computing the longitudinal field components, E_z and H_z , that can be supported by the waveguide. From these, the transverse components (such as E_x and E_y) can easily be found simply by taking spatial derivatives of the longitudinal fields (Collin, 1992).

When the waveguide properties are constant along the z axis, E_z and H_z vary in the longitudinal direction as $E_z, H_z \propto \exp(\omega t - \gamma z)$, where $\omega = 2\pi f$ is the radian frequency of operation and γ is a complex number of the form

$$\gamma = \alpha + j\beta \quad (4.10)$$

The parameters γ , α , and β are called the propagation, attenuation, and phase constants, respectively, and $j = \sqrt{-1}$. When there are no metal or dielectric losses, γ is always either purely real or imaginary. When γ is real, E_z and H_z have constant phase and decay exponentially with increasing z . When γ is imaginary, E_z and H_z vary in phase with increasing z but do not decay in amplitude. When this occurs, the fields are said to be propagating.

When the dielectric is uniform (i.e., homogeneous), E_z and H_z satisfy the scalar wave equation at all points within the waveguide

$$\nabla_t^2 E_z + h^2 E_z = 0 \quad (4.11)$$

and

$$\nabla_t^2 H_z + h^2 H_z = 0 \quad (4.12)$$

where

$$h^2 = (2\pi f)^2 \mu \epsilon + \gamma^2 = k^2 + \gamma^2 \quad (4.13)$$

Here, μ and ϵ are the permeability and permittivity of the dielectric media, respectively, and $k = 2\pi f \sqrt{\mu \epsilon}$ is the wave number of the dielectric. The operator ∇_t^2 is called transverse Laplacian operator. In Cartesian coordinates

$$\nabla_t^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$$

Most of the properties of the allowed modes in real waveguides can usually be found by assuming that the walls are perfectly conducting. Under this condition, $E_z = 0$ and $\partial H_z / \partial p = 0$ at the waveguide walls, where p is the direction perpendicular to the waveguide wall. When these conditions are imposed upon the general solutions of Eqs. (4.11) and (4.12), it is found that only certain values of h are allowed. These values are called the *modal eigenvalues* and are determined by the cross-sectional shape of the waveguide. Using Eq. (4.13), the propagation constant γ for each mode varies with frequency according to

$$\gamma = \alpha + j\beta = h \sqrt{1 - \left(\frac{f}{f_c}\right)^2} \quad (4.14)$$

where

$$f_c = \frac{h}{2\pi\sqrt{\mu\epsilon}} \tag{4.15}$$

The modal parameter f_c is in hertz and is called the **cutoff frequency** of the mode it is associated with. According to Eq. (4.14), when $f > f_c$, the propagation constant γ is imaginary, and thus the mode is propagating. On the other hand, when $f < f_c$, then γ is real, which means that the fields decay exponentially with increasing values of z . Modes operated at frequencies below their cutoff frequency are not able to propagate energy over long distances and are called evanescent modes.

The dominant mode of a waveguide is the one with the lowest cutoff frequency. Although higher order modes are often useful for a variety of specialized uses of waveguides, signal distortion is usually minimized when a waveguide is operated in the frequency range where only the dominant mode exists. This range of frequencies is called the *dominant range* of the waveguide.

The distance over which the fields of propagating modes repeat themselves is called the **guide wavelength** λ_g . From Eq. (4.14), it can be shown that λ_g always varies with frequency according to

$$\lambda_g = \frac{\lambda_o}{1 - \left(\frac{f_c}{f}\right)^2} \tag{4.16}$$

where $\lambda_o = 1/(f\sqrt{\mu\epsilon})$ is the wavelength of a plane wave of the same frequency in an infinite sample of the waveguide dielectric. For $f \gg f_c, \lambda_g \approx \lambda_o$. Also, $\lambda_g \rightarrow \infty$ as $f \rightarrow f_c$, which is one reason why it is usually undesirable to operate a waveguide mode near modal cutoff frequencies.

Although waveguide modes are not plane waves, the ratio of their transverse electric and magnetic field magnitudes is constant throughout the cross section of the waveguide, just as for plane waves. This ratio is called the modal **wave impedance** and has the following values for TE and TM modes:

$$Z_{TE} = \frac{E_T}{H_T} = \frac{j\omega\mu}{\gamma} \tag{4.17}$$

and

$$Z_{TM} = \frac{E_T}{H_T} = \frac{\gamma}{j\omega\epsilon} \tag{4.18}$$

where E_T and H_T are the magnitudes of the transverse electric and magnetic fields, respectively. In the limit as $f \rightarrow \infty$, both Z_{TE} and Z_{TM} approach $\sqrt{\mu/\epsilon}$, which is the intrinsic impedance of the dielectric medium. On the other hand, as $f \rightarrow f_c, Z_{TE} \rightarrow \infty$ and $Z_{TM} \rightarrow 0$, which means that the transverse electric fields are dominant in TE modes near cutoff and vice versa for TM modes.

Rectangular Waveguides

A rectangular waveguide is shown in Fig. 4.11. The conducting walls are formed such that the inner surfaces form a rectangular cross section, with dimensions a and b along the x and y coordinate axes, respectively.

If the walls are perfectly conducting and the dielectric material is lossless, the field components for

FIGURE 4.11 A rectangular waveguide.

the TE_{mn} modes are given by

$$E_x = H_0 \frac{j\omega\mu}{h_{mn}^2} \left(\frac{n\pi}{b} \right) \cos \left(\frac{m\pi}{a} x \right) \sin \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.19)$$

$$E_y = -H_0 \frac{j\omega\mu}{h_{mn}^2} \left(\frac{m\pi}{a} \right) \sin \left(\frac{m\pi}{a} x \right) \cos \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.20)$$

$$E_z = 0$$

$$H_x = H_0 \frac{\gamma_{mn}}{h_{mn}^2} \left(\frac{m\pi}{a} \right) \sin \left(\frac{m\pi}{a} x \right) \cos \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.21)$$

$$H_y = H_0 \frac{\gamma_{mn}}{h_{mn}^2} \left(\frac{n\pi}{b} \right) \cos \left(\frac{m\pi}{a} x \right) \sin \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.22)$$

$$H_z = H_0 \cos \left(\frac{m\pi}{a} x \right) \sin \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.23)$$

where

$$h_{mn} = \left(\frac{m\pi}{a} \right)^2 + \left(\frac{n\pi}{b} \right)^2 = 2\pi f_{c_{mn}} \sqrt{\mu\epsilon} \quad (4.24)$$

For the TM_{mn} modes, m and n can be any positive integer value, including zero, as long as both are not zero.

The field components for the TM_{mn} modes are

$$E_x = -E_0 \frac{\gamma_{mn}}{h_{mn}^2} \left(\frac{m\pi}{a} \right) \cos \left(\frac{m\pi}{a} x \right) \sin \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.25)$$

$$E_y = -E_0 \frac{\gamma_{mn}}{h_{mn}^2} \left(\frac{n\pi}{b} \right) \sin \left(\frac{m\pi}{a} x \right) \cos \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.26)$$

$$E_z = E_0 \sin \left(\frac{m\pi}{a} x \right) \sin \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.27)$$

$$H_x = E_0 \frac{j\omega\epsilon}{h_{mn}^2} \left(\frac{n\pi}{b} \right) \sin \left(\frac{m\pi}{a} x \right) \cos \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.28)$$

$$H_y = -E_0 \frac{j\omega\epsilon}{h_{mn}^2} \left(\frac{m\pi}{a} \right) \cos \left(\frac{m\pi}{a} x \right) \sin \left(\frac{n\pi}{b} y \right) \exp(j\omega t - \gamma_{mn} z) \quad (4.29)$$

$$H_z = 0 \quad (4.30)$$

where the values of h_{mn} and $f_{c_{mn}}$ are given by Eq. (4.24). For the TM_{mn} modes, m and n can be any positive integer value except zero.

The dominant mode in a rectangular waveguide is the TE_{10} mode, which has a cutoff frequency

$$f_{c_{10}} = \frac{1}{2a\sqrt{\mu\epsilon}} = \frac{c}{2a} \quad (4.31)$$

where c is the speed of light in the dielectric media. The modal field patterns for this mode are shown in Fig. 4.12.

Table 4.3 shows the cutoff frequencies of the lowest order rectangular waveguide modes (as referenced to the cutoff frequency of the dominant mode) when $a/b = 2.1$.

The modal field patterns for several lower order modes are shown in Fig. 4. 13.

Circular Waveguides

A circular waveguide with inner radius a is shown in Fig. 4.14. Here the axis of the waveguide is aligned with the z axis of a circular-cylindrical coordinate system, where ρ and ϕ are the radial and azimuthal coordinates, respectively. If the walls are perfectly conducting and the dielectric material is lossless, the equations for the TE _{nm} modes are

FIGURE 4.14 A circular waveguide.

$$E_\rho = H_0 \frac{j\omega\mu n}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.32}$$

$$E_\phi = H_0 \frac{j\omega\mu}{h_{nm}} J_n'(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.33}$$

$$E_z = 0 \tag{4.34}$$

$$H_\rho = -H_0 \frac{\gamma_{nm}}{h_{nm}} J_n'(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.35}$$

$$H_\phi = H_0 \frac{\gamma_{nm}}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.36}$$

$$H_z = H_0 J_n(h_{nm}) \cos(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.37}$$

where n is any positive valued integer, including zero, and $J_n(x)$ and $J'_n(x)$ are the regular Bessel functions of order n and its first derivative, respectively. The allowed values of the modal eigenvalues h_{nm} satisfy

$$J'_n(h_{nm}a) = 0 \tag{4.38}$$

where m signifies the root number of Eq. (4.38). By convention, $1 < m < \infty$, where $m = 1$ indicates the smallest root.

The equations that define the TM_{nm} modes in circular waveguides are

$$E_\rho = -E_0 \frac{\gamma_{nm}}{h_{nm}} J'_n(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.39}$$

$$E_\phi = E_0 \frac{\gamma_{nm}}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.40}$$

$$E_z = E_0 J_n(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.41}$$

$$H_\rho = -E_0 \frac{j\omega\epsilon n}{h_{nm}^2 \rho} J_n(h_{nm}\rho) \sin(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.42}$$

$$H_\phi = -E_0 \frac{j\omega\epsilon}{h_{nm}} J'_n(h_{nm}\rho) \cos(n\phi) \exp(j\omega t - \gamma_{nm}z) \tag{4.43}$$

$$H_z = 0 \tag{4.44}$$

where n is any positive valued integer, including zero. For the TM_{nm} modes, the values of the modal eigenvalues are solutions of

$$J_n(h_{nm}a) = 0 \tag{4.45}$$

where m signifies the root number of Eq. (4.35). As in the case of the TE modes, $1 < m < \infty$.

The dominant mode in a circular waveguide is the TE_{11} mode, which has a cutoff frequency given by

$$f_{c11} = \frac{0.293}{a\sqrt{\mu\epsilon}} \tag{4.46}$$

The configuration of the electric and magnetic fields of this mode is shown in Fig. 4.15.

Table 4.4 shows the cutoff frequencies of the lowest order modes for circular waveguides, referenced to the cutoff frequency of the dominant mode.

The modal field patterns for several lower order modes are shown in Fig. 4.16.

Commercially Available Waveguides

The dimensions of standard rectangular waveguides are given in Table 4.5.

In addition to rectangular and circular waveguides, several other waveguide types are commonly used in microwave applications. Among these are ridge waveguides and elliptical waveguides. The modes of elliptical waveguides can be expressed in terms of Mathieu functions (Kretzschmar, 1970) and are similar to those of circular waveguides but are less perturbed by minor twists and bends of the waveguide. This property makes them attractive for coupling to antennas.

Single-ridge and double-ridge waveguides are shown in Fig. 4.17. The modes of these waveguides bear similarities to those of rectangular guides, but can only be derived numerically (Montgomery, 1971). Ridge

FIGURE 4.17 Single- and double-ridged waveguides.

waveguides are useful because their dominant ranges exceed those of rectangular waveguides. However, this range increase is obtained at the expense of higher losses.

Waveguides are also available in a number of constructions, including rigid, semirigid, and flexible. In applications where it is not necessary for the waveguide to bend, rigid construction is always the best since it exhibits the lowest loss. In general, the more flexible the waveguide construction, the higher the loss.

Waveguide Losses

There are two mechanisms that causes losses in waveguides: dielectric losses and metal losses. In both cases, these losses cause the amplitudes of the propagating modes to decay as $\exp(-\alpha z)$, where α is the attenuation constant, measured in neper/meter. Typically, the attenuation constant is considered as the sum of two components: $\alpha = \alpha_{\text{die}} + \alpha_{\text{met}}$, where α_{die} and α_{met} are the dielectric and metal attenuation constants, respectively.

The attenuation constant α_{die} can be found directly from Eq. (4.14) simply by generalizing the dielectric wave number k to include the effect of the dielectric conductivity σ . For a lossy dielectric, the wave number is given by $k^2 = \omega^2 \mu \epsilon (1 + (\sigma/j\omega\epsilon))$. Thus, from Eqs. (4.13) and (4.14) the attenuation constant α_{die} due to dielectric losses is given by

$$\alpha_{\text{die}} = \text{real} \left[\sqrt{h^2 - \omega^2 \mu \epsilon \left(1 + \frac{\sigma}{j\omega\epsilon} \right)} \right] \tag{4.47}$$

where the allowed values of h are given by Eq. (4.24) for rectangular modes and Eqs. (4.38) and (4.45) for circular modes.

The metal loss constant α_{met} is usually obtained by assuming that the wall conductivity is high enough to have only a negligible effect on the transverse properties of the modal field patterns. Using this assumption, the power loss in the walls per unit distance along the waveguide can then be calculated to obtain α_{met} (Marcuvitz, 1986). Figure 4.18 shows the metal attenuation constants for several circular waveguide modes, each normalized to the resistivity R_s of the walls, where $R_s = \sqrt{(\pi f \mu / \sigma)}$ and where μ and σ are the permeability and conductivity of the metal walls, respectively. As can be seen from this figure, the TE_{0m} modes exhibit particularly low loss at frequencies significantly above their cutoff frequencies, making them useful for transporting microwave energy over large distances.

Mode Launching

When coupling electromagnetic energy into a waveguide, it is important to ensure that the desired modes are excited and that reflections back to the source are minimized. Similar concerns must be considered when coupling energy from a waveguide to a transmission line or circuit element. This is achieved by using (or coupling) structures that allow strong coupling between the desired modes on both structures.

FIGURE 4.18 Values of metallic attenuation constant α for the first few waveguide modes in a circular waveguide of diameter d , plotted against normalized wavelength. (Source: Baden Fuller, A.J. 1979. *Microwaves*, 2nd ed., p. 138. Pergamon, New York. With permission.)

Figure 4.19 shows a mode launching structure for coaxial cable to rectangular waveguide transitions. This structure provides good coupling between the TEM (transmission line) mode on a coaxial cable and the TE_{10} mode in the waveguide because the antenna probe excites a strong transverse electric field in the center of the waveguide, directed between the broad walls. The distance between the probe and the short circuit back wall is chosen to be approximately $\lambda/4$, which allows the TE_{10} mode launched in this direction to reflect off the short circuit and arrive in phase with the mode launched toward the right.

FIGURE 4.19 Coaxial to rectangular waveguide transition that couples the transmission line mode to the dominant waveguide modes. (Source: Liao, S.Y. 1990. *Microwave Devices and Circuits*, 3rd ed., p. 117. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

Launching structures can also be devised to launch higher order modes. Mode launchers that couple the transmission line mode on a coaxial cable to the TM_{11} and TM_{21} waveguide mode are shown in Fig. 4.20.

FIGURE 4.20 Coaxial to rectangular waveguide transitions that couples the transmission line mode to the TM_{11} and TM_{21} waveguide modes. (Source: Liao, S.Y. 1990. *Microwave Devices and Circuits*, 3rd ed., p. 117. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

Defining Terms

Cutoff frequency: The minimum frequency at which a waveguide mode will propagate energy with little or no attenuation.

Guide wavelength: The distance over which the fields of propagating modes repeat themselves in a waveguide.

Waveguide: A closed metal cylinder, filled with a dielectric, used to transport electromagnetic energy over short or long distances.

Waveguide modes: Unique electromagnetic field configurations supported by a waveguide that have distinct electrical characteristics.

Wave impedance: The ratio of the transverse electric and magnetic fields inside a waveguide.

4.3 Passive Microwave Devices

Michael B. Steer

4.3.1 Introduction

Wavelengths in air at microwave and millimeter-wave frequencies range from 1 m at 300 MHz to 1 mm at 300 GHz and are comparable to the physical dimensions of fabricated electrical components. For this reason circuit components commonly used at lower frequencies, such as resistors, capacitors, and

FIGURE 4.21 Incident, reflected, and transmitted traveling voltage waves at: (a) A passive microwave element, (b) a transmission line.

inductors, are not readily available. The relationship between the wavelength and physical dimensions enables new classes of distributed components to be constructed that have no analogy at lower frequencies. Components are realized by disturbing the field structure on a transmission line, resulting in energy storage and thus reactive effects. Electric (E) field disturbances have a capacitive effect and the magnetic (H) field disturbances appear inductive. Microwave components are fabricated in waveguide, coaxial lines, and strip lines. The majority of circuits are constructed using strip lines as the cost is relatively low and they are highly reproducible due to the photolithographic techniques used. Fabrication of waveguide components requires precision machining but they can tolerate higher power levels and are more easily realized at millimeter-wave frequencies (30–300 GHz) than either coaxial or microstrip components.

4.3.2 Characterization of Passive Elements

Passive microwave elements are defined in terms of their reflection and transmission properties for an incident wave of electric field or voltage. In Fig. 4.21(a) a traveling voltage wave with phasor V_1^+ is incident at port 1 of a two-port passive element. A voltage V_1^- is reflected and V_2^- is transmitted. In the absence of an incident voltage wave at port 2 (the voltage wave V_2^- is totally absorbed by Z_0), at port 1 the element has a voltage reflection coefficient

$$\Gamma_1 = \frac{V_1^-}{V_1^+} \tag{4.48}$$

and transmission coefficient

$$T = \frac{V_2^-}{V_1^+} \tag{4.49}$$

More convenient measures of reflection and transmission performance are the **return loss** and **insertion loss** as they are relative measures of power in transmitted and reflected signals. In decibels

$$\text{return loss} = -20 \log \Gamma_1 \quad \text{insertion loss} = -20 \log T \tag{4.50}$$

The input impedance at port 1, Z_{in} , is related to Γ_1 by

$$Z_{in} = Z_0 \frac{1 + \Gamma_1}{1 - \Gamma_1} \tag{4.51}$$

The reflection characteristics are also described by the **voltage standing wave ratio (VSWR)**, a quantity which is more easily measured. The VSWR is the ratio of the maximum voltage amplitude on a transmission line ($|V_1^+| + |V_1^-|$) to the minimum voltage amplitude ($|V_1^+| - |V_1^-|$). Thus,

$$\text{VSWR} = \frac{1 + |\Gamma_1|}{1 - |\Gamma_1|} \tag{4.52}$$

These quantities will change if the loading conditions are changed. For this reason scattering parameters are used which are defined as the reflection and transmission coefficients with a load referred to as a

reference impedance. Simple formulas relate the S parameters to other network parameters (Vendelin et al., 1990, pp. 16–17). Thus,

$$S_{11} = \Gamma_1 \quad S_{21} = T \quad (4.53)$$

S_{11} and S_{12} are similarly defined when a voltage wave is incident at port 2. For a multiport

$$S_{pq} = \frac{\mathbf{V}_p^-}{\mathbf{V}_q^+} \quad (4.54)$$

with all of the ports terminated in the reference impedance. S parameters are the most convenient network parameters to use with distributed circuits as a change in line length results in a phase change. Also, they are the only network parameters that can be measured directly at microwave and millimeter-wave frequencies. Most passive devices, with the notable exception of ferrite devices, are reciprocal and so $S_{pq} = S_{qp}$. A loss-less passive device also satisfies the unitary condition: $\sum_q |S_{pq}|^2 = 1$, which is a statement of power conservation indicating that all power is either reflected or transmitted. A passive element is fully defined by its S parameters together with its reference impedance, here Z_0 . In general, the reference impedance at each port can be different.

Circuits are designed to minimize the reflected energy and maximize transmission at least over the frequency range of operation. Thus the return loss is high, and the VSWR $\simeq 1$ for well-designed circuits. Individual elements may have high reflection, and the interaction of elements is used in design.

A terminated transmission line such as that in Fig. 4.21(b) has an input impedance

$$Z_{\text{in}} = Z_0 \frac{Z_L + jZ_0 \tanh \gamma d}{Z_0 + jZ_L \tanh \gamma d} \quad (4.55)$$

Thus a short section ($\gamma d \ll 1$) of short-circuited ($Z_L = 0$) transmission line looks like an inductor, and a capacitor if it is open circuited ($Z_L = \infty$). When the line is a half-wavelength long, an open circuit is presented at the input to the line if the other end is short circuited.

4.3.3 Transmission Line Sections

The simplest microwave circuit element is a uniform section of transmission line which can be used to introduce a time delay or a frequency-dependent phase shift. Other line segments for interconnections include bends, corners, twists, and transitions between lines of different dimensions. (See Fig. 4.22.) The dimensions and shapes are designed to minimize reflections and so maximize return loss and minimize insertion loss.

4.3.4 Discontinuities

The waveguide discontinuities shown in Fig. 4.23(a) to Fig. 4.23(f) illustrate most clearly the use of E and H field disturbances to realize capacitive and inductive components. An E-plane discontinuity (Fig. 4.23(a)) can be modeled approximately by a frequency-dependent capacitor. H-plane discontinuities (Fig. 4.23(b) and Fig. 4.23(c)) resemble inductors as does the circular iris of Fig. 4.23(d). The resonant waveguide iris of Fig. 4.23(e) disturbs both the E and H fields and can be modeled by a parallel LC resonant circuit near the frequency of resonance. Posts in waveguide are used both as reactive elements (Fig. 4.23(f)) and to mount active devices (Fig. 4.23(g)). The equivalent circuits of microstrip discontinuities (Fig. 4.23(k) to Fig. 4.23(o)) are again modeled by capacitive elements if the E field is interrupted and by inductive elements if the H field (or current) is interrupted. The stub shown in Fig. 4.23(j) presents a short circuit to the through transmission line when the length of the stub is $\lambda_g/4$. When the stubs are electrically short ($\ll \lambda_g/4$) they introduce shunt capacitances in the through transmission line.

FIGURE 4.22 Sections of transmission lines used for interconnecting components: (a) waveguide tapered section, (b) waveguide E-plane bend, (c) waveguide H-plane bend, (d) waveguide twist, (e) microstrip taper.

4.3.5 Impedance Transformers

Impedance transformers are used to interface two sections of line with different **characteristic impedances**. The smoothest transition and the one with the broadest bandwidth is a tapered line as shown in Fig. 4.22(a) and Fig. 4.22(e). This element tends to be very long and so step terminations called quarter-wave impedance transformers (see Fig. 4.23(h) and Fig. 4.23(i)) are sometimes used although their bandwidth is relatively small centered on the frequency at which $l = \lambda_g/4$. Ideally, $Z_{0,2} = \sqrt{Z_{0,1}Z_{0,3}}$.

4.3.6 Terminations

In a termination, power is absorbed by a length of lossy material at the end of a shorted piece of transmission line (Fig. 4.24(a) and Fig. 4.23(c)). This type of termination is called a matched load as power is absorbed and reflections are very small irrespective of the characteristic impedance of the transmission line. This is generally preferred as the characteristic impedance of transmission lines varies with frequency, particularly so for waveguides. When the characteristic impedance of a line does not vary much with frequency, as is the case with a coaxial line, a simpler smaller termination can be realized by placing a resistor to ground (Fig. 4.24(b)).

4.3.7 Attenuators

Attenuators reduce the level of a signal traveling along a transmission line. The basic construction is to make the line lossy but with a characteristic impedance approximating that of the connecting lines so as to reduce reflections. The line is made lossy by introducing a resistive vane in the case of a waveguide (Fig. 4.24(d)), replacing part of the outer conductor of a coaxial line by resistive material (Fig. 4.24(e)), or covering the line by resistive material in the case of a microstrip line (Fig. 4.24(f)). If the amount of lossy material introduced into the transmission line is controlled, a variable attenuator is achieved, for example, Fig. 4.24(d).

FIGURE 4.23 Discontinuities. Waveguide discontinuities: (a) capacitive E-plane discontinuity, (b) inductive H-plane discontinuity, (c) symmetrical inductive H-plane discontinuity, (d) inductive circular iris discontinuity, (e) resonant window discontinuity, (f) capacitive post discontinuity, (g) diode post mount, and (h) quarter-wave impedance transformer. Microstrip discontinuities: (i) quarter-wave impedance transformer, (j) open microstrip stub, (k) step, (l) notch, (m) gap, (n) crossover, (o) bend.

4.3.8 Microwave Resonators

In a lumped element resonant circuit, stored energy is transferred between an inductor which stores magnetic energy and a capacitor which stores electric energy, and back again every period. Microwave resonators function the same way, exchanging energy stored in electric and magnetic forms but with the energy stored spatially. Resonators are described in terms of their quality factor

$$Q = 2\pi f_0 \left(\frac{\text{maximum energy stored in the resonator at } f_0}{\text{power lost in the cavity}} \right) \tag{4.56}$$

where f_0 is the resonant frequency. The Q is reduced and thus the resonator bandwidth is increased by the power lost due to coupling to the external circuit so that the loaded Q

$$Q_L = 2\pi f_0 \left(\frac{\text{maximum energy stored in the resonator at } f_0}{\text{power lost in the cavity and to the external circuit}} \right) \tag{4.57}$$

$$= \frac{1}{1/Q + 1/Q_{\text{ext}}}$$

where Q_{ext} is called the external Q . Q_L accounts for the power extracted from the resonant circuit and is typically large. For the simple response shown in Fig. 4.25(a) the half-power (3-dB) bandwidth is f_0/Q_L .

FIGURE 4.24 Terminations and attenuators: (a) waveguide matched load, (b) coaxial line resistive termination, (c) microstrip matched load, (d) waveguide fixed attenuator, (e) coaxial fixed attenuator, (f) microstrip attenuator, (g) waveguide variable attenuator.

Near resonance the response of a microwave resonator is very similar to the resonance response of a parallel or series R, L, C resonant circuit (Fig. 4.25(f) and Fig. 4.25(g)). These equivalent circuits can be used over a narrow-frequency range.

Several types of resonators are shown in Fig. 4.25. Figure 4.25(b) is a rectangular cavity resonator coupled to an external coaxial line by a small coupling loop. Figure 4.25(c) is a microstrip patch reflection resonator. This resonator has large coupling to the external circuit. The coupling can be reduced and photolithographically controlled by introducing a gap as shown in Fig. 4.25(d) for a microstrip gap-coupled transmission line reflection resonator. The Q of a resonator can be dramatically increased by using a high dielectric constant material as shown in Fig. 4.25(e) for a dielectric transmission resonator

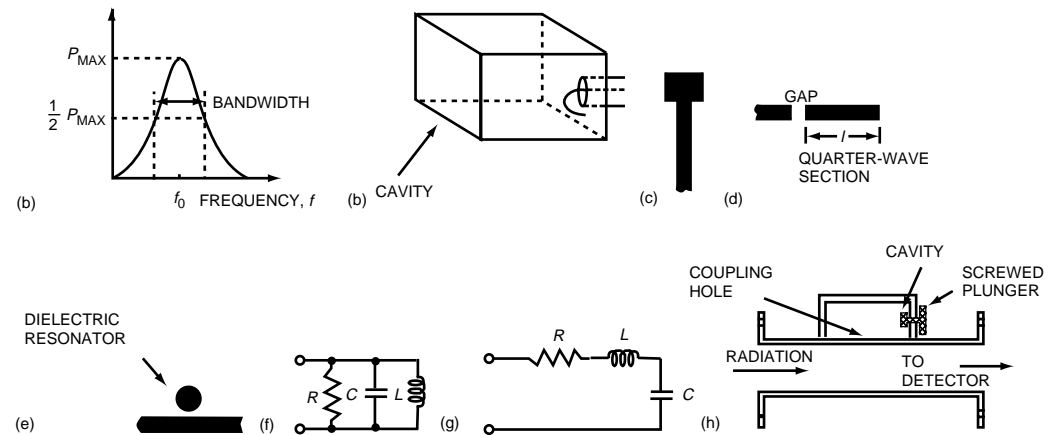

FIGURE 4.25 Microwave resonators: (a) resonator response, (b) rectangular cavity resonator, (c) microstrip patch resonator, (d) microstrip gap-coupled reflection resonator, (e) transmission dielectric transmission resonator in microstrip, (f) parallel equivalent circuits, (g) series equivalent circuits, (h) waveguide wavemeter.

FIGURE 4.26 Tuning elements: (a) waveguide sliding short circuit, (b) coaxial line slug tuner, (c) microstrip stub with tuning pads.

in microstrip. One simple application of a cavity resonator is the waveguide wavemeter (Fig. 4.25(h)). Here the resonant frequency of a rectangular cavity is varied by changing the physical dimensions of the cavity with a null of the detector indicating that the frequency corresponds to the resonant cavity frequency.

4.3.9 Tuning Elements

In rectangular waveguide the basic adjustable tuning element is the sliding short shown in Fig. 4.26(a). Varying the position of the short will change resonance frequencies of cavities. It can be combined with hybrid tees to achieve a variety of tuning functions. The post in Fig. 4.23(f) can be replaced by a screw to obtain a screw tuner, which is commonly used in waveguide filters. Sliding short circuits can be used in coaxial lines and in conjunction with branching elements to obtain stub tuners. Coaxial slug tuners are also used to provide adjustable matching at the input and output of active circuits. The slug is movable and changes the characteristic impedance of the transmission line. It is more difficult to achieve variable tuning in passive microstrip circuits. One solution is to provide a number of pads as shown in Fig. 4.26(c), which, in this case, can be bonded to the stub to obtain an adjustable stub length. Variable amounts of phase shift can be inserted by using a variable length of line called a line stretcher, or by a line with a variable propagation constant. One type of waveguide variable phase shifter is similar to the variable attenuator of Fig. 4.24(d) with the resistive material replaced by a low-loss dielectric.

4.3.10 Hybrid Circuits and Directional Couplers

Hybrid circuits are multipoint components that preferentially route a signal incident at one port to the other ports. This property is called directivity. One type of hybrid is called a directional coupler, the schematic of which is shown in Fig. 4.27(a). Here the signal incident at port 1 is coupled to ports 2 and 3, whereas very little is coupled to port 4. Similarly, a signal incident at port 2 is coupled to ports 1 and 4 but very little power appears at port 3. The feature that distinguishes a directional coupler from other types of hybrids is that the power at the output ports (here ports 2 and 3) is different. The performance of a directional coupler is specified by three parameters:

$$\begin{aligned}
 \text{Coupling factor} &= P_1/P_3 \\
 \text{Directivity} &= P_3/P_4 \\
 \text{Isolation} &= P_1/P_4
 \end{aligned}
 \tag{4.58}$$

Microstrip and waveguide realizations of directional couplers are shown in Fig. 4.27(b) and Fig. 4.27(c) where the microstrip coupler couples in the backward direction and the waveguide coupler couples in the forward direction. The powers at the output ports of the hybrids shown in Fig. 4.28 and Fig. 4.29 are equal and so the hybrids serve to split a signal into two equal half power signals, as well as having directional sensitivity.

FIGURE 4.27 Directional couplers: (a) schematic, (b) backward-coupling microstrip directional coupler, (c) forward-coupling waveguide directional coupler.

FIGURE 4.28 Waveguide hybrids: (a) E-plane tee and (b) its signal flow; (c) H-plane tee and (d) its signal flow; (e) magic tee and (f) its signal flow. The negative sign indicates 180° phase reversal.

FIGURE 4.29 Microstrip hybrids: (a) Rat race hybrid, (b) Lange coupler.

4.3.11 Filters

Filters are combinations of microwave passive elements designed to have a specified frequency response. Typically, a topology of a filter is chosen based on established lumped element filter design theory. Then computer-aided design techniques are used to optimize the response of the circuit to the desired response.

4.3.12 Ferrite Components

Ferrite components are nonreciprocal in that the insertion loss for a wave traveling from port A to port B is not the same as that from port B to port A.

Circulators and Isolators

The most important type of ferrite component is a circulator (Fig. 4.30(a) and Fig. 4.30(b)). The essential element of a circulator is a piece of ferrite, which when magnetized becomes nonreciprocal, preferring

FIGURE 4.30 Ferrite components: (a) schematic of a circulator, (b) a waveguide circulator, (c) microstrip isolator, (d) a YIG tuned bandpass filter.

progression of electromagnetic fields in one circular direction. An ideal circulator has the scattering matrix

$$[S] = \begin{bmatrix} 0 & 0 & S_{13} \\ S_{21} & 0 & 0 \\ 0 & S_{32} & 0 \end{bmatrix} \quad (4.59)$$

In addition to the insertion and return losses, the performance of a circulator is described by its isolation, which is its insertion loss in the undesired direction. An isolator is just a three-port circulator with one of the ports terminated in a matched load as shown in the microstrip realization of Fig. 4.30(c). It is used in a transmission line to pass power in one direction but not in the reverse direction. It is commonly used to protect the output of equipment from high reflected signals. The heart of isolators and circulators is the nonreciprocal element. Electronic versions have been developed for microwave monolithic integrated circuits (MMICs). A four-port version is called a duplexer and is used in radar systems and to separate the received and transmitted signals in a transceiver.

YIG Tuned Resonator

A magnetized YIG (yttrium iron garnet) sphere, shown in Fig. 4.30(d), provides coupling between two lines over a very narrow bandwidth. The center frequency of this bandpass filter can be adjusted by varying the magnetizing field.

4.3.13 Passive Semiconductor Devices

A semiconductor diode can be modeled by a voltage-dependent resistor and capacitor in shunt. Thus an applied DC voltage can be used to change the value of a passive circuit element. Diode optimized to produce a voltage variable capacitor are called varactors. In detector circuits a diode voltage variable resistance is used to achieve rectification and, through design, produce a DC voltage proportional to the power of an incident microwave signal. A controllable variable resistance is used in a *p-i-n* diode to realize an electronic switch.

Defining Terms

Characteristic impedance: Ratio of the voltage and current on a transmission line when there are no reflections.

Insertion loss: Power lost when a signal passes through a device.

Reference impedance: Impedance to which scattering parameters are referenced.

Return loss: Power lost upon reflection from a device.

Voltage standing wave ratio (VSWR): Ratio of the maximum voltage amplitude on a line to the minimum voltage amplitude.

4.4 Passive Filters

Cecil Harrison

4.4.1 Introduction

A **filter** is a multiport network designed specifically to respond differently to signals of different frequency. This definition excludes networks which behave as filters incidentally, sometimes to the detriment of their main purpose. **Passive filters** are constructed exclusively with passive elements (i.e., resistors, inductors, and capacitors).

Filters are generally categorized by

- Type
- Alignment (or class)
- Order

4.4.2 Filter Type

Filters are categorized by **type**, according to the magnitude of the frequency-response, as

- Lowpass (LP)
- Highpass (HP)
- Bandpass (BP)
- Bandstop (BS)

The terms *band reject* or *notch* are also used as descriptive of the BS filter. The term *all pass* is sometimes applied to a filter whose purpose is to alter the *phase angle* without affecting the magnitude of the frequency response. Ideal and practical interpretations of filter types and the associated terminology are illustrated in Fig. 4.31.

In general, the voltage gain of a filter in the **stopband** (or *attenuation band*) is less than $\sqrt{2}/2$ (≈ 0.707) times the maximum voltage gain in the **pass band**. In logarithmic terms, the gain in the stopband is at least 3.01 dB less than the maximum gain in the pass band. The **cutoff** (or *break* or *corner*) **frequency** separates the pass band from the stop band. In BP and BS filters, there are two cutoff frequencies, sometimes referred

FIGURE 4.31 Filter characteristics by type: (a) low-pass, (b) high-pass, (c) bandpass, (d) bandstop.

to as lower and upper cutoff frequencies. Another term for cutoff frequency is *half-power frequency*, since the power delivered to a resistive load at cutoff frequency is half the maximum power delivered to the same load in the pass band. For BP and BS filters, the **center frequency** is the frequency of maximum or minimum response magnitude, respectively, and **bandwidth** is the difference between upper and lower cutoff frequencies. **Rolloff** is the transition from pass band to stop band and is specified in gain unit per frequency unit (e.g., dB/decade, dB/octave, etc.)

4.4.3 Filter Alignment

The *alignment* (or *class*) of a filter refers to the shape of the frequency response. Fundamentally, **filter alignment** is determined by the coefficients of the filter network transfer function, and so there are an infinite number of filter alignments, some of which may not be realizable. The more common alignments are:

- **Butterworth**
- **Chebyshev**
- Bessel
- Inverse Chebyshev
- Elliptic (or Cauer)

Each filter alignment has a frequency response with a characteristic shape (Fig. 4.32), which provides some particular advantage. For example, filters with Butterworth, Chebyshev, or Bessel alignment are called all-pole filters because their lowpass transfer functions have no zeros. Table 4.6 summarizes the characteristics of the standard filter alignments.

4.4.4 Filter Order

The **order** of a filter is equal to the number of poles in the filter network transfer function. For a lossless L-C (inductance- capacitance) filter with resistive (nonreactive) termination, the number of reactive elements

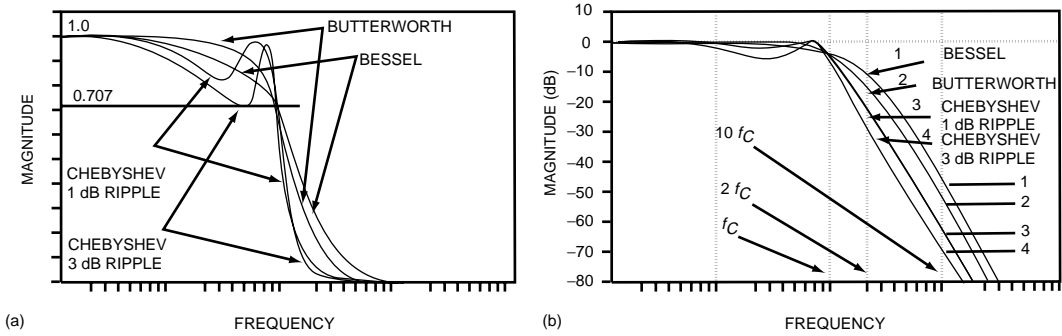

FIGURE 4.32 Filter characteristics by alignment, third-order, all-pole filters: (a) magnitude, (b) magnitude in decibel.

(inductors or capacitors) required to realize a LP or HP filter is equal to the order of the filter. Twice the number of reactive elements is required to realize a BP or a BS filter of the same order. In general, the order of a filter determines the slope of the rolloff: the higher the order, the steeper the rolloff. At frequencies greater than approximately one octave above cutoff (i.e., $f > 2 f_C$), the rolloff for all-pole filters is $20n$ dB/decade (or approximately $6n$ dB/octave), where n is the order of the filter (Fig. 4.33). In the vicinity of f_C , both filter alignment (Fig. 4.32) and filter order determine rolloff.

TABLE 4.6 Summary of Standard Filter Alignments

Alignment	Pass-Band Description	Stop Band Description	Comments
Butterworth	Monotonic	Monotonic	All-pole; maximally flat
Chebyshev	Rippled	Monotonic	All-pole
Bessel	Monotonic	Monotonic	All-pole; constant phase shift
Inverse Chebyshev	Monotonic	Rippled	
Elliptic (or Cauer)	Rippled	Rippled	

FIGURE 4.33 Effect of filter order on rolloff (Butterworth alignment).

4.4.5 Constraints

Filter networks are so diverse, and so much has been written about filter analysis and design, that several constraints are imposed here in order to present this discussion in a few pages. Accordingly, the discussion is limited to the following:

- Two-port filter networks. The exclusion of some passive filters with multiple outputs is not as significant here as it would be in a discussion of active filters.
- Lumped-parameter elements. High-frequency and microwave filters may rely on *distributed-parameter* elements; however, much of the analysis and many of the design procedures are applicable to distributed-parameter filters.
- Low-order filters. The unavoidable *insertion loss* associated with a passive filter increases with the number of elements in the filter. Consequently, it is usually more practical to use *active filters*, which can be designed to offset insertion loss (or even to provide insertion gain) for applications requiring higher than a third- or fourth-order transfer function.
- Magnitude response. Although a filter alters both the magnitude and the phase angle of the input signal, the predominant applications are those in which the magnitude of the signal is of greater interest.
- Single, resistive termination. The transfer function for a filter depends on both the load and the source impedances; hence, a filter is said to be *doubly terminated*. To avoid complications, the discussion here assumes that source impedance is negligible (i.e., the filter is *singly terminated*) and that the load impedance is nonreactive.
- All-pole filters with Butterworth or Chebyshev alignment. The Bessel alignment is primarily of interest in for *phase filters*, which will not be discussed here, and the techniques for obtaining transfer functions for the other alignments are too lengthy to be treated here. Once the transfer functions are obtained, however, the design procedures presented are generally applicable to all filters of all alignments.

The principal advantage of the Butterworth alignment is the flatness of the amplitude response within the pass band. The principal disadvantage is that the rolloff is not as steep in the vicinity of cutoff as that of some other filter designs of the same complexity (number of poles). The Chebyshev filter has a frequency response with a steeper rolloff in the vicinity of cutoff than that of the Butterworth filter, but *ripples* are present in the pass band. The Chebyshev filter is sometimes called an *equiripple* filter because the ripples have the same peak-to-peak amplitude throughout the pass band.

4.4.6 Summary of Design Procedures

The design procedures suggested here are based on what is sometimes called *modern filter theory*. Modern filter theory (as contrasted with *classical filter theory* relies more on *ad hoc* design calculations and less on the use of tabulated parameters. In brief, the design procedure is as follows:

- Design a LP **prototype filter** with a cutoff frequency of 1 rad/s ($1/2\pi$ Hz) and a resistive load termination of 1 Ω .
- **Frequency map** the LP design if a HP, BP, or BS response is required.
- **Frequency scale** the network elements for the required cutoff frequency.
- **Load scale** the network elements for the actual load resistance.

LP Prototype Design

For Butterworth alignment, a LP prototype filter must realize the frequency response magnitude function

$$\left| \frac{V_2(\omega)}{V_1(\omega)} \right| = \frac{1}{\sqrt{1 + \omega^{2n}}} \quad (4.60)$$

TABLE 4.7 Frequency Response Magnitude Functions for Butterworth LP Prototype Filters

Order n	$\left \frac{V_2(\omega)}{V_1(\omega)} \right $ Eq. (22.1)
2	$\frac{1}{\sqrt{1 + \omega^4}}$
3	$\frac{1}{\sqrt{1 + \omega^6}}$
4	$\frac{1}{\sqrt{1 + \omega^8}}$

where

ω = frequency, rad/s

n = filter order

$|V_2|$ = magnitude of the output voltage

$|V_1|$ = magnitude of the input voltage (usually 1 V in experimental and computational procedures)

The magnitude functions are given in Table 4.7 for Butterworth LP prototype filters of second, third, and fourth order.

For Chebyshev alignment, a LP prototype filter must realize the frequency response magnitude function

$$\left| \frac{V_2(\omega)}{V_1(\omega)} \right| = \frac{1}{\sqrt{1 + \epsilon^2 T_n^2(\omega)}} \tag{4.61}$$

where

$T_n(\omega)$ = n th-order Chebyshev polynomial of the first kind (Table 4.8)

ϵ = ripple parameter for the allowable pass-band ripple [Eq. (4.62)]

$$\begin{aligned} \text{ripple} &= 1 - \frac{1}{\sqrt{1 + \epsilon^2}} \\ \text{ripple (dB)} &= 10 \log_{10}(1 + \epsilon^2) \\ \epsilon^2 &= 10^{0.1 \times \text{ripple(dB)}} - 1 \end{aligned} \tag{4.62}$$

The magnitude functions for selected Chebyshev LP prototype filters are given in Table 4.8.

	4	1.000	0.582	1.169	0.405	0.177

To design L–C networks to realize the magnitude functions in [Tables 4.7](#) or [4.8](#), it is necessary to know the *s*-domain voltage transfer functions from which the magnitude functions are derived. The general form of these transfer functions is

$$\frac{V_2(s)}{V_1(s)} = \frac{c_0}{c_n s^n + c_{n-1} s^{n-1} + \dots + c_1 s + c_0} \tag{4.63}$$

where

- s* = Laplace transform domain variable, *s*⁻¹
- c*_{*i*} = polynomial coefficients

Filter alignment is determined by the coefficients *c*_{*i*} in the denominator polynomial of the transfer function. [Table 4.9](#) provides the coefficients for Butterworth and Chebyshev alignment for second-, third-, and fourth-order filters.

Phase response is not tabulated here, but may be determined by

$$\phi(\omega) = -\tan^{-1} \frac{c_1 \omega - c_3 \omega^3 + c_5 \omega^5 - \dots}{c_0 - c_2 \omega^2 + c_4 \omega^4 - \dots} \tag{4.64}$$

where $\phi(\omega)$ is the phase angle in radian.

Passive filters are very often (but not always) realized with an L–C ladder network, which takes on one of the forms shown in [Fig. 4.34](#). The configuration of [Fig. 4.34\(a\)](#) is used for odd-order filters, and the configuration of [Fig. 4.34\(b\)](#) is used for even-order filters. In either case, the inductors provide low impedance between input and output at low frequencies and high impedance at high frequencies, and the capacitors provide low admittance to ground at low frequencies and high admittance at high frequencies. This discussion of filter realization is limited to *lossless* L–C ladder networks; i.e., the capacitors are assumed to have no dielectric conductance and the inductors are assumed to have no winding resistance. (The network configuration in [Fig. 4.34](#) is known as a *Cauer network* after Wilhelm Cauer, one of the preeminent network theorists of the early 20th century.)

When terminated by a load *Z*_{*L*}(*s*), the entire circuit consisting of L–C ladder network filter and load ([Fig. 4.35](#)) must have the transfer function *V*₂(*s*)/*V*₁(*s*), as specified in [Eq. \(4.63\)](#). The L–C ladder network

FIGURE 4.34 Passive LP filters: (a) lossless L-C ladder network, odd order, (b) lossless L-C ladder network, even order.

can be characterized by its network admittance parameters

$$y_{11} = \frac{I_1}{V_1} \Big|_{V_2=0} \quad y_{12} = \frac{I_1}{V_2} \Big|_{V_1=0} \quad y_{21} = \frac{I_2}{V_1} \Big|_{V_2=0} \quad y_{22} = \frac{I_2}{V_2} \Big|_{V_1=0} \quad (4.65)$$

such that

$$I_1 = y_{11} V_1 + y_{12} V_2 \quad (4.66)$$

and

$$I_2 = y_{21} V_1 + y_{22} V_2 \quad (4.67)$$

When the filter network is terminated by $Z_L(s)$

$$I_2 = -V_2 Z_L \quad (4.68)$$

and so Eq. (4.67) becomes

$$-V_2 Z_L = y_{21} V_1 + y_{22} V_2 \quad (4.69)$$

or

$$\frac{V_2}{V_1} = \frac{-y_{21}}{Z_L + y_{22}} \quad (4.70)$$

In a prototype filter, $Z_L = 1 \Omega$ (resistive); thus

$$\frac{V_2}{V_1} = \frac{-y_{21}}{1 + y_{22}} \quad (4.71)$$

The voltage transfer function in Eq. (4.63) can be manipulated into the form of Eq. (4.71) by separating the denominator terms into one group of odd-degree terms and another group of even-degree terms. When the numerator and denominator are both divided by the group of odd-degree terms, the result is as follows.

Even order:

$$\frac{V_2(s)}{V_1(s)} = \frac{\frac{c_0}{c_{n-1}s^{n-1} + c_{n-3}s^{n-3} + \dots + c_1s}}{1 + \frac{c_n s^n + c_{n-2}s^{n-2} + \dots + c_0}{c_{n-1}s^{n-1} + c_{n-3}s^{n-3} + \dots + c_1s}} \quad (4.72a)$$

FIGURE 4.35 L-C ladder network with load.

TABLE 4.10 Admittance Parameters for LP Prototype Filters

Order n	$\frac{V_2(s)}{V_1(s)}$	$y_{21}(s)$	$y_{22}(s)$
2	$\frac{\frac{Ac_0}{c_1s}}{1 + \frac{c_2s^2 + c_0}{c_1s}}$	$-\frac{Ac_0}{c_1s}$	$\frac{c_2s^2 + c_0}{c_1s}$
3	$\frac{\frac{Ac_0}{c_3s^3 + c_1s}}{1 + \frac{c_2s^2 + c_0}{c_3s^3 + c_1s}}$	$-\frac{Ac_0}{c_3s^3 + c_1s}$	$\frac{c_2s^2 + c_0}{c_3s^3 + c_1s}$
4	$\frac{\frac{Ac_0}{c_3s^3 + c_1s}}{1 + \frac{c_4s^4 + c_2s^2 + c_0}{c_3s^3 + c_1s}}$	$-\frac{Ac_0}{c_3s^3 + c_1s}$	$\frac{c_4s^4 + c_2s^2 + c_0}{c_3s^3 + c_1s}$

Odd order:

$$\frac{V_2(s)}{V_1(s)} = \frac{\frac{c_0}{c_n s^n + c_{n-2} s^{n-2} + \dots + c_1 s}}{1 + \frac{c_{n-1} s^{n-1} + c_{n-3} s^{n-3} + \dots + c_0}{c_n s^n + c_{n-2} s^{n-2} + \dots + c_1 s}} \tag{4.72b}$$

The expressions for y_{21} and y_{22} are obtained by matching terms from Eq. (4.71) with terms from Eq. (4.72a) or (4.72b). These results are provided in Table 4.10 for LP filters.

LP Prototype Design Example

The next step in designing an LP prototype filter network is to select inductors and capacitors so that the admittance parameters y_{21} and y_{22} are as specified in Table 4.10. The procedure is demonstrated for a representative fourth-order filter (Chebyshev with 3-dB ripple), and the results are given in Table 4.11 for

TABLE 4.11 L-C Elements for Prototype LP Filter

Alignment	Order n	L_1, H	C_2, F	L_3, H	C_4, F
Butterworth	2	1.414	0.707		
	3	1.500	1.333	0.500	
	4	1.531	1.577	1.082	0.383
Chebyshev ripple: 0.1 dB $\epsilon = 0.1526$	2	0.716	0.442		
	3	1.090	1.086	0.516	
	4	1.245	1.458	1.199	0.554
Chebyshev ripple: 0.1 dB $\epsilon = 0.5088$	2	0.995	0.911		
	3	1.509	1.333	1.012	
	4	1.279	1.912	1.412	1.049
Chebyshev ripple: 3.0 dB $\epsilon = 0.9976$	2	0.911	1.550		
	3	2.024	1.175	1.675	
	4	1.057	2.529	1.230	1.718

FIGURE 4.36 Design example, fourth-order LP prototype filter: (a) singly terminated LP filter, (b) network model for obtaining y_{22} , (c) network model for obtaining y_{21} .

second-, third-, and fourth-order Butterworth and selected Chebyshev filters. This procedure is based on satisfying the requirements for y_{22} , which necessarily satisfies the requirements for y_{21} .

1. The singly terminated filter network is shown in Fig. 4.36(a).
2. To obtain the network parameter y_{22} , port 1 is shorted (i.e., $V_1 = 0$), which makes the admittance at port 2 equivalent to y_{22} (Fig. 4.36(b)).
3. To simplify analysis, the network is divided into subnetworks A, B, and C, as shown, which leads to

$$\begin{aligned}
 y_{22} &= Y_4 + Y_A = C_4s + \frac{1}{Z_A} \\
 Z_A &= Z_3 + Z_B = L_3s + \frac{1}{Y_B} \\
 Y_B &= Y_2 + Y_C = C_2s + \frac{1}{Z_C} \\
 Z_C &= Z_1 = L_1s
 \end{aligned}
 \tag{4.73}$$

4. Back substitution in Eq. (4.73) yields

$$y_{22} = C_4s + \frac{1}{L_3s + \frac{1}{C_2s + \frac{1}{L_1s}}}
 \tag{4.74}$$

5. The form of Eq. (4.74) suggests that the values of L_1 , C_2 , L_3 , and C_4 can be determined by comparing Eq. (4.74) to a long division of the required y_{22} . From [Tables 4.9](#) and [4.10](#)

$$y_{22} = \frac{s^4 + 1.169s^2 + 0.177}{0.582s^3 + 0.405s}
 \tag{4.75}$$

6. Long division of the right member of Eq. (4.75) yields

$$\begin{aligned}
 y_{22} &= 1.718s + \frac{0.473s^2 + 0.177}{0.582s^3 + 0.405} \\
 &= 1.718s + \frac{1}{1.230s + \frac{0.187s}{0.473s^2 + 0.177}} \\
 &= 1.718s + \frac{1}{1.230s + \frac{1}{2.529s + \frac{0.177s}{0.187}}} \\
 &= 1.718s + \frac{1}{1.230s + \frac{1}{2.529s + \frac{1}{1.057s}}}
 \end{aligned} \tag{4.76}$$

7. Comparison of Eq. (4.74) and (4.76) indicates that

$$L_1 = 1.057 \text{ H}; \quad C_2 = 2.529 \text{ F}; \quad L_3 = 1.230 \text{ H}; \quad C_4 = 1.718 \text{ F}$$

These values are prototype values and must be appropriately scaled for the actual cutoff frequency (other than 1 rad/s) and the actual load resistance (other than 1 Ω).

8. Confirmation that the prototype values for L_1 , C_2 , L_3 , and C_4 yield the required value of y_{21} (as obtained from Tables 4.9 and 4.10) is not necessary, but serves as a test of the design procedure. In Fig. 4.36(c)

$$\begin{aligned}
 I_1 &= \frac{V_1}{Z_1 + Z_D} = \frac{V_1}{L_1s + \frac{1}{Y_D}} \\
 Y_D &= Y_2 + Y_E = C_2s + \frac{1}{Z_E} \\
 Z_E &= L_3s
 \end{aligned} \tag{4.77}$$

Back substitution in Eq. (4.77) yields

$$I_1 = \frac{V_1}{L_1s + \frac{1}{C_2s + \frac{1}{L_3s}}} \tag{4.78}$$

Because of current division

$$I_2 = -I_1 \frac{Y_E}{Y_2 + Y_E} = -I_1 \frac{\frac{1}{L_3s}}{C_2s + \frac{1}{L_3s}} \tag{4.79}$$

9. The admittance parameter y_{21} is obtained by combining Eqs. (4.78) and (4.79)

$$\begin{aligned}
 y_{21} &= -\frac{I_2}{V_1} = -\frac{1}{L_1C_2L_3s^3 + (L_1 + L_3)s} \\
 &= -\frac{1}{3.288s^3 + 2.287s} = -\frac{0.177}{0.582s^3 + 0.405s}
 \end{aligned} \tag{4.80}$$

which confirms y_{21} as given in Tables 4.9 and 4.10.

TABLE 4.12 Frequency Mapping of Network Elements

Type	Series Branch(es)	Shunt Branch(es)
Low pass		
High pass		
Bandpass		
Bandstop		

Frequency Mapping

Once a LP prototype filter has been designed, a prototype HP, BP, or BS L-C filter is realized by replacing the LP network elements according to the scheme shown in Table 4.12. This technique is called frequency mapping. Recall that prototype means that the cutoff frequency of a frequency-mapped HP filter or the center frequency of a frequency-mapped BP or BS filter is 1 rad/s (Fig. 4.37) when operating with a 1-Ω load. The bandwidth parameter *B* in Table 4.12 expresses bandwidth of a BS or BP filter as the ratio of bandwidth to center frequency. If, for example, the bandwidth and center frequency requirements for a BP or BS filter are 100 Hz and 1 kHz, respectively, then the prototype bandwidth parameter *B* is 0.1. The general network configurations for HP, BP, and BS L-C filters are shown in Fig. 4.38.

The mathematical basis for frequency mapping is omitted here; however, the technique involves replacing the LP transfer function variable (*s* or ω) with the mapped variable, as presented in Table 4.13. The mapped amplitude response for a Butterworth filter or a Chebyshev filter is obtained by performing the appropriate operation from column two of Table 4.13 on Eq. (4.60) or (4.61), respectively. The mapped phase response

FIGURE 4.37 Mapped frequency responses.

FIGURE 4.38 Mapped filter networks: (a) high pass, (b) bandpass, (c) bandstop.

is obtained by performing the same indicated operation on Eq. (4.64). The mapped s -domain transfer function is realized, when required, by performing the appropriate operation from column 3 of Table 4.13 on Eq. (4.63).

The highest degree term in the denominator of a mapped BP or BS transfer function is twice that of the original LP transfer function. This means that the s -domain transfer function must have twice as many poles, and the L–C ladder network must correspondingly have twice as many elements (Fig. 4.38).

Frequency and Load Scaling

A prototype filter is designed to operate at a cutoff or center frequency of 1 rad/s (≈ 0.159 Hz) and with a 1- Ω load, and so the inductor and capacitor values for the prototype must be *scaled* for operation of the filter at a specified cutoff or center frequency f_c and with a specified load resistance R_L . Frequency scaling produces a *frequency scale factor* k_f , which is the ratio of the cutoff or center frequency f_c to 1 rad/s

$$k_f = \frac{\omega_C}{1} = 2\pi f_C \tag{4.81}$$

TABLE 4.13 Frequency Mapping of Transfer Functions Variables

Function Type	Frequency Domain	s domain
LP \rightarrow HP	$\omega \rightarrow \frac{1}{\omega}$	$s \rightarrow \frac{1}{s}$
LP \rightarrow BP	$\omega \rightarrow \frac{ 1 - \omega^2 }{B\omega}$	$s \rightarrow \frac{1 + s^2}{Bs}$
LP \rightarrow BS	$\omega \rightarrow \frac{B\omega}{ 1 - \omega^2 }$	$s \rightarrow \frac{Bs}{1 + s^2}$

FIGURE 4.39 Scale factor.

and load scaling produces a *load scale factor* k_R , which is the ratio of the load resistance R_L to 1Ω

$$k_R = \frac{R_L}{1} = R_L \tag{4.82}$$

In practice, the frequency and impedance scale factors are combined to produce a single scale factor K_L for inductors

$$K_L = \frac{k_R}{k_f} = \frac{R_L}{2\pi f_C} \tag{4.83}$$

and a single scale factor K_C for capacitors

$$K_C = \frac{1}{k_f k_R} = \frac{1}{2\pi f_C R_L} \tag{4.84}$$

The inductor and capacitor scale factors are used as multipliers for the prototype values

$$L = K_L L_P \tag{4.85}$$

$$C = K_C C_P \tag{4.86}$$

where

- L = scaled inductance
- L_P = corresponding inductance in prototype filter
- C = scaled capacitance
- C_P = corresponding capacitance in prototype filter

The graphs in Fig. 4.39 can be used for quick estimates of the scaled values of inductance and capacitance.

Defining Terms

Bandwidth: The absolute difference between the lower and upper cutoff frequencies of a bandpass or bandstop filter.

Butterworth alignment: A common filter alignment characterized by a maximally flat, monotonic frequency response.

Center frequency: The frequency of maximum or minimum response for a bandpass or a bandstop filter, respectively; often taken as the geometric mean of the lower and upper cutoff frequencies.

Chebyshev alignment: A common filter alignment characterized by ripples of equal amplitude within the pass-band and a steep rolloff in the vicinity of cutoff frequency.

Cutoff frequency: The frequency separating a pass-band from a stop-band; by convention, the response is 3 dB less than maximum response at the cutoff frequency; also called break, corner, or half-power frequency.

Filter alignment: Categorization of a filter according to the shape of the frequency response; also called filter class.

Filter order: Categorization of a filter by the number of poles in its transfer function; generally equates to the number of reactive elements required to realize a passive low-pass or high-pass filter, and one-half the number required to realize a bandpass or bandstop filter.

Filter type: Categorization of a filter according to its frequency response as lowpass, highpass, bandpass, or bandstop. Bandstop filters are also referred to as bandreject or notch filters.

Frequency mapping: Procedure by which a lowpass prototype filter is converted to a highpass, bandpass, or bandstop prototype.

Frequency scaling: Procedure by which the values of prototype filter elements are adjusted to allow the filter to operate at a specified cutoff frequency (other than 1 rad/s).

Load scaling: Procedure by which the values of prototype filter elements are adjusted to allow the filter to operate with a specified load (other than 1 Ω).

Pass-band: A range of frequency over which the filter response is, by convention, within 3 dB of its maximum response.

Passive filter: An electrical network comprised entirely of passive elements and designed specifically to respond differently to signals of different frequency.

Prototype filter: A filter designed to operate with a cutoff frequency of 1 rad/s and with a load termination of 1 Ω .

Rolloff: Transition from pass-band to stop-band.

Stop-band: A range of frequency over which the filter response is, by convention, at least 3 dB less than its maximum response; also called the attenuation band.

5.1 Electron Tube Fundamentals

Clifford D. Ferris

5.1.1 Introduction

Although widely used in many electronic applications until the 1960s, the traditional electron vacuum tube has now largely been replaced by semiconductor devices. Notable exceptions include cathode-ray tubes used in oscilloscopes and video displays, power grid tubes used in radio and television broadcast transmitters, and various classes of vacuum microwave devices. This chapter presents an introduction to the operation of electron tubes. Subsequent chapters are concerned with specific vacuum devices and their applications.

The elementary vacuum-tube structure is illustrated in Fig. 5.1. An evacuated volume is enclosed by an envelope, which may be glass, metal, ceramic, or a combination of these materials. Metallic electrodes

contained within the envelope form the working device, and external connections are made via metal wires that pass through vacuum seals in the envelope. The three basic internal structures are the **cathode** (K), the anode (A) (often called the **plate**), which are solid surfaces, and a single open wire-mesh structure that is the **grid**. Under typical operating conditions, the anode is held at a more positive potential than the cathode, and the grid is held at a voltage that is negative relative to the cathode. In this regard, operation is analogous to that of an n -channel junction field-effect transistor (JFET). The cathode, grid, and plate are analogous to the source, gate, and drain, respectively.

The function of the cathode is to provide a source of free electrons, and this is accomplished by heating the cathode to a high temperature, a process known as **thermionic emission**. Because the electrons are negatively charged and the cathode is lower in potential than the plate, the emitted electrons are accelerated toward the positively charged plate. The electron flow from the cathode to the plate can be controlled by adjusting the electric potential (grid-to-cathode voltage) applied between the grid and cathode. If the grid is made sufficiently negative relative to the cathode, the electron flow to the plate can be cut off completely. As the grid becomes less negative, electrons pass through the grid structure to the plate. The grid potential, however, must not increase to the point that it collects electrons in place of the plate. The grid is composed of fine wires that are not designed to support high current and is easily damaged by any significant electron collection.

FIGURE 5.1 The basic vacuum tube.

5.1.2 Cathodes and Thermionic Emission

There are two fundamental cathode structures, directly heated (filament) and indirectly heated. The filament type of cathode is similar to the tungsten filament in an incandescent light bulb. To increase the efficiency of electron emission, thorium is added to the tungsten (1 or 2% by weight of thorium oxide), thus forming a **thoriated** tungsten filament (after an activation process that converts the thorium oxide to metallic thorium). The actual mechanical configuration or geometry of the filament varies widely among vacuum tubes depending on the output-power rating of the vacuum tube. Typically, the filament (or heater, as it is often called) is supported by the lead wires that pass through the envelope.

Figure 5.2 represents a vacuum diode that contains a directly heated cathode (filament). The filament supply voltage may be either AC or DC (DC is shown), and historically is called the *A supply*. Depending on the service for which a vacuum tube has been designed, filament (heater) supply voltages typically range from 2.5 to 12.6 V. Filament currents vary from as low as 150 mA to hundreds of amperes. A DC potential (the plate supply voltage) is required between the plate and cathode. Under many conditions, the cathode is at 0 V DC so that the plate-to-cathode voltage is the same as the plate voltage.

FIGURE 5.2 Vacuum diode for directly heated cathode discussion.

The thermionic-emission current I_{th} , in amperes, generated by a heated filament is described by the Richardson–Dushman equation

$$I_{th} = AD_0T^2 \exp(-b_0/T) \tag{5.1}$$

where

- A = surface (emitting) area of the filament, m^2
- D_0 = material constant for a given filament type, $A/m^2 \cdot K^2$
- T = absolute temperature, K
- $b_0 = 11,600E_w, K$
- E_w = the work function of the emitting surface, eV

Some typical values for thoriated tungsten are $D_0 = 3.0 \times 10^4 A/m^2 \cdot K^2$, $T = 1900 K$, $b_0 = 30,500 K$, and $E_w = 2.63 eV$. Cathode efficiency is defined in terms of the number of amperes (or milliamperes) produced per square meter of emitting surface per watt of applied filament power. For a thoriated tungsten filament with plate voltages in the range from 0.75 to 5 kV, emission efficiency ranges from 50 to 1000 $A/m^2/W$. Thoriated tungsten filaments are normally incorporated into power grid tubes that generate output power levels from a few hundred watts to thousands of kilowatts. These devices are used in high-power radio and television broadcasting service and in industrial applications such as induction heating.

Oxide-coated cathodes that are indirectly heated are more efficient ($E_w \approx 1 eV$) than thoriated tungsten filaments, but they cannot sustain the high-voltage high-current operating conditions associated with power grid tubes. When the maximum output power required is below a few hundred watts, they are the device of choice and find application in low-power high-frequency transmitters. They are also widely used by audiophiles who feel that vacuum-tube power amplifiers produce a quality of sound output that is superior to that produced by semiconductor devices.

A typical geometry for an oxide-coated cathode is a nickel or Konal-metal sleeve or cylinder that surrounds a heating filament (the heater). The heater wire is usually tungsten or a tungsten-molybdenum alloy that is coated with a ceramic insulating material (alundum, aluminum oxide or beryllium oxide) to isolate the heater electrically from the cathode sleeve. The outside coating of the cathode is applied as a mixture of carbonates that are subsequently converted to oxides during final processing of the electron tube. Barium and strontium oxides are widely used. Typical heater temperatures are on the order of $1000^\circ C$, which produce an orange to yellow-orange glow from the heater. Cathode temperatures are on the order of $850^\circ C$. Maximum heater-power requirements are on the order of 12 W for oxide-coated cathode devices, whereas thoriated tungsten filaments may require many kilowatts of heater input power.

Figure 5.3 illustrates two of many possible heater configurations. The twisted configuration (Fig. 5.3(a)) and the folded linear arrangement (Fig. 5.3(b)) are commonly used. The ceramic oxide

FIGURE 5.3 Heater and cathode structures: (a) Twisted filament, (b) folded filament, (c) cathode sleeve.

coating that is applied to the wires prevents electrical short circuits between the wire segments. The heater is inserted into the cathode sleeve, and the ceramic coating applied to the heater surface insulates the heater electrically from the cathode sleeve. This ceramic layer cannot sustain a high potential difference between the heater and the cathode, and 200 V is a typical figure for the maximum heater-cathode voltage. For this reason, indirectly heated cathodes are not appropriate for power grid tube service.

Before we move on to specific vacuum-tube configurations, a final comment is required concerning electron emission from a cathode. To simplify mathematical derivations, it is often assumed that all of the electrons are emitted with zero initial velocity. If some of the electrons have initial velocities, a negative potential gradient is established at the cathode, which then produces a potential-energy barrier and corresponding space-charge region. Electrons emitted with very small initial velocities are then repelled toward the cathode. Equilibrium is established between emission of electrons and this space-charge region. In effect, the electrons that are accelerated toward the plate (the emission current) are drawn from the space-charge region.

5.1.3 Thermionic Diode

The fundamental thermionic diode has been illustrated in Fig. 5.2, and Fig. 5.4 illustrates the representation of a vacuum diode that has an oxide cathode. The plate current (I_p) vs plate-to-cathode voltage (V_p) description of diode operation is provided by the Langmuir–Child law that states that the plate current is proportional to the plate voltage raised to the three-halves power.

FIGURE 5.4 Vacuum diode with indirectly heated cathode.

$$I_p = k_0 V_p^{1.5} \quad (5.2)$$

The proportionality constant k_0 depends on the physical dimensions of the plate and cathode, their respective geometries, and the ratio of electronic charge to mass. It is sometimes called the *permeance*. It must be noted that the plate current cannot exceed the thermionic emission current, which provides an upper limit to the value of I_p in Eq. (5.2). A typical characteristic curve is presented in Fig. 5.5, in which $k_0 = 8.94 \times 10^{-6}$ (A/V^{1.5}).

Vacuum diodes are used as circuit elements in the same manner as modern semiconductor diodes. They may serve in rectifier circuits, and as voltage clippers, clamps, and DC restorers for high-voltage applications. From a circuit viewpoint, the only difference is the requirement of a heater voltage when a thermionic diode is used. The forward-voltage drop associated with vacuum diodes, however, is considerably larger than the fraction of a volt associated with a silicon device. It may range from a few volts to more than 100 V depending on the device, the plate current, and the plate-to-cathode voltage (plate voltage).

5.1.4 Grid Tubes

To achieve voltage and power amplification, or to produce electronic oscillation, at least one additional electrode must be added to the basic thermionic diode. This electrode is a control grid. As will be discussed subsequently, two additional grids may be added to produce specific operating characteristics of the grid tube. Figure 5.6 illustrates four device configurations. Depending on the maximum power dissipation of the device, either of the two cathode types shown may be used. For graphical convenience, the heater connections have been omitted in Fig. 5.6(a) to Fig. 5.6(d).

FIGURE 5.5 Vacuum diode characteristic for $k_o = 8.94 \times 10^{-6} (A/V^{1.5})$.

FIGURE 5.6 Four standard grid tube representations: (a) triode, (b) tetrode, (c) pentode, (d) beam power, (e) cathode types.

Physical geometries for grid tubes vary widely depending on operating frequency and power dissipated. Many devices use a modified concentric cylinder configuration as indicated in Fig. 5.7. The electrode structures are supported by stiff metal posts anchored at the base (and sometimes the top) of the device. Ceramic or mica wafer spacers (not shown in the diagram) hold the electrode structure rigidly within the enclosing envelope. The plate is frequently equipped with heat radiating fins. The grid is often an open helix constructed from fine wire, although other structures resembling window screening are used in some applications.

FIGURE 5.7 Cross section of a vacuum tube viewed from the top (tetrode shown).

Parallel planar geometries are used in some high-frequency **triodes**. A planar cathode is placed at the base of the tube, and a heavy planar plate is anchored at the top of the tube, with a flat-mesh control grid inserted between the cathode and plate. Close spacing between the plate and cathode is obtained in this manner so that electron-transit time from the cathode to the plate is minimized.

Nickel and various metals and alloys are used for the tube electrodes other than the heater. The plate is frequently blackened to improve heat radiation. In low-power grid tubes, the electrical connections are usually made through the base of the device. For low-power tubes there are various standard base-pin and corresponding socket configurations similar to those used for standard television picture tubes. In high-power and high-frequency tubes, the heater connections are usually made at the tube base, but the plate connection is at the top of the tube, and the grid connections are brought out as wires or rings along the side of the device. Power grid tubes are described in a separate chapter in this handbook.

By general convention, the cathode potential is assumed to be close to or at zero volts. Thus, references to grid volts, screen volts, and plate volts (rather than grid-to-cathode, screen-to-cathode, or plate-to-cathode) are standard in vacuum-tube literature. In low-power tubes, the control grid (G in Fig. 5.6) is operated at either zero volts or some negative voltage. The plate voltage is positive, the screen grid voltage (SG in Fig. 5.6) is positive but lower than the plate voltage, and the suppressor grid voltage ($SUPG$ in Fig. 5.6) is usually at the same potential as the cathode. In many tubes, the suppressor grid is connected internally to the cathode.

The signal processing attributes of vacuum tubes are characterized by three primary parameters, amplification factor μ (**mu**), dynamic transconductance g_m , and dynamic plate resistance r_p , which are defined as follows:

$$\begin{aligned}\mu &= \partial v_p / \partial v_g; & I_p \text{ and } V_{SG}, & \text{ held constant as applicable} \\ g_m &= \partial i_p / \partial v_g; & V_p \text{ and } V_{SG}, & \text{ held constant as applicable} \\ r_p &= \partial v_p / \partial i_p; & V_G \text{ and } V_{SG}, & \text{ held constant as applicable} \\ \mu &= g_m r_p\end{aligned}$$

Note that lowercase letters have been used to define signal parameters, and uppercase letters have been used to define DC values. Thus, μ , g_m , and r_p are defined for a fixed DC operating point (Q point) of the corresponding device. Additional signal parameters include the direct interelectrode capacitances, which are a function of the geometry of a specific tube type. These capacitances are generally a few picofarads at most in low-power grid tubes and include, as applicable: control grid to plate; control grid to heater, cathode, screen grid, suppressor grid.

The input resistance presented between the grid and cathode of a vacuum tube is extremely high and is generally assumed to be infinite at low frequencies. The input impedance, however, is not infinite because of the influence of the interelectrode capacitances. Input impedance is thus a function of frequency, and it depends on the tube parameters μ , g_m , and r_p as well. Reactive elements associated with the load also influence input impedance. If C_{gk} is the interelectrode capacitance between the grid and cathode, C_{pg} is the capacitance between the plate and grid, R_l is the effective AC load (no reactive/susceptive components), and

ω is the radian frequency of operation for an amplifier tube, then input *admittance* (Y_i) is, approximately, for triode

$$Y_i \approx j\omega\{C_{gk} + [\mu R_l / (r_p + R_l) C_{pg}]\} \tag{5.3a}$$

and **tetrode and pentode**

$$Y_i \approx j\omega C_{gk} \tag{5.3b}$$

At very high frequencies, lead inductances and stray capacitances associated with the tube itself and its external connections modify the expressions shown.

With the exception of cathode **emissivity**, the operating parameters of vacuum tubes depend solely on geometry and the placement of the electrodes within an evacuated envelope. If mechanical tolerances are rigidly held during manufacture, then there is very little variation in operating parameters across vacuum tubes of the same type number. Cathode manufacture can also be controlled to high tolerances. For this reason, when an operating point is specified, single numbers define μ , g_m , and r_p in vacuum tubes. The designer does not have to contend with the equivalent of beta spread in bipolar-junction transistors or transconductance spread in field-effect devices. To ensure reliable operation over the life of the tube, a barium *getter* is installed before the tube structure is sealed into an envelope and evacuated. After the tube has been evacuated and the final seal has been made, the getter is flashed (usually using a radio frequency induction-heating coil) and elemental barium is deposited on a portion of the inside of the envelope. The function of the getter is to trap gas molecules that are generated from the tube components with time. In this manner the integrity of the vacuum is preserved. Heater burnout or oxide-layer deterioration (in indirectly heated cathode tubes) are the usual causes of failure in vacuum tubes.

Triode

Historically, the triode shown in Fig. 5.6(a) was the first vacuum tube used for signal amplification. As noted in the introductory section (Fig. 5.1), the voltage applied between the grid (G) and the cathode (K) can be used to control the electron flow and, hence, the plate current. The dynamic operation of a triode is defined approximately by a modified form of the Langmuir–Child law as follows

$$i_p = k_0(v_g + v_p/\mu)^{1.5} \tag{5.4}$$

The quantity k_0 is the permeance (as defined in the diode discussion) of the triode, and its value is specific to a particular triode type. The plate characteristic curves generated by Eq. (5.4), for a triode in which $k_0 = 0.0012$, are illustrated in Fig. 5.8. As the plate characteristic curves indicate, the triode is approximately a voltage-controlled voltage source.

FIGURE 5.8 Triode plate characteristics.

The value of μ in triodes typically ranges from about 4 (low- μ triode) to 120 (high- μ triode). Typical ranges for r_p and g_m are, respectively, from 800 Ω to 100 k Ω , and from 1 to 5 mS.

Tetrode

In general, the triode exhibits a high direct capacitance (relatively speaking) between the control grid and the plate. To provide electrostatic shielding, a second grid (the screen grid) is added between the control grid and the plate. The screen grid must be configured geometrically to provide the amount of shielding desired, and arranged so that it does not appreciably affect electron flow. Insertion of the screen grid, however, does significantly change the plate characteristic curves, as is shown in Fig. 5.9. The negative-resistance region below 100 V may lead to unstable operation and care must be taken to assure that the plate voltage remains above this region. In the early days of radio, the negative-resistance of the tetrode was used in conjunction with tuned circuits to produce sinusoidal oscillators.

FIGURE 5.9 Tetrode plate characteristic for a single grid voltage (at constant screen voltage).

Pentode

To suppress the negative-resistance characteristic generated by the tetrode, a third coarse grid structure (the suppressor grid) is inserted between the screen grid and the plate. In this manner, the plate characteristic curves are smoothed and take the form shown in Fig. 5.10.

The dynamic operation of a pentode is described approximately by the relation

$$i_p = k_0(v_g + v_p/\mu_1 + v_{sg}/\mu_2)^{1.5} \tag{5.5}$$

where μ_1 is the amplification factor for the plate and control grid and μ_2 is the amplification factor for the plate and screen grid. As the plate characteristic curves indicate, the pentode is approximately a voltage-controlled current source, and the curves are similar to those generated by an n -channel depletion-mode metal oxide semiconductor field effect transistor (MOSFET). The screen grid draws an appreciable current that may amount to as much as 20–30% of the plate current.

FIGURE 5.10 Typical pentode plate characteristics ($V_s = 150$ V).

The value of μ is not normally provided on the specifications sheets for pentodes, and only the values for g_m and r_p are listed. Transconductance values are typically on the order of 5–6 mS, and plate resistance values vary from 300 k Ω to over 1 M Ω .

Pentodes are sometimes operated in a triode connection, in which the screen grid is connected to the plate. In the 1950s, this mode of operation was popular in high-fidelity vacuum-tube audio power amplifiers.

Beam Power Tube

The beam power tube is a modified form of the tetrode or pentode that utilizes directed electron beams to produce a substantial increase in the output power. Beam-forming electrodes are used to shape the electron beam into the form of a fan (as indicated by the dotted lines in Fig. 5.11). An optional suppressor grid may be included. The control and screen grids are exactly aligned such that the electron beam is broken into dense fan-shaped layers or sheets. Beam power tubes are characterized by high-power output, high-power sensitivity, and high efficiency. The operating screen current ranges from approximately 5–10% of the plate current, as opposed to pentodes in which the screen current is on the order of 20–30% of the plate current.

FIGURE 5.11 Cross-section of a beam power tetrode as viewed from the top.

5.1.5 Vacuum Tube Specifications

Data sheets for vacuum tubes typically provide the information shown in Table 5.1 for a hypothetical low-power beam power tube. Some of the parameters and operating conditions specified in the table have yet to be addressed, and these matters are discussed subsequently.

5.1.6 Biasing Methods to Establish a DC Operating Point

As is the case with any electronic active device that is used in amplifier service, vacuum tubes must be biased for a DC operating point (Q point). Figure 5.12 illustrates this process graphically for a triode when the plate supply voltage is 400 V and the grid potential is -8 V. The DC load line is $R_L = (400 \text{ V}) / (80 \text{ mA}) = 5 \text{ k}\Omega$.

In fixed-bias operation, the control grid is supplied from a negative fixed-voltage bias supply (historically called the C supply). The plate is operated from a high-voltage positive supply. The circuit diagram for a resistor–capacitor- (RC-) coupled triode audio amplifier operating under fixed-bias conditions is shown in Fig. 5.13(a). The DC load line is achieved by using a 5-k Ω resistor in the plate circuit. The cathode is connected directly to ground, and the control grid is connected through a series resistor to the negative 8-V bias supply. The value of the grid resistor is generally not critical. It is inserted simply to isolate the applied input signal from the bias supply. Based on the Q-point location in Fig. 5.12, the plate current is approximately 28 mA and the voltage at the plate is approximately 260 V. Thus the Q-point parameters are: $V_G = -8$ V, $V_P = 260$ V, $I_P = 28$ mA. Based on the data (not included here) used to generate the characteristic curves, $\mu = 16$, $g_m = 4.5$ mS, and $r_p = 3550 \Omega$.

Figure 5.13(b) illustrates the same audio amplifier configured for self-bias operation. The IR drop across a cathode resistor is used to place the cathode at the positive value of the grid potential above ground, whereas the grid is returned to ground through a resistor. Traditionally the grid resistor is called the *grid-leak* resistor, because its function is to bleed away from the grid any static charge that might build up

TABLE 5.1 Operating Specifications for Hypothetical Beam Power Pentode Single-Tube Operation

General:		
Heater voltage (AC/DC), V	6.3	
Heater current, A	0.9	
Direct interelectrode capacitances		
Control grid to plate, pF	0.4	
Control grid to cathode, pF	10	
Plate to cathode, heater, screen, suppressor, pF	12	
Maximum Ratings:		
Plate voltage, V	400	
Screen voltage, V	300	
Plate dissipation, W	20	
Screen-grid input, W	2.5	
Peak heater-to-cathode voltage (positive or negative), V	180	
Typical Operating Conditions (class A amplifier):		
	Fixed bias	Cathode bias
Plate supply voltage, V	350	300
Screen supply voltage, V	250	200
Control-grid voltage, V	-18	—
Cathode-bias resistor, Ω	—	220
Peak audio-frequency control-grid voltage, V	18	13
Zero-signal plate current, mA	54	51
Maximum-signal plate current, mA	66	55
Zero-signal screen-grid current, mA	2.5	3
Maximum-signal screen-grid current, mA	7	4.5
Plate resistance, Ω	33000	—
Transconductance, mS	5.2	—
Load resistance, Ω	4200	4500
Total harmonic distortion, %	15	10
Maximum-signal power output, W	11	7
Maximum Ratings (Triode Connection: Screen Grid Connected to Plate):		
Plate voltage, V		300
Plate dissipation, W		20
Peak heater-to-cathode voltage (positive or negative), V		180
Typical Operating Conditions (Class A Amplifier):		
	Fixed bias	Cathode bias
Plate supply voltage, V	250	250
Control-grid voltage, V	-20	—
Cathode-bias resistor, Ω	—	470
Peak audio-frequency control-grid voltage, V	20	20
Zero-signal plate current, mA	40	40
Maximum-signal plate current, mA	45	43
Plate resistance, Ω	1700	—
Amplification factor	8	—
Transconductance, mS	4.7	—
Load resistance, Ω	5000	6000
Total harmonic distortion, %	5	6
Maximum-signal power output, W	1.4	1.3

on the grid structure. Since in normal operation the grid draws no current, the grid voltage rests at ground potential or zero volts. The cathode is biased above ground to provide the required value of grid-to-cathode potential. In the example case, if the cathode is at +8 V and the grid at 0 V, the effective grid-to-cathode voltage is -8 V. The value of the cathode resistor is calculated as $(8 \text{ V})/(28 \text{ mA}) = 286 \Omega$. The closest standard value is 270 Ω , as is shown in Fig. 5.13(b). To achieve maximum signal gain from the amplifier, the cathode resistor is bypassed by an appropriate value of capacitance.

A graphical approach may also be applied to evaluate the amplification properties of the circuits shown in Fig. 5.13. The AC load line (R_l) for the circuits shown is the parallel combination of the 5-k Ω plate

FIGURE 5.12 Triode plate characteristics with superimposed DC load line for Q-point calculations.

resistor and the external signal load. Let us assume that $R_l = 3.3 \text{ k}\Omega$ and we now add it to Fig. 5.12 with the new plot shown in Fig. 5.14. The AC and DC load line intersect at the Q point. The amplifier gain is evaluated from the plot as follows. Apply to the grid a sinusoidal signal (v_i) with a peak value of 8 V. Thus, the grid voltage will swing from the Q-point value of -8 V to 0 V and -16 V , as indicated by the double-headed arrow. The corresponding plate voltages are indicated by the vertical arrows. When $v_i = +8 \text{ V}$, $v_g = 0 \text{ V}$ and the plate voltage is $\approx 190 \text{ V}$; when $v_i = -8 \text{ V}$, $v_g = -16 \text{ V}$ and the plate voltage

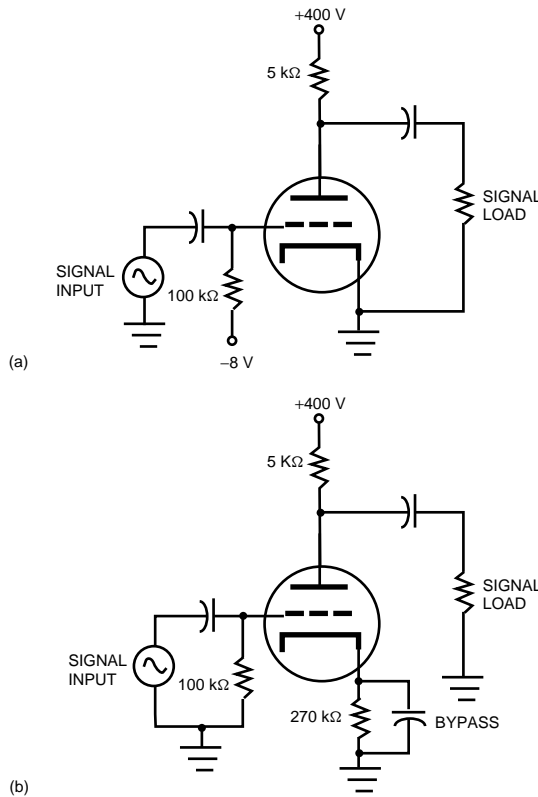

FIGURE 5.13 Triode audio amplifier circuits: (a) audio amplifier with fixed bias, (b) audio amplifier with cathode bias (self-bias).

FIGURE 5.14 Load-line constructions to evaluate amplifier voltage gain.

is ≈ 320 V. Note that plate voltage decreases when grid voltage increases, thus the output signal is 180° out of phase with the input signal. The voltage gain is, thus, $A_v = -(320 - 190)/16 = -8.1$.

The output current has the same phase as the grid voltage, and the peak values are indicated by the horizontal arrows. When the grid voltage is 0 V, the plate current is ≈ 49 mA, and when the grid voltage is -16 V, the plate current is ≈ 9 mA. Note that the output-voltage swing about the Q point is not quite symmetric. The Q-point value of the plate voltage is ≈ 260 V. The positive swing in plate voltage is $320 - 260 = 60$ V, and the negative swing is $260 - 190 = 70$ V. This asymmetry is caused by the fact that the AC load line intersects the -16 -V grid line at the onset of its curvature.

Based on a small-signal model of the triode, it can be shown analytically that the voltage gain of the amplifier configurations shown in Fig. 5.13 is

$$A_v = -\mu/(1 + r_p/R_l) = -16/(1 + 3550/3300) = -7.7 \tag{5.6}$$

Note that there is a slight discrepancy between the voltage gain of -8.1 found graphically and the calculated value of -7.7 . Some estimation errors occur when graphical analysis is used, and the solution is to use expanded graphical curves. The main source of error, however, is the use of a small-signal analysis result as predicted by Eq. (5.6) when the actual operation is a large-signal swing along the AC load line. Because vacuum tubes of the same type number are nearly identical and the plate characteristic curves are meaningful, in many cases more accurate results are obtained by graphical analysis than by small-signal calculations.

As is illustrated in Fig. 5.15, a DC load line is applied to the pentode plate characteristics in the same manner as for the triode. In the example shown, $R_L = 1$ k Ω and the Q-point values are $V_P = 300$ V, $I_P = 200$ mA, $V_G \approx -9$ V. Note for this device that positive-grid operation is possible and that nonlinearities occur for large negative grid voltage because the curves are not evenly spaced. An AC load is added to the pentode plate characteristics in the same manner as for the triode case, and the graphical analysis proceeds in the same manner as for the triode.

Two audio amplifier circuits (fixed bias and self-bias) are illustrated in Fig. 5.16. In the self-bias case, Fig. 5.16(b), the Q-point conditions have been assumed: $I_P = 180$ mA, $V_G = -10$ V, $I_{SG} = 5$ mA, $V_{SG} = 350$ V. The cathode resistor is, thus, $(10$ V)/ $(180$ mA) = 55.6 Ω , and the closest standard value is 56 Ω . The screen resistor is $(500$ V $-$ 350 V)/ $(5$ mA) = 30 k Ω , which is a standard value.

At low frequencies, the voltage gain of a pentode amplifier, such as the circuits shown in Fig. 5.16 is given by

$$A_v = -g_m R_l \tag{5.7}$$

FIGURE 5.15 Pentode plate characteristics with superimposed DC load line for Q-point calculations.

5.1.7 Power Amplifier Classes

Power amplifiers may be divided into various classes, designated by letters of the alphabet, according to how long the power grid tube conducts during one complete cycle of a sinusoidal input signal. Classes A, B, and C apply to analog operation, whereas additional designations (D–S) apply to pulsed operation. Pulsed-mode classes are addressed in other chapters.

In class A operation (sometimes designated as A_1), the tube is biased as in Fig. 5.12 and Fig. 5.15, and conduction occurs for a full cycle. Because the tube is always on and drawing quiescent power ($P_Q = V_{PQ} I_{PQ}$), operating efficiency is low. In class B operation, the tube is biased such that it conducts for exactly one-half cycle. In class C operation, the tube is biased such that it conducts for less than one-half cycle but more than one-quarter of a cycle. Class C is the most efficient mode of these classes, and it is used in radio-telephony power amplifiers in which the associated high-Q circuits restore the missing portions of each cycle.

Class B operation is adopted for push-pull amplifier design in which the two tubes conduct during alternate half-cycles, thus reproducing the complete input signal. Harmonic distortion is introduced if

FIGURE 5.16 Pentode audio amplifier circuits: (a) audio amplifier with fixed bias, (b) audio amplifier cathode bias (self-bias).

either of the two devices fails to conduct for a full half-cycle. To avoid this eventuality, push-pull power amplifiers are frequently operated in a class AB mode in which both tubes conduct for slightly more than one-half cycle. Various designations, such as AB₁ and AB₂, have traditionally been applied to indicate the conduction time per cycle.

For single-tube operation, the maximum efficiency figures are 25% for class A, 50% for class B, and on the order of 70% for class C. In push-pull amplifier configurations, the maximum theoretical efficiency obtainable with transformer-coupled class A operation is 50%, and 78.5% in class B transformer-coupled or complementary-symmetry designs.

5.1.8 Power-Output Calculation

To complete this section, a sample power-output calculation is provided for the class A amplifier operation described by Fig. 5.14. The peak-to-peak swings of the output voltage and current along the AC load line are, respectively, $\Delta v_p = (320 - 190) = 130$ V, $\Delta i_p = (49 - 9) = 40$ mA. The output-signal power (P_0) is, thus

$$P_0 = \Delta v_p \Delta i_p / 8 = 0.125 \times 130 \text{ V} \times 0.04 \text{ A} = 650 \text{ mW}$$

In power triodes, output distortion is primarily generated by a second harmonic component, and the percentage distortion may be calculated from the empirical relation

$$\% \text{ distortion} = 100 \times [0.5(i_{p \min} + i_{p \max}) - I_{PQ}] / \Delta i_p \quad (5.8)$$

In our example, $I_{PQ} = 28$ mA = 0.028 A, $i_{p \min} = 9$ mA = 0.009 A, $i_{p \max} = 49$ mA = 0.049 A, $\Delta i_p = 40$ mA = 0.04 A, therefore

$$\% \text{ distortion} = 100 \times (0.5(0.058) - 0.028) / 0.04 = 2.5\%$$

The quiescent (zero-signal) power (P_Q) is $260 \text{ V} \times 28 \text{ mA} = 7.28$ W. Thus the percent efficiency is

$$\% \text{ efficiency} = 100 \times P_0 / P_Q = 100 \times 0.65 / 7.28 = 8.9\%$$

Defining Terms

Cathode: The heated electrode in a vacuum tube that emits electrons.

Emissivity: A measure of the degree of emission of thermionic electrons from a hot cathode or filament.

Mu: Dimensionless voltage amplification factor of a vacuum tube.

Pentode: Vacuum tube with five active electrodes: cathode, control grid, screen grid, suppressor grid, plate.

Plate: The positive electrode or anode in a vacuum tube.

Tetrode: Vacuum tube with four active electrodes: cathode, control grid, screen grid, plate.

Thermionic: Pertaining to thermal generation of electrons.

Thoriated: Pertains to a metal to which the element thorium has been added.

Triode: Vacuum tube with three active electrodes: cathode, control grid, plate.

5.2 Power Grid Tubes

Jerry C. Whitaker

5.2.1 Introduction

A power-grid tube is a device using the flow of free electrons in a vacuum to produce useful work.¹ It has an emitting surface (the cathode), one or more grids that control the flow of electrons, and an element that collects the electrons (the anode). As discussed in the previous chapter, power tubes can be separated into groups according to the number of electrodes (grids) they contain. The physical shape and location of the grids relative to the plate and cathode are the main factors that determine the *amplification factor* μ and other parameters of the device. The physical size and types of material used to construct the individual elements determines the power capability of the tube. A wide variety of tube designs are available to commercial and industrial users. By far the most common are triodes and tetrodes.

5.2.2 Vacuum Tube Design

Any particular power vacuum tube may be designed to meet a number of operating parameters, the most important of which are usually high operating efficiency and high-gain/bandwidth properties. Above all, the tube must be reliable and provide long operating life. The design of a new power tube is a lengthy process that involves computer-aided calculations and modeling. The design engineers must examine a laundry list of items, including

- *Cooling*: how the tube will dissipate heat generated during normal operation. A high-performance tube is of little value if it will not provide long life in typical applications. Design questions include whether the tube will be air cooled or water cooled, the number of fins the device will have, and the thickness and spacing of the fins.
- *Electro-optics*: how the internal elements line up to achieve the desired performance. A careful analysis must be made of what happens to the electrons in their paths from the cathode to the anode, including the expected power gain of the tube.
- *Operational parameters*: what the typical interelectrode capacitances will be, and the manufacturing tolerances that can be expected. This analysis includes: spacing variations between elements within the tube, the types of materials used in construction, the long-term stability of the internal elements, and the effects of thermal cycling.

FIGURE 5.17 The relationship between anode dissipation and cooling method.

Device Cooling

The first factor that separates tube types is the method of cooling used: air, water, or vapor. *Air-cooled* tubes are common at power levels below 50 kW. A *water-cooling* system, although more complicated, is more effective than air cooling—by a factor of 5–10 or more—in transferring heat from the device. Air cooling at the 100-kW level is not normally used because it is virtually impossible to physically move sufficient air through the device (if the tube is to be of reasonable size) to keep the anode sufficiently cool. **Vapor cooling** provides an even more efficient method of cooling a power amplifier (PA) tube than water cooling. Naturally, the complexity of the external blowers, fans, ducts, plumbing, heat exchangers, and other hardware must be taken into consideration in the selection of a cooling method. Figure 5.17 shows how the choice of cooling method is related to anode dissipation.

Air Cooling

A typical air-cooling system for a transmitter is shown in Fig. 5.18. Cooling system performance for an air-cooled device is not necessarily related to airflow volume. The cooling capability of air is a function of its mass, not its volume. An appropriate airflow rate within the equipment is established by the manufacturer, resulting in a given resistance to air movement.

The altitude of operation is also a consideration in cooling system design. As altitude increases, the density (and cooling capability) of air decreases. To maintain the same cooling effectiveness, increased airflow must be provided.

FIGURE 5.18 A typical transmitter PA stage cooling system.

Water Cooling

Water cooling is usually preferred over air cooling for power outputs above about 50 kW. Multiple grooves on the outside of the anode, in conjunction with a cylindrical jacket, force the cooling water to flow over the surface of the anode, as illustrated in Fig. 5.19.

Because the water is in contact with the outer surface of the anode, a high degree of purity must be maintained. A resistivity of 1 m Ω /cm (at 25°C) is typically specified by tube manufacturers. Circulating water can remove about 1 kW/cm² of effective internal anode area. In practice, the temperature of water leaving the tube must be limited to 70°C to prevent the possibility of spot boiling.

After leaving the anode, the heated water is passed through a heat exchanger where it is cooled to 30–40°C before being pumped back to the tube.

FIGURE 5.19 Water cooled anode with grooves for controlled water flow.

Vapor-Phase Cooling

Vapor cooling allows the permissible output temperature of the water to rise to the boiling point, giving higher cooling efficiency compared with water cooling. The benefits of vapor-phase cooling are the result of the physics of boiling water. Increasing the temperature of one gram of water from 40 to 70°C requires 30 cal of energy. However, transforming one gram of water at 100°C into steam vapor requires 540 cal. Thus, a vapor-phase cooling system permits essentially the same cooling capacity as water cooling, but with greatly reduced water flow. Viewed from another perspective, for the same water flow, the dissipation of the tube may be increased significantly (all other considerations being the same).

A typical vapor-phase cooling system is shown in Fig. 5.20. A tube incorporating a specially designed anode is immersed in a boiler filled with distilled water. When power is applied to the tube, anode dissipation heats the water to the boiling point, converting the water to steam vapor. The vapor passes to a condenser, where it gives up its energy and reverts to a liquid state. The condensate is then returned to the boiler, completing the cycle. Electric valves and interlocks are included in the system to provide for operating safety and maintenance. A vapor-phase cooling system for a transmitter with multiple PA tubes is shown in Fig. 5.21.

Special Applications

Power devices used for research applications must be designed for transient overloading, requiring special considerations with regard to cooling. Oil, heat pipes, refrigerants (such as Freon), and, where high-voltage holdoff is a problem, gases (such as sulfahexafluoride) are sometimes used to cool the anode of a power tube.

Cathode Assembly

The ultimate performance of any vacuum tube is determined by the accuracy of design and construction of the internal elements. The requirements for a successful tube include the ability to operate at high temperatures and withstand physical shock. Each element is critical to achieving this objective.

The cathode used in a power tube obtains the energy required for electron emission from heat. The cathode may be directly heated (filament type) or indirectly heated. The three types of emitting surfaces most commonly used are

- Thoriated tungsten
- Alkaline-earth oxides
- Tungsten barium aluminate-impregnated emitters

FIGURE 5.20 Typical vapor-phase cooling system.

The thoriated tungsten and tungsten-impregnated cathodes are preferred in power tube applications because they are more tolerant to *ion bombardment*. The characteristics of the three emitting surfaces are summarized in Table 5.2.

A variety of materials may be used as a source of electrons in a vacuum tube. Certain combinations of materials are preferred, however, for reasons of performance and economics.

Oxide Cathode

The conventional production-type oxide cathode consists of a coating of barium and strontium oxides on a base metal such as nickel. Nickel alloys, in general, are stronger, tougher, and harder than most nonferrous alloys and many steels. The most important property of nickel alloys is their ability to retain strength and toughness at elevated temperatures. The oxide layer is formed by first coating a nickel structure (a can or disc) with a mixture of barium and strontium carbonates, suspended in a binder material. The mixture is approximately 60% barium carbonate and 40% strontium carbonate.

During vacuum processing of the tube, these elements are *baked* at high temperatures. As the binder is burned away, the carbonates are subsequently reduced to oxides. The cathode is then *activated* and will emit electrons.

An oxide cathode operates CW at 700–820°C and is capable of an average emission density of 100–500 mA/cm². High-emission current capability is one of the main advantages of the oxide cathode. Other advantages include high peak emission for short pulses and low operating temperature. As shown in Table 5.2, peak emission of up to 20 A/cm² is possible from an oxide cathode. A typical device is shown in Fig. 5.22.

Although oxide-coated emitters provide more peak emission per watt of heating power than any other type, they are not without their drawbacks. Oxide emitters are more easily damaged or poisoned than other emitters, and also deteriorate more rapidly when subjected to bombardment of high-energy particles.

The oxide cathode material will evaporate during the life of the tube, causing free barium to migrate to other areas within the device. This evaporation can be minimized in the design stage by means of a high-efficiency cathode that runs as cool as possible but still is not emission limited at the desired heater

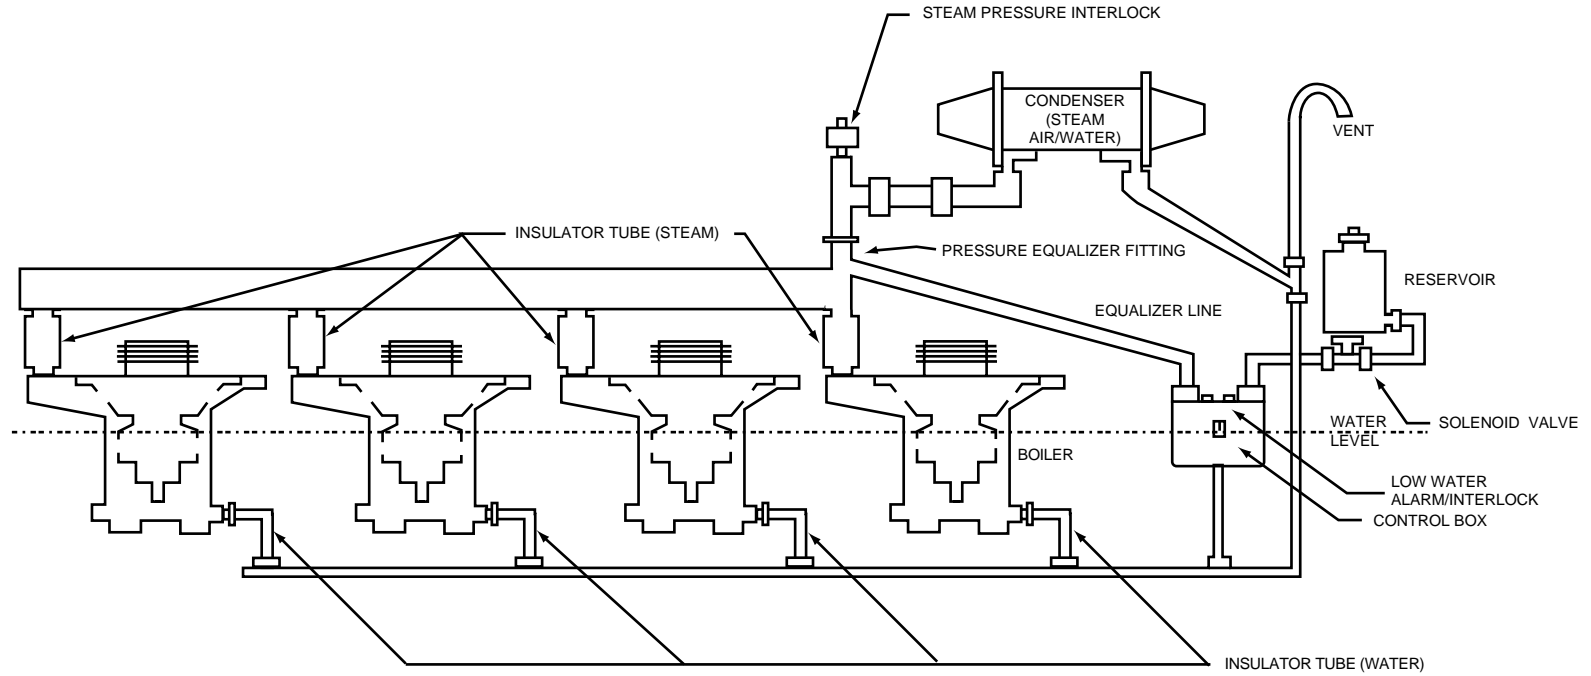

FIGURE 5.21 Vapour-phase cooling system for a 4-tube transmitter using a common waer supply.

TABLE 5.2 Characteristics of Common Thermionic Emitters

Emitter	Heating Method ^a	Operating Temperature, °C	Average Emission Density, A/cm ²	Peak Emission Density, A/cm ²
Oxide	Direct and indirect	700–820	0.10–0.50	0.10–20
Thoriated tungsten	Direct	1600–1800	0.04–0.43	0.04–10
Impregnated tungsten	Direct and indirect	900–1175	0.5–8.0	0.5–12

^aDirectly heated refers to a filament type cathode. (Source: Adapted from Fink, D. and Christiansen, D., eds. 1989. *Electronics Engineers' Handbook*. McGraw-Hill, New York.)

voltage. In the field, the heater voltage must not exceed the design value. An oxide cathode that is overheated produces little, if any, additional emission. The life of the tube under such operation, however, is shortened significantly.

Thoriated Tungsten Cathode

The thoriated tungsten filament is another form of atomic-film emitter commonly used in power grid tubes. Tungsten is stronger than any other common metal at temperatures over 3500°F. The melting point of tungsten is 6170°F, higher than that of any other metal. The electrical conductivity of tungsten is approximately $\frac{1}{3}$ that of copper, but much better than the conductivity of nickel, platinum, or iron-base alloys. The resistivity of tungsten in wire form is exploited in filament applications. The thoriated-tungsten filament (or cathode) is created in a high-temperature gaseous atmosphere to produce a layer of *ditungsten carbide* on the surface of the cathode element(s). Thorium is added to tungsten in the process of making tungsten wire. The thorium concentration is typically about 1.5%, in the form of thoria. By proper processing during vacuum pumping of the tube envelope, the metallic thorium is brought to the surface of the filament wire. The result is an increase in emission of approximately 1000 times over a conventional cathode.

At a typical operating temperature of 1600–1800°C, a thoriated tungsten filament will produce an average emission of 40–430 mA/cm². Peak current ranges up to 10 A/cm² or more.

FIGURE 5.22 Photograph of a typical oxide cathode. (Source: Varian/Eimac.)

One of the advantages of a thoriated tungsten cathode over an oxide cathode is the ability to operate the plate at higher voltages. Oxide cathodes are susceptible to deterioration caused by ion bombardment. To achieve reasonable life, plate voltage must be limited. A thoriated tungsten cathode is more tolerant of ion bombardment, and so higher plate voltages can be safely applied.

The end of useful life for a thoriated tungsten tube occurs when most of the carbon has evaporated or has combined with residual gas, depleting the carbide surface layer. Theoretically, a 3% increase in filament voltage will result in a 20 K increase in cathode temperature, a 20% increase in peak emission, and a 50% decrease in tube life because of carbon loss. This cycle works in reverse, too. For a small decrease in temperature and peak emission, the life of the carbide layer—and hence, the tube—may be increased.

Tungsten-Impregnated Cathode

The tungsten-impregnated cathode typically operates at 900–1175°C and provides the highest average emission density of the three types of cathodes discussed in this chapter (500 mA/cm²–8 A/cm²). Peak power performance ranges up to 12 A/cm².

Tungsten as an element is better able than other emitters to withstand bombardment by high-energy positive ions without having its emission impaired. These positive ions are always present in small numbers in vacuum tubes as a result of ionization by collision with the residual gas.

Cathode Construction

Power tube filaments can be assembled in several different configurations. [Figure 5.23](#) shows a spiral-type filament, and [Fig. 5.24](#) shows a bar-type design. The spiral filament is used extensively in low-power tubes. As the size of the tube increases, mechanical considerations dictate a bar-type filament with spring loading to compensate for thermal expansion. A mesh filament can be used for both small and large tubes. It is

FIGURE 5.23 Spiral-type tungsten filament. (Source: Varian/Eimac.)

FIGURE 5.24 Bar-type tungsten filament. (Source: Varian/Eimac.)

more rugged than other designs and less subject to damage from shock and vibration. The rigidity of a cylindrical mesh cathode is determined by the following parameters:

- The diameter of the cathode
- The number, thickness, and length of the wires forming the cathode
- The fraction of welded to total wire crossings

A mesh cathode is shown in [Fig. 5.25](#).

Some power tubes are designed as a series of electron gun structures arranged in a cylinder around a centerline. This construction allows large amounts of plate current to flow and to be controlled with a minimum of grid interception. With reduced grid interception, less power is dissipated in the grid structures. In the case of the control grid, less driving power is required for the tube.

In certain applications, the construction of the filament assembly can have an effect on the performance of the tube itself, and the performance of the RF system as a whole. For example, filaments built in a basket-weave mesh arrangement usually offer lower distortion in critical high-level AM modulation circuits.

Velocity of Emission

The electrons emitted from a hot cathode depart with a velocity that represents the difference between the kinetic energy possessed by the electron just before emission and the energy that must be given up to escape. Because the energy of different electrons within the emitter is not the same, the velocity of emission will vary as well, ranging from zero to a maximum value determined by the type and style of emitter.

Grid Structures

The type of grid used for a power tube is determined principally by the power level and operating frequency required. For most medium-power tubes (5–25 kW dissipation) welded wire construction is common.

FIGURE 5.25 Mesh tungsten filament. (Source: Varian/Eimac.)

At higher power levels, laser-cut **pyrolytic** graphite **grids** may be found. The grid structures of a power tube must maintain their shape and spacing at elevated temperatures. They must also withstand shock and vibration.

Wire Grids

Conventional wire grids are prepared by operators that wind the assemblies using special *mandrels* (forms) that include the required outline of the finished grid. The operators spot weld the wires at intersecting points, shown in Fig. 5.26. Most grids of this type are made with tungsten or *molybdenum*, which exhibit stable physical properties at elevated temperatures. On a strength basis, pure molybdenum is generally considered the most suitable of all refractory metals at temperatures between 1600 and 3000°F. The thermal conductivity of molybdenum is more than three times that of iron and almost half that of copper.

Grids for higher power tubes are typically built using a bar-cage type of construction. A number of vertical supports are fastened to a metal ring at the top and to a base cone at the bottom. The lower end of the assembly is bonded to a contact ring. The construction of the ring, metal base cone, and cylindrical metal base give the assembly low lead inductance and low RF resistance.

The external loading of a grid during operation and the proximity of the grid to the hot cathode impose severe demands on both the mechanical stability of the structure and the physical characteristics of its surface. The grid absorbs a high proportion of the heat radiated by the cathode. It also intercepts the

FIGURE 5.26 Mesh grid structure. (Source: Varian/Eimac.)

electron beam, converting part of its kinetic energy into heat. Further, high-frequency capacitive currents flowing in the grid results in additional heat.

The end result is that grids are forced to work at temperatures as high as 1500°C. Their primary and secondary emission must, however, be low. To prevent grid emission, high electron affinity must be ensured throughout the life of the tube, even though it is impossible to prevent material evaporated from the cathode from contaminating the grid surface.

In tubes with oxide cathodes, grids made of tungsten or molybdenum wire are coated with gold to reduce primary emission caused by deposition. The maximum safe operating temperature for gold plating, however, is limited (about 550°C). Special coatings have, therefore, been developed for high-temperature applications that are effective in reducing grid emission. In tubes with thoriated tungsten cathodes, grids made of tungsten or molybdenum are coated with proprietary compounds to reduce primary emission.

Primary grid emission is usually low in a thoriated tungsten cathode device. In the case of an oxide cathode, however, free barium can evaporate from the cathode coating material and find its way to the control and screen grids. The rate of evaporation is a function of cathode temperature and time. A grid contaminated with barium will become another emitting surface. The hotter the grid, the greater the emissions.

Pyrolytic Grid

Pyrolytic grids are a high-performance alternative to wire or bar grid assemblies. Used primarily for high-power devices, pyrolytic grids are formed by laser-cutting a graphite cup of the proper dimensions. The computer-controlled laser cuts numerous holes in the cup to simulate a conventional-style grid. Figure 5.27 shows a typical pyrolytic-type grid before and after laser processing.

Pyrolytic (or oriented) graphite is a form of crystallized carbon produced by the decomposition of a hydrocarbon gas at high temperatures in a controlled environment. A layer of pyrolytic graphite is deposited on a special form. The thickness of the layer is proportional to the time that deposition is allowed to continue. The structure and mechanical properties of the deposited graphite depend on the imposed conditions.

Pyrolytic grids are ideal vacuum-tube elements because they do not expand like metal. Their small coefficient of expansion prevents movement of the grids inside the tube at elevated temperatures. This preserves the desired electrical characteristics of the device. Because tighter tolerances can be maintained, pyrolytic grids can be spaced more closely than conventional wire grids. Additional benefits include

- The grid is a single structure having no weld points.
- The grid has a thermal conductivity in two of the three planes nearly that of copper.
- The grid can operate at high temperatures with low vapor pressure.

FIGURE 5.27 Pyrolytic graphite grid: (a) before laser processing, (b) completed assembly. (Source: Varian/Eimac.)

FIGURE 5.28 The screen grid assembly of a typical tetrode PA tube.

Grid Physical Structure

The control, screen, and suppressor grids are cylindrical and concentric. Each is slightly larger than the previous grid, as viewed from the cathode. Each is fastened to a metal base cone, the lower end of which is bonded to a contact ring. Figure 5.28 shows the construction of a typical screen grid assembly. Figure 5.29 illustrates a cutaway view of a tetrode power tube.

The shape of the control grid and its spacing from the cathode defines, in large part, the operating characteristics of the tube. For best performance, the grid must be essentially transparent to the electron path from the cathode to the plate. In a tetrode, the control and screen grids must be precisely aligned to minimize grid current. For pentode tubes, the previous two conventions apply, in addition to the requirement for precise alignment and minimum beam interception for the suppressor grid.

FIGURE 5.29 The internal arrangement of the anode, screen, control grid, and cathode assemblies of a tetrode power tube.

FIGURE 5.30 Circuit for providing a low impedance screen supply for a tetrode.

Secondary Emission Considerations

The relationship of the properties of secondary electrons to the grid structures and other elements of a vacuum tube must be carefully considered in any design. As the power capability of a tube increases, the physical size of the elements also increase. This raises the potential for secondary emission from the control, screen, and suppressor grids. Secondary emission can occur regardless of the type of cathode used. The yield of secondary electrons may be reduced through the application of surface treatments.

In a tetrode, the screen is operated at a relatively low potential, necessary to accelerate the electrons emitted from the cathode. Not all electrons pass through the screen on their way to the plate. Some are intercepted by the screen grid. As the electrons strike the screen, other low-energy electrons are emitted. If these electrons have a stronger attraction to the screen, they will fall back to that element. If, however, they pass into the region between the screen and the plate, the much higher anode potential will attract them. The result is electron flow from screen to plate.

Because of the physical construction of a tetrode, the control grid will have virtually no control over screen-to-plate current flow as a result of secondary electrons. During a portion of the operating cycle of the device, it is possible that more electrons will leave the screen grid than will arrive. The result will be a reverse electron flow on the screen element, a condition common to high-power tetrodes. A low-impedance path for reverse electron flow must be provided.

Tube manufacturers typically specify the recommended value of bleeding current from the screen power supply to counteract the emission current. Two common approaches are illustrated in Fig. 5.30 and Fig. 5.31. If the screen power supply impedance is excessively high in the direction of reverse electron flow, the screen voltage will attempt to rise to the plate voltage. Note the emphasis on low impedance in the reverse electron flow direction. Most regulated power supplies are low impedance in the forward electron flow direction only. If the supply is not well bled, the reverse electrons will try to flow from anode to cathode in the regulator series pass element. As the screen voltage rises, the secondary and plate currents will increase, and the tube will enter a runaway condition.

As shown in Fig. 5.30, the addition of a 12.5-k Ω resistor from screen to ground provides a path for screen grid emission (20 mA for the circuit shown). In the circuit of Fig. 5.31, plate current flows through the screen power supply, swamping the screen supply. The screen power supply must, obviously, carry the normal screen and plate currents. This scheme is used extensively in circuits where the screen is operated at DC ground potential. The plate-to-cathode voltage is then the sum of the E_b and E_{c2} power supplies.

FIGURE 5.31 Series power supply configuration for swamping the screen circuit of a tetrode.

The suppressor grid of a pentode reduces the effects of secondary emission in the device. This attribute, thus, reduces the requirement to provide a reverse electron flow path for the screen grid power supply. The screen current requirement for a pentode may, however, be somewhat higher than for a tetrode of the same general characteristics.

The designer must also consider the impedance of the control grid circuit. Primary grid emission can result in operational problems if the grid circuit impedance is excessively high. Primary grid emission, in the case of an oxide cathode tube, will increase with tube life.

The size and power of gridded tubes dictate certain characteristics of electrical potential. As this geometry increases in electrical terms, significant secondary emission from the control grid can occur.

Control grid secondary emission can exist whether the cathode is a thoriated tungsten or oxide emitter, and can occur in a triode, tetrode, or pentode. A typical curve of grid current as a function of grid voltage for a high-power thoriated tungsten filament tetrode is shown in Fig. 5.32. As shown in the figure, grid current decreases and eventually takes a reverse direction as the grid voltage increases. This reduction and reversal of grid current can be explained by the normal secondary emission characteristics of the metals used in the grid structure. The secondary emission characteristics of common metals are presented in curve form in Fig. 5.33. The ratio of secondary-to-primary electron current is given as a function of primary electron potential. An examination of the chart will show the region between 200 and 600 V to be rather critical as far as secondary emission is concerned. Any power grid tube that normally operates with 200–600 V on the grid can exhibit the negative resistance characteristic of decreasing grid current with increasing grid voltage when another electrode, such as the anode in a triode or the screen grid in a tetrode, is at a sufficiently high potential to attract the emitted electrons from the control grid. A driver stage that works into such a nonlinear load normally must be designed in such a manner as to tolerate this condition. One technique involves swamping the driver so that changes in load resulting from secondary grid emission is a small percentage of the total load the driver works into.

FIGURE 5.32 Typical curve of grid current as a function of control grid voltage for a high power thoriated tungsten filament tetrode.

Plate Assembly

The plate assembly of a power tube is typically a collection of many smaller parts that are machined and assembled to tight specifications. Copper is generally used to construct the anode. It is an excellent

FIGURE 5.33 Secondary emission characteristics of various metals under ordinary conditions.

FIGURE 5.34 A cutaway view of the anode structure of an RF power amplifier tube.

material for this purpose because copper has the highest electrical conductivity of any metal except pure silver. Further, copper is easily fabricated and ideally suited to cold-forming operations such as deep drawing, bending, and stamping.

The anode and cooling fins (in the case of an air-cooled device) begin as flat sheets of copper. They are stamped by the tube manufacturer into the necessary sizes and shapes. After all of the parts have been machined, the anode and cooling fins are stacked in their proper positions, clamped, and brazed into one piece in a brazing furnace.

The plate of a power tube resembles a copper cup with the upper-half of a plate contact ring welded to the mouth and cooling fins silver soldered or welded to the outside of the assembly. The lower-half of the anode contact ring is bonded to a base ceramic spacer. At the time of assembly, the two halves of the ring are welded together to form a complete unit, as shown in Fig. 5.34.

In most power tubes, the anode is a part of the envelope, and, because the outer surface is external to the vacuum, it can be cooled directly. Glass envelopes were used in older power tubes. Most have been replaced, however, with devices that use ceramic as the envelope material.

Ceramic Elements

Ceramics are an integral part of modern power vacuum tubes. Three types of ceramics are in common usage in the production of vacuum devices:

- *Aluminum oxide*-based ceramics
- *Beryllium oxide*- (BeO-) based ceramics
- *Aluminum nitride*- (AlN-) based ceramics

Aluminum Oxide Ceramics

Aluminum oxide-based ceramic insulators are a common construction material for a wide variety of electrical components, including vacuum tubes. Aluminum oxide is 20 times higher in thermal conductivity than most oxides. The flexure strength of commercial high-alumina ceramics is 2–4 times greater than that of most oxide ceramics. There are drawbacks, however, to the use of alumina ceramics, including

- Relatively high thermal expansion (approximately 7 ppm/°C), compared to other ceramic materials, such as BeO
- Moderately high dielectric constant (approximately 10)

Aluminas are fabricated from aluminum oxide powders with various percentages of *sintering promoters*, which produce the so-called *glassy phase*. The later additives reduce the densification temperatures to

between 1500 and 1600°C. Based on the final application, the powders may be pressed, extruded, or prepared in slurries for slip casting or tape casting. The surface finish of aluminas is typically 3–25 $\mu\text{m}/\text{in}$ as a result of normal processing. For very smooth finishes (2 $\mu\text{m}/\text{in}$) the surfaces can be lapped or polished.

Alumina ceramics for vacuum tube applications are rarely used apart from being bonded to metals. The means by which this is accomplished frequently dictate the processing technique. Metallization of aluminas is usually accomplished by either high-temperature firing or low-temperature thick-film processing. Fired, shaped aluminas are usually postmetallized by refiring the formed article after coating with a slurry of molybdenum and manganese powder or tungsten metal powder. Based on the purity of the alumina, glass powder may be added to the metal powder. The mechanism of metallization requires an internal glassy phase or the added glassy phase for proper bonding. This is accomplished by firing in slightly reducing and moist atmospheres at temperatures above 1500°C. The resulting metallization is usually plated electrochemically with nickel or copper, or both.

Thick-film processing of alumina ceramics has traditionally been performed in oxidizing atmospheres at moderate temperatures (800–1000°C). Precious metals are used, such as gold, silver, platinum, palladium, and their combinations. A glassy phase is usually incorporated in the thick-film paste.

Each approach to metallization has advantages and disadvantages. The advantage of the high-temperature metallization schemes with molybdenum or tungsten is their moderate cost. The disadvantage is the high resistivity of the resulting films. These relative merits are reversed for thick-film materials. Another advantage of thick-film metallization is that the process is often applied by the device fabricator, not the ceramic vendor. This can allow for greater efficiency in design modification.

Beryllium Oxide Ceramics

Beryllium oxide-based ceramics are in many ways superior to alumina-based ceramics. The major drawback is the toxicity of BeO. Beryllium and its compounds are a group of materials that are potentially hazardous and must be handled properly. With the necessary safeguards, BeO has been used successfully in many tube designs.

Beryllium oxide materials are particularly attractive for use in power vacuum tubes because of their electrical, physical, and chemical properties. The thermal conductivity of BeO is approximately 10 times higher than that of alumina-based materials. Figure 5.35 compares the thermal conductivity of BeO to that of alumina and some alternative materials. As the chart illustrates, BeO has a lower dielectric constant and coefficient of thermal expansion than alumina. It is, however, also slightly lower in strength.

Beryllia materials are fabricated in much the same way as alumina compounds, although the toxic properties of the powders mandate that they be processed in laboratories equipped to handle them safely.

FIGURE 5.35 Thermal conductivity of common ceramics. (Source: Adapted from Harpter, C.A. 1991. *Electronic Packaging and Interconnection Handbook*, pp. 1–64. McGraw-Hill, New York.)

Simple cutting, drilling, and postmetallization are also handled by vendors with special equipment. Reliable thick-film systems may be applied to BeO substrates. Such coatings usually necessitate less elaborate safety precautions and are often applied by the device fabricator.

Other Ceramics

Aluminum nitride- (AlN-) based ceramics have been developed as an alternative to the toxicity concerns of BeO-based materials. As shown in Fig. 5.35, the thermal conductivity of AlN is comparable to that of BeO but deteriorates less with temperature. The dielectric constant of AlN is comparable to that of alumina (a drawback) but its thermal expansion is low (4 ppm/°C).

Other ceramic materials that find some use in vacuum devices include silicon carbide- (SiC-) based substances and boron nitride ceramics.

Tube Construction

Each type of power grid tube is unique insofar as its operating characteristics is concerned. The basic physical construction, however, is common to most devices. A vacuum tube is built in essentially two parts:

- The base, which includes the filament and supporting stem, control grid, screen grid, and suppressor grid (if used)
- The anode, which includes the heat-dissipating fins made in various machining steps

The base subassembly is welded using a *tungsten-inert gas* (TIG) process in an oxygen-free atmosphere (a process sometimes referred to as *Heliarc* welding) to produce a finished base unit.

The ceramic elements used in a vacuum tube are critical elements of the device. Assembled in sections, each element builds on the previous one to form the base of the tube. The ceramic-to-metal seals are created using a material that is *painted* onto the ceramic and then heated in a brazing oven. After preparation in a high-temperature oven, the painted area provides a metallic structure that is molecularly bonded to the ceramic, and provides a surface suitable for brazing.

This process requires temperature sequences that dictate completion of the highest temperature stages first. As the assembly takes form, lower oven temperatures are used so that completed bonds will not be damaged.

Despite all of the advantages that make ceramics one of the best insulators for a tube envelope, their brittleness is a potential cause of failure. The smallest cracks in the ceramic, not in themselves damaging, can cause the ceramic to break when mechanically stressed by temperature changes.

After the base assembly has been matched with the anode, the completed tube is brazed into a single unit. The device then goes through a **bake-out** procedure. Baking stations are used to evacuate the tube and bake out any oxygen or other gases from the copper parts of the assembly. Although oxygen-free copper is used in tube construction, some residual oxygen exists in the metal and must be driven out for long component life. A typical vacuum reading of 10^{-8} torr is specified for most power tubes (formerly expressed as 10^{-8} mm of mercury). For comparison, this is the degree of vacuum in outer space about 200 mi above the Earth.

A vacuum offers excellent electrical insulation characteristics. This property is essential for reliable operation of a vacuum tube, the elements of which typically operate at high potentials with respect to each other and to the surrounding environment. An electrode containing absorbed gases, however, will exhibit reduced breakdown voltage because the gas will form on the electrode surface, increasing the surface gas pressure and lowering the breakdown voltage in the vicinity of the gas pocket.

To maintain a high vacuum during the life of the component, power tubes contain a *getter* device. The name comes from the function of the element: to get or trap and hold gases that may evolve inside the tube. Materials used for getters include zirconium, cerium, barium, and titanium.

The operation of a vacuum tube is an evolving chemical process. End of life in a vacuum tube is generally caused by loss of emission.

FIGURE 5.36 Cross section of the base of a tetrode showing the connection points. (Source: Varian/Eimac.)

Connection Points

The high-power levels and frequencies at which vacuum tubes operate place stringent demands on the connectors used to tie the outside world to the inside elements. Figure 5.36 shows a cutaway view of the base of a tetrode. Tubes are designed to be mounted vertically on their electrical connectors. The connectors provide a broad contact surface and mechanical support for the device.

The cathode and grids are mounted on ring-shaped *Kovar*TM bases, which also serve as contact rings for the external connections. Kovar is an iron-nickel-cobalt alloy whose coefficient of thermal expansion is comparable with that of aluminum oxide ceramic. The different diameters of the various contact rings allow them to be grouped coaxially. The concentric tube/connector design provides for operation at high frequencies. Conductivity is improved by silver plating.

Tube Sockets

Any one tube design may have several possible socket configurations, depending on the frequency of operation. If the tube terminals are large cylindrical surfaces, the contacting portions of the socket consist of either spring **collets** or an assembly of spring finger stock. Usually, these multiple-contacting surfaces are made of beryllium copper to preserve spring tension at the high temperatures present at the tube terminals. The fingers are silver plated to reduce RF resistance.

If the connecting fingers of a power-tube socket fail to provide adequate contact with the tube element rings, a concentration of RF currents will result. Depending on the extent of this concentration, damage may result to the socket. After a connecting finger loses its spring action, the heating effect is aggravated and tube damage is possible.

A series of specialized power tubes is available with no sockets at all. Intended for cathode-driven service, the grid assembly is formed into a flange that is bolted to the chassis. The filament leads are connected via studs on the bottom of the tube. Such a configuration completely eliminates the tube socket. This type of device is useful for low-frequency applications, such as induction heating.

5.2.3 High Frequency Operating Limits

Like most active devices, performance of a given vacuum tube deteriorates as the operating frequency is increased beyond its designed limit. **Electron transit time** is a significant factor in the upper frequency limitation of electron tubes. A finite time is taken by electrons to traverse the space from the cathode, through the grid, and on to the plate. As the operating frequency increases, a point is reached at which the electron transit time effects become significant. This point depends on the accelerating voltages at the grid and anode, and their respective spacings. Tubes with reduced spacing in the grid-to-cathode region exhibit reduced transit time effects.

FIGURE 5.37 Continuous-wave output power capability of a gridded vacuum tube.

There is also a power limitation that is interrelated with the high-frequency limit of a device. As the operating frequency is increased, closer spacing and smaller-sized electrodes must be used. This reduces the power handling capability of the tube. Figure 5.37 illustrates the relationship.

Gridded tubes at all power levels for frequencies up to about 1 GHz are invariably cylindrical in form. At higher frequencies, planar construction is almost universal. As the operating frequency is increased beyond design limits, output power and efficiency both decrease. Figure 5.38 illustrates the relationship.

Transit Time Effects

When class C, class B, or similar operations are carried out at frequencies sufficiently high that the transit time of the electrons is not a negligible fraction of the waveform cycle, the following complications are observed in grid-based vacuum tubes:

- **Back heating** of the cathode
- Loading of the control grid circuit as a result of energy transferred to electrons that do not necessarily reach the grid to produce a DC grid current

FIGURE 5.38 Performance of a class C amplifier as the operating frequency is increased beyond the design limits of the vacuum tube.

- Debunching of plate current pulses
- Phase differences between the plate current and the exciting voltage applied to the control grid

Back heating of the cathode occurs when the transit time in the grid-cathode space is sufficiently great to cause an appreciable number of electrons to be in transit at the instant the plate current pulse would be cut off in the case of a low-frequency operation. A considerable fraction of the electrons thus trapped in the interelectrode space are returned to the cathode by the negative field existing in the grid-cathode space during the cutoff portion of the cycle. These returning electrons act to heat the cathode. At very high frequencies this back heating is sufficient to supply a considerable fraction of the total cathode heating required for normal operation. Back heating may reduce the life of the cathode as a result of electron bombardment of the emitting surface. It also causes the required filament current to depend on the conditions of operation within the tube.

Energy absorbed by the control grid as a result of input loading is transferred directly to the electron stream in the tube. Part of this stream is then used by the electrons in producing back heating of the cathode. The remainder affects the velocity of the electrons as they arrive at the anode of the tube. This portion of the energy is not necessarily all wasted. In fact, a considerable percentage of it may, under favorable conditions, appear as useful output in the tube. To the extent that this is the case, the energy supplied by the exciting voltage to the electron stream is simply transferred directly from the control grid to the output circuits of the tube without amplification.

An examination of the total time required by electrons to travel from the cathode to the anode in a triode, tetrode, or pentode operated as a class C amplifier reveals that the resulting transit times for electrons at the beginning, middle, and end of the current pulse will differ as the operating frequency is increased. In general, electrons traversing the distance during the first segment of the pulse will have the shortest transit time, whereas those near the middle and end of the pulse will have the longest transit times, as illustrated in Fig. 5.39. The first electrons in the pulse have a short transit time because they approach the plate before the plate potential is at its minimum value. Electrons near the middle of the pulse approach the plate with the instantaneous plate potential at or near minimum and, consequently, travel less rapidly in the grid-plate space. Finally, those electrons that left the cathode late in the current pulse (those just able to escape being trapped in the control grid-cathode space and returned toward the cathode) will be slowed as they approach the grid, and so have a large transit time. The net effect is to cause the pulse of plate current to be longer than it would in operation at a low frequency. This causes the efficiency of the amplifier to drop at high frequencies, because a longer plate current pulse increases plate losses.

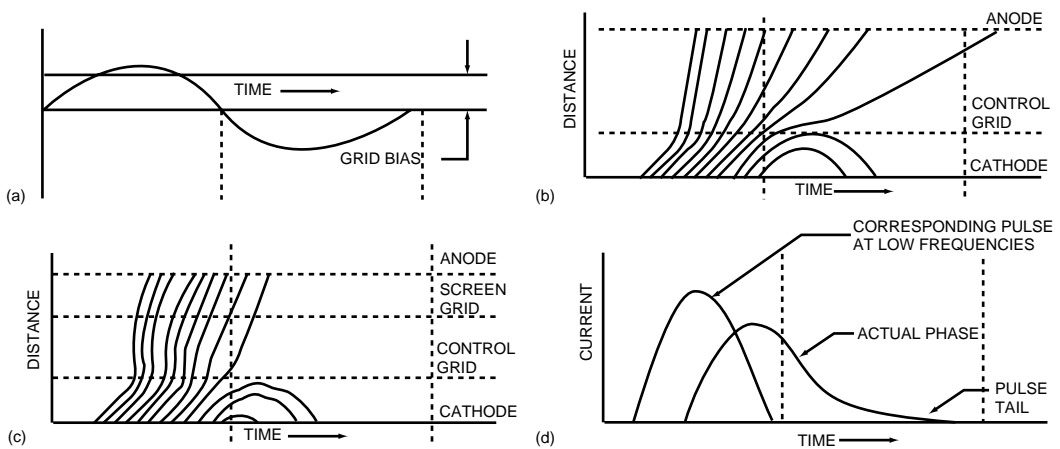

FIGURE 5.39 Transit time effects in a class C amplifier: (a) control grid voltage, (b) electron position as a function of time (triode case), (c) electron position as a function of time (tetrode case), (d) plate current (triode case). Defining Terms

- Back heating:** The effect on the cathode of a power vacuum tube when the transit time in the grid-cathode space is sufficiently great to cause, under certain conditions, an appreciable number of electrons to be trapped in the interelectrode space and returned to the cathode, thereby heating the cathode.
- Bake-out:** A process during tube manufacture in which the device is heated to a high temperature while the envelope is evacuated.
- Collet:** A circular spring fingerstock connection element for a power vacuum tube.
- Electron transit time:** The finite time taken by electrons to traverse the space from the cathode, through the grid(s), and on to the plate of a vacuum tube.
- Pyrolytic grid:** A grid structure made of pyrolytic (oriented) graphite that is laser-cut to the proper geometry for use in a power vacuum tube.
- Thoriated tungsten:** A form of atomic-film emitter commonly used in power tubes. Through proper processing, the hybrid material is made to provide high-emissions capabilities and long life.
- Vapor cooling:** A cooling technique for power vacuum tubes utilizing the conversion of hot water to steam as a means of safely conducting heat from the device and to a heat sink.

5.3 Neutralization Techniques

Jerry C. Whitaker

5.3.1 Introduction

An RF power amplifier must be properly neutralized to provide acceptable performance in most applications.² The means to accomplish this end can vary considerably from one design to another. An RF amplifier is neutralized when two conditions are met:

- The **interelectrode capacitance** between the input and output circuits is canceled.
- The inductance of the screen grid and cathode assemblies (in a tetrode) is canceled.

Cancellation of these common forms of coupling between the input and output circuits of vacuum tube amplifiers prevents self-oscillation and the generation of spurious products.

5.3.2 Circuit Analysis

Figure 5.40 illustrates the primary elements that effect **neutralization** of a vacuum tube RF amplifier operating in the VHF band. (Many of the following principles also apply to lower frequencies.) The feedback elements include the residual grid-to-plate capacitance C_{gp} , plate-to-screen capacitance C_{ps} , and screen grid lead inductance L_s . The RF energy developed in the plate circuit E_p causes a current I to flow through the plate-to-screen capacitance and the screen lead inductance. The current through the screen inductance develops a voltage $-E$ with a polarity opposite that of the plate voltage E_p . The $-E$ potential is often used as a method of neutralizing tetrode and pentode tubes operating in the VHF band.

Figure 5.41 graphically illustrates the electrical properties at work. The circuit elements of the previous figure have been arranged so that the height above or below the zero potential line represents magnitude

FIGURE 5.40 The elements involved in the neutralization of a tetrode PA stage.

²Portions of this chapter were adapted from: Varian. 1982. *Care and Feeding of Power Grid Tubes*. Varian/Eimac, San Carlos, CA. Used with permission.

and polarity of the RF voltage for each part of the circuit with respect to ground (zero). For the purposes of this illustration, assume that all of the circuit elements involved are pure reactances. The voltages represented by each, therefore, are either in phase or out of phase and can be treated as positive or negative with respect to each other.

The voltages plotted in the figure represent those generated as a result of the RF output circuit voltage E_p . No attempt is made to illustrate the typical driving current on the grid of the tube. The plate P has a high positive potential above the zero line, established at the ground point. Keep in mind that the distance above the baseline represents increasing positive potential. The effect of the out-of-phase screen potential developed as a result of inductance L_s is shown, resulting in the generation of $-E$.

As depicted, the figure constitutes a perfectly neutralized circuit. The grid potential rests at the zero baseline. The grid operates at filament potential insofar as any action of the output circuit on the input circuit is concerned.

The total RF voltage between plate and screen is made up of the plate potential and screen lead inductance voltage, $-E$. This total voltage is applied across a divider circuit that consists of the grid-to-plate capacitance and grid-to-screen capacitance (C_{gp} and C_{gs}). When this potential divider is properly matched for the values of plate RF voltage (E_p) and screen lead inductance voltage ($-E$), the control grid will exhibit zero voltage difference with respect to the filament as a result of E_p .

Circuit Design

There are a variety of methods that may be used to neutralize a vacuum tube amplifier. Generally speaking, a grounded-grid, cathode-driven triode can be operated into the VHF band without external neutralization components. The grounded-grid element is sufficient to prevent spurious oscillations. Tetrode amplifiers generally will operate through the MF band without neutralization. However, as the gain of the stage increases, the need to cancel feedback voltages caused by tube interelectrode capacitances and external connection inductances becomes more important. At VHF frequencies and above, it is generally necessary to provide some form of stage neutralization.

Below VHF

For operation at frequencies below the VHF band, neutralization for a tetrode typically employs a capacitance bridge circuit to balance out the RF feedback caused by residual plate-to-grid capacitance. This method assumes that the screen is well bypassed to ground, providing the expected screening action inside the tube.

Neutralization of low-power push-pull tetrode or pentode tubes can be accomplished with cross neutralization of the devices, as shown in Fig. 5.42. Small-value neutralization capacitors are used. In some cases, neutralization can be accomplished with a simple wire connected to each side of the grid circuit and brought through the chassis deck. Each wire is positioned to look at the plate of the tube on the opposite-half of the circuit. Typically, the wire (or a short rod) is spaced a short distance from the plate of each tube. Fine adjustment is accomplished by moving the conductor in or out from its respective tube.

A similar method of neutralization can be used for a cathode-driven symmetrical stage, as shown in Fig. 5.43. Note that the neutralization capacitors C_n are connected from the cathode of one tube to the plate of the opposite tube. The neutralizing capacitors have a value equal to the internal cathode-to-plate capacitance of the PA tubes.

FIGURE 5.41 A graphical representation of the elements involved in the neutralization of a tetrode RF stage when self-neutralized.

FIGURE 5.42 Push-pull grid neutralization.

FIGURE 5.43 Symmetrical stage neutralization for a grounded-grid circuit.

In the case of a single-ended amplifier, neutralization can be accomplished using either a push-pull output or push-pull input circuit. Figure 5.44 shows a basic push-pull grid neutralization scheme that provides the out-of-phase voltage necessary for proper neutralization. It is usually simpler to create a push-pull network in the grid circuit than the plate because of the lower voltages present. The neutralizing capacitor C_n is small and may consist of a simple feed-through wire (described previously). Padding capacitor C_p is often added to maintain the balance of the input circuit while tuning. C_p is generally equal in size to the input capacitance of the tube.

Single-ended tetrode and pentode stages can be neutralized using the method shown in Fig. 5.45. The input resonant circuit is placed above ground by a small amount because of the addition of capacitor C_{in} .

FIGURE 5.44 Push-pull grid neutralization in a single-ended tetrode stage.

FIGURE 5.45 Single-ended grid neutralization for a tetrode.

The voltage to ground that develops across C_{in} upon the application of RF drive is out of phase with the grid voltage, and is fed back to the plate through C_n to provide neutralization. In such a design, C_n is considerably larger in value than the grid-to-plate interelectrode capacitance.

The single-ended grid neutralization circuit is redrawn in Fig. 5.46 to show the capacitance bridge that makes the design work. Balance is obtained when the following condition is met

$$\frac{C_n}{C_{in}} = \frac{C_{gp}}{C_{gf}}$$

where

- C_n = neutralization capacitance
- C_{in} = input circuit bypass capacitor
- C_{gp} = grid-to-plate interelectrode capacitance
- C_{gf} = total input capacitance, including tube and stray capacitance

A single-ended amplifier also can be neutralized by taking the plate circuit slightly above ground and using the tube capacitances as part of the neutralizing bridge. This circuit differs from the usual RF amplifier design in that the plate bypass capacitor is returned to the screen side of the screen bypass capacitor, as shown in Fig. 5.47. The size of screen bypass capacitor C_s and the amount of stray capacitances in C_p are chosen to balance the voltages induced in the input by the internal tube capacitances, grid-to-plate C_{gp} and screen-to-grid C_{sg} . This circuit is redrawn in Fig. 5.48 in the usual bridge form. Balance is obtained when the following condition is met

$$\frac{C_p}{C_s} = \frac{C_{gp}}{C_{sg}}$$

In usual tetrode and pentode structures, the capacitance from screen-to-grid is approximately half the published tube input capacitance. The tube input capacitance is primarily the sum of the grid-to-screen capacitance and the grid-to-cathode capacitance.

FIGURE 5.46 The previous figure redrawn to show the elements involved in neutralization.

FIGURE 5.47 Single-ended plate neutralization.

It should be noted that in the examples given, it is assumed that the frequency of operation is low enough so that inductances in the socket and connecting leads can be ignored. This is basically true in MF applications and below. At higher bands, however, the effects of stray inductances must be considered, especially in single-ended tetrode and pentode stages.

VHF and Above

Neutralization of power-grid tubes operating at VHF frequencies provides special challenges and opportunities to the design engineer. At VHF frequencies and above, significant RF voltages can develop in the residual inductance of the screen, grid, and cathode elements. If managed properly, these inductances can be used to accomplish neutralization in a simple, straightforward manner.

At VHF and above, neutralization is required to make the tube input and output circuits independent of each other with respect to reactive currents. Isolation is necessary to ensure independent tuning of the input and output. If variations in the output voltage of the stage produce variations of phase angle of the input impedance, phase modulation will result.

As noted previously, a circuit exhibiting independence between the input and output circuits is only half of the equation required for proper operation at RF frequencies. The effects of incidental inductance of the control grid must also be canceled for complete stability. This condition is required because the suppression of coupling by capacitive currents between the input and output circuits is not, by itself, sufficient to negate the effects of the output signal on the cathode-to-grid circuit. Both conditions, input and output circuit independence and compensation for control grid lead inductance, must be met for complete stage stability at VHF and above.

Figure 5.49 shows a PA stage employing stray inductance of the screen grid to achieve neutralization. In this grounded-screen application, the screen is tied to the cavity deck using six short connecting straps. Two additional adjustable ground straps are set to achieve neutralization.

Triode amplifiers operating in a grounded-grid configuration offer an interesting alternative to the more common grounded-cathode system. When the control grid is operated at ground potential, it serves to

FIGURE 5.48 Single-ended plate neutralization showing the capacitance bridge present.

FIGURE 5.49 A grounded-screen PA stage neutralized through the use of stray inductance between the screen connector and the cavity deck: (a) circuit diagram, (b) mechanical implementation.

shield capacitive currents from the output to the input circuit. Typically, provisions for neutralization are not required until the point at which grid lead inductance becomes significant.

Grounded-Grid Amplifier Neutralization

Grounded-grid amplifiers offer an attractive alternative to the more common grid-driven circuit. The control grid is operated at RF ground and serves as a shield to capacitive currents from the output to the input circuit. Generally, neutralization is not required until the control grid lead inductive reactance becomes significant. The feedback from the output to the input circuit is no longer the result of plate-to-filament capacitance. The physical size of the tube and the operating frequency determine when neutralization is required.

Two methods of neutralization are commonly used with grounded-grid amplifiers. In the first technique, the grids of a push-pull amplifier are connected to a point having zero impedance to ground, and a bridge of neutralizing capacitances is used that is equal to the plate-filament capacitances of the tubes.

The second method of neutralization requires an inductance between the grid and ground or between the grids of a push-pull amplifier of a value that will compensate for the coupling between input and output circuits resulting from the internal capacitances of the tubes.

FIGURE 5.50 Circuit of grounded-grid amplifier having grid impedance and neutralized for reactive currents.

Behavior of these two circuits is quite different. They may be considered as special forms of the more general case in which the neutralizing capacitors have values differing from the internal capacitances of the tubes, and in which an appropriate reactance is connected between the grids. Under these conditions, the value of neutralizing capacitance permits continuous variation of power amplification, stability, and negative feedback.

The purpose of neutralization is to make the input and output circuits independent of each other with respect to reactive currents. The input current must be independent of the output voltage, and vice versa. This condition is necessary to permit independent tuning of the input and output circuits, so that variations in output voltage do not produce variations of phase angle of the input impedance, resulting in phase modulation.

The condition of independence between input and output circuits, which may be called the neutralized condition, does not necessarily imply stability. This is because the suppression of coupling by capacitive currents between input and output circuits is not sufficient to remove the effect of the output voltage on the cathode-to-grid voltage. A second condition, distinct from neutralization, must be met for complete stability: the effect of the control grid lead inductance must be canceled.

Grid Impedance

In the special case of a grounded-grid amplifier having a grid impedance and the reactive currents neutralized, the following equations apply (see Fig. 5.50):

$$C_n = C_{fp} - \frac{C_{fg}}{\mu}$$

$$Z_g = \frac{1}{j\omega C_{fg} + C_{gp}(1 + \mu)}$$

If in solving the equation for \$C_n\$ the sign is negative, this indicates that in-phase neutralization is required. Conversely, if the sign of \$C_n\$ is positive, then out-of-phase neutralization is needed. A negative value of \$Z_g\$ indicates capacitive reactance required, and a positive value indicates that inductive reactance is to be used.

Application Example

If the grids of a push-pull cathode-driven amplifier are not at ground potential because the inductance of the leads is not negligible, coupling may exist between the input and output circuits through the plate-grid capacitances, cathode-grid capacitances, and grid-to-grid inductance. One method of reducing this coupling is to insert between the grids a series tuned circuit that has zero reactance at the operating frequency. This technique is illustrated in Fig. 5.51. This neutralization scheme is useful only for the case where no grid current flows. If grid current flows, a grid resistance will appear in parallel with the grid-to-filament capacitance. If the resistance is small in comparison to the reactance of this grid-to-filament capacitance, phase modulation will result.

Another important property of the preceding neutralization scheme is that power amplification is a function of the neutralizing capacitance, whereas the independence of cathode and plate circuits from

FIGURE 5.51 Neutralization by cross-connected capacitors of a symmetrical cathode-excited amplifier with compensation of lead inductance.

the viewpoint of reactive currents may be obtained with any value of neutralizing capacitance. If the neutralizing capacitance is less than the plate-to-filament capacitance of the tube, the stage will operate with low-excitation power and high-power amplification.

If the neutralizing capacitance is greater than the plate-to-filament capacitance, the power amplification would be quite low, but the total output power possibly would be increased.

5.3.3 Self-Neutralizing Frequency

The voltage dividing action between the plate-to-grid capacitance C_{pg} and the grid-to-screen capacitance C_{gs} will not change with changes in operating frequency. The voltage division between the plate and screen, and screen and ground caused by the charging current I , will however, vary significantly with frequency. There will be a particular frequency, therefore, where this potential dividing circuit will effectively place the grid at filament potential insofar as the plate is concerned. This point is known as the **self-neutralizing frequency** illustrated in Fig. 5.52.

FIGURE 5.52 Graphical representation of the elements of a tetrode when self-neutralized.

At the self-neutralizing frequency, the tetrode or pentode is inherently neutralized by the circuit elements within the device itself, and external screen inductance to ground. When a device is operated below its self-neutralizing frequency, the normal cross-neutralization circuits apply. When the operating frequency is above the self-neutralizing frequency, the voltage developed in the screen lead inductance is too large to give the proper voltage division between the internal capacitances of the device. One approach to neutralization in this case involves adjusting the inductive reactance of the screen lead to ground so as to lower the total reactance. In the example shown in Fig. 5.53, this is accomplished with a series variable capacitor.

Another approach is shown in Fig. 5.54, in which the potential divider network made up of the tube capacitance is changed. In the example, additional plate-to-grid capacitance is added external to the tube. The external capacitance C_{ext} can take the form of a small wire or rod positioned adjacent to the plate of the tube. This approach is similar to the one described previously for conventional neutralization, except

that in this case the neutralizing probe is connected to the grid of the tube, rather than to an opposite polarity in the circuit.

If the RF power amplifier is operating above the self-neutralizing frequency of the tube and must be tuned over a range of frequencies, it is probably easier to use the screen series tuning capacitor method and make this control available to the operator. If operation is desired over a range of frequencies including the self-neutralizing frequency of the tube, this circuit is also desirable because the incidental lead inductance in the variable capacitor lowers the self-neutralizing frequency of the circuit so that the neutralizing series capacitor can be made to operate over the total desired frequency range. If this range is too great, switching of neutralizing circuits will be required. A small 50–100 pF variable capacitor in the screen lead has often been found to be satisfactory. Another method of changing the self-neutralizing frequency of a tetrode or pentode can be fashioned from the general bypassing arrangement of the screen and filament shown in Fig. 5.55. The screen lead is bypassed with minimum inductance to the filament terminal of the tube. Some inductance is introduced in the common filament and screen ground leads. The grid is shown below the zero voltage or chassis potential, indicating that the voltage developed in the screen lead inductance to chassis is excessive. If the filament is tapped on this inductance, a point can be found where the voltage difference between the grid and filament is zero, as far as the components of plate voltage are concerned. This arrangement will be found to self-neutralize at a higher frequency than if the filament and screen were separately bypassed to

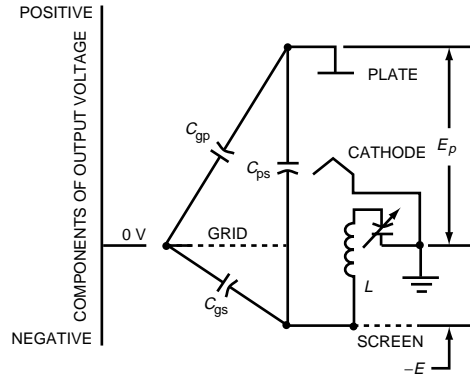

FIGURE 5.53 Components of the output voltage of a tetrode when neutralized by added series screen-lead capacitance.

FIGURE 5.54 Components of the output voltage of a tetrode when neutralized by added external grid-to-plate capacitance.

FIGURE 5.55 Components of the output voltage of a tetrode neutralized by adding inductance common to the screen and cathode return.

the chassis. Thus, by increasing the self-neutralizing frequency of the tube and screen bypass arrangement, the tendency of the VHF parasitic to occur is reduced.

If the frequency of the VHF parasitic is reduced by increasing the inductance of the plate lead (presuming this is the principle frequency-defining circuit), the circuit can be made to approach the self-neutralizing frequency of the tube and, therefore, suppress the parasitic.

5.3.4 Neutralization Adjustment

Most neutralization circuits must be adjusted for operation at a given frequency. The exact procedure followed to make these adjustments vary from one circuit to the next. The following generalizations, however, apply to most systems.

The first step in the process of neutralization is to break the DC connections to the plate voltage and screen voltage supplies, leaving the RF circuits intact. If the DC current path is not broken, some current can flow in either one of these circuits even though the voltages are zero. The presence of this current causes the amplifier to work in the normal manner, generating RF power in the plate circuit. It will then be incorrect to adjust for zero power in the plate circuit. Sufficient RF grid drive must be applied to provide some grid current or to cause a sensitive RF meter coupled to the plate to give an indication of feedthrough power. When the plate circuit is tuned through resonance, the grid current will dip when the circuit is out of neutralization or the RF meter will peak. The neutralization adjustments are made until the indication is minimum.

Another powerful tool for roughly neutralizing an RF amplifier is to feed the power output from a signal generator into the grid circuit. A sensitive RF detector is inserted between the output connector and the load. Neutralization can then be adjusted for minimum feedthrough. This technique is useful in working with prototype equipment. Actual qualitative measurements can be made. If the insertion loss of the amplifier is less than the expected gain, oscillation will occur. Circuit modifications can be made until the isolation is sufficient to warrant a test with high voltages applied. The advantages of this cold system test include

- No components are subjected to unusual stress if the amplifier is unstable.
- Circuit adjustments can be made safely because no high voltages are present.

For final trimming of the neutralization adjustment, the stage should be returned to operating condition at reduced power (similar to that used when testing for parasitic oscillations), or under the final loaded operating conditions. At the higher frequencies and in the VHF region, it will be found that a small additional trimming adjustment of the neutralization circuit is usually required. When the plate circuit is tuned through resonance, minimum plate current and maximum control grid current should occur simultaneously. In the case of the tetrode and pentode, the DC screen current should be maximum at the same time.

These neutralizing procedures apply not only to the HF radio frequencies, but also in the VHF or UHF regions. In the latter cases, the neutralizing circuit is different and the conventional cross-neutralization schemes may not apply.

Defining Terms

Interelectrode capacitance: The effective capacitances between the internal elements of a power vacuum tube. In a triode these typically include the cathode-to-grid capacitance, grid-to-plate capacitance, and cathode-to-plate capacitance.

Neutralization: The condition of stability and independence between the input and output circuits of a power grid tube stage.

Self-neutralizing frequency: The frequency of operation of a power vacuum tube stage where the potential dividing circuit of the inherent device capacitances will effectively place the grid at filament potential insofar as the plate is concerned.

5.4 Amplifier Systems

Jerry C. Whitaker

5.4.1 Introduction

Any number of configurations may be used to generate RF signals using vacuum tubes.³ Circuit design is dictated primarily by the operating frequency, output power, type of modulation, duty cycle, and available power supply. Tube circuits can be divided generally by their **operating class** and type of modulation employed. The angle of plate current flow determines the class of operation:

- Class A = 360° conduction angle
- Class B = 180° conduction angle
- Class C = conduction angle less than 180°
- Class AB = conduction angle between 180° and 360°

The class of operation has nothing to do with whether the amplifier is grid driven or cathode driven. A cathode-driven amplifier, for example, can be operated in any desired class. The class of operation is only a function of the plate current conduction angle. The efficiency of an amplifier is also a function of the plate current conduction angle.

The efficiency of conversion of DC to RF power is one of the most important characteristics of a vacuum tube amplifier circuit. The DC power that is not converted into useful output energy is, for the most part, converted to heat. This heat represents wasted power; the result of low efficiency is increased operating cost for energy. Low efficiency also compounds itself. This wasted power must be dissipated, requiring increased cooling capacity. The efficiency of the amplifier must, therefore, be carefully considered, consistent with the other requirements of the system. [Figure 5.56](#) shows the theoretical efficiency attainable with a tuned or resistive load assuming that peak AC plate voltage is equal to the plate supply voltage.

Class A Amplifier

A class A amplifier is used in applications requiring low harmonic distortion output power. A class A amplifier can be operated with low intermodulation distortion in linear RF amplifier service. Typical plate efficiency for a class A amplifier is about 30%. Power gain is high because of the low drive power required. Gains as high as 30 dB are typical.

Class B and AB Amplifiers

A class AB power amplifier is capable of generating more power—using the same tube—than the class A amplifier, but more intermodulation distortion will also be generated. A class B RF linear amplifier will generate still more intermodulation distortion, but is acceptable in certain applications. The plate efficiency is typically 66%, and stage gain is about 20–25 dB.

Class C Amplifiers

A class C power amplifier is used where large amounts of RF energy need to be generated with high efficiency. Class C RF amplifiers must be used in conjunction with tuned circuits or cavities, which restore the amplified waveform through the flywheel effect.

The grounded cathode class C amplifier is the building block of RF technology. It is the simplest method of amplifying CW, pulsed, and FM signals. The basic configuration is shown in Fig. 5.57. Tuned input and output circuits are used for impedance matching and to resonate the stage at the desired operating frequency. The cathode is bypassed to ground using low-value capacitors. Bias is applied to the grid as shown. The bias power supply may be eliminated if a self-bias configuration is used. The typical operating efficiency of a class C stage ranges from 65 to 85%.

Figure 5.58 illustrates the application of a zero-bias triode in a grounded-grid arrangement. Because the grid operates at RF ground potential, this circuit offers stable performance without the need for neutralization (at medium frequency (MF) and below). The input signal is coupled to the cathode through a matching network. The output of the triode feeds a pi network through a blocking capacitor.

5.4.2 Principles of RF Power Amplification

In an RF power amplifier, a varying voltage is applied to the control grid (or cathode in the case of a grounded-grid circuit) from a driver stage whose output is usually one of the following:

- Carrier frequency signal only
- Modulation (intelligence) signal only
- Modulated carrier signal

FIGURE 5.57 Basic grounded-cathode RF amplifier circuit.

Simultaneous with the varying control grid signal, the plate voltage will vary in a similar manner, resulting from the action of the amplified current flowing in the plate circuit. In RF applications with resonant circuits, these voltage changes are smooth sinewave variations, 180° out of phase with the input. The relationship is illustrated in Fig. 5.59. Note how these variations center about the DC plate voltage and the DC control grid bias. In Fig. 5.60 the variations have been indicated next to the plate voltage and grid voltage scales of a typical constant current curve. At some instant in time, shown as t on the time scales, the grid voltage has a value denoted e_g on the grid voltage sinewave.

Any point on the operating line (when drawn on constant current curves as illustrated in Fig. 5.60) indicates the instantaneous values of plate current, screen current, and grid current that must flow when

FIGURE 5.58 Typical amplifier circuit using a zero-bias triode. Grid current is measured in the return lead from ground to the filament.

FIGURE 5.59 Variation of plate voltage as a function of grid voltage.

these particular values of grid and plate voltage are applied to the tube. Thus, by plotting the values of plate and grid current as a function of time t , a curve of instantaneous values of plate and grid current can be produced. Such plots are shown in Fig. 5.61.

By analyzing the plate and grid current values it is possible to predict with accuracy the effect on the plate circuit of a change at the grid. It follows that if a properly loaded resonant circuit is connected to

FIGURE 5.60 Relationship between grid voltage and plate voltage plotted on a constant-current curve.

FIGURE 5.61 Instantaneous values of plate and grid current as a function of time.

the plate, a certain amount of RF power will be delivered to that circuit. If the resonant circuit is tuned to the fundamental frequency (the same frequency as the RF grid voltage), the power delivered will be that of the fundamental or principal RF component of plate current. If the circuit is tuned to a harmonic of the grid voltage frequency, the power delivered will be the result of a harmonic component of the plate current.

Drive Power Requirements

The technical data sheet for a given tube type provides the approximate drive power required for various operating modes. As the frequency of operation increases and the physical size of the tube structure becomes large with respect to this frequency, the drive power requirements will also increase.

The drive power requirements of a typical grounded-cathode amplifier consist of six major elements

- The power consumed by the bias source, given by

$$P_1 = I_{c1} \times E_{c1}$$

- The power dissipated in the grid as a result of rectified grid current

$$P_2 = I_{c1} \times e_{cmp}$$

- The power consumed in the tuned grid circuit

$$P_3 = I_{c,rms}^2 \times R_{rf}$$

- The power loss as a result of transit time effects

$$P_4 = \left[\frac{e_{c,rms}}{R_t} \right]^2$$

R_t is that part of the resistive component of the tube input impedance resulting from transit time effects, and is given by

$$R_t = \frac{1}{Kg_m f^2 T^2}$$

- The power consumed in that part of the resistive component of the input impedance resulting from cathode lead inductance

$$P_5 = \frac{e_g^2}{R_s}$$

- Input resistance resulting from the inductance of the cathode leads is found from the following

$$R_s = \frac{1}{\omega^2 g_m L_k C_{gk}}$$

- The power dissipated in the tube envelope because of dielectric loss

$$P_6 = 1.41 f E_1^2 v$$

where

I_{c1}	= DC grid current
E_{c1}	= DC grid voltage
E_{cmp}	= maximum positive grid voltage
$I_{c,rms}$	= rms value of RF grid current
R_{rf}	= RF resistance of grid circuit
$e_{c,rms}$	= rms value of RF grid voltage
R_t	= resistance resulting from transit time loading
K	= a constant (function of the tube geometry)
g_m	= transconductance
f	= frequency, Hz
T	= transit time, cathode-to-grid
R_s	= cathode lead inductance input resistance loading
ω	= $2\pi f$
L_k	= cathode lead inductance, H
C_{gk}	= grid-to-cathode capacitance, F
E_1	= voltage gradient, kV/in, rms
ν	= loss factor of dielectric materials

The total drive power P_t is, then, equal to

$$P_t = P_1 + P_2 + P_3 + P_4 + P_5 + P_6$$

Particular attention must be given to grid dissipation when a tube is operated in the VHF and UHF regions. The total driving power required for a given output may be greater than the grid dissipation capability of the device.

Operational Considerations for VHF and UHF

When operating a tube in the VHF and UHF regions, several techniques may be applied to minimize the driving power without appreciably affecting plate conversion efficiency. These techniques include

- Use the minimum DC control bias. Frequently, it is advisable to bring the bias down to approximately cutoff.
- Maintain a high value of DC screen voltage, even though it appears to increase the fraction of the cycle during which plate current flows.
- Use the minimum RF excitation voltage necessary to obtain the desired plate circuit performance, even though the DC grid current is considerably lower than would be expected at lower frequencies.
- Keep the cathode lead inductance to the output and input circuits as low as possible. This can be accomplished by (1) using short and wide straps, (2) using two separate return paths for the input and output circuits, or (3) proper choice of cathode bypass capacitor(s).

These techniques do not necessarily decrease the plate efficiency significantly when the circuit is operated at VHF and UHF. The steps should be tried experimentally to determine whether the plate circuit efficiency is appreciably affected. It is usually acceptable—and even preferable—to sacrifice some plate efficiency for improved tube life when operating at VHF and UHF.

Optimum power output at these frequencies is obtained when the loading is greater than would be used at lower frequencies. Fortunately, the same condition reduces driving power and screen current (for the tetrode and pentode cases), and improves tube life expectancy in the process.

Mechanical and Electrical Considerations

To maintain proper isolation of the output and input circuits, careful consideration must be given to the location of the component parts of the amplifier. All elements of the grid or input circuit and any earlier

stages must be kept out of the plate circuit compartment. Similarly, plate circuit elements must be kept out of the input compartment. It should be noted, however, that in the case of the tetrode and pentode, the screen lead of the tube and connections via the socket are common to both the output and input resonant circuits. Because of the plate-to-screen capacitance of a tetrode or pentode, the RF plate voltage (developed in the output circuit) causes an RF current to flow out the screen lead to the chassis. In the case of a push-pull stage, this current may flow from the screen terminal of one tube to the screen terminal of the other tube. Similarly, because of the grid-to-screen capacitance of the tube, the RF voltage in the input circuit will cause an RF current to flow in this same screen lead to the chassis, or to the opposite tube of the push-pull circuit.

The inductance of the lead common to both the output and input circuits has the desirable feature of providing voltage of opposite polarity to neutralize the feedback voltage of the residual plate to control grid capacitance of the tube. It should be noted, however, that the mutual coupling from the screen lead to the input resonant circuit may be a possible source of trouble, depending on the design.

Power Supply Considerations

The power supply requirements for a triode are straightforward. The degree of regulation and ripple depends on the requirements of the system. In the case of a linear RF amplifier, it is important to have good plate power supply regulation. Without tight regulation, the plate voltage will drop during the time the plate is conducting current heavily. This drop will cause **flat topping** and will appear as distortion in the output. In push-pull applications where grid current flows, it is important to keep the grid circuit resistance to a minimum. If this is not done, positive peak clipping will occur.

In the case of the tetrode and pentode, the need for screen voltage introduces some new considerations and provides some new possibilities. Voltage for the screen grid of a low-power tetrode or pentode can readily be taken from the power supply used for the plate of the tube. In this case, a series resistor, or potential dividing resistor, is chosen so that with the intended screen current flowing the voltage drop through the resistor is adequate to give the desired screen voltage. The potential dividing resistor is the preferred technique for those tubes with significant secondary screen emission.

It is possible to take the screen voltage from a separate low-voltage supply. A combination scheme may also be employed, where a dropping resistor is used in conjunction with a low-voltage or intermediate-voltage supply. Frequently a combination of series resistor and voltage source can be chosen so that the rated screen dissipation will not be exceeded regardless of variations in screen current. With a fixed screen supply, there are advantages in using an appreciable amount of fixed grid bias so as to provide protection against the loss of **excitation**, or for cases where the driver stage is being keyed.

If the screen voltage is taken through a dropping resistor from the plate supply, there is usually little point in using a fixed grid bias because an unreasonable amount of bias would be required to protect the tube if the excitation failed. Under operating conditions with normal screen voltage, the cutoff bias is low (screen voltage divided by the screen μ). When a stage loses excitation and runs statically, the screen current falls to nearly zero. (See the static curves of the tube in question.) If the screen voltage is obtained through a simple dropping resistor from the plate supply, the screen voltage will then rise close to full plate voltage. Because the cutoff bias required is proportional to screen voltage, the grid bias required will be much greater than the amount of bias desired under normal operating conditions. When a screen dropping resistor is used, most of the bias is normally supplied through a grid resistor and other means are used for tube protection.

The power output from a tetrode or pentode is sensitive to screen voltage. For this reason, any application requiring a high degree of linearity through the amplifier requires a well-regulated screen power supply. A screen dropping resistor from the plate supply is not recommended in such applications.

The suppressor grid power supply requirements are similar to the control grid power supply. The suppressor grid intercepts little current and, therefore, a low power supply may be used. Any variation in suppressor voltage as a result of ripple or lack of regulation will appear at the output of the amplifier because of suppressor grid modulation of the plate current.

FIGURE 5.62 Interelectrode capacitances supporting VHF parasitic oscillation in an HF RF amplifier.

Parasitic Oscillations

Most self-oscillations in RF power amplifiers using gridded tubes have been found to fall in the following three classes:

- Oscillation at VHF from about 40 to 200 MHz, regardless of the operating frequency of the amplifier.
- Self-oscillation on the fundamental frequency of the amplifier.
- Oscillation at a low radio frequency below the normal frequency of the amplifier.

Low-frequency oscillation in an amplifier usually involves the RF chokes, especially when chokes are used in both the output and input circuits. Oscillation near the fundamental frequency involves the normal resonant circuits, and brings up the question of neutralization. When a parasitic self-oscillation is found on a very high frequency, the interconnecting leads of the tube, tuning capacitor, and bypass capacitors are typically involved.

VHF oscillation occurs commonly in amplifiers where the radio frequency circuits consist of coils and capacitors, as opposed to cavity designs. As illustrated in Fig. 5.62, the tube capacitances effectively form a tuned-plate tuned-grid oscillator.

The frequency of a VHF parasitic is typically well above the self-neutralizing frequency of the tube. However, if the self-neutralizing frequency of the device can be increased and the frequency of the parasitic lowered, complete suppression of the parasitic may result, or its suppression by resistor-inductor parasitic suppressors may be made easier.

It is possible to predict with the use of a grid dip wave meter the parasitic frequency to be expected in a given circuit. The circuit should be complete and with no voltages on the tube. Couple the meter to the plate or screen lead and determine the resonant frequency.

Elimination of the VHF parasitic oscillation may be accomplished using one of the following techniques:

- Place a small coil and resistor combination in the plate lead between the plate of the tube and the tank circuit, as shown in Fig. 5.63(a). The resistor-coil combination is usually made up of a noninductive resistor of about 25–100 Ω , shunted by three or four turns approximately 1/2-in diameter and frequently wound around the resistor. In some cases it may be necessary to use such a suppressor in both the plate and grid leads. The resistor-coil combination operates on the principle that resistor loads the VHF circuit but is shunted by the coil for the lower fundamental frequency. In the process of adjusting the resistor-coil combination, it is often found that the resistor runs hot. This heat is usually caused by the dissipation of fundamental power in the resistor, and is an indication of too many turns in the suppressor coil. Just enough turns should be used to suppress the parasitic and no more. Once the parasitic has been suppressed there will be no parasitic voltage or current present. Therefore, there is no parasitic power to be dissipated.
- Use small parasitic chokes in the plate lead as shown in Fig. 5.63(b). The size of the coil will vary considerably depending on the tube and circuit layout. A coil of 4–10 turns measuring approximately 1/2-in diameter is typical. The presence of the choke in the frequency determining part of the circuit

FIGURE 5.63 Placement of parasitic suppressors to eliminate VHF parasitic oscillations in an HF RF amplifier: (a) resistor-coil combination, (b) parasitic choke.

lowers the frequency of a possible VHF parasitic so that it falls near the self-neutralizing frequency of the tube and bypass leads. In addition to varying the size of the suppressor choke, the amount of inductance common to the screen and filament in the filament grounding strap may be a factor. This parameter can be varied simultaneously with the suppressor choke.

Of the two methods outlined for suppressing VHF parasitic oscillations, the first is probably the simpler to use and has been widely employed.

Dynatron Oscillation

Another form of commonly encountered self-oscillation is known as *dynatron* oscillation. Dynatron oscillation is caused when any electrode in a vacuum tube has negative resistance. At times there may be more electrons leaving the screen grid than are arriving. If the screen voltage is allowed to increase under these conditions, even more electrons will leave the grid. This phenomenon implies a negative resistance characteristic. If there is high alternating current impedance in the circuit from the screen grid through the screen grid power supply, and from the plate power supply to the plate, dynatron oscillation may be sustained.

Dynatron oscillation typically occurs in the region of 1–20 Hz. This low-frequency oscillation is usually accompanied by another oscillation in the 1–2 kHz region. Suppression of these oscillations can be accomplished by placing a large bypass capacitor (1000 μF) across the output of the screen grid power supply. The circuit supporting the oscillation can also be detuned by a large inductor. Increasing the circuit losses at the frequency of oscillation is also effective.

Harmonic Energy

It is generally not appreciated that the pulse of grid current contains energy on harmonic frequencies and that control of these harmonic energies may be important. The ability of the tetrode and pentode to isolate the output circuit from the input circuit over a wide range of frequencies is important in avoiding feed through of harmonic voltages from the grid circuit. Properly designed tetrode and pentode amplifiers provide for complete shielding in the amplifier layout so that coupling external to the tube is prevented.

In RF amplifiers operating either on the fundamental or a desired harmonic frequency, the control of unwanted harmonics is important. The following steps permit reduction of the unwanted harmonic energies present in the output circuit:

- Keep the circuit impedance between the plate and cathode low for the high harmonic frequencies. This requirement may be achieved by having some or all of the tuning capacitance of the resonant circuit close to the tube.
- Completely shield the input and output compartments.
- Use inductive output coupling from the resonant plate circuit and possibly a capacitive or Faraday shield between the coupling coil and the tank coil, or a high-frequency attenuating circuit such as a π or π - L network.

- Use low-pass filters on all supply leads and wires coming into the output and input compartments.
- Use resonant traps for particular frequencies.
- Use a low-pass filter in series with the output transmission line.

Shielding

In an RF amplifier, shielding between the input and output circuits must be considered. Triode amplifiers are more tolerant of poor shielding because power gain is relatively low. If the circuit layout is reasonable and no inductive coupling is allowed to exist, a triode amplifier can usually be built without extensive shielding. Even if shielding is not necessary to prevent fundamental frequency oscillation, it will aid in eliminating any tendency toward parasitic oscillation. The higher the gain of an amplifier the more important the shielding.

Pierced Shields

Tetrode and pentode amplifiers require comprehensive shielding to prevent input-to-output circuit coupling. It is advisable to use nonmagnetic materials such as copper, aluminum, or brass in the RF fields to provide the shielding. Quite often a shield must have holes through it to allow the passage of cooling air. In the LF and part of the HF range, the presence of small holes will not impair shield effectiveness. As the frequency is increased, however, the RF currents flowing around the hole in one compartment cause fields to pass through the hole into another compartment. Currents are, therefore, induced on the shield in the other compartment. This problem can be eliminated by using holes that have significant length. A piece of pipe with a favorable length-to-diameter ratio as compared to the frequency of operation will act as a *waveguide beyond cutoff* attenuator. If more than one hole is required to pass air, a material resembling a honeycomb may be used. This material is commercially available and provides excellent isolation with a minimum air pressure drop. A section of honeycomb shielding is shown in Fig. 5.64. Some tube sockets incorporate a waveguide beyond cutoff air path. These sockets allow the tube in the amplifier to operate at high gain and up through VHF.

FIGURE 5.64 A section of honeycomb shielding material used in an RF amplifier.

FIGURE 5.65 A selection of common finger stock.

Compartments

By placing the tube and related circuits in completely enclosed compartments and properly filtering incoming supply wires, it is possible to prevent coupling radio frequency energy out of the circuit by means other than the desired output coupling. Such filtering prevents the coupling of energy that may be radiated or fed back to the input section or earlier stages in the amplifier chain. Energy fed back to the input circuit causes undesirable interaction in tuning and/or self-oscillation. If energy is fed back to earlier stages, significant operational problems may result because of the large-power gain over several stages.

In the design of an RF amplifier, doors or removable panels must typically be used. The requirement for making a good, low-resistance joint at the discontinuity must be met. There are several materials available commercially for this purpose. Finger stock, shown in Fig. 5.65, has been used for many years.

Protection Measures

Power grid tubes are designed to withstand considerable abuse. The maximum ratings for most devices are conservative. For example, the excess anode dissipation resulting from detuning the plate circuit will have no ill effects on most tubes if not applied for periods of time sufficient to overheat the envelope and the seal structure.

Similarly, the control, screen, and suppressor grids will stand some excess dissipation. Typically, the maximum dissipation for each grid indicated on the data sheet should not be exceeded except for time intervals of less than 1 s. The maximum dissipation rating for each grid structure is usually considerably above typical values used for maximum output so that ample operating reserve is provided. The time of duration of overload on a grid structure is necessarily short because of the small heat storage capacity of the grid wires. Furthermore, grid temperatures cannot be measured or seen, and so no warning of accidental overload is apparent.

The type and degree of protection required in an RF amplifier against circuit failure will vary with the type of screen and grid voltage supply. Table 5.3 lists protection criteria for tetrode and pentode devices. The table provides guidelines on the location of a suitable relay that should act to remove the principal supply voltage from the stage or transmitter to prevent damage to the tube.

For designs where screen voltage taken through a dropping resistor from the plate supply, a plate relay provides almost universal protection. For the case of a fixed screen supply, a relay provides protection in most cases. For protection against excessive antenna loading and consequent high plate dissipation, a screen undercurrent relay may also be used in some services.

The plate, screen, and bias voltages may be applied simultaneously to a tetrode. The same holds true for a pentode, plus the application of the suppressor voltage. In a grid-driven amplifier, grid bias and excitation can usually be applied alone to the tube, especially if a grid leak resistor is used. Plate voltage can be applied to the tetrode and pentode before the screen voltage with or without excitation to the control grid. Never apply screen voltage before the plate voltage. The only exception would be when the tube is cut off so that no space current (screen or plate current) will flow, or when the excitation and screen voltage are low. If screen voltage is applied before the plate voltage and screen current can

TABLE 5.3 Protection Guidelines for Tetrode and Pentode Devices

Circuit Failure Type	Fixed Screen Supply		Screen Voltage through Dropping Resistor	
	Fixed Grid Bias	Resistor Grid Bias	Fixed Grid Bias	Resistor Grid Bias
Loss of excitation	No protection required	Plate current relay	Plate current relay	Plate current relay or screen control circuit
Loss of antenna loading	Screen current relay	Screen current relay	Grid current relay	No protection required
Excess antenna loading	Screen undercurrent relay	Screen undercurrent relay	Plate current relay	Plate current relay
Failure of plate supply	Screen current relay	Screen current relay	Grid current relay	No protection required
Failure of screen supply	Grid current relay	No protection required	Does not apply	Does not apply
Failure of grid bias supply	Plate current relay or screen current relay	Does not apply	Plate current relay or grid current relay	Does not apply

flow, the maximum allowable screen dissipation will almost always be exceeded and tube damage will result.

Table 5.4 lists protection guidelines for a triode. The table covers the grid-driven triode amplifier and the high- μ (zero-bias) cathode-driven triode amplifier. Drive voltage must never be applied to a zero-bias triode amplifier without plate voltage. The table indicates the recommended location of a suitable relay that should act to remove the principal supply voltage from the stage or transmitter to prevent damage to the tube or transmitter.

5.4.3 Cavity Amplifier Systems

Power grid tubes are ideally suited for use as the power generating element in a **cavity amplifier**. Because of the physical dimensions involved, cavity designs are typically limited to VHF frequencies and above. Lower frequency RF generators utilize discrete L and C devices to create the needed tank circuit. Two types of cavity amplifiers are commonly used: 1/4-wavelength and 1/2-wavelength systems.

In a cavity amplifier, the tube becomes part of a resonant transmission line. The stray interelectrode and distributed capacity and inductance of the tube are used to advantage as part of the resonant line. This resonant line is physically larger than the equivalent lumped constant LRC resonant circuit operating at the same frequency, and this larger physical size aids in solving the challenges of high- power operation, skin effect losses, and high-voltage standoff concerns.

A shorted 1/4-wavelength transmission line has a high, purely resistive input impedance. Electrically, it appears as a parallel resonant circuit, as shown in Fig. 5.66. When the physical length of the line is less than

TABLE 5.4 Protection Guidelines for a Triode

Circuit Failure Type	Triode		
	Fixed Grid Bias	Resistor Grid Bias	Zero-Bias Triode

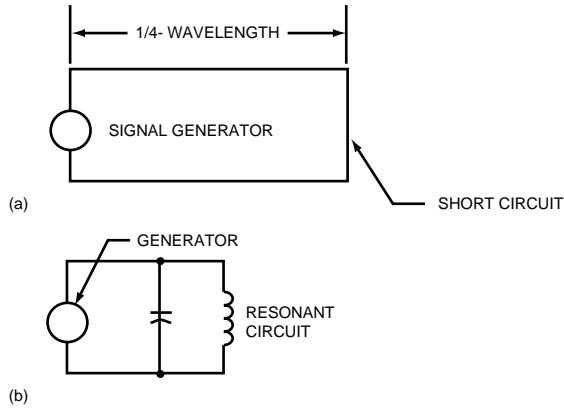

FIGURE 5.66 Shorted 1/4-wavelength line: (a) physical circuit, (b) electrical equivalent.

1/4-wavelength, the impedance will be lower and the line will appear inductive, as illustrated in Fig. 5.67. This inductance is used to resonate with the capacitive reactance in the tube and the surrounding circuit.

Bandwidth and Efficiency

Power amplifier bandwidth has a significant effect on modulation performance. Available bandwidth determines the amplitude response, phase response, and group delay response. Performance tradeoffs must often be considered in the design of a cavity amplifier, including bandwidth, gain, and efficiency.

Power amplifier bandwidth is restricted by the equivalent load resistance across the parallel tuned circuits in the stage. Tuned circuits are necessary to cancel the low reactive impedance presented by the relatively high input and output capacitances of the amplifying device. The bandwidth for a single tuned circuit is proportional to the ratio of capacitive reactance X_c to load resistance R_l appearing across the tuned circuit

$$BW \approx \frac{K}{2\pi f_c C R_l} \approx \frac{K X_c}{R_l}$$

where

- BW = bandwidth between half-power (-3 dB) points
- K = proportionality constant
- R_l = load resistance appearing across tuned circuit

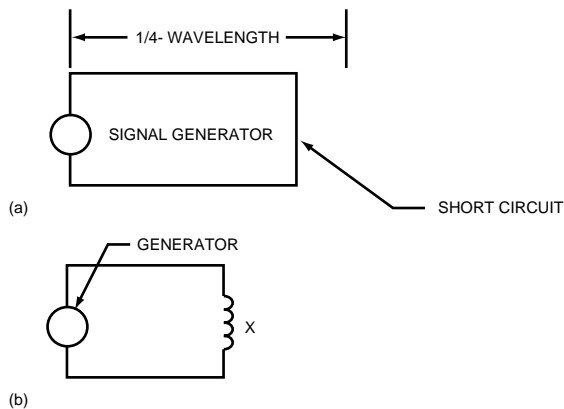

FIGURE 5.67 Shorted line less than 1/4-wavelength: (a) physical circuit, (b) electrical equivalent.

C = total capacitance of tuned circuit (includes stray capacitances and output or input capacitances of the tube)

X_c = capacitive reactance of C

f_c = carrier frequency

The RF voltage swing across the tuned circuit also depends on the load resistance. For the same power and efficiency, the bandwidth can be increased if the capacitance is reduced.

The efficiency of a cavity power amplifier (PA) depends primarily on the RF plate voltage swing, the plate current conduction angle, and the cavity efficiency. Cavity efficiency is related to the ratio of loaded to unloaded Q as follows:

$$N = 1 - \frac{Q_l}{Q_u} \times 100$$

where

N = cavity efficiency,

Q_l = cavity loaded Q

Q_u = cavity unloaded Q

The loaded Q is determined by the plate load impedance and output circuit capacitance. Unloaded Q is determined by the cavity volume and the RF resistivity of the conductors resulting from the skin effect. For best cavity efficiency, the following conditions are desirable:

- High unloaded Q
- Low loaded Q

As the loaded Q increases, the bandwidth decreases. For a given tube output capacitance and power level, loaded Q decreases with decreasing plate voltage or with increasing plate current. The increase in bandwidth at reduced plate voltage occurs because the load resistance is directly related to the RF voltage swing on the tube anode. For the same power and efficiency, the bandwidth can also be increased if the output capacitance is reduced. Power tube selection and minimization of stray capacitance are important considerations when designing for maximum bandwidth.

Current Paths

The operation of a cavity amplifier is an extension of the current paths inside the tube. Two elements must be examined in this discussion:

- The input circulating currents
- The output circulating currents

Input Circuit

The grid/cathode assembly resembles a transmission line whose termination is the RF resistance of the electron stream within the tube. Fig. 5.68 shows the current path of an RF generator (the RF driver stage output) feeding a signal into the grid/cathode circuit.

The outer contact ring of the cathode heater assembly makes up the inner conductor of a transmission line formed by the cathode and control grid assemblies. The filament wires are returned down the center of the cathode. For the input circuit to work correctly, the cathode must have a low RF impedance to ground. This cathode bypassing may be accomplished in one of several ways.

Below 30 MHz, the cathode can be grounded to RF voltages by simply bypassing the filament connections with capacitors, as shown in Fig. 5.69(a). Above 30 MHz, this technique does not work well because of the stray inductance of the filament leads. Notice that in Fig. 5.69(b), the filament leads appear as RF chokes, preventing the cathode from being placed at RF ground potential. This causes negative feedback and reduces the efficiency of the input and output circuits.

FIGURE 5.68 A simplified representation of the grid input circuit of a PA tube.

FIGURE 5.69 Three common methods for RF bypassing of the cathode of a tetrode PA tube: (a) grounding the cathode below 30 MHz, (b) grounding the cathode above 30 MHz, (c) grounding the cathode via a 1/2-wave transmission line.

In Fig. 5.69(c) the cathode circuit is configured to simulate a 1/2-wave transmission line. The line is bypassed to ground with large value capacitors 1/2-wavelength from the center of the filament (at the filament voltage feed point). This transmission line RF short is repeated 1/2-wavelength away at the cathode (heater assembly) and effectively places it at ground potential.

Because 1/2-wavelength bypassing is usually bulky at VHF frequencies (and may be expensive), RF generators are often designed using certain values of inductance and capacitance in the filament/cathode circuit to create an artificial transmission line that will simulate a 1/2-wavelength shorted transmission line. As illustrated in the figure, the inductance and capacitance of the filament circuit can resemble an artificial transmission line of 1/2-wavelength, if the values of L and C are properly selected.

Output Circuit

The plate-to-screen circulating current of the tetrode is shown in Fig. 5.70. For the purposes of example, consider that the output RF current is generated by an imaginary current generator located between the plate and screen grid. The RF current travels along the inside surface of the plate structure (because of the skin effect), through the ceramic at the lower-half of the anode contact ring, across the bottom of the fins, and to the band around the outside of the fins. The RF current then flows through the plate bypass capacitor to the RF tuned circuit and load, and returns to the screen grid.

The return current travels through the screen bypass capacitor (if used) and screen contact ring, up the screen base cone to the screen grid, and back to the imaginary generator.

The screen grid has RF current returning to it, but because of the assembly's low impedance, the screen grid is effectively at RF ground potential. The RF current generator, therefore, appears to be feeding an open-ended transmission line consisting of the anode (plate) assembly and the screen assembly. The RF voltage developed by the anode is determined by the plate impedance (Z_p) presented to the anode by the resonant circuit and its load.

When current flows on one conductor of a transmission line cavity circuit, an equal magnitude current flows in the opposite direction on the other conductor. This means that a large value of RF circulating current is flowing in a cavity amplifier outer conductor (the cavity box). All of the outer conductor circulating currents start at and return to the screen grid (in a tetrode-based system). The front or back

FIGURE 5.70 RF circulating current path between the plate and screen in a tetrode PA tube.

FIGURE 5.71 The physical layout of a common type of 1/4-wavelength PA cavity designed for VHF operation.

access panel (door) of the cavity is part of the outer conductor and large values of circulating current flow into it, through it, and out of it. A mesh contact strap is generally used to electrically connect the access panel to the rest of the cavity.

1/4-Wavelength Cavity

The 1/4-wavelength PA cavity is common in transmitting equipment. The design is simple and straightforward. A number of variations can be found in different RF generators, but the underlying theory of operation is the same.

A typical 1/4-wave cavity is shown in Fig. 5.71. The plate of the tube connects directly to the inner section (tube) of the plate-blocking capacitor. The exhaust chimney/inner conductor forms the other plate of the blocking capacitor. The cavity walls form the outer conductor of the 1/4-wave transmission line circuit. The DC-plate voltage is applied to the PA tube by a cable routed inside the exhaust chimney and inner tube conductor. In the design shown in the figure, the screen-contact fingerstock ring mounts on a metal plate that is insulated from the grounded cavity deck by an insulating material. This hardware makes up the screen-blocking capacitor assembly. The DC-screen voltage feeds to the fingerstock ring from underneath the cavity deck through an insulated feedthrough assembly.

A grounded-screen configuration may also be used in this design in which the screen-contact fingerstock ring is connected directly to the grounded cavity deck. The PA cathode then operates at below ground potential (in other words, at a negative voltage), establishing the required screen voltage to the tube.

The cavity design shown in the figure is set up to be slightly shorter than a full 1/4-wavelength at the operating frequency. This makes the load inductive and resonates the tube's output capacity. Thus, the physically foreshortened shorted transmission line is resonated and electrically lengthened to 1/4-wavelength.

Figure 5.72 illustrates the paths taken by the RF-circulating currents in the circuit. RF energy flows from the plate, through the plate-blocking capacitor, along the inside surface of the chimney/inner conductor (because of the skin effect), across the top of the cavity, down the inside surface of the cavity box, across the cavity deck, through the screen-blocking capacitor, over the screen-contact fingerstock and into the screen grid.

FIGURE 5.72 The RF circulating current paths for the 1/4-wavelength cavity shown in Fig. 5.71.

Figure 5.73 shows a graph of RF current, voltage, and impedance for a 1/4-wavelength coaxial transmission line. It shows that infinite impedance, zero RF current, and maximum RF voltage occur at the feed point. This would not be suitable for a practical PA circuit because arcing would result from the high RF voltage, and poor efficiency would be caused by the mismatch between the tube and the load.

Notice, however, the point on the graph marked at slightly less than 1/4-wavelength. This length yields an impedance of 600–800 Ω and is ideal for the PA-plate circuit. It is necessary, therefore, to physically foreshorten the shorted coaxial transmission-line cavity to provide the correct plate impedance. Shortening the line also is a requirement for resonating the tube’s output capacity, because the capacity shunts the transmission line and electrically lengthens it.

FIGURE 5.73 Graph of the RF current, RF voltage, and RF impedance for a 1/4-wavelength shorted transmission line. At the feed point RF current is zero, RF voltage is maximum, and RF impedance is infinite.

FIGURE 5.74 Graph of the RF current, RF voltage, and RF impedance produced by the physically foreshortened coaxial transmission line cavity.

Figure 5.74 shows a graph of the RF current, voltage, and impedance presented to the plate of the tube as a result of the physically foreshortened line. This plate impedance is now closer to the ideal 600–800 Ω value required by the tube anode.

Tuning the Cavity

Coarse tuning of the cavity is accomplished by adjusting the cavity length. The top of the cavity (the cavity shorting deck) is fastened by screws or clamps and can be raised or lowered to set the length of the cavity for the particular operating frequency. Fine tuning is accomplished by a variable-capacity plate-tuning control built into the cavity. In a typical design, one plate of the tuning capacitor, the stationary plate, is fastened to the inner conductor just above the plate-blocking capacitor. The movable tuning plate is fastened to the cavity box, the outer conductor, and is mechanically linked to the front-panel tuning control. This capacity shunts the inner conductor to the outer conductor and is used to vary the electrical length and resonant frequency of the cavity.

The 1/4-wavelength cavity is inductively coupled to the output port. This coupling is usually on the side opposite the cavity access door. The inductive pickup loop can take several forms. In one design it consists of a half-loop of flat copper bar stock that terminates in the loading capacitor at one end and feeds the output transmission line inner conductor at the other end. This configuration is shown in Fig. 5.75. The inductive pickup ideally would be placed at the maximum current point in the 1/4-wavelength cavity. However, this point is located at the cavity shorting deck and when the deck is moved for coarse tuning, the magnetic coupling will be changed. A compromise in positioning, therefore, must be made. The use of a broad, flat copper bar for the coupling loop adds some capacitive coupling to augment the reduced magnetic coupling.

Adjustment of the loading capacitor couples the 50- Ω transmission-line impedance to the impedance of the cavity. Heavy loading lowers the plate impedance presented to the tube by the cavity. Light loading reflects a higher load impedance to the amplifier plate.

Methods commonly used to increase the operating bandwidth of the cavity include minimizing added tuning capacitance. The ideal case would be to resonate the plate capacitance alone with a perfect inductor. Practical cavities, however, require either the addition of a variable capacitor or a variable inductor using

FIGURE 5.75 Basic loading mechanism for a VHF 1/4-wave cavity.

sliding contacts for tuning. Other inherent mechanical and electrical compromises include:

- The requirement for a plate DC blocking capacitor.
- The presence of maximum RF current at the grounded end of the simulated transmission line where the conductor may be nonhomogeneous. This can result in accompanying losses in the contact resistance.

Wideband Cavity

The cavity systems discussed so far in this section provide adequate bandwidth for many applications. Some uses, however, dictate an operating bandwidth beyond what a conventional cavity amplifier can provide. One method of achieving wider operating bandwidth involves the use of a double-tuned overcoupled amplifier, shown in Fig. 5.76. The system includes four controls to accomplish tuning:

- *Primary tune*, which resonates the plate circuit and tends to tilt the response and slide it up and down the bandpass.
- *Coupling*, which sets the bandwidth of the PA. Increased coupling increases the operating bandwidth and lowers the PA efficiency. When the coupling is adjusted, it can tilt the response and change the center of the bandpass, necessitating readjustment of the plate tune control.
- *Secondary tune*, which resonates the secondary cavity and will tilt the response if so adjusted. The secondary tune control typically can be used to slide the response up and down the bandpass, as the primary tune control.
- *Loading*, which determines the value of ripple in the bandpass response. Adjustment of the loading control usually tilts the response and changes the bandwidth, necessitating readjustment of the secondary tune and coupling controls.

Output Coupling

Coupling is the process by which RF energy is transferred from the amplifier cavity to the output transmission line. Wideband cavity systems use coupling to transfer energy from the primary cavity to the secondary cavity. Coupling in tube type power amplifiers usually transforms a high (plate or cavity) impedance to a lower output (transmission line) impedance. Both capacitive (electrostatic) and inductive (magnetic) coupling methods are used in cavity RF amplifiers. In some designs, combinations of the two methods are used.

FIGURE 5.76 Double-tuned overcoupled **broadband cavity amplifier**. (Source: Adapted from Weirather, R., Best, G., and Plonka, R. 1992. TV transmitters. In *NAB Engineering Handbook*, ed. E.B. Crutchfield, 8th ed. p. 524. National Association of Broadcasters, Washington, DC.)

Inductive Coupling

Inductive (magnetic) coupling employs the principles of transformer action. The efficiency of the coupling depends on three conditions:

- The cross-sectional area under the coupling loop, compared to the cross-sectional area of the cavity (see Fig. 5.77). This effect can be compared to the turns ratio principle of a transformer.
- The orientation of the coupling loop to the axis of the magnetic field. Coupling from the cavity is proportional to the cosine of the angle at which the coupling loop is rotated away from the axis of the magnetic field, as illustrated in Fig. 5.78.
- The amount of magnetic field that the coupling loop intercepts (see Fig. 5.79). The strongest magnetic field will be found at the point of maximum RF current in the cavity. This is the area where maximum inductive coupling is obtained. Greater magnetic field strength also is found closer to the center conductor of the cavity. Coupling, therefore, is inversely proportional to the distance of the coupling loop from the center conductor.

FIGURE 5.77 The use of inductive coupling in a 1/4-wavelength PA stage.

FIGURE 5.78 Top view of a cavity showing the inductive coupling loop rotated away from the axis of the magnetic field of the cavity.

In 1/4-wavelength cavities, the coupling loop generally feeds a 50- Ω transmission line (the load). The loop is in series with the load and has considerable inductance at VHF frequencies. This inductance will reduce the RF current that flows into the load, thus reducing power output. This effect can be overcome by placing a variable capacitor in series with the output coupling loop. The load is connected to one end of the coupling loop and the variable capacitor ties the other end of the loop to ground. The variable capacitor cancels some or all of the loop inductance. It functions as the PA-stage loading control.

Maximum loop current and output power occurs when the loading capacitor cancels all of the inductance of the loading loop. This lowers the plate impedance and results in heavier loading.

Light loading results if the loading capacitance does not cancel all of the loop inductance. The loop inductance that is not canceled causes a decrease in load current and power output, and an increase in plate impedance.

Capacitive Coupling

Capacitive (electrostatic) coupling, which physically appears to be straightforward, often baffles the applications engineer because of its unique characteristics. Figure 5.80 shows a cavity amplifier with a capacitive-coupling plate positioned near its center conductor. This coupling plate is connected to the

FIGURE 5.79 Cutaway view of the cavity showing the coupling loop rotated away from the axis of the magnetic field.

FIGURE 5.80 The 1/4-wavelength cavity with capacitive coupling to the output load.

output load, which can be a transmission line or a secondary cavity (for wideband operation). The parameters that control the amount of capacitive coupling include

- The area of the coupling-capacitor plate (the larger the area, the greater the coupling)
- The distance from the coupling plate to the center conductor (the greater the distance, the lighter the coupling)

Maximum capacitive coupling occurs when the coupling plate is at the maximum voltage point on the cavity center conductor.

To understand the effects of the capacitive coupling, the equivalent circuit of the cavity must be observed. Fig. 5.81 shows the PA tube, cavity (functioning as a parallel resonant circuit), and output section. The plate-blocking capacitor isolates the tube’s DC voltage from the cavity. The coupling capacitor and output load are physically in series, but electrically they appear to be in parallel, as shown in Fig. 5.82. The resistive component of the equivalent parallel circuit is increased by the coupling reactance. The equivalent parallel coupling reactance is absorbed into the parallel resonant circuit. This explains the necessity to retune the plate after changing the PA stage coupling (loading). The coupling reactance can be a series capacitor or inductor.

The series-to-parallel transformations are described by the following formulas

$$R_p = \frac{R_s^2 + X_s^2}{R_s}$$

$$X_p = \frac{R_s^2 + X_s^2}{X_s}$$

where

- R_p = effective parallel resistance
- R_s = actual series resistance
- X_s = actual series reactance
- X_p = effective parallel reactance

PA Loading

Proper **loading** of a cavity PA stage to the output transmission line is critical to dependable operation and optimum efficiency of the overall system. Light coupling produces light loading and results in a high plate impedance; conversely, heavy coupling results in heavier loading and a lower plate impedance. Maximum output power, coinciding with maximum efficiency and acceptable dissipation, dictates a specific plate impedance for a cavity of given design. This plate impedance is also dependent upon the values of DC plate voltage (E_p) and plate current (I_p).

Plate impedance dictates the cavity parameters of loaded Q , RF circulating current, and bandwidth. The relationships can be expressed as follows:

- Loaded Q is directly proportional to the plate impedance and controls the other two cavity parameters. Loaded $Q = Z_p / X_l$, where Z_p is the cavity plate impedance and X_l is the cavity inductive reactance.
- Circulating current in the cavity is much greater (by a factor of the loaded Q) than the RF current supplied by the tube. Circulating current = $Q \times I_p$, where I_p is the RF current supplied to the cavity by the tube.
- The cavity bandwidth is dependent on the loaded Q and operating frequency. Bandwidth is equal to F_r / Q , where F_r is the cavity resonant frequency.

Heavy loading lowers the PA plate impedance and cavity Q . A lower Q reduces the cavity RF circulating currents. In some cavities, high circulating currents can cause cavity heating and premature failure of the plate or screen blocking capacitors. The effects of lower plate impedance, a byproduct of heavy loading, are higher RF and DC plate currents and reduced RF plate voltage. The instantaneous plate voltage is the result of the RF plate voltage added to the DC plate voltage. The reduced swing of plate voltage causes less positive DC screen current to flow. Positive screen current flows only when the plate voltage swings close to or below the value of the positive screen grid.

Light loading raises the plate impedance and cavity Q . A higher Q will increase the cavity circulating currents, raising the possibility of component overheating and failure. The effects of higher plate impedance

are reduced RF and DC plate current and increased RF and DC plate voltage excursions. The higher cavity RF or peak DC voltages may cause arcing in the cavity.

There is one value of plate impedance that will yield optimum output power, efficiency, dissipation, and dependable operation. It is dictated by cavity design and the values of the various DC and RF voltages and currents supplied to the stage.

Depending on the cavity design, light loading may seem deceptively attractive. The DC plate voltage is constant (set by the power supply), and the lower DC plate current resulting from light loading reduces the tube's overall DC input power. The RF output power may change with light loading, depending on the plate impedance and cavity design, while efficiency will probably increase or, at worst, remain constant. Caution must be exercised with light loading, however, because of the increased RF voltages and circulating currents that such operation creates. Possible adverse effects include cavity arcing and overheating of cavity components, such as capacitors. The manufacturer's recommendations on PA tube loading should, therefore, be carefully observed.

Although there are many similarities among various cavity designs, each one imposes its own set of operational requirements and limitations. No two cavity systems will tune up in exactly the same fashion. Given proper maintenance, a cavity amplifier will provide years of reliable service.

Mechanical Design

Understanding the operation of a cavity amplifier is usually difficult because of the nature of the major component elements. It is often difficult to relate the electrical schematic diagram to the mechanical assembly that exists within the transmitter. Consider the PA cavity schematic diagram shown in Fig. 5.83. The grounded-screen stage is of conventional design. Decoupling of the high-voltage power supply is accomplished by $C1, C2, C3$, and $L1$. Capacitor $C3$ is located inside the PA chimney (cavity inner conductor). The RF sample lines provide two low-power RF outputs for a modulation monitor or other test instrument. Neutralization inductors $L3$ and $L4$ consist of adjustable grounding bars on the screen grid ring assembly.

FIGURE 5.83 Typical VHF cavity amplifier.

FIGURE 5.84 Electrical equivalent of the cavity amplifier shown in Fig. 5.83.

Figure 5.84 shows the electrical equivalent of the PA cavity schematic diagram. The $1/4$ -wavelength cavity acts as the resonant tank for the PA. Coarse tuning of the cavity is accomplished by adjustment of the shorting plane. Fine tuning is performed by the PA tuning control, which acts as a variable capacitor to bring the cavity into resonance. The PA loading control consists of a variable capacitor that matches the cavity to the load. The assembly made up of $L2$ and $C6$ prevents spurious oscillations within the cavity.

(a)

(b)

(c)

FIGURE 5.85 VHF cavity amplifiers: (a) cross-sectional view of a broadband design, (b) cavity designed for television service, (c) FM broadcast cavity amplifier.

Blocking capacitor C_4 is constructed of a roll of Kapton™ insulating material sandwiched between two circular sections of aluminum. (Kapton is a registered trademark of Du Pont.) PA plate tuning control C_5 consists of an aluminum plate of large surface area that can be moved in or out of the cavity to reach resonance. PA loading control C_7 is constructed much the same as the PA tuning assembly, with a large-area paddle feeding the harmonic filter, located external to the cavity. The loading paddle may be moved toward the PA tube or away from it to achieve the required loading. The L_2 - C_6 damper assembly consists of a 50- Ω noninductive resistor mounted on the side of the cavity wall. Component L_2 is formed by the inductance of the connecting strap between the plate tuning paddle and the resistor. Component C_6 is the equivalent stray capacitance between the resistor and the surrounding cavity box.

It can be seen that cavity amplifiers involve as much mechanical engineering as they do electrical engineering. The photographs of Fig. 5.85 show graphically the level of complexity that a cavity amplifier may involve. Figure 5.85(a) depicts a VHF power amplifier (Philips) with broadband input circuitry. Figure 5.85(b) shows a wideband VHF amplifier intended for television service (Varian). Figure 5.85(c) illustrates a VHF cavity amplifier designed for FM broadcast service (Varian).

Defining Terms

Broadband cavity amplifier: A cavity amplifier made to operating over a broad range of frequencies, typically through the addition of a secondary cavity that is coupled to the primary.

Cavity amplifier: A vacuum tube-based amplifying stage in which the physical elements of the output resonating circuit consist of the tube chimney and enclosing box. These and related components in the output circuit typically simulate a 1/4- or 1/2-wavelength transmission line.

Excitation: The input signal (typically to the grid of a power vacuum tube) that controls the operation of the stage, usually an amplifier or oscillator.

Flat topping: A distortion mechanism in an amplifying stage in which the stage is unable to faithfully reproduce the positive peaks of the output signal. Reasons for such problems include poor regulation of the plate voltage supply.

Loading: The process of extracting energy from a cavity amplifier through either inductive or capacitive coupling.

Operating class: A division of operating modes for an amplifying device. In the case of power vacuum tubes, the operating class is determined by the angle of plate current flow as follows: class A = 360° conduction angle, class B = 180° conduction angle, class C = conduction angle less than 180°, and class AB = conduction angle between 180 and 360°.

5.5 Image Capture Devices

Steve Epstein

5.5.1 Introduction

The invention of image capture tubes, and cathode ray tube (CRT) technology for display, is at the heart of what eventually became television. Near the end of the 19th century, when early work was being done on these devices, generating artificial images (i.e., test patterns) simply was not practical. Image capture devices allowed real world images to be captured and turned into an electronic signal. Early attempts were mechanical, followed later by electronic vacuum tube devices. As tube technology improved, picture **resolution** increased to the point where, during the 1960s and 1970s, a variety of tubes were found in professional video cameras throughout the world.

Ultimately tube technology improved to the point where reasonably high-resolution images (>750 TV lines) could be obtained with compact, lightweight devices. These units found their way into the electronic news gathering (ENG) cameras of the mid-1970s. These cameras, along with portable videocassette recorders, changed the face of television news forever. No longer burdened by the requirement of film, television news became more immediate. Stories shot within minutes of newscasts could be edited and aired.

By the 1980s, solid-state charge-coupled devices (CCDs) were finding their way into cameras. Early CCDs, like early tubes, had their problems. Today, however, CCDs offer high resolution, long-life, high **sensitivity**, and negligible maintenance costs. Tube devices did see a short resurrection during the early design phase of high-definition television, however, increased resolution CCDs became available and high definition development work quickly moved toward the CCD. The majority of the image pickup tubes available in quantity today are of the Plumbicon™ variety.

5.5.2 The Plumbicon

The development of the Plumbicon in 1965 (Philips Components) was an enormous technological achievement. At a time when color television was just getting off the ground, the Plumbicon paved the way for its explosive growth. The Plumbicon and similar tubes, including the Leddicon™ (English Electric Value Company, Ltd. (EEV)), used a lead-oxide photoconductive layer. Lead oxide is a solid-state semiconductor, a porous vaporgrown crystalline layer of lead monoxide.

The basic physical construction of the Plumbicon is shown in Fig. 5.86. The photosensitive PbO layer is deposited on a transparent electrode of SnO₂ on the window of the tube. This conducting layer is the

target electrode and is typically biased at about 40 V positive with respect to the cathode. The remainder of the tube structure is designed to provide a focused, low-energy electron beam for scanning the target.

Figure 5.87 provides a more detailed schematic of the operation of the Plumbicon. The side of the PbO layer facing the gun is reduced to cathode potential by the charge deposited by the scanning beam. Thus, the full target voltage appears across the layer. In the absence of an optical signal (lower-half of figure), there is no mechanism for discharging, and the surface charges to such a potential that further charge deposition, often called *beam landing*, is prevented. At this point, there is no further current induced in the external circuit. When light is incident as in the upper-half of the figure, photocarriers are generated. Under the influence of the electric field across the layer, these carriers move in the appropriate direction to discharge the stored charge on the surface. As the scanning beam passes across the varied potential of the surface, an additional charge can be deposited on the higher positive potential regions. The amount of charge deposited is equal to that discharged by the light. The attendant current in the external circuit is the photosignal.

In the Plumbicon, the lead oxide layer acts as a *p-i-n* diode. The *n*-region is formed at the PbO : SnO₂ interface (window side). The *p*-region is a thin layer on the electron-gun side of the layer. The bulk of the material behaves as if it were intrinsic, the *i*-layer. Thus, the electron beam landing on the *p*-region charges it negatively with respect to the *n*-region. The *p-i-n* layer is thus biased in the reverse or low conduction direction, and in the absence of illumination, little or no current flows.

Figure 5.88 shows a simplified diagram of a reverse biased *p-i-n* diode. Virtually all of the applied voltage *V* appears across the *i*-region. The **dark current** of this device is determined by the inverse currents through the *p-i* and *i-n* junctions and the thermal generation of carriers in the *i*-region. To ensure that the dark current in the tube due to these sources is sufficiently low at ambient temperatures, a semiconductor of bandgap greater than 1.0 eV is required. For the somewhat elevated temperatures that are likely to be encountered in a camera, a still larger bandgap is needed. The bandgap of the tetragonal lead oxide used in a Plumbicon is about 1.9 eV, and extremely low dark currents result.

When the target structure is illuminated, the amount of current is dependent on photon energy and wavelength. Both blue and green light generate reasonable amounts of current. Plumbicons, however, are not particularly responsive to wavelengths in the red region. To improve the red response photoconductors

are doped, usually with sulfur. These specially prepared tubes, often called *extended reds*, are then used in the red channel to improve camera performance (Fig. 5.89).

5.5.3 Operating Characteristics

For camera tubes, two important parameters to consider are **modulation depth** and **lag**. Modulation depth is determined by the spot diameter of the electron beam and by the thickness of the photoconductive layer. Lag is governed by the process of recharging the photoconductive layer. This is accomplished by the electron beam. The speed of the process is limited by the capacitance of the photoconductive layer and the differential resistance of the electron beam. The photoconductive layer is essentially capacitive in nature; as the layer thickness increases, the capacitance decreases. As the capacitance is reduced, response time for recharging is improved, but due to additional light dispersion, depth of modulation decreases.

Differential beam resistance is determined by the velocity spread of individual electrons in the beam and by the charging current. Less velocity spread gives a lower differential beam resistance and, therefore, faster response. Early Plumbicons used a conventional **triode gun**, whereas later versions took advantage of a **diode gun**. The diode gun was able to provide reduced velocity spread and, therefore, offered an improvement in lag characteristics. Lag can be further reduced through the use of a *bias light*. A bias light is placed at the base of the tube and projects light onto the photoconductive layer. This has the effect of offsetting the zero point of the charging current.

Designing for Tubes

For tubes, factors that influence **resolution** include the following.

- Lenses: Lenses have their own *modulation transfer function* (MTF) characteristics that change with aperture of f setting.
- Wavelength of the light: The color of the light will affect lens MTF, which will influence resolution.

FIGURE 5.89 Differences in the light sensitivity of (1) standard and (2) extended red Plumbicons.

- Imaging tube properties: The photosensitive layer and the beam spot size will affect maximum resolution.
- Yoke properties: The predominant function of the yoke is to provide the scanning action of the beam and to focus the beam. The focus field, along with the G_2 , G_3 , and G_4 electrodes, forms an electromagnetic lens. This lens influences the beam shape at the target. Focus field strength in the vicinity of the target strongly influences spot size, as does the voltage ratio of G_4 to G_3 .
- Flare or veiling glare: Flare can reduce resolution by softening edges. Various methods are employed to reduce flare including special coatings on lens surfaces and antihalation pills on the front surface of Plumbicons.
- Signal preamps: Preamp frequency response directly effects output resolution. Preamps should be swept with a device that accurately simulates the tube to verify that high-frequency **noise** is minimal and that overall response is flat.
- Noise: Noise is the electrical equivalent of attempting to view objects through a snowstorm. Resolution is reduced by the noise. Poor signal-to-noise response results in pictures with apparently poor resolution due to the noise inherent in the image.
- Beam alignment: If beam alignment is not optimized, the beam will not land perpendicular to the center of the target, thereby reducing center resolution.

When designing circuitry for tubes, it is best to consult the manufacturer for data specific to the device to be used. For general purposes, the specifications of a generic 1.5-in tube will be discussed here so that designers will be familiar with the concepts involved. Because a 1.5-in tube is fairly large, voltage and current specifications will generally be higher than what would be required in smaller tubes. Like most tubes, imaging tubes require relatively high voltage and significant amounts of current and, generally, produce heat that must be dissipated. Because circuit requirements and output characteristics can vary with temperature, dissipation must be considered at the design stage.

Imaging tubes generally have seven or eight pins on their base, arranged around the center. Many times a slot is left for a ninth pin, which is used as an alignment reference. Other tubes have a registration mark on the side. This mark is used to align the tube within the deflection yokes. This orients the internal tube structures within the external magnetic fields such that tube performance is maximized. Bias lights are internal on some tubes, others have external units that fit over the base pins and remain in place when the socket is installed. Most bias lights use the heater supply as their power source, adding approximately 100 mA each to the power supply requirements. In existing cameras adapted for operation with a bias light, the added current is not usually a problem and modifications are not usually required. Additional heating is negligible.

Imaging tubes require heaters that normally draw less than 1 A at 6 V. Cathode voltage is generally 0 V; however, most are driven positive during blanking periods. Current requirements are usually less than 250 nA. The target is typically biased at +40 V for Plumbicons and up to +125 V for vidicons. The signal electrode is attached to the target and is generally brought out of the glass envelope near the front of the unit rather than through the base at the rear. Because of the small currents involved, the target ring and its mating connector within the camera head must be kept clean.

Up to four internal grid structures are connected to pins located on the base along with the heater and cathode pins. Grid 1 (G_1) is used to blank the beam when necessary, and is typically biased from 0 (beam on) to -100 V (beam off). G_2 is used to accelerate the beam and is biased at +300 V or thereabouts. G_3 is used to focus the beam and is normally set from +800 to +1000 V. G_4 is the mesh assembly located adjacent to the target and is typically biased at +1400 V.

External structures are also required for proper tube operation. These structures fall into two categories, mechanical and electrical. Mechanical structures include the mounting assembly and its associated adjustments. In a typical application, a locking unit holds the tube and its electromagnetic coils rigidly in place. When loosened, the tube and coils can be adjusted within a small range. One adjustment moves the tube back and forth to obtain optimal optical focus, the other rotates the assembly to align the tube with the horizontal and vertical axes of the image. An additional unit, usually a locking ring, is used to hold the tube in place within the deflection coil assembly.

FIGURE 5.90 Internal and external structures used in the design, operation, and alignment of a Plumbicon tube.

External electrical structures include the deflection coils, external focusing coils, and alignment coils (Fig. 5.90). For the focusing coil, field strength should be of the order of 4–5 mT. Alignment coils are used to correct slight misalignments that result from tube and yoke manufacturing. Typical field strengths required are less than 0.5 mT. Two coils are generally used: one to correct horizontally, the other to correct vertically. Deflection coils are used to deflect the beam in such a manner as to produce a raster. For a typical national television system committee (NTSC) raster, coil current for horizontal deflection will be on the order of 250 mA, with another 50 mA required for vertical deflection.

Other considerations include the ability to *beam down* and cap the tubes when they are not in use. Tubes have a finite lifetime; eventually cathode emissions fall to a point where the tube becomes unusable. Circuitry that turns off the beam when not in use can extend tube life considerably. A capping mechanism, either in the camera's filter wheel or a physical lens cap, should be used to prevent highlights from reaching the tube when the camera is not in operation.

Tubes should not be subjected to vibration or shock when oriented vertically with the base in the uppermost position. Under these circumstances, particles can be dislodged within the tube. These loose particles can land on the target, causing spots or blemishes. Large particles landing on the target within the image area can effectively ruin an otherwise good tube. Optical quality glass is used on the surface of the tube and care should be taken to ensure it is kept clean and scratch free.

Defining Terms

Anticommet tail (ACT): A special type of electron gun designed to handle highlights by increasing beam current with a defocused beam during line retrace.

Blooming: An area of the target that is unstable due to insufficient beam current. The area normally appears as a white puddle without definition. Insufficient beam current may be the result of a low beam control setting.

Dark current: Current flow from the photosensitive layer in the absence of incident light. This could be compared to leakage current through a reverse-biased diode.

Diode gun Plumbicon: A Plumbicon tube with an electron gun that operates with a positive voltage applied to G_1 with respect to the cathode. The diode gun principle provides a finer beam spot size and lower beam temperature. This results in higher resolution and improved lag performance compared to triode gun tubes. The diode gun also provides a much higher current reserve for highlight handling when used in conjunction with a **dynamic beam control (DBC)** circuit.

Dynamic beam control: A circuit in a camera designed to instantaneously increase beam current to handle highlights in a scene. This is an alternative to the ACT solution of highlight control.

Dynamic resolution: The ability to distinguish fine detail in a moving object in a scene.

High stability (HS) diode gun Plumbicon: A diode gun Plumbicon tube, with electrostatic focus and magnetic deflection, which uses a high stability electrode structure evaporated and bonded to the tube envelope.

- Image retention:** A short-term after-image created by a high-contrast stationary scene within the beaming capabilities of the tube.
- Lag:** The inability of an imaging tube to respond to instantaneous changes in light. For measurement purposes, lag has two components: *rise lag* is the response time from dark to light, whereas *decay lag* is the response time from light to dark. Lag is a very short-term effect, and should not be confused with **image retention**, image burn, or **sticking**.
- Low output capacitance (LOC) Plumbicon tube:** The LOC Plumbicon tube is designed to reduce the capacitance of the target to ground, resulting in an improved signal-to-noise ratio.
- MS diode gun Plumbicon:** A diode gun Plumbicon tube with magnetic focus and electrostatic deflection.
- Modulation depth:** The ratio of the peak-to-peak amplitudes of, for example, 0.5–5 MHz (40–400 television lines) signal as measured on a waveform monitor. When measuring modulation depth, consideration of the frequency response of the preamplifiers well as the MTF of the lens must be taken into account.
- Noise:** The lower limit of useable dynamic range of the camera. Signal-to-noise is defined as the ratio of the peak value of the maximum signal [100 Institute of Radio Engineers (IRE) units] to the RMS noise voltage when the camera is capped.
- Picture quality:** Cleanliness of the scanned raster area with respect to spots and blemishes.
- Resolution:** The ability to distinguish fine detail in a video scene. The resolution of a camera tube is commonly expressed in terms of modulation depth.
- Sensitivity:** The signal current developed per unit of incident light, measured in microamps per lumen.
- Shading:** The variation of sensitivity across the target with reference to image center.
- Stabilized beam current:** The amount of beam current required to stabilize the target when a given amount of light is incident on the target. The beam current is normally set at two times picture white (commonly referred to as one F stop past 100 IRE or one F stop of head room).
- Sticking:** Very short-term image retention created in a high-contrast moving or stationary scene. Sticking takes on the appearance of lag except that it occurs under normal lighting conditions, whereas lag is generally a low light level phenomenon.
- Triode gun:** An electron gun that operates with a negative voltage applied to G_1 with respect to the cathode.

Broadcast Engineering magazine is a monthly periodical dealing with television and radio technology. The magazine, published in Overland Park, KS, is free to qualified subscribers.

The Society of Motion Picture and Television Engineers (SMPTE) publishes a monthly *Journal*, and holds an annual technical conference in February and a convention in the Fall. The SMPTE is headquartered in White Plains, NY.

The Society of Broadcast Engineers (SBE) holds technical conferences throughout the year. The SBE is located in Indianapolis, IN.

The National Association of Broadcasters (NAB) holds an annual engineering conference and trade show in the Spring. The NAB is headquartered in Washington, D.C.

5.6 CRT Devices and Displays

Jerry C. Whitaker

5.6.1 Introduction

The cathode ray tube (CRT) is the dominant display technology for a wide range of applications—both consumer and professional.⁴ As the requirements for greater resolution and color purity have increased, improvements have also been made in the design and manufacture of CRT devices and signal-driving circuits. Improvements to the basic monochrome and/or color CRT have been pushed within the last 10 years by the explosion of the personal computer industry and the increased resolution demanded by end users. Display size has also been a key element in CRT development. Consumer interest in large-screen home television has been strong within the last decade, and the roll-out of high-definition television has accelerated this trend.

5.6.2 Basic Operating System

The CRT produces visible or ultraviolet radiation by bombardment of a thin layer of phosphor material by an energetic beam of electrons. Nearly all commercial applications involve the use of a sharply focused electron beam directed time sequentially toward relevant locations on the phosphor layer by means of externally controlled electrostatic or electromagnetic fields. In addition, the current in the electron beam can be controlled or modulated in response to an externally applied varying electric signal. A generalized CRT consists of the following elements:

- An electron beam-forming system
- Electron-beam deflecting system (electrostatic or electromagnetic)
- Phosphor screen
- Evacuated envelope

Figure 5.91 shows the basic design of a monochrome CRT. The electron beam is formed in the electron gun, where it is modulated and focused. The beam then travels through the deflection region, where it is directed toward a specific spot or sequence of spots on the phosphor screen. At the phosphor screen the electron beam gives up some of the energy of the electrons in producing light or other radiation, some in generating secondary electrons, and the remainder in producing heat.

FIGURE 5.91 A generalized schematic of a cathode ray tube using electrostatic deflection.

Classification of CRT Devices

Tubes may be classified in terms of bulb parameters and screen/gun geometry. The principle categories that separate one class of device from another include

- Tube size. Conventionally, tube size is measured as the screen diagonal dimension in rounded inch units. This number is included in tube-type numbers.
- Neck diameter (OD). The gun, yoke, neck hardware, and socketing are affected by this dimension (typically given in millimeter). Common neck sizes are 36.5, 29, and 22.5 mm.
- Deflection angle. This parameter is calculated from the rated full-screen diagonal and glassware drawings, using the yoke reference plane as an assumed center of deflection. Angles in common use include 90, 100, and 110°. Higher deflection angles enable shorter tubes but entail other tradeoffs.
- Other characteristics, including gun type (**delta** or **in-line**), screen structure (stripes or dots) for color CRTs, and flat or curved face plates.

The CRT Envelope

The cathode ray tube envelope consists of the faceplate, bulb, funnel, neck, base press, base, faceplate safety panels, shielding, and potting. (Not all CRTs incorporate each of these components.) The faceplate is the most critical component of the envelope because the display on the phosphor must be viewed through it. Most faceplates are pressed in molds from molten glass and trimmed and annealed before further processing. Some specialized CRTs for photographic recording or flying-spot scanning use optical-quality glass faceplates sealed to the bulb section in such a way as to produce minimum distortion.

To minimize the return scattering of ambient light from the white phosphor, many CRT types use a neutral-gray-tinted faceplate. While the display information is attenuated as it makes a single pass through this glass, ambient light will be attenuated both going in and coming out, thus squaring the attenuation ratio and increasing contrast.

Certain specialized CRTs have faceplates made wholly or partially of fiber optics, which may have extraordinary characteristics, such as high ultraviolet transmission. A fiber optic region in the faceplate permits direct-contact exposure of photographic or other sensitive film without the necessity for external lenses or physical space for optical projection.

The bulb section of the CRT is the transition element necessary to enclose the full deflection volume of the electron beam between the deflection region and the phosphor screen on the faceplate. In most

FIGURE 5.92 Particle size distribution of four representative phosphors.

CRTs, this is a roughly cone-shaped molded-glass component. Instead of an ordinary glass bulb, many large CRTs include metal cone sections made of a glass-sealing iron alloy. The metal cones are generally lighter in weight than the corresponding glass sections.

The junction region of the bulb of a CRT with the neck section is critical to the geometry of the device. Tubes made with these separate sections are intended for electromagnetic deflection, and this region is where the deflection yoke is located.

The neck diameter of a CRT depends to a great extent on the type of deflection used and the intended application of the CRT. In general, electrostatic deflection CRTs have large neck diameters, whereas the electromagnetic-deflection devices have small diameters.

Phosphor and Screen Characteristics

Many materials, naturally occurring and synthetic, organic, and inorganic, have the ability to give off light. For video applications, the materials of interest are crystalline inorganic solids that are stable under cathode-ray tube fabricating and operating conditions. These materials are generally powders having average particle sizes in the range of 5–15 μm . Figure 5.92 shows some typical particle size distributions. Because of defects and irregularities in the crystal lattice structure, these materials have the ability to absorb incident energy and convert this energy into visible light. This process involves the transfer of energy from the electron beam to electrons in the phosphor crystal. The phosphor electrons are thereby excited or raised to levels higher than the ground state. Light is emitted when the electrons return to the more stable states. Figure 5.93 illustrates these changes in energy levels.

Phosphors are composed of a host crystal that comprises the bulk of the material and one or more *activators*, which may be present in amounts from parts per million to a few mole percent. Either the host or activator can determine the luminescent properties of a phosphor system. For example, in the zinc sulfide/cadmium sulfide: silver (ZnS:Ag/CdS:Ag) system, the emitted color ranges from blue at zero cadmium through green, to yellow, and into red as the cadmium content is increased.

In the commercial preparation of phosphors, the highly purified host and the required amount of activator are intimately mixed, normally with a flux, such as an alkali or alkaline earth halide or phosphate, which supplies a low-temperature melting phase. The flux controls the particle development and aids in the diffusion of the activator into the lattice. This mixture is then fired at high temperature, 1472–2192°F (800–1200°C) on a prescribed schedule in order to develop the desired physical and luminescent properties.

FIGURE 5.93 Energy transitions of electrons leading to luminescence.

In some cases the firing is carried on under specific controlled atmospheres. After firing, the resultant cake is broken up, residual soluble materials are removed by washing, and any required coatings are applied.

Phosphor Screen Types

A phosphor screen is used to convert electron energy into radiant energy in a CRT display device. The screen is composed of a thin layer of luminescent crystals, phosphors, that emit light when bombarded by electrons. This property is referred to as **cathodoluminescence**. It occurs when the energy of the electron beam is transferred to electrons in the phosphor crystal. The property of light emission during excitation is termed **fluorescence**, and that immediately after excitation is removed is termed **phosphorescence**.

Standardization of phosphor types has been accomplished by registration of the various phosphors with the *Joint Electron Device Engineering Council* (JEDEC) of the Electronic Industries Association (EIA). Registered phosphors are designated by a number series known as *P numbers*, as shown in Table 5.5.

Luminescent Properties

Phosphors are commercially available with cathodoluminescent emission over the entire visible band, including ultraviolet and near-infrared. Table 5.6 lists the important characteristics of the most common phosphors used in video display applications. Absolute phosphor efficiency is measured as the ratio of total absolute energy emitted to the total excitation energy applied. When evaluating or comparing picture

tubes, it is more meaningful to measure luminescence in footlambert using a system the response of which matches the eye. In addition to the use of a suitable detector, a number of other parameters must be controlled if meaningful measurements are to be obtained. Most important of these is the total energy to the screen, which includes

- Anode voltage
- Cathode current
- Raster size

FIGURE 5.94 Linearity characteristics of five common phosphors. Conditions: $E_{a2} = 25$ kV (1 fL = 3426 cd/m²).

Under normal CRT operating conditions, the luminescence of phosphors is essentially proportional to the beam current applied. However, when high beam currents are employed, some phosphors saturate and depart from linear behavior. The same effect can be observed in a direct-view color video display in areas of highlight brightness and with electron guns having small spot size. If linearity of the three primary phosphors is not closely matched, noticeable shift in white field color can result in highlight areas. Figure 5.94 shows some typical light output/ beam current curves.

Thermal quenching is another mechanism that may result in a loss of phosphor efficiency. In most phosphors the energy transitions become less efficient as screen temperature increases. This phenomenon can be quite pronounced in projection systems where the high-power loading can be responsible for a large increase in screen temperature. Figure 5.95 shows some examples of thermal quenching. Quenching is a transient condition, and the screen returns to normal efficiency after being cooled.

Electron Gun

The electron gun is basic to the structure and operation of any cathode-ray device, specifically display devices. In its simplest schematic form, an electron gun may be represented by the diagram in Fig. 5.96, which shows a triode gun in cross section. Electrons are emitted by the cathode, which is heated by the filament to a temperature sufficiently high to release the electrons. Because this stream of electrons emits from the cathode as a cloud rather than a beam, and it is necessary to accelerate, focus, deflect, and

FIGURE 5.95 The loss in phosphor efficiency as a display screen heats at high-current operation (rare-earth green).

FIGURE 5.96 Triode electron gun structure.

otherwise control the electron emission so that it becomes a beam and can be made to strike a phosphor at the proper location and with the desired beam cross section.

Electron Motion

The properties of motion for an electron in a uniform electrostatic field are obtained from Newton's second law. The velocity of an emitted electron is given by the following:

$$V = \left(\frac{2 eV}{m} \right)^{\frac{1}{2}} \quad (5.9)$$

where

$$e = 1.6 \times 10^{-19} \text{ C}$$

$$m = 9.1 \times 10^{-28} \text{ g}$$

$$V = -Ex, \text{ the potential through which the electron has fallen}$$

When practical units are substituted for the values in the previous equation, the following results:

$$V = 5.93 \times 10^5 V^{1/2} \text{ m/s} \quad (5.10)$$

This expression represents the velocity of the electron. If the electron velocity is at the angle θ to the potential gradient in a uniform field, the motion of the electron is specified by

$$y = \frac{Ex^2}{4V_0 \sin^2 \theta} + \frac{x}{\tan \theta} \quad (5.11)$$

where θ = the electron potential at initial velocity

This equation defines a parabola. The electron trajectory is illustrated in Fig. 5.97, in which the following conditions apply:

$$y_m = \text{maximum height}$$

$$x_m = x \text{ displacement at the maximum height}$$

$$a = \text{the slope of the curve}$$

Tetrode Gun

The tetrode electron gun includes a fourth electrode, illustrated in Fig. 5.98. The main advantage of the additional electrode is improved convergence of the emitted beam.

Nearly all CRT electron guns currently available have indirectly heated cathodes in the form of a small capped nickel sleeve or cylinder with an insulated coiled tungsten heater inserted from the back end. Most heaters operate at 6.3 V AC at a current of 300–600 mA. Low-power heaters are also available that operated at 1.5 V (typically, 140 mA).

The cathode assembly is mounted on the axis of the modulating or *control grid* cylinder (or simply *grid*), which is a metal cup of low permeability or stainless steel about 0.5-in in diameter and 0.375–0.5 in long.

FIGURE 5.97 The electron trajectory from an electron gun using the parameters specified in the text.

A small aperture on the order of 10 mils diameter is punched or drilled in the cap. The grid (G_1) voltage is usually negative with respect to the cathode (K).

To obtain electron current from the cathode through the grid aperture, there must be another electrode beyond the aperture at a positive potential great enough for its electrostatic field to penetrate the aperture to the cathode surface. Figure 5.99 illustrates a typical *accelerating electrode* (G_2) in relation to the cathode structure. The accelerating electrode may be implemented in any given device in a number of ways. In a simple accelerating lens in which successive electrodes have progressively higher voltages, the electrode may also be used for focusing the electron beam upon the phosphor, in which case it may be designated the *focusing* (or *first*) anode (A_1). This element is usually a cylinder, longer than its diameter and probably containing one or more disk apertures.

Electron Beam Focusing

The general principles involved in focusing the electron beam can be best understood by initially examining optical lenses and then establishing the parallelism between them and electrical focusing techniques.

Figure 5.100 shows a simplified diagram of an electrostatic lens. An electron emitted at zero velocity enters the V_1 region and moves in that region at a constant velocity (because the region has a constant potential). The velocity of the electron in that region is defined by Eq. (5.10) for the straightline component,

FIGURE 5.98 Basic structure of the tetrode electron gun.

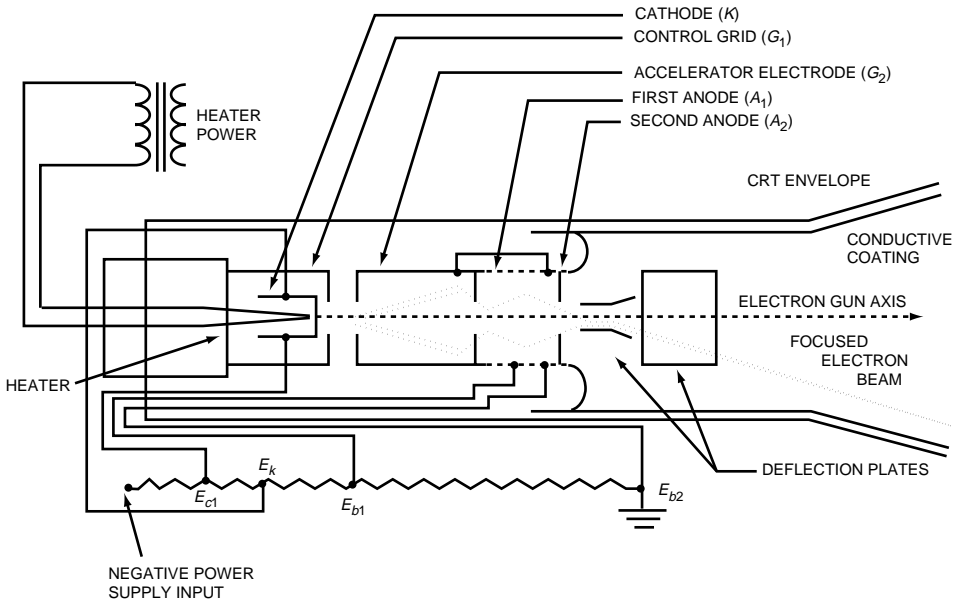

FIGURE 5.99 Generalized schematic of a CRT grid structure and accelerating electrode in a device using electrostatic deflection.

with V_1 replacing V in the equation. After passing through the surface into the V_2 region, the velocity changes to a new value determined by V_2 . The only component of the velocity that is changed is the one normal to the surface, so that the following conditions are true:

$$V_r = V_1 \sin I_1$$

$$V_1 \sin I_1 = V_2 \sin I_2$$

Snell's law, also known as the law of refraction, has the form:

$$N_1 \sin I_1 = N_2 \sin I_2$$

where

- N_1 = index of refraction for the first medium
- N_2 = index of refraction for the second medium
- I_1 = angle of the incident ray with the surface normal
- I_2 = angle of the refracted ray with the surface normal

The parallelism between the optical and the electrostatic lens is apparent if the appropriate substitutions

FIGURE 5.100 The basic principles of electron optics.

FIGURE 5.101 A unipotential lens. (After Sherr, S. 1979. *Electronic Displays*, pp. 67–70. Wiley, New York.)

are made,

$$V_1 \sin I_1 = V_2 \sin I_2$$

$$\frac{\sin I_1}{\sin I_2} = \frac{V_2}{V_1}$$

For Snell’s law, the following applies:

$$\frac{\sin I_1}{\sin I_2} = \frac{N_2}{N_1}$$

The analogy between the optical lens and the electrostatic lens is, thus, apparent. The magnification of the electrostatic lens is given by the following:

$$m = \frac{(V_1/V_2)^{1/2} S_2}{S_1}$$

The condition of a thin, unipotential lens, where \$V_1 = V_2\$, is illustrated in Fig. 5.101. The following applies:

$$m = \frac{h_2}{h_1} = \frac{f_2}{X_1} = -\frac{X_2}{f_2}$$

The shape of the electron beam under the foregoing conditions is shown in Fig. 5.102. If the potential at the screen is the same as the potential at the anode, the crossover is imaged at the screen with the magnification

FIGURE 5.102 Electron beam shape. (After Moss, H. 1968. *Narrow Angle Electron Guns and Cathode Ray Tubes*. Academic, New York.)

given by

$$m = \frac{X_2}{X_1}$$

The magnification can be controlled by changing this ratio, which in turn changes the size of the spot. This is one way to control the quality of the focus. Although the actual lens may not be thin, and in general is more complicated than is shown in the figure, the illustration is sufficient to understand the operation of electrostatic focus.

The size of the spot can be controlled by changing the ratio of V_1 to V_2 or of X_2 to X_1 in the previous equations. Because X_1 and X_2 are established by the design of the CRT, the voltage ratio is the parameter available to the circuit designer to control the size or focus of the spot. It is by this means that focusing is achieved for CRTs using electrostatic control.

5.6.3 Color CRT Devices

The shadow-mask CRT is the most common type of color display device. As illustrated in Fig. 5.103, it utilizes a cluster of three electron guns in a wide neck, one gun for each of the colors red, green, and blue. All of the guns are aimed at the same point at the center of the shadow-mask, which is an iron-alloy grid with an array of perforations in triangular arrangement, generally spaced 0.025-in between centers for entertainment television. For high-resolution studio monitor or computer graphic monitor applications, color CRTs with shadow mask aperture spacing of 0.012-in center-to-center or less are readily available. This triangular arrangement of electron guns and shadow-mask apertures is known as the delta-gun configuration. Phosphor dots on the faceplate just beyond the shadow mask are arranged so that after passing through the perforations, the electron beam from each gun can strike only the dots emitting one color.

All three beams are deflected simultaneously by a single large-diameter deflection yoke, which is usually permanently bonded to the CRT envelope by the tube manufacturer. The three phosphors together are designated P-22, individual phosphors of each color being denoted by the numbers P-22R, P-22G, and P-22B. Most color CRTs are constructed with rare-earth-element-activated phosphors, which offer superior color and brightness compared with previously used phosphors.

Because of the close proximity of the phosphor dots to each other and the strict dependence on angle of penetration of the electrons through the apertures, tight control over electron optics must be maintained. Close attention is also paid to shielding the CRT from extraneous ambient magnetic fields and to degaussing of the shield and shadow mask (usually carried out automatically when the equipment is switched on or off).

Even if perfect alignment of the mask and phosphor triads is assumed, the shadow-mask CRT is still subject to certain limitations, mainly in regard to resolution and luminance. The resolution restriction is the result of the necessity for aligning the mask apertures and the phosphor dot triads; the mask aperture size controls the resolution that can be attained by the device.

Electron beam efficiency in a shadow-mask tube is low, relative to a monochrome CRT. Typical beam efficiency is 9%; considering the three beams of the color tube, total efficiency is approximately 27%. By comparison, a monochrome tube may easily achieve 80% electron beam efficiency. This restriction leads to a significant reduction in luminance for a given input power for the shadow-mask CRT.

Parallel-Stripe Color CRT

The parallel-stripe class of CRT, such as the popular **Trinitron**, incorporates fine stripes of red-, green-, and blue-emitting phosphors deposited in continuous lines repetitively across the faceplate, generally in a vertical orientation. (Trinitron is a registered trademark of Sony.) The Trinitron is illustrated in Fig. 5.104. This device, unlike a shadow-mask CRT, uses a single electron gun that emits three electron beams across a diameter perpendicular to the orientation of the phosphor stripes. This type of gun is called the in-line gun. Each beam is directed to the proper color stripe by means of the internal beam-aiming structure and a slitted aperture grille.

FIGURE 5.103 Basic concept of a shadow-mask color CRT: (a) overall mechanical configuration, (b) delta gun arrangement on the tube base, (c) shadow-mask geometry.

The Trinitron phosphor screen is built in parallel stripes of alternating red, green, and blue elements. A grid structure placed in front of the phosphors, relative to the CRT gun, is used to focus and deflect the beams to the appropriate color stripes. Because the grid spacing and stripe width can be made smaller than the shadow-mask apertures and phosphor dot triplets, higher resolutions may be attained with the Trinitron system.

FIGURE 5.104 Basic concept of the Trinitron color CRT: (a) overall mechanical configuration, (b) in-line gun arrangement on the tube base, (c) mask geometry.

Elimination of conventional mask transmission loss, which reduces the electron beam-to-luminance efficiency of the shadow mask tube, permits the Trinitron to operate with significantly greater luminance output for a given beam input power.

The in-line gun is directed through a single lens of large diameter. The tube geometry minimizes beam focus and deflection aberrations, greatly simplifying convergence of the red, green, and blue beams on the phosphor screen.

Basics of Color CRT Design

The shadow-mask CRT is the workhorse of the video display industry. Used in the majority of color video displays since the introduction of color television in the early 1950s, the shadow-mask technique has been refined to yield greater performance and lower manufacturing cost.

Figure 5.105 illustrates the shadow-mask geometry for a tube at face center using in-line guns and a shadow mask of round holes. As an alternative, the shadow-mask may consist of vertical slots, as shown in Fig. 5.106. The three guns and their undeflected beams lie in the horizontal plane. The beams are

FIGURE 5.105 Shadow-mask CRT using in-line guns and round mask holes: (a) overall tube geometry, (b) detail of phosphor dot layout.

shown converged at the mask surface. The beams may overlap more than one hole and the holes are encountered only as they happen to fall in the scan line. By convention, a beam in the figure is represented by a single straight line projected backward at the incident angle from an aperture to an apparent *center of deflection* located in the *deflection plane*. In Fig. 5.105, the points B' , G' , and R' , lying in the deflection plane, represent such apparent centers of deflections for blue, green, and red beams striking an aperture under study. (These deflection centers move with varying deflection angles.) Extending the rays forward to the facepanel denotes the printing location for the respective colored dots (or stripes) of a tricolor group. Thus, centers of deflection become color centers with a spacing S in the deflection plane. The distance S projects in the ratio Q/P as the dot spacing within the trio. Figure 5.105 also shows how the mask hole horizontal pitch b projects as screen horizontal pitch in the ratio L/P . The same ratio applies for projection of mask vertical pitch a . The Q -space (mask to panel spacing) is optimized to obtain the largest possible theoretical dots without overlap. At panel center, the ideal screen geometry is then a mosaic of equally spaced dots (or stripes).

The stripe screen shown in Fig. 5.106 is used extensively in color CRTs. One variation of this stripe (or line) screen uses a cylindrical faceplate with a vertically tensioned grill shadow-mask without tie bars. Prior to the stripe screen, the standard construction was a tridot screen with a delta gun cluster as shown in Fig. 5.107.

Guard Band

The use of **guard bands** is a common feature for aiding purity in a CRT. The guard band, where the lighted area is smaller than the theoretical tangency condition, may be either *positive* or *negative*. In Fig. 5.105, the leftmost red phosphor exemplifies a positive guard band; the lighted area is smaller than the

FIGURE 5.106 Shadow-mask CRT using in-line guns and vertical stripe mask holes.

actual phosphor segment, accomplished by mask hole diameter design. Figure 5.106, on the other hand, shows negative guard band (NGB) (or *window-limited*) construction for stripe screens. Vertical black stripes about 0.1 mm (0.004-in) wide separate the phosphor stripes forming windows to be lighted by a beam wider than the window opening by about 0.1 mm. Figure 5.107 shows NGB construction of a triidot screen.

Electron Gun Classifications

Electron guns for color tubes can be classified according to the main lens configuration, which include

- Unipotential
- Bipotential
- Tripotential
- Hybrid lenses

The unipotential gun, discussed previously in this chapter as it applies to monochrome operation, is the simplest of all designs. This type of gun is rarely used for color applications, except for small-screen sizes. The system suffers from a tendency toward arcing at high anode voltage, and relatively large low current spots.

The bipotential lens is the most commonly used gun in shadow-mask color tubes. The arrangement of gun electrodes is shown in Fig. 5.108 along with a computer-generated plot of equipotential lines and electron trajectories. The main lens of the gun is formed in the gap between grid 3 and grid 4. When grid 3 operates at 18–22% of the grid-voltage, the lens is referred to as a *low bipotential* configuration, often called simply *LoBi*. When grid 3 operates at 26–30% of the grid-4 voltage, the lens is referred to as a *high bipotential* or *HiBi* configuration.

FIGURE 5.107 Delta-gun, round-hole mask negative guard band tridot screen. The taper on the mask holes is shown in the detail drawing only.

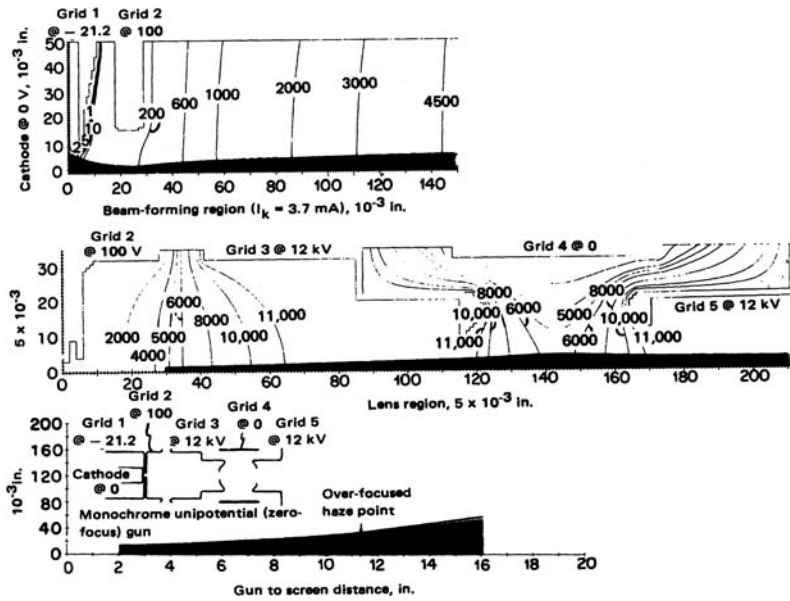

FIGURE 5.108 Bipotential electron gun configuration, shown with the corresponding field and beam plots. (After Benson, K.B. and Whitaker, J.C., eds. 1991. *Television Engineering Handbook*, rev. ed., p. 12.13. McGraw-Hill, New York.)

FIGURE 5.109 Triopotential electron gun configuration shown with the corresponding field and beam plots. (After Benson, K.B. and Whitaker, J.C., eds. 1991. *Television Engineering Handbook*, rev. ed., p. 12.14. McGraw-Hill, New York.)

The LoBi configuration has the advantages of a short grid 3 and shorter overall length, with parts assembly generally less critical than the HiBi configuration. However, with its shorter object distance (grid-3 length), the lens suffers from somewhat larger spot size than the HiBi. The HiBi, on the other hand, with a longer grid-3 object distance, has improved spot size and resolution. The focus voltage supply for the LoBi also can be less expensive.

It can be seen in the plot Fig. 5.108 that the bipotential beam starts with a crossover of the beam near the cathode, rising to a maximum diameter in the lens. After a double bending action in the lens region the rays depart in a convergent attitude toward the screen of the tube.

Further improvement in focus characteristics has been achieved with a triopotential lens. The electrode arrangement is shown in the computer model of Fig. 5.109. The lens region has more than one gap and requires two focus supplies, one at 40% and the other at 24% of the anode potential. With this refinement the lens has lower spherical aberration. Together with a longer object distance (grids 3–5), the resulting spot size at the screen is smaller than the bipotential designs. Drawbacks of the triopotential gun include

- The assembly is physically longer.
- It requires two focus supplies.
- It requires a special base to deliver the high focus voltage through the stem of the tube.

Hybrid Lenses

Improved performance may be realized by combining elements of the unipotential and bipotential lenses in series. The more common of these configurations are known as *UniBi* and *BiUni*. The UniBi structure (sometimes referred to as *quadripotential focus*) combines the HiBi main lens gap with the unipotential type of lens structure to collimate the beam. As shown in Fig. 5.110, the grid-2 voltage is tied to a grid 4 inserted in the object region of the gun, causing the beam bundle to collimate to a smaller diameter in the main lens. With this added focusing, the gun is slightly shorter than a bipotential gun having an equal focus voltage.

The BiUni structure, illustrated in Fig. 5.111, achieves a similar beam collimation by tying the added element to the anode, rather than to grid 2. The gun structure is shorter because of the added focusing early in the device. With three high gradient gaps, arcing can be a problem in the BiUni configuration.

FIGURE 5.110 Electrode arrangement of UniBi gun.

Trinitron

The Trinitron gun consists of three beams focused through the use of a single large main focus lens of unipotential design. Figure 5.112 shows the three in-line beams mechanically tilted to pass through the center of the lens, then reconverged toward a common point on the screen. The gun is somewhat longer than other color guns, and the mechanical structuring of the device requires unusual care and accuracy in assembly.

Gun Arrangements

Prior to 1970 most color gun clusters used a delta arrangement. Since that time the design trend has been toward the three guns in-line on the horizontal axis of the tube.

The electron optical performance of a delta gun is superior to in-line, in its basic form, by virtue of a larger lens diameter, resulting from more efficient use of the available area inside the neck. Larger neck diameters improve lens diameter, but at the expense of higher deflection power and more difficult convergence problems over the face of the tube. Typical delta gun lens diameters include

- 12 mm (0.5 in) for a 51-mm (2-in) neck OD
- 9 mm (0.4 in) for a 36-mm (1.4-in) neck
- 7 mm (0.3 in) for a 29-mm (1.1-in) neck

Delta guns use individual cylinders to form the electron lenses, and the three guns are tilted toward a common point on the screen. The individual cylinders are subject to random errors in position that can

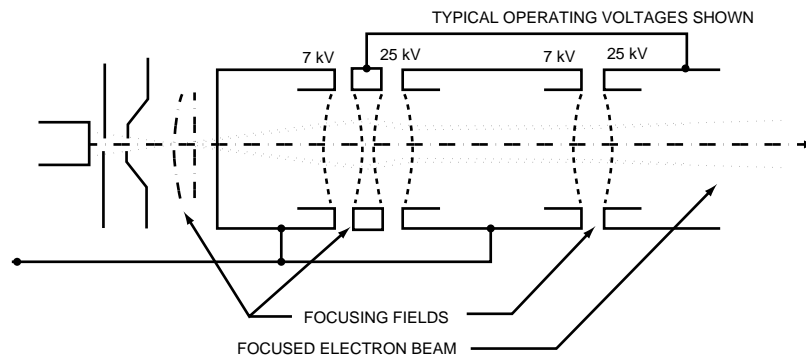

FIGURE 5.111 Electrode arrangement of a BiUni gun.

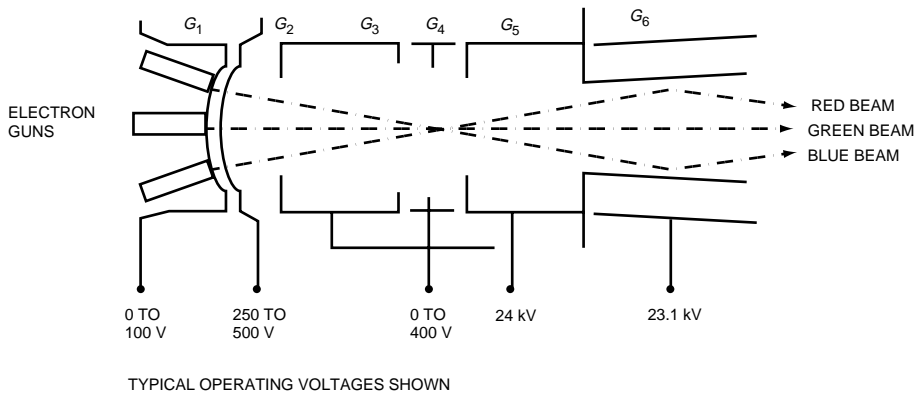

FIGURE 5.112 Electrode arrangement of the Trinitron gun. (After Morrell, A. et al. 1974. *Color Picture Tubes*, pp. 91–98. Academic, New York.)

cause misconvergence of the three undeflected spots. Further, carefully tailored current waveforms are applied to magnetic pole pieces on the separate guns to dynamically converge the three beams over the full face of the tube.

In-line guns enjoy one major advantage that more than offsets their less efficient use of available neck area. That is, with three beams on the horizontal axis, a deflection yoke can be built that will maintain dynamic convergence over the full face of the tube, without the need for correcting waveforms. With this major simplification in needed circuitry almost all guns now being built for commercial video applications are of the in-line design. In-line guns are available for 36-, 29-, and 22.5-mm neck diameters (among others). Typical lens diameters for these three guns are 7.5, 5.5, and 3.5 mm, respectively.

Unitized Construction

Most in-line guns are of *unitized construction* in which the three apertures or lens diameters are formed from a single piece of metal. With this arrangement the apertures and lens diameters are accurately fixed with respect to each other so that beam landings at the screen are more predictable than with the cylinder guns. Also, self-converging deflection yokes need the more accurate positioning of the beams in the yoke area. The only trio of gun elements not electrically tied together are the cathodes. Therefore, all varying voltages controlling luminance and color must be applied to the cathodes only. It should be noted that the three beams in unitized guns travel parallel until they reach the final lens gap. Here, an offset, or tilted, lens on the two outboard beams bends the two outer beams toward the center beam at the screen. Any change in the strength of this final lens gap, such as a focus voltage adjustment, will cause a slight change in the undeflected convergence pattern at the screen.

Guns for High-Resolution Applications

Improved versions of both the delta and in-line guns noted previously are used in high-resolution data display applications. In both cases the guns are adjusted for the lower beam current and higher resolution needed in data and/or graphics display. The advantages and disadvantages noted in earlier sections for delta and in-line guns apply here also. For example, the use of a delta-type cylinder, or *barrel-type* gun, requires as many as 20 carefully tailored convergence waveforms to obtain near-perfect convergence over the full face of the tube. The in-line gun, with a self-converging yoke, avoids the need for these waveforms, at the expense of slightly larger spots, particularly in the corners where overfocused haze tails can cause problems.

Figure 5.113 compares spot sizes, at up to 1 mA of beam current, for high-resolution designs compared with commercial receiver-type devices. Both delta and in-line 13- and 19-in vertical (13 V and 19 V)

FIGURE 5.113 Spot-size comparison of high-resolution guns vs commercial television guns: (a) 13-in vertical display, (b) 19-in vertical display. (After Benson, K.B. and Whitaker, J.C., eds. *Television Engineering Handbook*, rev. ed., p. 12.20. McGraw-Hill, New York.)

devices are shown. Note the marked improvement in spot size at current levels below 500 μA for the high-resolution devices.

Deflecting Multiple Electron Beams

Deflection of the electron beams in a color CRT represents a difficult technical exercise. The main problems that occur when the three beams are deflected by a common deflection system are associated with the spot distortions that occur in single-beam tubes. However, the effect is intensified by the need for the three beams to cross over and combine as a spot on the shadow mask. The two most significant effects are curvature of field and astigmatism.

Misalignment and misregistration of the three beams of the color CRT will lead to loss of purity for colors produced by combinations of the primary colors. Such reproduction distortions can also result in a reduction in luminance output because a smaller part of the beams are passing through the apertures. Additional errors that must be considered include

- Deflection-angle changes in the yoke-deflection center
- Stray electromagnetic fields

Defining Terms

Cathodoluminescence: The property of luminescent crystals (phosphors) to emit visible light with bombarded by electrons.

Delta gun: In a color CRT, a triangular arrangement of electron guns and shadow-mask apertures positioned so as to permit individual excitation of red, green, and blue phosphor elements.

Fluorescence: The property of light emission from a crystal during excitation by electrons.

- Guard band:** A design technique for a color CRT intended to improve the purity performance of the device by making the lighted area of the screen smaller than the theoretical tangency condition of the device geometry.
- In-line gun:** In a color CRT, a linear arrangement of electron guns and shadow-mask apertures positioned so as to permit individual excitation of red, green, and blue phosphor elements.
- Phosphorescence:** The property of light emission from a crystal for some period of time immediately after excitation by electrons is removed.
- Thermal quenching:** The undesirable mechanism of a phosphor in a CRT device in which phosphor efficiency decreases as the temperature of the phosphor screen increases.
- Trinitron:** Trade name for a class of color CRTs using in-line guns and in-line shadow-mask/phosphor geometry. Trinitron is a registered trademark of Sony.

Further Information

The SPIE (the international optical technology society) offers a wide variety of publications on the topic of display systems engineering. The organization also holds technical seminars on this and other topics several times each year. SPIE is headquartered in Bellingham, WA. The Society for Information Display (SID) also holds regular technical seminars and offers a number of publications on the topic of display systems. SID is headquartered in Santa Ana, CA. Furthermore, two books on the topic of display systems are recommended:

- Sherr, S. 1994. *Fundamentals of Display System Design*, 2nd ed. Wiley-Interscience, New York.
- Whitaker, J.C. 2001. *Video Displays*. McGraw-Hill, New York.

The Electronic Industries Association (EIA), Washington, DC, also offers several publications on the topic of display systems as they relate to consumer products.

5.7 Projection Systems

Jerry C. Whitaker

5.7.1 Introduction

The use of large-screen projection displays continues to grow at a rapid rate as the need to present high-resolution video and graphics information steadily increases.⁵ High definition television (HDTV) will require large screens (greater than 40-in diagonal) to provide effective presentation. Some form of projection is, therefore, the only practical solution. The role of HDTV and film in future theaters is also being explored, along with performance criteria for effective large-screen video presentations.

⁵Portions of this chapter were adapted from: Whitaker, J.C. 1994. *Electronic Displays: Technology, Design and Application*. McGraw-Hill, New York.

New projection system hardware is taking advantage of liquid crystal (LC) and thin film transistor (TFT) technology originally developed for direct-view flat panel displays. Also, new deformable-membrane light valves used in Schlieren systems are being developed to update oil film light-valve projectors, which have been the mainstay of large-screen projection technology for many years.

The number of specific applications for large-screen displays continues to grow. Military command centers provide a stringent test where high resolution, brightness, and reliability are critical. Flight simulation presents perhaps some of the greatest challenges, as large images must be presented on domes with high brightness, contrast, and resolution. Success in this application may lead to new entertainment vehicles, where domed entertainment theaters will combine traditional presentations with dynamic, high-definition video enhancements.

Extensive developmental efforts are being conducted into large-screen display systems. Much of this research is aimed at advancing new technologies such as plasma, electroluminescent and LCD, lasers, and new varieties of CRTs. Because this section is concerned with vacuum tube technologies, this chapter will focus on CRT-based projection systems. Light valve and laser technologies will also be examined. Solid-state projection systems are covered in Chapter 41.

Display Types

Large-screen projectors fall into four broad classes, or grades:

- *Graphics*. Graphics projectors are the highest quality, and generally most expensive, projectors. These systems are capable of the highest operating frequency and resolution. They can genlock to almost any computer or image source and typically offer resolutions of 2000×2000 pixels and greater with horizontal sweep rates up to 89 kHz or more.
- *Data*. Data projectors are less expensive than graphics projectors and are suitable for use with common computer image generators, such as PCs equipped with EGA, VGA, and Macintosh standard graphics cards.
- *HDTV*. HDTV projectors provide the quality level necessary to take full advantage of high-definition imaging systems. Resolution on the order of 1125 TV lines is provided at an aspect ratio of 16:9.
- *Video*. Video projectors provide resolution suitable for National Television Systems Committee (NTSC) level images. Display performance of 380–480 TV lines is typical.

Computer signal sources can follow many different, and sometimes incompatible, standards. Multisync projectors are common. Generally speaking, projectors are *downward compatible*. In other words, most graphic projectors can function as data projectors, HDTV projectors, and video projectors; most data projectors can also display HDTV and video, and so on.

Displays for HDTV Applications

The most significant difference between a conventional display and one designed for high-definition video is the increased resolution and wider aspect ratio of HDTV. Three technologies are practical for viewing high-definition images of 40-in diagonal and larger:

- *Light valve projection display*. Capable of modulating high-power external light sources, light valves are mainly used for large screen displays.
- *CRT projection displays*. Widely used for middle-sized screen displays, CRT projection systems are popular because of their relative ease of manufacturing (and hence competitive cost) and good performance. These displays are likely to be the mainstay technology for HDTV in the near-term future.
- *Flat panel plasma display panel (PDP) and liquid crystal display (LCD)*. Flat panel PDP displays are available demonstrated in 40-in and larger sizes.

TABLE 5.7 Performance Requirements for Large-Screen Military Display Applications

Parameter	Performance Requirement
Output luminance ^a :	
Small conference room	50–200 lm
Large conference room	200–600 lm
Control center	600–2000 lm
Addressable resolution	1280 × 1024 pixels
Visual resolution	15% absolute minimum modulation depth to an alternate pixel input
Video interface	15.75–80 kHz horizontal scan, 60–120 Hz noninterlaced refresh
Video sources	10–20 different sources, autosynchronous lock
Response to new update	Less than 1 s, no smear to dynamic response
Reliability	1000 h MTBF, excluding consumables
Operating cost	Less than \$10/h per projector, including AC power
Maintenance	Level 5 maintenance technician

^aAmbient lighting of 20–40 fc is assumed. The values shown are modulated luminance, spatially averaged over the full screen area. (Source: Blaha, R.J. 1990. Large screen display technology assessment for military applications. *Large Screen Projection Displays II*, ed. W.P. Bleha, Jr., pp. 80–92. Proc. SPIE 1255.)

Displays for Military Applications

Full-color, large-screen display systems can enhance military applications that require group presentation, coordinated decisions, or interaction between decision makers. Projection display technology already plays an important role in operations centers, simulation facilities, conference rooms, and training centers. Each application requires unique values of luminance, resolution, response time, reliability, and video interface. The majority of large-screen applications involve fixed environments where commanders and their staff interact as a group to track an operation and make mission-critical decisions. As sensor technology improves and military culture drives toward *scene presence*, future applications will require large-screen display systems that offer greater realism and real-time response. Table 5.7 lists the basic requirements for military display applications. The available technologies meeting these demands are illustrated in Fig. 5.114.

5.7.2 Projection System Fundamentals

Video projection systems provide a method of displaying a much larger image than can be generated on a direct-view cathode-ray picture tube. Optical magnification and other techniques are employed to throw an expanded image on a passive viewing surface that may have a diagonal dimension of 75-in or more. Direct-view CRTs are generally restricted to less than 39-in diagonal. A primary factor limiting CRT size is glass strength. To withstand atmospheric pressure on the evacuated envelope, CRT weight increases exponentially with linear dimension.

The basic elements of a projection system, illustrated in Fig. 5.115, include

- Viewing screen
- Optical elements
- Image source
- Drive electronics

The major differences of projection systems from direct-view displays are embodied in the first three areas, whereas the electronics assembly is (typically) essentially the same as for direct-view systems.

Projection Requirements

To provide an acceptable image, a projection system must approach or equal the performance of a direct-view device in terms of brightness, contrast, and resolution. Whereas the first two parameters may be compromised to some extent, large displays must excel in resolution because of the tendency of viewers

FIGURE 5.114 Basic grading of full-color display technologies vs. display area for military applications.

to be positioned less than the normal relative distance of four to eight times the picture height from the viewing surface. Table 5.8 provides performance levels achieved by direct-view video displays and conventional film theater equipment.

Evaluation of overall projection system brightness B , as a function of its optical components, can be calculated using the following equation:

$$B = \frac{L_g G T R^M D}{4W_g (f/N)^2 (1 + m)^2}$$

where

L_g = luminance of the green source (CRT or other device)

G = **screen gain**

T = lens transmission

FIGURE 5.115 Principal elements of a video projection system.

TABLE 5.8 Performance Levels of Video and Theater Displays

Display System	Luminous Output (brightness), nits, f L	Contrast Ratio at Ambient Illumination, fc	Resolution (TVL)
Television receiver	200–400, 60–120	30:1 at 5	275
Theater (film projector)	34–69, 10–20 ^a	100:1 at 0.1 ^b	4800

^aU.S. standard (PH-22.124-1969); see Luxenberg and Kuehn, 1968, p. 29.

^bLimited by lens flare.

- R = mirror reflectance
- M = number of mirrors
- D = dichroic efficiency
- W_G = green contribution to desired white output, %
- f/N = lens f -number
- m = magnification

For systems in which dichroics or mirrors are not employed, those terms drop out.

Two basic categories of viewing screens are employed for projection video displays. As illustrated in Fig. 5.116, the systems are

- **Front projection**, where the image is viewed from the same side of the screen as that on which it is projected.
- **Rear projection**, where the image is viewed from the opposite side of the screen as that on which it is projected.

Front projection depends on reflectivity to provide a bright image, whereas rear projection requires high transmission to achieve that characteristic. In either case, screen size influences display brightness inversely as follows:

$$B = \frac{L}{A}$$

where

- B = apparent brightness, cd/m^2
- L = projector light output, lm
- A = screen viewing area, m^2

Thus, for a given projector luminance output, viewed brightness varies in proportion to the reciprocal of the square of any screen dimension (width, height, or diagonal). An increase in screen width from the

FIGURE 5.116 Projection system screen characteristics: (a) front projection, (b) rear projection.

TABLE 5.9 Screen Gain Characteristics for Various Materials

Screen Type	Gain, cd/m ²
Lambertian (flat-white paint, magnesium oxide)	0.85–0.90
White semigloss	1.5
White pearlescent	1.5–2.5
Aluminized	1–12
Lenticular	1.5–2
Beaded	1.5–3
Ektalite (Kodak)	10–15
Scotch-light (3 M)	Up to 200

conventional aspect ratio of 4:3 (1.33) to an HDTV ratio of 16:9 (1.777) requires an increase in projector light output of approximately 33% for the same screen brightness.

To improve apparent brightness, directional characteristics can be designed into viewing screens. This property is termed *screen gain* G , and the preceding equation becomes

$$B = G \times \frac{L}{A}$$

Gain is expressed as screen brightness relative to a *lambertian surface*. Table 5.9 lists some typical front-projection screens and their associated gains.

Screen contrast is a function of the manner in which ambient illumination is treated. Figure 5.116 illustrates that a highly reflective screen (used in front projection) reflects ambient illumination as well as the projected illumination (image). The reflected light thus tends to dilute contrast, although highly directional screens diminish this effect. A rear-projection screen depends on high transmission for brightness but can capitalize on low reflectance to improve contrast. A scheme for achieving this is equivalent to the black matrix utilized in tricolor CRTs. Illustrated in Fig. 5.117, the technique focuses projected light through lenticular lens segments onto strips of the viewing surface, allowing intervening areas to be coated with a black (non-reflective) material. The lenticular segments and black stripes normally are oriented in the vertical dimension to broaden the horizontal viewing angle. The overall result is a screen that transmits most of the light (typically, 60%) incident from the rear while absorbing a large percentage of the light (typically, 90%) incident from the viewing side, thus providing high contrast.

Rear-projection screens usually employ extra elements, including diffusers and directional correctors, to maximize brightness and contrast in the viewing area.

As with direct-view CRT screens, resolution can be affected by screen construction. This is not usually a problem with front-projection screens, although granularity or lenticular patterns can limit image detail. In general, any screen element, such as the matrix arrangement described previously, that quantizes the image

**FIGURE 5.117** High contrast rear projection system.

(breaks it into discrete segments) limits resolution. For 525- and 625-line video, this factor does not provide the limiting aperture. High-resolution applications, however, may require attention to this parameter.

Projectors for Cinema Applications

Screen brightness is a critical element in providing an acceptable HDTV large-screen display. Without adequate brightness, the impact on the audience is reduced. Theaters have historically utilized front projection systems for 35-mm film. This arrangement provides for efficient and flexible theater seating. Large-screen HDTV is likely to maintain the same arrangement. Typical motion picture theater projection system specifications are as follows:

- Screen width 30 ft
- Aspect ratio 2.35:1
- Contrast ratio 300:1
- Screen luminance 15 fL
- Center-to-edge brightness uniformity 85%

These specifications meet the expectations of motion picture viewers. It follows that for HDTV projectors to be competitive in theatrical display applications, they must meet similar specifications.

Optical Projection Systems

Both refractive and reflective lens configurations have been used for the display of a CRT raster on screens 40-in or more in diagonal width. The first attempts merely placed a lenticular Fresnel lens, or an inefficient $f/1.6$ projection lens in front of a shadow mask direct view tube, as shown in Fig. 5.118(a). The resulting brightness of no greater than 2 or 3 fL was suitable for viewing only in a darkened room. Figure 5.118(b) shows a variation on this basic theme. Three individual CRTs are combined with cross reflecting mirrors and then focused onto the screen. The in-line projection layout is shown in Fig. 5.118(c) using three tubes, each with its own lens. This is the most common system used for multitube displays. Typical packaging to reduce cabinet size for front or rear projection is shown in Fig. 5.118(d) and 5.118(e), respectively.

Because of the off-center positioning of the outboard color channels, the optical paths differ from the center channel, and keystone scanning height modulation is necessary to correct for differences in optical throw from left to right. The problem, illustrated in Fig. 5.119, is more severe for wide-screen formats.

Variables to be evaluated in choosing among the many schemes include the following:

- Source luminance
- Source area
- Image magnification
- Optical-path transmission
- Light collection efficiency (of the lens)
- Cost, weight, and complexity of components and corrective circuitry

The lens package is a critical factor in rendering a projection system cost effective. The package must possess good luminance collection efficiency (small f -number), high transmission, good modulation transfer function (MTF), light weight, and low cost. Table 5.10 compares the characteristics of some available lens complements.

The total light incident upon a projection screen is equal to the total light emerging from the projection optical system, neglecting losses in the intervening medium. The distribution of this light generally is not uniform. Its intensity is less at screen edges than at the center in most projection systems as a result of light ray obliquity through the lens ($\cos^4 \theta$ law) and *vignetting effects* [Luxenberg and Kuehn 1968].

Light output from a lens is determined by collection efficiency and transmittance, as well as source luminance. Typical figures for these characteristics are

- Collection efficiency: 15–25%
- Transmittance: 75–90%

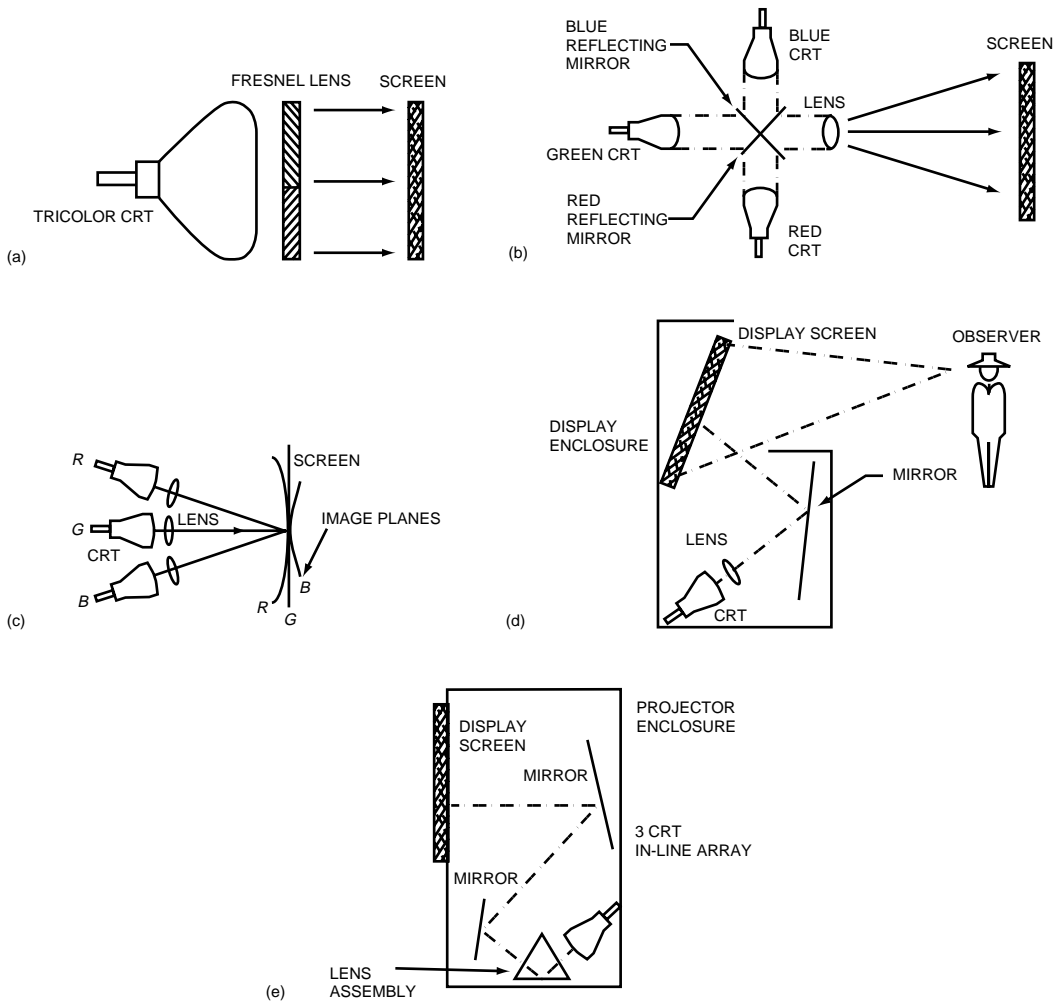

FIGURE 5.118 Optical projection configurations: (a) single tube, single lens rear projection system; (b) crossed-mirror trinescope rear projection; (c) three tube, three lens rear projection systems; (d) folded optics, front projection with three tubes in-line and a dichroic mirror; (e) folded optics, rear projection.

Collection efficiency is partially a function of the light source, and the figure given is typical for a lambertian source (CRT) and lens having a half-field angle of approximately 25° .

Optical Distortions

Optical distortions are important to image geometry and resolution. Geometry is generally corrected electronically, both for pincushion/barrel effects and keystone, which result from the fact that the three image sources are not coaxially disposed in the common in-line array.

Resolution, however, is affected by lens astigmatism, coma, spherical aberration, and chromatic aberration. The first three factors are dependent on the excellence of the lens, but chromatic aberration can be minimized by using line emitters (monochromatic) or narrow-band emitters for each of the three image sources. Because a specific lens design possesses different magnification for each of the three primary colors (the index of refraction varies with wavelength), throw distance for each must also be adjusted independently to attain perfect registration.

In determining final display luminance, transmission, reflectance, and scattering by additional optical elements such as dichroic filters, optical-path folding mirrors, or corrective lenses must also be accounted

FIGURE 5.119 Three tube in-line array. The optical axis of the outboard (red and blue) tubes intersect the axis of the green tube at screen center. Red and blue rasters show trapezoidal (*keystone*) distortion and result in misconvergence when superimposed on the green raster, thus requiring electrical correction of scanning geometry and focus.

for. Dichroics exhibit light attenuations of 5–30% and mirrors can reduce light transmission by as much as 5% each. Front-surface mirrors exhibit minimum absorption and scattering but are susceptible to damage during cleaning. Contrast is also affected by the number and nature of optical elements employed in the projection system. Each optical interface generates internal reflections and scattering, which dilute contrast and reduce MTF amplitude response. Optical coatings may be utilized to minimize these effects, but their contribution must be balanced against their cost.

Image Devices

CRTs and light valves are the two most common devices for creating images to be optically projected. Each is available in a multitude of variations. Projection CRTs have historically ranged in size from 1 in (2.5 cm) to 13 in (33 cm) diagonal (diameter for round envelope types). Because screen power must increase in proportion to the square of the magnification ratio, it is clear that faceplate dissipation for CRTs used in projection systems must be extremely high. Electrical-to-luminance conversion efficiency for common video phosphors is on the order of 15% (McKechnie, 1981). A 50-in (1.3-m) diagonal screen at 60 fL requires a 5-in (12.7-cm) CRT to emit 6000 fL, exclusive of system optical losses, resulting in

TABLE 5.10 Performance of Various Types of Projection Lenses

Lens type	Aperture, <i>f</i> / <i>l</i>	Image Diagonal, mm	Focal Length, mm	Magnification	Response at 300 TVL, %
Refractive, glass	1.6	196	170	8	33
Refractive, acrylic	1.0	127	127	10	13
Schmidt .	0.7	76	87	30	15
Fresnel	1.7	305	300	5	6

FIGURE 5.120 Mechanical construction of a liquid-cooled projection CRT.

a faceplate dissipation of approximately 20 W in a 3-in (7.6-cm) \times 4-in (10.2-cm) raster. A practical limitation for ambient air-cooled glass envelopes (to minimize thermal breakage) is 1 mW/mm² or 7.74 W for this size display. Accommodation of this incompatibility must be achieved in the form of improved phosphor efficiency or reduced strain on the envelope via cooling. Because phosphor development is a mature science, maximum benefits are found in the latter course of action with liquid cooling assemblies employed to equalize differential strain on the CRT faceplate. Such implementations produce an added benefit through reduction of phosphor thermal quenching and thereby supply up to 25% more luminance output than is attainable in an uncooled device at equal screen dissipation (Kikuchi et al., 1981).

A liquid-cooled CRT assembly, shown in Fig. 5.120, depends on a large heat sink to carry away and dissipate a substantial portion of the heat generated in the CRT. Large-screen projectors using such assemblies commonly operate CRTs at four to five times their rated thermal capacities. Economic constraints mitigate against the added cost of cooling assemblies, however, and methods to improve phosphor conversion efficiency and optical coupling/transmission efficiencies continue to be investigated.

Concomitant to high power are high voltage and/or high beam current. Each has benefits and penalties. Resolution, dependent on spot diameter, is improved by increased anode voltage and reduced beam current. For a 525- or 625-line display, spot diameter should be 0.006 in (0.16 mm) on the 3-in \times 4-in (7.6-cm \times 10.2-cm) raster discussed previously. Higher resolving power displays require yet smaller spot diameters, but a practical maximum anode-voltage limit is 30–32 kV when X radiation, arcing, and stray emission are considered. Exceeding 32 kV typically requires special shielding and CRT processing during assembly.

One form of the in-line array benefits from the relatively large aperture and light transmission efficiency of Schmidt reflective optics by combining the electron optics and phosphor screen with the projection optics in a single tube. The principle components of an integral Schmidt system are shown in Fig. 5.121.

FIGURE 5.121 Projection CRT with integral Schmidt optics.

Electrons emitted from the electron gun pass through the center opening in the spherical mirror of the reflective optical system to scan a metal-backed phosphor screen. Light from the phosphor (red, green, or blue, depending on the color channel) is reflected from the spherical mirror through an *aspheric corrector lens*, which serves as the face of the projection tube. Schmidt reflective optical systems are significantly more efficient than refractive systems because of the lower f characteristic and the reduced attenuation by glass in the optical path.

Discrete-Element Display Systems

The essential characteristic defining discrete-element display devices is division of the viewing surface (volume for three-dimensional displays) into separate segments that are individually controlled to generate an image. Each element, therefore, embodies a dedicated controlling switch or valve as opposed to raster display devices, which employ one (or a small number of) control device(s) for activation of all display elements.

Flood Beam CRT

Large displays (20 m diagonal and larger) have been employed for mass audiences in stadiums to provide special coverage of sporting events. These consist of flood beam CRT arrays in which each device fulfills the function of a single phosphor dot in a delta-gun shadow-mask CRT. Thus, each display element consists of a trio of flood beam tubes, one red, one green, one blue, each with a 1–6 in (2.5–15 cm) diameter. A fully NTSC-capable display would require in excess of 400,000 such tubes (147,000 of each color) to be individually addressed. Practical implementations have employed less than 40,000, thus requiring substantially reduced drive complexity.

Matrix Addressing

Provision for individual control of each element of a discrete-element display implies a proliferation of electrical connections and, therefore, rapidly expanding cost and complexity. These factors are minimized in discrete-element displays through *matrixing* techniques wherein a display element must receive two or more gating signals before it is activated. Geometric arrangements of the matrixing connectors guarantee that only the appropriate elements are activated at a given time.

Matrix addressing requires that the picture elements of a panel be arranged in rows and columns, as illustrated Fig. 5.122 for a simplified 4×4 matrix. Each element in a row or column is connected to all other elements in that row or column by active devices (typically transistors). Thus, it is possible to select the drive signals so that when only a row or column is driven, no elements in that row or column is activated. However, when both the row and column containing a selected element are driven, the sum of the two signals will activate a given element. The resulting reduction in the number of connections required, compared to a discrete-element drive, is significant because the number of lines is reduced from one-per-element to the sum of the number of rows and columns in the panel.

For active matrix addressing to work properly, it is necessary to have a sharp discontinuity in the transfer characteristic of the device at each pixel at the intersection of the row and column address lines. In some cases, the characteristics of the display device itself can be used to provide this discontinuity. The breakdown potential of a gas discharge can be used (for plasma displays) or alternatively, liquid crystals can be made to have a reasonably sharp transfer curve.

Stadium applications require color video displays that can be viewed in sunlight. In such cases, the high brightness required is achieved with a matrix system. A bright source at each pixel is controlled by its own drive circuit, as illustrated in Fig. 5.123. Light sources are typically either color incandescent light bulbs or electron-excited fluorescent phosphors. The switching matrix must control the intensity of each color in each pixel of the display. For video, the system must have a continuous gray scale. Because of the cost and complexity of providing individual control of each pixel light source, such displays usually have somewhat lower resolution than those using light valves.

FIGURE 5.122 Matrix addressing for a discrete-element display.

5.7.3 Projection Display Systems

The use of large-screen video displays has been increasing for a wide variety of applications. Because of the greater resolution provided by HDTV and advanced computer graphics systems, higher image quality is being demanded from large-screen display systems. Available technologies include the following:

- CRT-based display systems
- *Eidophor* reflective optical system
- *Talaria* transmissive color system
- Dual light valve system for HDTV
- Laser beam projection scanning system
- LCD projection system

HDTV applications present additional, more stringent requirements than conventional 525/625-line color displays, including

- Increased light output for wide screen presentation
- Increased horizontal and vertical resolution
- Broader gamut of color response to meet system specifications
- Projection image aspect ratio of 16:9 rather than 4:3

FIGURE 5.123 Principle of active matrix addressing for a large-screen display.

CRT Projection Systems

Large-screen color projection systems typically employ three monochrome CRT assemblies (red, green, blue) and the necessary optics to project full-color images. CRT systems based on 5- and 7-in CRT technology are popular because of their low cost; however, they suffer from low luminance levels (usually less than 50–60 average lumens). Higher luminance levels are provided by 9-in CRTs (160 lumens is typical). The larger CRT surface area permits increased beam energy without sacrificing resolution. Still higher luminance and resolution are offered by 13-in CRT projection systems.

Static and dynamic convergence circuitry is used to align the three beams over the display area. Digital convergence circuits permit convergence files tailored for each video source to be stored within a dedicated microprocessor. Advanced operating capabilities include autosync to a variety of input sources, built-in diagnostics, and automatic setup.

With CRT technology, high luminance and high resolution are conflicting requirements. For a given acceleration voltage, increased beam current will provide increased luminance, but reduced resolution because the spot size tends to increase. High-luminance levels also raise the operating temperature of the device, which may shorten its expected lifetime.

Multiple sets of CRT-based projection systems can be linked to increase luminance and resolution for a given application. The multiple beams overlay each other to yield the improved performance. Convergence of the 6–12 CRT assemblies, however, can become quite complex. Multiple CRT systems are satisfactory for NTSC video sources, but are usually inadequate for the display of computer-generated graphics data with single pixel characters.

The *mosaic* approach to improved luminance and resolution subdivides the screen into segments, each allocated to an individual projection system. As a result, larger images are delivered with higher overall performance. This scheme has been used effectively in simulation training to provide seamless, panoramic

TABLE 5.11 Operating Characteristics of Light Valve Projectors

Trade Name	Company	Addressing Method	Control Layer	Optical Effect
Eidophor	Gretag	Electron beam	Oil film on spheric mirror	Diffraction in reflection

SVS(TITUS)	SODERN (Philips)	Electron beam	Electro-optic crystal	<i>Pockels effect</i> in reflection
Super-projector	GM/Hughes	CRT + photo-conductor	ECB/liquid-crystal cell	Birefringence in reflection
HDTV LCD projector	Sharp	Active TFT matrix in amorphous Si	TN-liquid crystal cell	Polarization rotation in transmission

displays. Real-time processors divide the input image(s) into the proper display subchannels. Careful edge correction is necessary to prevent brightness falloff and geometric linearity distortions.

Light Valve Systems

Light valves may be defined as devices which, like film projectors, employ a fixed light source modulated by an optical-valve intervening the source and projection optics. Light valve display technology is a rapidly developing discipline. Light valve systems offer high brightness, variable image size, and high resolution. Table 5.11 lists some of the more common light valve systems and their primary operating parameters. The first four systems are based on *electron-beam addressing* in a CRT. The last system is based on *liquid crystal light valve* (LCLV) technology. Progress in light valve technology for HDTV depends on developments in two key areas:

- Materials and technologies for light control
- Integrated electronic driving circuits for addressing picture elements

Eidophor Reflective Optical System

Light valve systems are capable of producing images of substantially higher resolution than are required for 525/625-line systems. They are ideally suited to large screen theater displays.

In a manner similar to film projectors, a fixed light source is modulated by an optical valve system (Schlieren optics) located between the light source and the projection optics (see Fig. 5.124). In the basic Eidophor system, collimated light typically from a 2-kW xenon source (component 1 in the figure) is directed by a mirror to a viscous oil surface in a vacuum by a grill of mirrored slits (component 3).

The slits are positioned relative to the oil-coated reflective surface so that when the surface is flat, no light is reflected back through the slits. An electron beam scanning the surface of the oil with a video picture raster (components 4–6) deforms the surface in varying amounts, depending on the video modulation of the scanning beam. Where the oil is deformed by the modulated electron scanning beam, light rays from the mirrored slits are reflected at an angle that permits them to pass through the slits to the projection lens. The viscosity of the liquid is high enough to retain the deformation over a period slightly greater than a television field.

Projection of color signals is accomplished through the use of three units, one for each of the red, green, and blue primary colors converged on a screen.

Talaria Transmissive Color System

The Talaria system also uses the principle of deformation of an oil film to modulate light rays with video information. However, the oil film is transmissive rather than reflective. In addition, for full-color displays, only one gun is used to produce red, green, and blue colors. This is accomplished in a single light valve by the more complex Schlieren optical system shown in Fig. 5.125.

FIGURE 5.124 Mechanical configuration of the Eidophor projector optical system.

FIGURE 5.125 Functional operation of the General Electric single-gun light valve system.

Colors are created by writing *diffraction grating*, or grooves, for each pixel on the fluid by modulating the electron beam with video information. These gratings break up the transmitted light into its spectral colors, which appear at the output bars where they are spatially filtered to permit only the desired color to be projected onto the screen.

Green light is passed through the horizontal slots and is controlled by modulating the width of the raster scan lines. This is done by means of a high-frequency carrier, modulated by the green information, applied to the vertical deflection plates. Magenta light, composed of red and blue primaries, is passed through the vertical slots and is modulated by diffraction gratings created at right angles (*orthogonal diffraction*) to the raster lines by velocity modulating the electron beam in the horizontal direction. This is done by applying 16-MHz and 12-MHz carrier signals for red and blue, respectively, to the horizontal deflection plates and modulating them with the red and blue video signals. The grooves created by the 16-MHz carrier have the proper spacing to diffract the red portion of the spectrum through the output slots while the blue light is blocked. For the 12-MHz carrier, the blue light is diffracted onto the screen while the red light is blocked. The three primary colors are projected simultaneously onto the screen in registry as a full-color picture.

To meet the requirements of HDTV, the basic Talaria system can be modified as shown in Fig. 5.126. In the system, one monochromatic unit with green dichroic filters produces the green spectrum. Because of the high scan rate for HDTV (on the order of 33.75 kHz), the green video is modulated onto a 30-MHz carrier instead of the 12 or 15 MHz used for 525- or 625-line displays. Adequate brightness levels are produced using a 700-W xenon lamp for the green light valve and a 1.3-kW lamp for the magenta (red and blue) light valve.

A second light valve with red and blue dichroic filters produces the red and blue primary colors. The red and blue colors are separated through the use of orthogonal diffraction axes. Red is produced when the writing surface diffracts light vertically. This is accomplished by negative amplitude modulation of a 120-MHz carrier, which is applied to the vertical diffraction plates of the light valve. Blue is produced when the writing surface diffracts light horizontally. This is accomplished by modulating a 30-MHz carrier with the blue video signal and applying it to the horizontal plate, as is done in the green light valve.

The input slots and the output bar system of the conventional light valve are used, but with wider spacing of the bars. Therefore, the resolution limit is increased. The wider bar spacing is achievable because the red and blue colors do not have to be separated on the same diffraction axis as in the single light valve system. This arrangement eliminates the cross-color artifact present with the single light valve system. This arrangement eliminates the cross-color artifact present with the single light valve system, and therefore improves the overall colorimetric characteristics, as shown in Fig. 5.127.

High-performance electron guns help provide the required resolution and modulation efficiency for HDTV systems of up to 1250 lines. The video carriers have been optimized to increase the signal bandwidth capability to 30 MHz.

In the three-element system, all three devices are monochrome light valves with red, blue, and green dichroic filters. The use of three independent light valves improves color brightness, resolution, and colorimetry. Typically, the three light valves are individually illuminated by xenon arc lamps operating at 1 kW for the green and at 1.3 kW for the red and blue light valves.

The contrast ratio is an important parameter in light valve operation. The amount of light available from the arc lamp is basically constant; the oil film modulates the light in response to picture information. The key parameter is the amount of light that is blocked during picture conditions when totally dark scenes are being displayed (the **darkfield performance**). Another important factor is the ability of the display device to maintain a linear relationship between the original scene luminance and the reproduced picture. The amount of predistortion introduced by the camera must be compensated for by an opposite amount of distortion at the display device.

Laser Beam Projection Scanning System

Several approaches to laser projection displays have been implemented. The most successful employs three optical laser light sources whose coherent beams are modulated electro-optically and deflected by electromechanical means to project a raster display on a screen. The scanning functions are typically

FIGURE 5.126 Functional operation of the two-channel HDTV light valve system.

provided by a rotating polygon mirror and a separate vibrating mirror. A block diagram of the basic system is shown in Fig. 5.128.

The flying spots of light used in this approach are one scan line (or less) in height and a small number of pixels wide. This means that any part of the screen may only be illuminated for a few nanoseconds. The scanned laser light projector is capable of high contrast ratios (as high as 1000:1) in a darkened environment. A laser projector may, however, be subject to a brightness variable referred to as **speckle**. Speckle is a sparkling effect resulting from interference patterns in coherent light. This effect causes a flat, dull projection surface to look as though it had a beaded texture. This tends to increase the perception of brightness, at the expense of image quality.

Figure 5.129 shows the configuration of a laser projector using continuous-wave lasers and mechanical scanners. The requirements for the light wavelengths of the lasers are critical. The blue wavelength must

FIGURE 5.127 Color characteristics of the GE HDTV light valve system.

be shorter than 477 nm, but as long as possible. The red wavelength should be longer than 595 nm, but as short as possible. Greens having wavelengths of 510, 514, and 532 nm have been used with success. Because laser projectors display intense colors, small errors in color balance can result in significant distortions in gray scale or skin tone. The requirement for several watts of continuous-wave power further limits the usable laser devices. Although several alternatives have been considered, most color laser projectors use argon ion lasers for blue and green, and an argon ion laser pumped dye laser for red.

To produce a video signal, a modulator is required with a minimum operating frequency of 6 MHz. Several approaches are available. The bulk acousto-optic modulator is well suited to this task in high-power laser projection. A directly modulated laser diode is used for some low-power operations. The modulator does not absorb the laser beam, but rather deflects it as needed. The angle of deflection is determined by the frequency of the acoustic wave.

FIGURE 5.128 Block diagram of a laser-scanning projection display.

FIGURE 5.129 Configuration of a color laser projector.

The scanner is the component of the laser projector that moves the point of modulated light across and down the image plane. Several types of scanners may be used including mechanical, acousto-optic, and electro-optic. Two categories of scanning devices are used in the system:

- *Line scanner*, which scans the beam in horizontal lines across the screen. Lines are traced at 15,000–70,000 times per second. The rotating polygon scanner is commonly used, featuring 24–60 mirrored facets. Figure 5.130 illustrates a mechanical rotating polygon scanner.
- *Frame scanner*, which scans the beam vertically and forms frames of horizontal scan lines. The frame scanner cycles 50–120 times per second. A galvanometer-based scanner is typically used in conjunction with a mirrored surface. Because the mirror must fly back to the top of the screen in less than a millisecond, the device must be small and light. Optical elements are used to force the horizontally scanned beam into a small spot on the frame scanner mirror.

FIGURE 5.130 Rotating polygon line scanner for a laser projector.

FIGURE 5.131 Laser-screen projection CRT.

The operating speed of the deflection components may be controlled either from an internal clock, or locked to an external timebase.

The laser projector is said to have **infinite focus**. To accomplish this, optics are necessary to keep the scanned laser beam thin. Such optics allow a video image to remain in focus from approximately 4 ft to infinity. For high-resolution applications, the focus is more critical.

There is an undesirable byproduct of high-power laser operation. Most devices are water cooled and use a heat exchanger to dump the waste heat.

Another approach large-screen display employs an electron beam pumped monocrystalline screen in a CRT to produce a 1-in raster. The raster screen image is projected by conventional optics, as shown in Fig. 5.131. This technology promises three optical benefits:

- High luminance in the image plane
- Highly directional luminance output for efficient optical coupling
- Compact, lightweight, and inexpensive projection optics

Full-color operations is accomplished using three such devices, one for each primary color.

FIGURE 5.132 The relationship between misconvergence and display resolution.

TABLE 5.12 Appearance of Scan Line Judder in a Projection Display

Condition of Adjacent Lines	S/N (<i>p-p</i>)
Clearly overlapped	Less than 69 dB
Just before overlapped	75 dB
No judder	Greater than 86 dB

5.7.4 Operational Considerations

Accurate convergence is critical to display resolution. Figure 5.132 shows the degradation in resolution resulting from convergence error. It is necessary to keep convergence errors to less than half the distance between the scanning lines to hold resolution loss below 3 dB. Errors in convergence also result in color contours in a displayed image. Estimates have put the detectable threshold of color contours at 0.75–0.5 min of arc. This figure also indicates that convergence error must held under 0.5 scanning lines.

Raster stability influences the short-term stability of the display. The signal-to-noise ratio (S/N) and raster stability relationships for deflection circuits are shown in Table 5.12. A S/N equivalent of 1/5 scanning line is necessary to obtain sufficient raster stability. In HDTV applications, this translates to approximately 80 dB. Other important factors are high speed and improved efficiency of the deflection circuit.

A number of projection manufacturers have begun to incorporate automatic convergence systems into their products. These usually take the form of a charge-coupled device (CCD) camera sensor that scans various portions of the screen as test patterns are displayed.

FIGURE 5.133 Relationship between screen type and viewing angle: (a) conventional (flat) screen, (b) high gain (curved) screen.

Screen Considerations

Because most screens reflect both ambient light in the room and the incident light from the projector (in a front projection system), lighting levels are an important consideration. A rear screen system can reduce this problem. Ambient light on the screen's projector side reflects harmlessly back toward the projector, away from the audience. Light on the viewing side of the screen may fall on the screen but the human eye has experience in filtering out this kind of reflection. The result is that a rear screen projector provides an increased contrast ratio (all other considerations being equal); it can, therefore, be used in lighter areas. Special screen coatings can also help scatter ambient light away from the viewers, enhancing the rear screen image. Coatings can also increase the apparent brightness of screens operated from the front. The biggest gains, however, are made by using a screen that is curved slightly. Such screens can increase the apparent brightness of an image. Curved screens, however, also narrow the acceptable field of view. High-gain screens provide a typical viewing angle of $\pm 50^\circ$ from the centerline of the screen. Conventional (low-gain) screens can provide viewing of up to $\pm 90^\circ$ from the centerline. Figure 5.133 illustrates the tradeoffs involved.

Defining Terms

Darkfield performance: The amount of light that is blocked in a light valve projector when a totally dark scene is being displayed. This parameter is critical to good contrast ratio.

Front projection system: A projection device where the image is viewed from the same side of the screen as that on which it is projected.

Infinite focus: A characteristic of a laser projector in which the video image remains in focus from approximately four feet to infinity.

Light valve: A projection device that employs a fixed light source modulated by an optical-valve intervening the source and projection optics.

Matrix addressing: The control of a display panel consisting of individual light-producing elements by arranging the control system to address each element in a row/column configuration.

Rear projection system: A projection device where the image is viewed from the opposite side of the screen as that on which it is projected.

Screen gain: The improvement in apparent brightness relative to a lambertian surface of a projection system screen by designing the screen with certain directional characteristics.

Speckle: A sparkling effect in a laser beam projection system resulting from interference patterns in coherent light.

6.1 Microwave Power Tubes

Jerry C. Whitaker

6.1.1 Introduction

Microwave power tubes span a wide range of applications, operating at frequencies from 300 MHz to 300 GHz with output powers from a few hundred watts to more than 10 MW. Applications range from the familiar to the exotic. The following devices are included under the general description of microwave power tubes:

- Klystron, including the *reflex* and *multicavity* klystron
- *Multistage depressed collector* (MSDC) klystron
- *Klystrode* (IOT) tube
- Traveling-wave tube (TWT)
- **Crossed-field tube**

- Coaxial magnetron
- Gyrotron
- **Planar triode**
- High-frequency tetrode

This wide variety of microwave devices has been developed to meet a wide range of applications. Some common uses include

- UHF-TV transmission
- Shipboard and ground-based radar
- Weapons guidance systems
- Electronic countermeasure (ECM) systems
- Satellite communications
- Tropospheric scatter communications
- Fusion research

As new applications are identified, improved devices are designed to meet the need. Microwave power tubes manufacturers continue to push the limits of frequency, operating power, and efficiency. Microwave technology is an evolving science. Figure 6.1 charts device type as a function of operating frequency and power output.

Two principal classes of microwave vacuum devices are in common use today:

- **Linear beam tubes**
- Crossed-field tubes

Each class serves a specific range of applications. In addition to these primary classes, some power grid tubes are also used at microwave frequencies.

Linear Beam Tubes

As the name implies, in a linear beam tube the electron beam and the circuit elements with which it interacts are arranged linearly. The major classifications of linear beam tubes are shown in Fig. 6.2. In

FIGURE 6.1 Microwave power tube type as a function of frequency and output power.

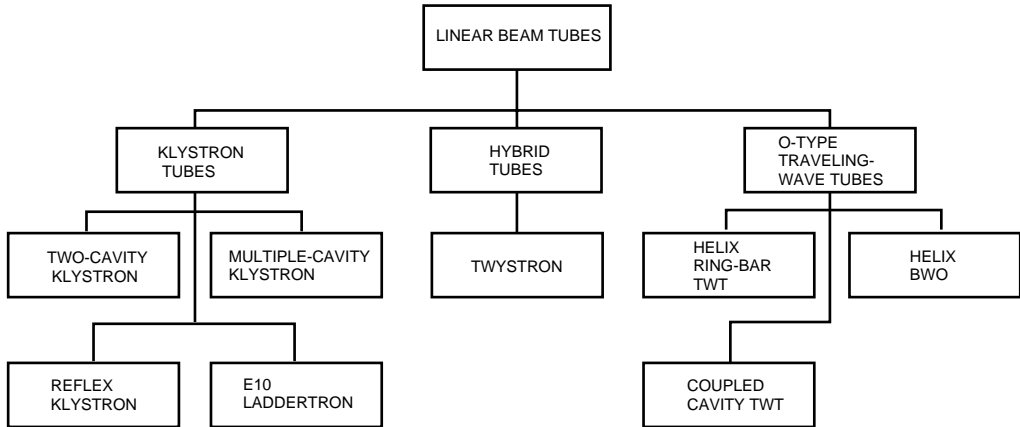

FIGURE 6.2 Types of linear beam microwave tubes.

such a device, a voltage applied to an anode accelerates electrons drawn from a cathode, creating a beam of kinetic energy. Power supply potential energy is converted to kinetic energy in the electron beam as it travels toward the microwave circuit. A portion of this kinetic energy is transferred to microwave energy as RF waves slow down the electrons. The remaining beam energy is either dissipated as heat or returned to the power supply at the collector. Because electrons will repel one another, there usually is an applied magnetic focusing field to maintain the beam during the interaction process. The magnetic field is supplied either by a solenoid or permanent magnets. Figure 6.3 shows a simplified schematic of a linear beam tube.

Crossed-Field Tubes

The magnetron is the pioneering device of the family of crossed-field tubes. The family tree of this class of devices is shown in Fig. 6.4. Although the physical appearance differs from that of linear beam tubes, which are usually circular in format, the major difference is in the interaction physics that requires a magnetic field at right angles to the applied electric field. Whereas the linear beam tube sometimes requires a magnetic field to maintain the beam, the crossed-field tube always requires a magnetic focusing field.

Figure 6.5 shows a cross section of the magnetron, including the magnetic field applied perpendicular to the cathode–anode plane. The device is basically a diode with the anode composed of a plurality of resonant

FIGURE 6.3 Schematic diagram of a linear beam tube.

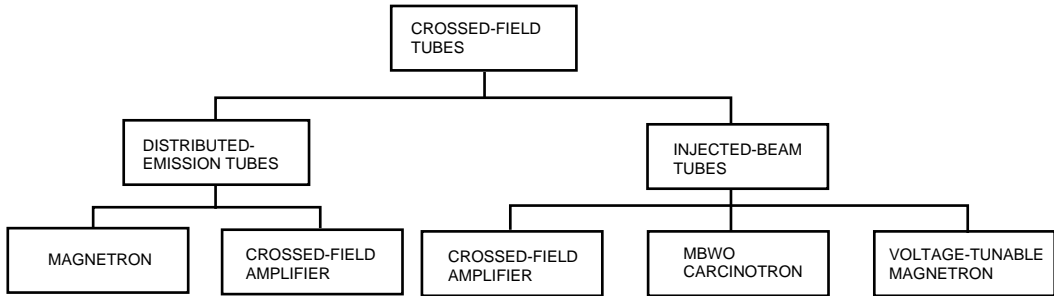

FIGURE 6.4 Types of crossed-field microwave tubes.

cavities. The interaction between the electrons emitted from the cathode and the crossed electric and magnetic fields produces a series of space charge spokes that travel around the anode–cathode space in a manner that transfers energy to the RF signal supported by the multicavity circuit. The mechanism is highly efficient.

Crossed-Field Amplifiers

Figure 6.6 shows the family tree of the crossed-field amplifier (CFA). The configuration of a typical present day distributed emission amplifier is similar to that of the magnetron except that the device has an input for the introduction of RF into the circuit. Current is obtained primarily by secondary emission from the negative electrode that serves as a cathode throughout all or most of the interaction space. The earliest versions of this tube type were called **amplitrons**.

The CFA is deployed in radar systems operating from the UHF to the Ku band and at power levels up to several megawatts. In general, bandwidth ranges from a few percent to as much as 25% of the center frequency.

6.1.2 Grid Vacuum Tubes

The physical construction of a vacuum tube causes the output power and available gain to decrease with increasing frequency. The principal limitations faced by grid-based devices include the following:

- Physical size. Ideally, the RF voltages between electrodes should be uniform; however, this condition cannot be realized unless the major electrode dimensions are significantly less than $\frac{1}{4}$ -wavelength

FIGURE 6.5 Magnetron electron path looking down into the cavity with the magnetic field applied.

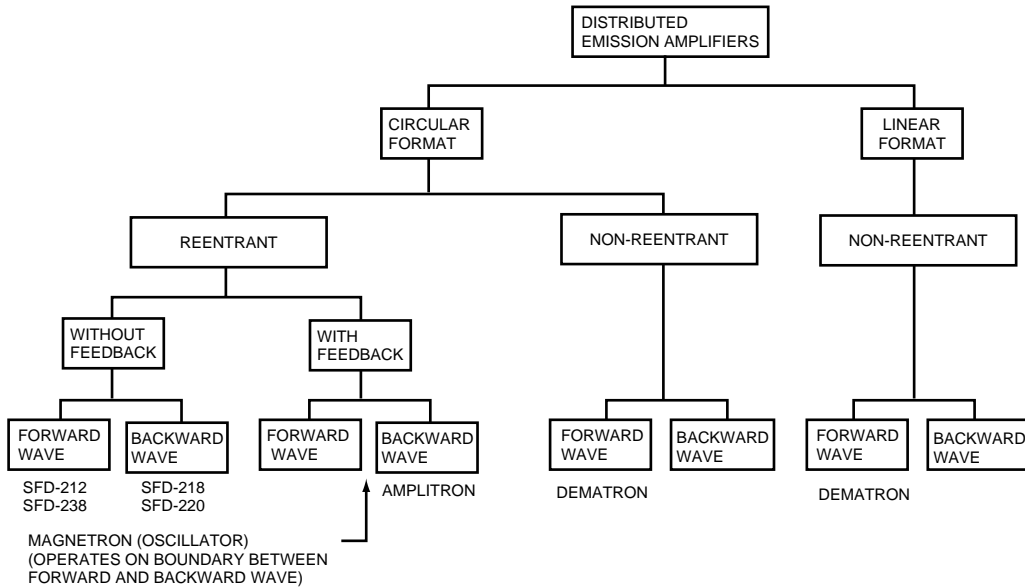

FIGURE 6.6 Family tree of the distributed emission crossed-field amplifier (CFA).

at the operating frequency. This restriction presents no problems at VHF frequencies; however, as the operating frequency increases into the microwave range, severe restrictions are placed on the physical size of individual tube elements.

- Electron transit-time. Interelectrode spacing, principally between the grid and the cathode, must be scaled inversely with frequency to avoid problems associated with electron transit time. Possible adverse conditions include: (1) excessive loading of the drive source, (2) reduction in power gain, (3) back heating of the cathode as a result of electron bombardment, and (4) reduced conversion efficiency.
- Voltage standoff. High-power tubes operate at high voltages. This presents significant problems for microwave vacuum tubes. For example, at 1 GHz the grid-cathode spacing must not exceed a few mils. This places restrictions on the operating voltages that may be applied to individual elements.
- Circulating currents. Substantial RF currents may develop as a result of the inherent interelectrode capacitances and stray inductances/capacitances of the device. Significant heating of the grid, connecting leads, and vacuum seals may result.
- Heat dissipation. Because the elements of a microwave grid tube must be kept small, power dissipation is limited.

Still, some grid vacuum tubes find applications at high frequencies. Planar triodes are available that operate at several gigahertz, with output powers of 1–2 kW in pulsed service. Efficiency (again for pulsed applications) ranges from 30 to 60%, depending on the frequency.

Planar Triode

A cross-sectional diagram of a planar triode is shown in Fig. 6.7. The envelope is made of ceramic, with metal members penetrating the ceramic to provide for connection points. The metal members are shaped either as disks or as disks with cylindrical projections.

The cathode is typically oxide coated and indirectly heated. The key design objective for a cathode is high-emission density and long tube life. Low-temperature emitters are preferred because high cathode temperatures typically result in more evaporation and shorter life.

FIGURE 6.7 Cross section of a 7289 planar triode. (Source: Varian/Eimac.)

The grid of the planar triode represents perhaps the greatest design challenge for tube manufacturers. Close spacing of small-sized elements is needed, at tight tolerances. Good thermal stability is also required, because the grid is subjected to heating from currents in the element itself, plus heating from the cathode and bombardment of electrons from the cathode.

The anode, usually made of copper, conducts the heat of electron bombardment to an external heat sink. Most planar triodes are air cooled.

Planar triodes designed for operation at 1 GHz and above are used in a variety of circuits. The grounded grid configuration is most common. The plate resonant circuit is cavity based, using waveguide, coaxial line, or stripline. Electrically, the operation of planar triode is much more complicated at microwave frequencies than at low frequencies. Figure 6.8 compares the elements at work for a grounded-grid amplifier operating at (a) low frequencies and (b) at microwave frequencies. The equivalent circuit is made more complicated by

- Stray inductance and capacitance of the tube elements
- Effects of the tube contact rings and socket elements
- Distributed reactance of cavity resonators and the device itself
- Electron transit-time effects, which result in resistive loading and phase shifts

Reasonable gains of 5–10 dB may be achieved with a planar triode. Increased gain is available by cascading stages. Interstage coupling may consist of waveguide or coaxial-line elements. Tuning is accomplished by varying the cavity inductance or capacitance. Additional bandwidth is possible by stagger tuning cascaded stages.

High-Power UHF Tetrode

New advancements in vacuum tube technology have permitted the construction of high-power UHF transmitters based on tetrodes. Such devices are attractive because they inherently operate in an efficient class A–B mode. UHF tetrodes operating at high-power levels provide essentially the same specifications, gain, and efficiency as tubes operating at lower powers. The anode power supply is much lower in voltage than the collector potential of a klystron-based system (8 kV is common). The tetrode also does not require focusing magnets.

FIGURE 6.8 Grounded-grid equivalent circuits: (a) low-frequency operation, (b) microwave frequency operation. The cathode-heating and grid-bias circuits are not shown.

Efficient removal of heat is the key to making a tetrode practical at high-power levels. Such devices typically use water or vapor-phase cooling. Air cooling at such levels is impractical because of the fin size that would be required. Also, the blower for the tube would have to be quite large, reducing the overall transmitter AC-to-RF efficiency.

The expected lifetime of a tetrode in UHF service is usually shorter than a klystron of the same power level. Typical lifetimes of 8000–15,000 h have been reported.

Defining Terms

Amplitron: A classic crossed-field amplifier in which output current is obtained primarily by secondary emission from the negative electrode that serves as a cathode throughout all or most of the interaction space.

Crossed-field tube: A class of microwave devices where the electron beam and the circuit elements with which it interact are arranged in a nonlinear, usually circular, format. The interaction physics of a crossed-field tube requires a magnetic field at right angles to the applied electric field.

Linear beam tube: A class of microwave devices where the electron beam and the circuit elements with which it interacts are arranged linearly.

Planar triode: A grid power tube whose physical design make it practical for use at microwave frequencies.

6.2 Klystron

Robert R. Weirather

6.2.1 Introduction

Energy in a microwave system may be viewed as with the passage of traveling electromagnetic waves along a waveguide axis. The generation of these waves can be resolved to one of energy conversion: the source potential energy (DC) is converted to the energy of the electromagnetic fields. At lower radio frequencies one use of the familiar multielectrode vacuum tube is as a valve controlling the flow of electrons in the anode conductor. (RF sources can use semiconductor devices for microwave power but these are generally limited to less than a kilowatt per device.) To generate considerable power at higher frequencies, the vacuum tube is less desirable than other means such as klystrons.

Conventional vacuum tubes are not efficient sources of currents at microwave frequencies. The assumption upon which their efficient design is based, namely, that the electrons pass from **cathode** to **anode** in a time short compared with the period of the anode potential, no longer holds true at 10^9 – 10^{10} Hz. The transit time of the order of magnitude of 10^{-8} s may be required for an electron to travel from cathode to

anode of a conventional vacuum tube at higher frequencies. The anode and grid potentials may alternate from 10 to 100 times during the electron transit. The anode potential during the negative part of its cycle thus removes energy that was given to the electrons during the phase of positive anode potential. The overall result of transit-time effects is that of a reduction in the operating efficiency of the vacuum tube becoming more marked with increasing frequency. Reducing the transit time by decreasing cathode-to-anode spacing and increasing anode potential creates excessive interelectrode capacitance and overheating of the anode. Thus, the necessity for the design of tubes that are specifically suited for operation in the higher frequency range. Consider a tube the electron beam of which interacts with the time-varying fields of that part of the microwave system that is included within the tube. This interaction proceeds in such a way that the velocity of the electrons is lower after the interaction than before, the kinetic energy removed from the electrons can reappear as energy of the electromagnetic fields. Practical tubes in use differ among themselves in the details of the mode of interaction between the electron beam and the rapidly varying fields. this chapter reviews one such tube: the klystron and some of its derivatives.

6.2.2 The Klystron

The three major functions of the high-power linear-beam tube (beam generation, interaction, and dissipation) are accomplished in three separate and well-defined sections of the tube, each of which can be optimized almost independently of the others. A relatively large high-convergence **electron gun** may be used to provide a small beam diameter (compared to wavelength) for interaction with a high-frequency circuit. Beam focusing can be made sufficiently good so that interception of current can often be neglected, and only RF circuit losses need be considered. The beam is usually allowed to expand into a large collector when it leaves the interaction region. Electron guns, beam focusing, **collectors**, and output windows are independent of the type of interaction structure used and are common to all tubes.

6.2.3 Typical Klystron Amplifier

Figure 6.9 shows a cutaway representation of a typical klystron amplifier. Schematically it is very similar to a triode tube in that it includes an electron source, resonant circuits, and a collector (which is roughly equivalent to the plate of a triode). In fact, the klystron amplifier consists of three separate sections—the electron gun for beam generation, the RF section for beam interaction, and the collector section for electron energy dissipation.

FIGURE 6.9 Sectional view of a klystron showing the principal elements.

The Electron Gun

Let us consider, first, the electron gun structure: As in the triode, the electron gun consists of heater and cathode, a control grid (sometimes), and an anode. Electrons are emitted by the hot cathode surface and are drawn toward the anode, which is operated at a positive potential with respect to the cathode. The electrons are formed into a small, dense beam by either electrostatic or magnetic focusing techniques, similar to the techniques used for beam formation in a cathode ray tube. In some klystron amplifiers, a control grid is used to permit adjustment of the number of electrons that reach the anode region; this control grid may be used to turn the tube completely on or completely off in certain pulsed-amplifier applications. The electron beam is well formed by the time it reaches the anode. It passes through a hole in the anode, passes on to the RF section of the tube, and eventually the electrons are intercepted by the collector. The electrons are returned to the cathode through an external power supply. It is evident that the collector in the klystron acts much like the plate of a triode insofar as collecting of the electrons is concerned, however, there is one important difference; the plate of a triode is normally connected in some fashion to the output RF circuit, whereas, in a klystron amplifier, the collector has no connection to the RF circuitry at all. From the preceding discussion, it is apparent that the klystron amplifier, insofar as the electron flow is concerned, is quite analogous to a stretched-out triode tube in that electrons are emitted by the cathode, controlled in number by the control grid, and collected eventually by the collector.

RF Section

Now let us consider the RF section of a klystron amplifier. This part of the tube is physically quite different from a gridded tube amplifier. One of the major differences is in the physical configuration of the resonant circuit used in a klystron amplifier. The resonant circuit used with a triode circuit, at lower frequencies, is generally composed of an inductance and a capacitor, whereas the resonant circuit used in a microwave tube is almost invariably a metal-enclosed chamber known as a cavity resonator. A very crude analogy can be made between the resonant cavity and a conventional L-C resonant circuit. The gap in the cavity is roughly analogous to the capacitor in a conventional low-frequency resonant circuit in that alternating voltages, at the RF frequencies, can be made to appear across the cavity gap. Circulating currents will flow between the two sides of the gap through the metal walls of the cavity, roughly analogous to the flow of RF current in the inductance of an L-C resonant circuit. Since RF voltages appear across the sides of the cavity gap, it is apparent that an electric field will be present, oscillating at the radio frequency, between the two surfaces of the cavity gap. When a cavity is the correct size, it will resonate. To bring to resonance, a cavity can be tuned by adjusting its size by some mechanical means.

As shown in Fig. 6.9, electrons pass through the cavity in each of the resonators, and pass through cylindrical metal tubes between the various gaps. These metal tubes are called *drift tubes*. In a klystron amplifier the low-level RF input signal is coupled to the first or input resonator, which is called the *buncher* cavity. The signal may be coupled in through either a waveguide or a coaxial connection. The RF input signal will excite oscillating currents in the cavity walls. These oscillating currents will cause the alternate sides of the buncher gap to become first positive and then negative in potential at a frequency equal to the frequency of the RF input signal. Therefore, an electric field will appear across the buncher gap, alternating at the RF frequency. This electric field will, for half a cycle, be in a direction that will tend to speed up the electrons flowing through the gap; on the other half of the cycle the electric field will be in a direction that will tend to slow down the electrons as they cross the buncher gap. This effect is called velocity modulation, and it is the mechanism that permits the klystron amplifier to operate at frequencies higher than the triode.

After leaving the buncher gap the electrons proceed toward the collector in the drift tube region. Ignore for the moment the intermediate resonators shown in Fig. 6.9, and let us consider the simple case of a two-cavity klystron amplifier. In the drift tube region the electrons that have been speeded up by the electric field in the buncher gap will tend to overtake those electrons that have previously been slowed down (by the preceding half of the RF wave across the buncher gap). It is apparent that, since some electrons are tending to overtake other electrons, clumps or bunches of electrons will be formed in the drift tube region.

If the average velocity of the electron stream is correct, as determined by the original voltage between anode and cathode, and if the length of the drift tube is proper, these bunches of electrons will be quite completely formed by the time they reach the catcher gap of the last or output cavity (which is called the catcher). This results in bunches of electrons flowing through the catcher gap periodically, and during the time between these bunches relatively fewer electrons flow through the catcher gap. The time between arrival of bunches of electrons is equal to the time of one cycle of the RF input signal.

These bunches of electrons will induce alternating current flow in the metal walls of the catcher cavity as they pass through the catcher gap. The output cavity will have large oscillating currents generated in its walls. These currents cause electric fields to exist, at the radio frequency, within the output cavity. These electric fields can be coupled from the cavity (to output waveguide, or coaxial transmission lines) resulting in the RF output power from the tube.

Collector

The electron beam energy is coupled in the last or output cavity to provide the desired RF power. The residual electron beam energy is absorbed in the collector. Collector design is based on the shape and energy of the electron beam. Electrons may have considerable energy upon impact on the collector and thus create undesired secondary emissions. Collector design includes coating and geometry considerations to minimize secondary emission. The collector may have to dissipate the full energy of the beam and is most frequently liquid cooled at higher powers.

6.2.4 High-Efficiency Klystron Design

The early analysis of ballistic bunching in a two-cavity klystron led to a maximum predicted efficiency of 58%. Early researchers recognized very early that tuning the penultimate cavity to the high-frequency side of the carrier could increase the efficiency over that which had been predicted. This occurs because it presents an inductive impedance to the beam and creates fields that squeeze the bunch formed at previous cavities. Locating a cavity tuned to the second harmonic of the operating frequency at the point where the second-harmonic content of the beam had increased enough to interact with that cavity, one could form a bunch that contained a higher fundamental component of current than by using conventional fundamental bunching only. The combination of fundamental bunching plus properly phased second harmonic bunching at a subsequent cavity is an approximation to a sawtooth voltage at a single gap. In theory, 100% efficiency would be possible. As we will see, further improvements have led to very efficient DC power to RF power conversion.

External and Internal Cavities

The high-power, multicavity klystron can be manufactured with the cavities either integral with the body or as external to the body. These two types are generally referred to klystron constructions as either with external or internal cavities. The internal (integral) cavities are manufactured in place by the OEM and thus field replacement of a failed tube requires shipment back to the vendor. The advantage with internal cavities is that details of installation are completely under the control of the OEM and less subject to installation error. Additionally, the cooling and heat flow is controlled better. With external cavity models, the cavities can be removed and the tubes replaced. This is a feature that lowers cost and hastens repair.

Multistage Depressed Collector Klystron

Development efforts at NASA to achieve highly efficient microwave transmitters for space applications resulted in achieving multistage depressed collector (MSDC) technology with great potential for efficiency enhancement. The UHF television community recognized the potential of this technology for reducing operating costs, and preliminary analysis indicated that applying MSDC technology to the power klystron used in UHF-TV transmitters could reduce amplifier power consumption by half.

A development program was organized and achieved an MSDC klystron design. A four-stage design was selected that would operate with equal voltage steps per stage (see Fig. 6.10). These MSDC designs are identical to the ordinary klystron except a different collector is used. The collector is segmented by different voltage stages. These different stages collect the various electron energies at lower voltages and thus reduce the overall dissipation resulting in increased efficiency (see Fig. 6.11). Power efficiency varies from 74% with no RF output to 57% at saturated output. The overall efficiency is 71% with no RF output to 57% at saturation output. The overall efficiency is 71% at this point, compared with 55% without the MSDC. For television operation, the input power is reduced from 118 to 51.8 kW by use of the MSDC, consequently, reducing the power costs to less than one-half.

6.2.5 Broadband Klystron Operation

For television service in the U.S., at least a 5.25-MHz bandwidth is required. Some European systems require as much as 8 MHz. At the power levels used in television service, it is necessary to stagger tune the cavities of a klystron to obtain this bandwidth. This is particularly true at the low end of the UHF band, but less so at the high end where the percentage bandwidth is lower.

The stagger tuning of a klystron in order to improve bandwidth is much more complicated, from a theoretical point of view, than is, for example, the stagger tuning of an IF amplifier. In an IF amplifier, the gain functions of the various stages may simply be multiplied together. In the klystron, however, the velocity modulation applied to the beam at a cavity gap will contribute a component to the exciting current at each and every succeeding gap. Thus, the interaction of tuning and the beam shaping for optimum power, bandwidth, efficiency, and gain is a tradeoff. To achieve the desired operation, the OEM must do studies and tests to determine the cavity tuning.

6.2.6 Frequency of Operation

Practical considerations limit klystron designs at the lower frequencies. The length of a klystron would be several meters at 100 MHz, but only 1 m long at

FIGURE 6.10 Multistage depressed collector (MSDC) for a klystron. (Source: Courtesy of Varian Associates, San Carlos, CA.)

FIGURE 6.11 Cross-sectional view of a klystron multi-stage depressed collector with four stages. (Source: Courtesy of Varian Associates, San Carlos, CA.)

FIGURE 6.12 Typical gain and saturation characteristics of a klystron.

1 GHz. Triodes and tetrodes are more practical tubes at lower frequencies, whereas the klystron becomes practical at 300 MHz and above. At frequencies above 20 GHz, the design of klystrons is limited by the transit time.

6.2.7 Power and Linearity

The power of a klystron is limited to a theoretical 100% of that in the electron beam ($P_v = I_b V_b$). In some areas, efficiencies of 70–80% have been achieved. Normally, efficiency of 40–60% can be expected. RF power bandwidth, of course, is dependent on the number of cavities and their tuning. Typically, klystrons with multiple cavities can be staggered tuned to provide a flat RF passband at some reduction in efficiency and gain. For example, in four cavity tubes, staggered tuning results in a 1-dB bandwidth of 1% with a gain of 40 dB.

Klystron linearity (both amplitude and phase) is considered fair to good. For RF power, several decibels below saturation, the amplitude linearity exhibits a curvature as shown in Fig. 6.12. As drive is increased, the RF output reaches saturation and further increases in drive reduces power output. The linearity curvature and saturation characteristic will generate harmonic and intermodulation products, which may be filtered or precorrected.

The phase shift vs. drive is also nonlinear. As the output power reaches saturation, the phase shift increases and may reach 10° or more. This nonlinearity creates AM to PM conversion. Compensation circuits can be used in the RF drive to correct this condition.

6.2.8 Klystron Summary

When the need for high frequency and high power is indicated, the klystron is one of the first candidates for service. The klystron continues to be workhorse with long life and dependable performance. Klystrons are a powerful, high-frequency answer to many RF problems. Klystrons come in a variety of powers from a 1 kW to several megawatts. Modern designs have years of life, high gains, and improved efficiency. Found in radars, accelerators, television transmitters, and communication systems, these tubes operate in outer space to fixed base locations.

6.2.9 Inductive Output Tube A Derivative

The IOT, also known as the **klystrode**, is a hybrid device with some attributes of a gridded tube and a klystron. The distinct advantage of a klystron over a gridded tube is its ability to produce high powers at high frequencies. One shortcoming of a klystron is its cost. The IOT attempts to lower the cost gap by using a grid to do some bunching and utilizes a drift region to complete this process. Another shortcoming of a klystron is its class of operation (class A). Operation of a klystron conduction cycle is class A, which delivers superior linearity but comes up short in efficiency. On the other hand, the IOT grid can be biased to completely cut off **beam current** for class B or be biased with some beam current for class AB, or even used in class A mode. Thus, the application of the klystrode is best suited for high-power, high-efficiency operation, whereas the klystron is best for high linearity.

History and Names for the IOT Klystrode

The klystrode was invented by Varian in the 1980s. Its name was chosen for its hybrid nature and describes the device quite well. Other manufacturers began work on similar devices and use other descriptions. English Electric Valve, Ltd., of the UK, chose the name inductive output tube (IOT) (see Fig. 6.13). This name was chosen due to a reference in the literature to this device possibility in the 1930s. Thus, it was 50 years before the klystrode (or IOT) was made commercially practical.

IOT Description

The klystron relies on the velocity bunching of the electrons from a heated cathode over a body length of 1 m or more. This is necessary to permit orderly physical spacing of the buncher cavities and the individual electron velocities to form properly. The superiority of the klystron over the gridded tube (typically a tetrode) is its output coupling, a cavity. Contrasted, it is quite difficult to design circuits to couple from tetrodes at higher power due to the increasing capacitance, which lowers the impedance. The superiority of the gridded tube is in its compact size and the general possibility of lower cost.

The IOT takes advantage of two superior characteristics of the gridded tube and the klystron for high frequencies. A grid is used to provide simple control of the electron beam while a cavity is used to couple the RF energy from the beam. This combination makes possible a smaller, lower cost, high-frequency, high-power tube. Still required, however, are focus magnets to maintain the beam, liquid cooling at higher powers, high beam supply voltages to accelerate the electrons, and the necessity for an external circuit called a **crowbar**. A crowbar is required

FIGURE 6.13 60-kW IOT (Klystrode). (Source: Courtesy of EEV.)

TABLE 6.1 Comparison of Klystron and IOT Operating Parameters

Parameter	Klystron	IOT	Units
Frequency	UHF	UHF	—
Peak power	60	60	kW
Beam voltage	28	32	kV max
Beam current	7	4	A max
Drive power	8	300	W
Efficiency	42	60	%
Collector dis.	150	50	kW max

for a IOT due to the possibility of the tube developing an internal arc. This internal arc creates a surge of current from the stored energy of the power supply, which would damage the grid and thus must be diverted. A crowbar is a device such as a thyatron used in shunt that diverts the powers supply stored energy based on the onset of an internal arc.

Gun, Grid, and Gain

The IOT electron gun is identical to that of the klystron except a grid is inserted between the cathode and the anode to control the electrons created by the cathode. The grid bunches the gun generated electrons, and the beam drifts through the field free region and interacts with the RF field in an output cavity to produce the RF output. The gun resembles a klystron gun but also has a grid much like a tetrode. Thus, control of the beam is like a gridded tube and operation is similar. The grid can be used to turn on or off the beam, modulate with RF, or both. Various classes of operation are possible. The most desired is class B, which is the most efficient and linear. Frequently used is class AB, which permits some beam current with no RF drive thus minimizing the class B crossover distortions.

The IOT gain is not as high as that of the klystron. Gain is typically 20–23 dB whereas the klystron is 35–40 dB. These gains are compared to those of a tetrode, which are typically 15 dB at higher frequencies. The lack of gain is not a severe limit for the IOT since solid-state drivers at 100th the output power (20 dB less) usually can be economical. The even higher gain of the klystron simplifies the driver stages even more.

Typical Operation

The IOT and klystron can be compared in operational parameters by reviewing Table 6.1. As this data clearly shows the klystron and IOT are close cousins in the high-frequency tube family. Not shown with this data is the other important performance parameters of amplitude linearity, phase distortion, bandwidth, size, or expected life. Depending on the application, these parameters may be more important than efficiency or gain.

Acknowledgments

We kindly acknowledge the assistance of Earl McCune of Varian, Robert Symons of Litton, and Michael Kirk of EEV.

Defining Terms

Anode: A positive portion of the tube that creates the field to accelerate the electrons produced by the cathode for passage down the body of the tube.

Beam current: The current that flows from anode to cathode.

Cathode: The most negative terminal of a vacuum tube; the source of electrons.

Collector: The portion of the tube that collects the electrons. The most electrically positive portion of the tube and dissipates residual the beam energy.

Crowbar: A triggered, shunt device that diverts the stored energy of the beam power supply.

Electron gun (gun): An electron emission material that is heated to produce the electron beam. Usually physically shaped and electrically controlled to form a pencil lead sized beam.

Focus coil: Coils of wire encircling the tube forming an electromagnet to focus the beam electrons. The focus coils have DC applied during operation.

Grid or modulating anode: A terminal in the tube used to control the electron beam usually placed near the cathode.

Klystrode: A hybrid tube that uses elements from the klystron and the tetrode.

6.3 Traveling Wave Tubes

Thomas K. Ishii

6.3.1 Definitions (Ishii, 1989, 1990)

A **traveling wave tube** (TWT) is a vacuum device in which traveling microwave electromagnetic fields and an electron beam interact with each other. In most **traveling wave** tubes, the direction of traveling microwave propagation inside the tube is made parallel to and in the same direction with the **electron beam**. Microwaves propagating in the same direction as the electron beam are termed **forward waves**. Traveling wave tubes based on the interaction with forward waves and the electron beam are termed the *forward wave tubes*. Most forward wave tubes are microwave amplifiers.

To make interaction between the traveling microwave electromagnetic fields and the electron beam efficient, in a traveling wave tube, the phase velocity or propagation speed of microwaves in the tube is slowed down to approximately equal speed with the speed of electrons in the electron beam. In most

practical traveling wave tubes, the speed of electrons in the beam is approximately 1/10 of the speed of light. In most traveling wave tubes, there is a transmission line in the device. Microwave energy to be amplified is fed to one end of the transmission line to which the electron beam is coupled. The transmission line is designed so that the speed of microwave propagation is also slowed down to approximately 1/10 of speed of light. For the best result, the speed of microwave propagation on the transmission line and the speed of electrons in the coupled electron beam must be approximately equal. Because the speed of microwave propagation is slowed down in the transmission line, the line is termed a **slow-wave structure**.

Thus in a traveling wave tube, microwaves and electrons travel together with approximately the same speed and interact with each other. During the interaction, the kinetic energy of the electrons is transferred or converted into microwave energy. As both microwaves and electrons are traveling together, the electrons lose their kinetic energy and the microwaves gain the energy of electromagnetic fields. Thus microwave electromagnetic fields are amplified while traveling inside the traveling wave tube. Amplified microwave energy is extracted at the other end of the transmission line.

Since a traveling wave tube does not have a resonator, if the input circuit and the output circuit are well impedance matched, a wide operating frequency bandwidth can be expected. In practice, the operating frequency bandwidth usually exceeds an octave (EEV, 1991, 1995).

The gain of a traveling wave tube is, among other things, dependent on the length of the tube; the longer the tube, the higher is the gain. Therefore, the physical shape of a traveling wave tube is long to accommodate the transmission line. The transmission line must have an input coupling circuit to couple the input microwave signal that is to be amplified into the transmission line. At the end of the transmission line, there must be another coupling circuit to take the amplified microwave out to the output circuit.

In a traveling wave tube, the electron beam is generated by an **electron gun** that consists of a hot cathode and electrostatic focusing electrodes. Electrons are generated from the heated cathode by **thermionic emission**. The launched electron beam to couple with the transmission line is focused by longitudinally applied DC magnetic fields. These **focusing DC magnetic fields** are provided by either a stack of permanent magnet rings or a solenoid. Beyond the end of the transmission line, there is a positive electrode to collect the used electron beam. This electrode is termed the **collector**.

A generic configuration of a traveling wave tube is shown in Fig. 6.14. The electron beam is coupled to a slow-wave structure transmission line to which the microwave signal to be amplified is fed through an input waveguide and a coupling antenna. The amplified microwaves are coupled out to the output waveguide through the output coupling antenna and the coupling waveguide circuit. As seen from Fig. 6.14, the electron gun is biased negatively by the use of the DC power supply and radio frequency choke (RFC) against the waveguide, the transmission line, and the collector. During the interaction between the electron beam and microwaves, the electron beam loses kinetic energy, and the lost energy is transferred into the electromagnetic field energy of the microwaves traveling in the transmission line.

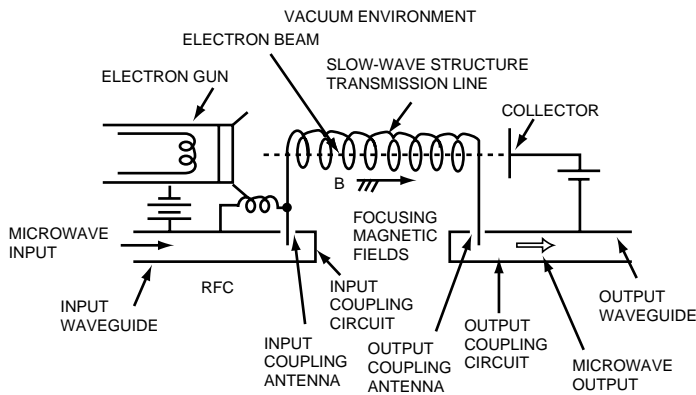

FIGURE 6.14 Generic configuration of a traveling wave tube.

Usually a traveling wave tube means a forward wave tube. In the vacuum tube, the electron beam and forward waves interact with each other. There is a vacuum tube in which the electron beam interacts with **backward waves**. This type of tube is termed the **backward wave tube**. The backward wave tube is inherently highly regenerative (built-in positive feedback); therefore, it is usually an oscillator. Such an oscillator is termed a **backward wave oscillator (BWO)**. The BWO has a **traveling wave** structure inside, but usually it is not called a traveling wave tube. Details of a BWO are presented in Chap. 6.4.3. The oscillation frequency of a BWO is dominated by the electron speed, which is determined by the anode voltage. Therefore, a BWO is a **microwave frequency voltage controlled oscillator (VCO)**.

6.3.2 Design Principles (Ishii, 1990)

By design, in a traveling wave tube, the speed of electrons in the electron beam u (m/s) and the **longitudinal phase velocity** of microwave electromagnetic field in the slow-wave structure transmission line v (m/s) are made approximately equal. When an electron comes out of the electron gun, the speed of an electron is

$$u_0 = \sqrt{\frac{2qV_a}{m}} \tag{6.1}$$

where q is the electric charge of an electron, 1.602×10^{-19} coulombs; m is the mass of an electron, 9.1085×10^{-31} kg; and V_a is the acceleration anode voltage.

But the speed of electrons changes as it travels within the beam due to interaction with traveling electromagnetic waves in the transmission line slow-wave structure. In the beginning, the electrons are velocity modulated. Some are accelerated and some are decelerated by the microwave electromagnetic field in the slow-wave transmission line. The result of **velocity modulation** is **electron bunching**. In a traveling wave tube, bunched electrons are traveling with the traveling electromagnetic waves. The speed of bunched electrons is given by

$$u = u_0 + u_m e^{-\alpha_e z} \cdot e^{-j(\beta_e z - \omega t)} \tag{6.2}$$

In this equation, a one-dimensional coordinate system z is laid along the direction of traveling waves and the electron beam. It is assumed that the interaction of electrons and traveling electromagnetic waves started at $z = 0$ and the time $t = 0$. In Eq. (6.2), u_m is the magnitude of velocity modulation at the initial location, α_e the attenuation constant of the velocity modulation, β_e the phase constant of the electronic velocity modulation waves in the beam, and ω the operating microwave frequency.

Both α_e and β_e are a function of the magnitude of interacting microwave electric fields and time, which change as the electrons travel in the beam. When the TWT is amplifying, the traveling wave electric field grows as it travels. Therefore, the magnitude of the velocity modulation also grows as the electronic waves travel in the beam.

The speed of the electromagnetic waves propagating on the slow-wave structure transmission line depends on the structure of the line itself. For example, if the structure is a simple helical device as shown in Fig. 6.15(a) is

$$v_z = c \sin \psi \tag{6.3}$$

FIGURE 6.15 Simple slow-wave transmission line structures: (a) helical transmission line, (b) zig-zag transmission line, (c) interdigital transmission line.

where c is the speed of light in the vacuum and ψ the pitch angle of the helix. If the slow-wave structure is a simple zig-zag transmission with the angle of the zig-zag at 2ψ (as shown in Fig. 6.2(b)), the longitudinal velocity of electromagnetic wave propagation in the z direction is

$$v_z = c \sin \psi \tag{6.4}$$

If the slow-wave structure is a simple interdigital circuit with the pitch dimensions a and b , as shown in Fig. 6.2(c),

$$v_z = \frac{a}{a + b} c \tag{6.5}$$

These equations assume that the coupling between the electron beam and the transmission line is light. It is further assumed that the waves propagate along the conducting wire slow-wave transmission line with the speed c . In reality, the electron beam will load these transmission lines. Then the speed of the electrons in the beam will be slightly different from these equations. In an electron beam coupled generic transmission line

$$v_z = \frac{\omega}{\beta_c - \frac{1}{2}b} \tag{6.6}$$

where ω is the operating angular frequency, β_c is the phase constant of the slow-wave transmission line with the series impedance \dot{Z} (Ω/m) and the shunt admittance of \dot{Y} (S/m), which is

$$\beta_c = I_m \sqrt{\dot{Z}\dot{Y}} \tag{6.7}$$

and

$$b = (\dot{\gamma} - \dot{\gamma}_c) \epsilon^{j \frac{5\pi}{6}} \tag{6.8}$$

where

$$\dot{\gamma}_c = \sqrt{\dot{Z}\dot{Y}} \tag{6.9}$$

and

$$\dot{\gamma} = \left(\alpha_c - \frac{\sqrt{3}}{2}b \right) + j \left(\beta_c - \frac{1}{2}b \right) \tag{6.10}$$

$$\alpha_c = R_e \sqrt{\dot{Z}\dot{Y}} \tag{6.11}$$

and β_c is given in Eq. (6.7).

The **voltage gain** per meter of propagation in **neper** per meter and **decibel** per meter is

$$\alpha = \alpha_c - \frac{\sqrt{3}}{2}b \tag{6.12}$$

$$\alpha = 8.686 \left[\alpha_c - \frac{\sqrt{3}}{2}b \right] \tag{6.13}$$

If the interaction transmission line length of the TWT is ℓ m long, then the voltage gain is

$$G = \epsilon^{\alpha \ell} \tag{6.14}$$

The **frequency bandwidth** is calculated by the following procedure. At the midband frequency ω_0

$$\epsilon^{\alpha(\omega_0)} = \epsilon \exp \left\{ \alpha_c(\omega_0) - \frac{\sqrt{3}}{2} b(\omega_0) \right\} \tag{6.15}$$

At the lower band edge ω^-

$$\epsilon \exp \left\{ \alpha_c(\omega^-) - \frac{\sqrt{3}}{2} b(\omega^-) \right\} = \frac{1}{\sqrt{2}} \epsilon^{\alpha(\omega_0)} \tag{6.16}$$

At the upper band edge ω^+

$$\epsilon \exp \left\{ \alpha_c(\omega^+) - \frac{\sqrt{3}}{2} b(\omega^+) \right\} = \frac{1}{\sqrt{2}} \epsilon^{\alpha(\omega_0)} \tag{6.17}$$

Solving Eq. (6.16) ω^- is found. Solving Eq. (6.17) ω^+ is found. Then the frequency bandwidth is

$$\Delta\omega = \omega^+ - \omega^- \tag{6.18}$$

$$\Delta f = \frac{\omega^+ - \omega^-}{2\pi} \tag{6.19}$$

The **noise figure** (NF) of a TWT ℓ -m-long interaction transmission line can be calculated by the following procedure:

$$NF = \frac{(kT\Delta f G_p + \int_0^\ell (P_s + P_p + P_f + kT_N\Delta f) dz + kT\Delta f)}{kT\Delta f G_p} \tag{6.20}$$

where T is the TWT circuit temperature of the input port and the output port, Δf the frequency bandwidth, G_p the **power gain** and

$$G_p = \epsilon^{2\alpha\ell} \tag{6.21}$$

and k is Boltzmann constant, 1.38054×10^{-23} J/K; P_s is the **shot noise** power per meter; P_p is the **partition noise** power per meter; P_f is the **flicker noise** per meter of propagation in the interaction transmission line section; and T_N is the **noise temperature** per meter of the interaction transmission line.

6.3.3 Electron Gun

The electron gun of a traveling wave tube is a device that supplies the electron beam to the tube. A schematic diagram of a generic electron gun is shown in Fig. 6.16. A generic electron gun consists of a hot cathode heated by an electric heater, a negatively biased **focusing electrode** or **focuser** and positively biased accelerating anode. Figure 6.16 is a cross-sectional view, and the structure can be a two-dimensional or three-dimensional coaxial structure (Liao, 1988; Sims and Stephenson, 1953). If it is two dimensional, it is for a ribbon-shaped electron beam and if it is coaxial, it is for a cylindrical electron beam. The focusing of the electron beam and the amount of the beam current can be adjusted by adjusting the heater voltage V_H and the bias voltage for the cathode V_c , for the focusing electrode or focuser V_f and the accelerator anode voltage V_a .

FIGURE 6.16 A schematic diagram of a generic electron gun.

Electron emission current density (A/m^2) can be calculated by the following **Richardson–Dushman equation** (Chodorow and Susskind, 1964):

$$J = 6.02 \times 10 T^2 \epsilon^{-b/T} \tag{6.22}$$

where T is the absolute temperature of the cathode in kelvin, and b also in kelvin is (Chodorow and Susskind, 1964)

$$b = 1.1605 \times 10^4 \phi \tag{6.23}$$

where ϕ is the **work function** of the cathode material. If the cathode material is tungsten, $\phi = 4.5$ V. If it is tantalum, $\phi = 4.1$ V. If it is an oxide coated cathode by B_aO , S_rO or C_aO , $\phi = 1-2$ V. If it is a combination of B_aO and S_rO , then $\phi = 1.0$ V. If it is thoriated tungsten, $\phi = 2.6$ V. The operating temperature of the cathode is about 1300~1600 K. Once electrons are thermally emitted from the cathode, electrons are pushed toward the center axis of the structure by the **coulomb force**

$$F_r = q E_r \tag{6.24}$$

where q is the electric charge of an electron 1.602×10^{-19} C and E_r is the radial electric field intensity (V/m). E_r is determined by the geometry of various electrodes and the bias voltages V_c , V_f , and V_a . However, V_f has the most direct influence on it. This negative electrode pushes the electron toward the center axis. The electrons are also pulled along the center axis by the positive **accelerator** anode. The longitudinal coulomb force acting on the electron is

$$F_z = q E_z \tag{6.25}$$

where E_z is the longitudinal electric field intensity in volt per meter.

E_z is determined by the geometry of the electrodes and the bias voltages V_c , V_f , and V_a . However, V_a has the most direct effect on pulling electrons out of the hot cathode.

The procedure to obtain the electron trajectory in the electron gun is to solve **Newton’s equations of motion** for the electron. In a generic electron motion, a tangential force may be involved, if it is not balanced. It is

$$F_\phi = q E_\phi \tag{6.26}$$

where E_ϕ is a tangential electric field. If the electron gun is structured axially circularly symmetrical, then E_ϕ does not exist. Otherwise, E_ϕ must be considered. Newton’s equations of motion of an electron in the electron gun are

$$m \frac{d^2 r}{dt^2} = q E_r \tag{6.27}$$

$$m \frac{d^2 z}{dt^2} = q E_z \tag{6.28}$$

$$m \frac{d^2 (r\phi)}{dt^2} = q E_\phi \tag{6.29}$$

E_r , E_z , and E_ϕ are obtainable from the electric potential V within the electron gun

$$E_r = -\frac{\partial V}{\partial r} \tag{6.30}$$

$$E_z = -\frac{\partial V}{\partial z} \tag{6.31}$$

$$E_\phi = -\frac{1}{r} \frac{\partial V}{\partial \phi} \tag{6.32}$$

The electric potential V within the electron gun is obtainable by solving a Laplace equation with specifically given boundary conditions,

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial V}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 V}{\partial \phi^2} + \frac{\partial^2 V}{\partial z^2} = 0 \quad (6.33)$$

An axially symmetrical solid cylindrical electron beam is produced by the gun structure illustrated in Fig. 6.16, if the structure is axially cylindrically symmetrical. If the middle of the hot cathode is made nonemitting and only the edge of the cathode is emitting, then the cathode becomes an **annular cathode**. The annular cathode produces a **hollow beam**. The annular electron beam can save the electron beam current for equal microwave output.

If the gun structure shown in Fig. 6.16 is two dimensional, then it produces a ribbon-shaped electron beam. A ribbon-shaped beam is used for a TWT of a two-dimensional structure.

If the angle of the focusing electrode against the axis of the electron beam is 67.5° and the anode is also tilted forward to produce a rectilinear flow, which is an electron flow parallel to the z axis in Fig. 6.16, then, such electron gun is termed the **Pierce gun**.

In practice the hot cathode surface is curved as shown in Fig. 6.17 to increase the electron emitting surface and to obtain a high-density electron beam.

FIGURE 6.17 Cross-sectional view of an electron gun with curved hot cathode.

6.3.4 Electron Beam Focusing

Electrons in an electron beam mutually repel each other by the electron's own coulomb force due to their own negative charge. In addition, the electron beam usually exists in proximity to the positively biased slow-wave structure as seen in Fig. 6.14. Therefore, the electron beam tends to diverge. The process of confining the electron beam within the designed trajectory against the mutual repulsion and diverging force from the slow-wave structure is termed *electron beam focusing*.

The electron beam in a TWT is usually focused by a DC magnetic flux applied parallel to the direction of the electron beam, which is coaxial to the slow-wave transmission line as illustrated in Fig. 6.14. If there is no focusing magnetic flux only at the output of the electron gun, then such electron flow in the beam is termed **Brillouin flow** (Hutter, 1960). If the electron gun itself is exposed to and unshielded from the focusing para-axial longitudinal magnetic flux, then the electron flow produced is termed the **immersed flow** (Hutter, 1960). If the electron gun is not shielded from focusing magnetic flux, which is not para-axial, then the electron flow produced in such a focusing system is neither Brillouin flow nor immersed flow, but it is a *generic flow*.

In a generic flow device, the focusing force or equation of motion of an electron in the electron beam is

$$m \frac{\partial^2 r}{\partial t^2} = mr \left(\frac{\partial \phi}{\partial t} \right)^2 + qr \frac{\partial \phi}{\partial t} B_z + \frac{qr_0^2 \rho_0}{2\epsilon_0 r} + qE_r \quad (6.34)$$

where r_0 is the radius of a part of the electron beam that is repelling the electron in question, (r, ϕ, z) is the cylindrical coordinate of the electron in question, q is the charge of the electron, which is 1.602×10^{-19} C. B_z is the z component of applied magnetic flux density, m is the mass of the electron, which is 9.109×10^{-31} kg. Also, ρ_0 is the electronic charge density of the electron beam, and ϵ_0 is the **permittivity** of the vacuum, which is 8.854×10^{-12} F/m.

The angular velocity of the electron trajectory $\partial\phi/\partial t$ may be calculated from the following equation of **Busch's theorem** (Hutter, 1960; Chodorow and Susskind, 1964; Harman, 1953):

$$\frac{\partial\phi}{\partial t} = \frac{\eta}{2\pi r^2}(\psi - \psi_c) \tag{6.35}$$

where η is a constant q/m , which is 1.759×10^{11} C/kg,

$$\psi = \pi r^2 B_z \tag{6.36}$$

$$\psi_c = \pi r_c^2 B_z \tag{6.37}$$

where r_c is the radial position of the electron in question where it first encountered the focusing magnetic flux.

If the electron beam is the immersed flow or Brillouin flow, then

$$m \frac{\partial^2 r}{\partial t^2} = mr \left(\frac{\partial\phi}{\partial t} \right)^2 + qr \frac{\partial\phi}{\partial t} B_z + \frac{qr_0^2 \rho_0}{2\epsilon_0 r} + qE_r \tag{6.38}$$

Focusing conditions are

$$\left. \frac{\partial r}{\partial t} \right|_{r=a} = 0 \tag{6.39}$$

$$\left. \frac{\partial^2 r}{\partial t^2} \right|_{r=a} = 0 \tag{6.40}$$

where a is the radius of the electron beam.

In practice, the focusing magnetic flux is created by either a solenoid or a structure of permanent magnetic rings.

6.3.5 Electron Velocity Modulation (Ishii, 1990)

If there are no microwaves on the slow-wave transmission line of a traveling wave tube, the velocity of an electron in the electron beam emitted from the electron gun is constant and uniform. As seen from Fig. 6.1, there is practically no longitudinal DC electric field in the transmission line section. Therefore, the electrons are just drifting with the speed given by the electron gun, which is

$$u_0 = \sqrt{\frac{2q V_a}{m}} \tag{6.41}$$

where q is the charge of the electron, m is the mass of the electron, and V_a is the accelerating electric potential of the electron gun. Now, if microwaves are launched on the slow-wave transmission line from the input as illustrated in Fig. 6.14 then there will be interaction between electrons in the electron beam and microwave electromagnetic fields on the slow-wave transmission line. In a traveling wave tube, it is designed that the electron velocity u_0 and the longitudinal propagation velocity of microwaves on the slow wave structure v_z are made approximately equal to each other.

$$u_0 \approx v_z \tag{6.42}$$

Therefore, electrons under the acceleration field due to traveling microwaves are kept accelerating and other electrons under the decelerating electric field of the traveling microwaves are kept decelerating. The longitudinal electric field component of traveling microwaves on the slow-wave transmission line is expressed by

$$E_z = E_0 \epsilon^{-\alpha z} \epsilon^{-j(\beta z - \omega t)} \tag{6.43}$$

where z is a one-dimensional coordinate set along the slow-wave transmission line and $z = 0$ is the point where microwaves are launched. E_0 is the magnitude of the longitudinal component of the microwave electric field at $z = 0$, α is the **attenuation constant** of the line, and β is the phase constant of the line. Depending on the phase angle of E_z at specific time t and location z , which is $(\beta z - \omega t)$, the electron may be kept accelerating or may be kept decelerating. This acceleration and deceleration of electrons due to applied microwave electric fields is termed the velocity modulation of an electron beam. The modulated electron velocity is

$$u = u_0 + u_m \exp\{-\alpha_e z - j(\beta_e z - \omega t)\} \quad (6.44)$$

where u_m is the magnitude of velocity modulation of the electron velocity. Here, α_e is the attenuation constant and β_e is the phase constant of the propagation of the velocity modulation on the electron beam.

6.3.6 Electron Bunching (Ishii, 1989)

If the speed of electrons in a focused electron beam is velocity modulated, as seen in Eq. (6.44), then the electron flow is no longer uniform and smooth. Some electrons in the beam are faster or slower than others, and as a result electrons tend to *bunch* together as they travel from the electron gun in the beginning to the electron **collector** at the end. The traveling electron charge density in the velocity modulated electron beam is expressed by

$$\rho = \rho_0 + \rho_m \epsilon^{-\alpha_e z} \epsilon^{-j(\beta_e z - \omega t)} \quad (6.45)$$

where ρ_0 is the electron charge density of an unmodulated electron beam, ρ_m is the magnitude of charge density modulation as the result of the velocity modulation of the electrons, α_e is the attenuation constant of the electron charge wave, and β_e is the phase constant of the wave.

The effect of electron bunching or propagation of electron charge waves in the electron beam is observed in a form of an electron beam current. If the cross-sectional area of the electron beam is S , (in square meter), then the electron beam current that contains bunched electrons is

$$I = I_0 + I_1 \epsilon^{-\alpha_e z} \cdot \epsilon^{-j(\beta_e z - \omega t)} + I_2 \epsilon^{-2\alpha_e z} \cdot \epsilon^{-2j(\beta_e z - \omega t)} \quad (6.46)$$

where I_0 is the DC beam current or unmodulated electron beam current, I_1 is the magnitude of beam current modulation at the frequency of microwaves ω , and I_2 is the magnitude of beam current modulation at the second harmonic frequency of operating frequency,

$$I_0 = S\rho_0 u_0 \quad (6.47)$$

$$I_1 = S(\rho_0 u_m + \rho_m u_0) \quad (6.48)$$

and

$$I_2 = S\rho_m u_m \quad (6.49)$$

6.3.7 Electron Beam Coupling

As seen from Fig. 6.14, to give electrons velocity modulation, microwave energy at or in proximity to the input must couple to the electron beam. To extract microwave energy from the bunched electrons at or in proximity to the output, the energy of the bunched electrons must be coupled to the slow-wave transmission line. This coupling of energy between the electron beam and the slow-wave transmission line is termed the **electron beam coupling**.

The strength of the beam coupling is represented by the beam coupling coefficient, which is defined as

$$k = \frac{I_c}{I_1} \quad (6.50)$$

where I_c is the microwave current in the slow-wave transmission line at operating frequency and I_1 is the magnitude of microwave beam current in the electron beam at the operating frequency ω . The beam coupling coefficient for a helical slow-wave line is obtained by

$$k = \frac{\pi u_0^2}{\omega \left(u_m \frac{\rho_0}{\rho_m} + u_0 \right) \sin \psi} \tag{6.51}$$

If the slow-wave transmission line is not a helix line, then the slow-wave ratio (less than 1) must be used instead of $\sin \psi$ where ψ is the **pitch angle of the helix**.

6.3.8 Power Gain

As microwaves propagate along the slow wave transmission line, they receive energy from the bunched electron beam. The loss of kinetic energy due to the microwave deceleration is the gain of microwave energy. Microwave power increase per meter of propagation is given by

$$\frac{dP}{dz} = \frac{d}{dz} \left(\frac{k^2}{2} m u^3 N S \right) = 2\alpha P \tag{6.52}$$

where P is microwave power flow on the transmission line, z is a one-dimensional coordinate set up along the slow-wave transmission line, k the beam coupling coefficient, m the mass of an electron, u the velocity of the electron, N the density of electrons in the beam, S the cross-sectional area of the beam, and α the gain parameter in neper/m that represents the neper power increase on the transmission line per meter of propagation.

The **gain parameter** α in neper per meter is given by (Hutter, 1960)

$$\alpha = \frac{\sqrt{3}}{2} \beta_e \left\{ Z_0 \frac{I_0}{4V_a} \right\}^{\frac{1}{3}} \tag{6.53}$$

where Z_0 is the **characteristic impedance** of the slow-wave transmission line, I_0 the DC beam current, V_a the DC acceleration anode voltage, and β_e the phase constant of the electron charge wave.

The output power P_0 of a traveling wave tube that is the length of the interaction of the slow-wave transmission line ℓ m long is

$$P_0 = P_i \epsilon^{2\alpha\ell} \tag{6.54}$$

where P_i is the input power to the slow wave transmission line. Therefore, the power gain in number is

$$G = \frac{P_0}{P_i} = \epsilon^{2\alpha\ell} \tag{6.55}$$

The power gain in neper is

$$G = \ln \frac{P_0}{P_i} = 2\alpha\ell \tag{6.56}$$

The power gain in decibel is

$$G = 10 \log_{10} \frac{P_0}{P_i} = 10 \log_{10} \epsilon^{2\alpha\ell} = 8.686 \alpha\ell \tag{6.57}$$

6.3.9 Frequency Bandwidth

The gain parameter of a traveling wave tube is frequency independent. As seen in Eq. (6.53)

$$\beta_e = \frac{\omega}{u_0} \quad (6.58)$$

where u_0 is the DC electron velocity, and

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}} = \sqrt{\frac{Z}{Y}} \epsilon^{j\frac{\phi - \psi}{2}} \quad (6.59)$$

where R , L , G , and C are resistance, inductance, conductance, and capacitance per meter of the slow-wave transmission line and

$$Z = \sqrt{R^2 + (\omega L)^2} \quad (6.60)$$

$$Y = \sqrt{G^2 + (\omega C)^2}$$

$$\phi = \tan^{-1} \frac{\omega L}{R} \quad (6.61)$$

$$\psi = \tan^{-1} \frac{\omega C}{G}$$

and

$$\alpha = \frac{\sqrt{3}}{2} \frac{\omega}{u_0} \left\{ \frac{Z(\omega)}{Y(\omega)} \frac{I_0}{4V_a} \right\}^{\frac{1}{3}} \cos \frac{\phi(\omega) - \psi(\omega)}{6} \quad (6.62)$$

If the maximum gain occurs at $\omega = \omega_0$, then the maximum power gain is

$$G(\omega_0) = \epsilon^{2\alpha(\omega_0)\ell} \quad (6.63)$$

If the power falls to $\frac{1}{2}\epsilon^{2\alpha(\omega_0)\ell}$ at $\omega = \omega_+$ and $\omega = \omega_-$, then

$$G(\omega_{\pm}) = \frac{1}{2} \epsilon^{2\alpha(\omega_0)\ell} \quad (6.64)$$

Solving Eq. (6.64) for both ω_+ and ω_- , the frequency bandwidth is obtained as

$$\Delta f = \frac{\omega_+ - \omega_-}{2\pi} \quad (6.65)$$

Equation (6.64) is usually written as transcendental equation:

$$\begin{aligned} & \exp \left[\frac{\sqrt{3}\omega_{\pm}}{u_0} \left\{ \frac{Z(\omega_{\pm})}{Y(\omega_{\pm})} \frac{I_0}{4V_a} \right\}^{\frac{1}{3}} \cos \frac{\phi(\omega_{\pm}) - \psi(\omega_{\pm})}{6} \right] \\ & = \frac{1}{2} \exp \left[\frac{\sqrt{3}\omega_0}{u_0} \left\{ \frac{Z(\omega_0)}{Y(\omega_0)} \frac{I_0}{4V_a} \right\}^{\frac{1}{3}} \cos \frac{\phi(\omega_0) - \psi(\omega_0)}{6} \right] \end{aligned} \quad (6.66)$$

6.3.10 Noise

As seen from Eq. (6.20), the **noise** output of a traveling wave tube with the interaction length of the electron beam and the slow-wave transmission line ℓ , power gain G_p , frequency bandwidth Δf , and temperature of both the input and the output circuits $T(K)$ is

$$P_N = kT\Delta f G_p + \int_0^\ell (P_s + P_p + P_F + kT_N\Delta f) dz + kT\Delta f \quad (6.67)$$

Other symbols are as defined after Eq. (6.20). Here, $kT\Delta f$ is the thermal noise input power, also, $kT\Delta f$ is the **thermal noise** generated at the output circuit. Boltzmann's constant k is 1.38×10^{-23} J/K.

The shot noise power in the beam coupled out to the transmission line per meter is

$$P_s = 2\xi q I_0 \Delta f \quad (6.68)$$

where q is the electron charge, I_0 the DC beam current, and ξ the power coupling coefficient between the beam and the transmission line.

The flicker noise P_F is due to random variation of **emissivity** of the cathode and

$$P_F = \eta \frac{1}{f} \quad (6.69)$$

where f is the operating frequency and η a proportionality constant.

The partition noise P_p is generated by electron hitting the slow-wave transmission line and is proportional to the speed of the electron u and the beam current I_0 ,

$$P_p = \zeta I_0 u \quad (6.70)$$

The noise figure of a traveling wave tube is presented with Eq. (6.20).

6.3.11 Sensitivity

The amount of the input power that makes the signal-to-noise ratio at the output of a traveling wave tube unity is termed the **tangential sensitivity** of the traveling wave tube. The output power of the traveling wave tube is

$$P_0 = P_i G_p \quad (6.71)$$

where P_i is the input power and G_p is the power gain of the traveling wave tube.

For the tangential sensitivity

$$P_0 = P_N \quad (6.72)$$

where P_N is the noise output power presented by Eq. (6.67). For the tangential sensitivity P_s , $P_i = P_s$ and

$$P_i = P_s \quad \text{and} \quad P_s G_p = P_N \quad (6.73)$$

Combining Eq. (6.73) with Eq. (6.67),

$$P_s = \frac{P_N}{G_p} = kT\Delta f + \frac{1}{G_p} \left[\int_0^\ell (P_s + P_p + P_F + kT_N\Delta f) dz + kT\Delta f \right] \quad (6.74)$$

For a generic **sensitivity**

$$P_0 = n P_N \quad (6.75)$$

where n is an arbitrary specified number.

Since

$$P_0 = nP_N \tag{6.76}$$

$$P_S = \frac{P_N}{G_P} = kT\Delta f + \frac{1}{G_P} \left[\int_0^\ell (P_s + P_p + P_F + kT_N\Delta f) dz + kT\Delta f \right] \tag{6.77}$$

The value of n can be

$$n \begin{matrix} > \\ \equiv \\ < \end{matrix} 1 \tag{6.78}$$

6.3.12 Collector

As seen from Fig. 6.14, the electron beam emitted from the electron gun goes through the interaction region with the microwave slow-wave transmission line and hits the electron collector at the end. Various configurations of the electron collector are shown schematically in Fig. 6.18. Collectors are hit by high-energy electrons of several thousand electron volts or more (EEV 1991, 1995). Collectors, therefore, often need forced air or water cooling. In practical traveling wave tubes, collectors and transmission lines are biased to the ground potential or near ground potential and the electron gun or cathode are biased to a high negative potential for operational security reasons.

For low-power traveling wave tubes, a flat collector as shown in Fig. 6.18(a) is adequate. To prevent electrons from returning to the transmission line, the collector is sometimes biased slightly positively. If electrons have sufficient kinetic energy and no chance of going back to the interaction region, then the collector may be biased negatively to make the electrons soft landing on the collector to prevent overheating the collector.

Regardless, the flat collector is not adequate for a high-power TWT. The cone-shaped collector as shown in Fig. 6.18(b) has more electron collection area than the flat collector shown in Fig. 6.18(a). Therefore, it reduces collector current density on the collector. This reduces the heating problem of the collector. A larger electron collection area can be obtained by making the collector configuration a curved cone shape, shown in Fig. 6.18(c), or a cylindrical shape, shown in Fig. 6.18(d) to reduce the heating of the collector by electron bombardment.

FIGURE 6.18 Schematic cross-sectional view of various collector configurations for a TWT: (a) plate, (b) cone, (c) curved cone, (d) cylinder, (e) depressed potential cylinder, (f) two stage, and (g) three stage.

For a high-power TWT, the electron energy may be on the order of tens of thousand electron volts (EEV 1991, 1995). Typically, electrons in the collector region are gradually slowed down for soft landing to prevent excess heating of the collector structure. In Fig. 6.18(e) (Liao, 1988) the cylindrical collector is negatively biased and electrons are pushed back and collected by a grounded plate at the end of the interaction region. The electron collection region may be expanded further as illustrated in Fig. 6.18(f) (Liao, 1988). The electron collection is accomplished in two stages, as seen from the figure. For an extremely high-power operation a three-stage collector, as shown in Fig. 6.18(g) (Liao, 1988), is employed. Each stage is progressively negatively biased for soft landing of electrons to prevent excess heating of the collector structure.

The energy of an electron at the collector is approximately,

$$w = qV_a \quad (6.79)$$

where q is the charge of an electron and V_a is the acceleration voltage. Therefore, for complete soft landing, the collector must provide

$$w_c = -qV_a = qV_c \quad (6.80)$$

where V_c is the collector voltage

$$V_c = -V_a \quad (6.81)$$

For any specified soft landing

$$V_c = -bV_a \quad (6.82)$$

where b is a specified constant that is less than unity.

6.3.13 Practical Examples

Traveling wave tubes are amplifiers. They are used for microwave communications, radar, industrial and biomedical sensing, and scientific research, as exemplified by the radio telescope. Traveling wave tube are used wherever wide frequency band microwave amplification is needed. They are widely used for multichannel telephone and television channel transmission. They are also useful for short pulsed radar amplification and high data rate data transmission. A traveling wave tube can be used as transmitter amplifier of high power, or it can be used as a receiver amplifier of high sensitivity. A traveling wave tube may be for continuous wave operation, or for pulsed operation. Depending on the application, there are a great variety of traveling wave tubes in terms of power, voltage, current, mode of operation, size and weight.

Defining Terms

Accelerator: A positive electrode in a vacuum tube to accelerate emitted electrons from its cathode by coulomb force in a desired direction.

Annular cathode: A cathode of a vacuum tube with the shape of the emitting surface of the cathode is annular. The annular cathode can produce a hollow electron beam.

Attenuation constant: A constant representing attenuation of magnitude of propagating quantity such as the electromagnetic waves and acoustic waves.

Backward wave: Electromagnetic wave that travels in the direction opposite to the direction of electrons in the coupled electron beam.

Backward wave oscillator (BWO): In which the electron beam and microwaves travel in opposite direction to each other.

Backward wave tube: A backward wave traveling wave tube; the microwave input is located in proximity to the collector and the microwave output is located in proximity to the electron gun. The direction of traveling microwave and direction of electron motion in the beam are opposite to one another.

- Brillouin flow:** A stream of electron beam emitted from an electron gun that is not exposed to a focusing magnetic field.
- Busch's theorem:** Angular velocity of an electron in a magnetically focused electron beam is proportional to the difference of magnetic flux at the electron beam cross section, where the electron first encounters the focusing magnetic field, and at the cross section that includes the observation point. It is inversely proportional to the beam cross-sectional area at the observation point. The proportionality constant is 0.879×10^{11} C/kg.
- Characteristic impedance:** Ratio of a transmission line voltage of a forward voltage traveling wave to the accompanying transmission line current of a forward current traveling wave.
- Collector:** An electron collector; a positive electrode against the cathode. It is located at the final termination of the electron beam in a vacuum tube to collect electrons finished by the electronic process of the vacuum tube.
- Coulomb force:** Electric force exerted on an electrically charged body, which is proportional to the amount of the charge and the electric field strength in which the charged body is placed.
- Decibel (dB):** Ten times the common logarithm of the power ratio or 20 times the common logarithm of voltage ratio.
- Duty cycle:** In a periodical on-off system, ratio of the on time duration to the entire period of time of repetition.
- Electron beam:** Collimated and focused stream of electrons.
- Electron beam coupling:** Electromagnetic coupling between an electron beam and an electric circuit or a transmission line.
- Electron bunching:** Gathering of electrons due to both the velocity modulation and the drifting of electrons.
- Electron gun:** An electronic structure that contains a thermionic cathode, an accelerator, and a focusing electrode to emit an electron beam.
- Electronic countermeasure:** Electronic equipment, system, or procedure to sense, detect, disturb, or destroy a transmitter by detecting the transmitter signals.
- Emissivity:** Ratio of emission current to the anode voltage under the given temperature of the cathode.
- Focuser:** A focusing electrode for an electron steam in a vacuum tube.
- Focusing electrode:** A special purpose electrode or an assembly of electrodes negatively charged to focus the electron beam by pushing electrons in desirable directions.
- Focusing magnetic fields:** Moving electrons are pushed by applied magnetic force or Lorentz force, when the direction and strength of magnetic fields are properly adjusted. It is possible to focus an electron beam in a desired direction. Such magnetic fields are termed the focusing magnetic fields.
- Forward waves:** In a traveling wave tube, microwaves propagate in the same direction with electrons in the electron beam. Electromagnetic waves travel in the positive direction of the coordinate system.
- Frequency bandwidth:** A range of frequencies within which the variation of the gain of the device is less than 3 dB.
- Flicker noise:** Electrical noise current in an electron stream due to stochastic variation of a heated cathode surface; it is inversely proportional to operating frequency of interest, the $1/f$ noise.
- Gain parameter:** Neper gain constant per meter of propagation.
- Hollow beam:** An electron beam with hollow core.
- Immersed flow:** A flow of electrons emitted from an electron gun exposed to the focusing magnetic fields.
- Longitudinal phase velocity:** Phase velocity of microwave propagation in the axial direction of a slow-wave structure of a traveling wave tube.
- Microwave voltage controlled oscillator (MVCO):** A backward wave oscillator (BWO) is an example.
- Neper:** A natural logarithm of a ratio.
- Newton's equation of motion:** The force is equal to a product of the mass and the acceleration.
- Noise:** Electrical noise that is unwanted and/or undesirable electrical variations.

- Noise temperature:** For a passive device, it is the ratio of noise power to the product of Boltzmann's constant and operating frequency bandwidth. For an amplifier, it is the ratio of output noise power to a product of Boltzmann's constant, power gain, and operating frequency bandwidth.
- Noise figure:** Ratio of actual noise output of an actual two-port network to fictitious ideal noise output of an ideal network that does not produce noise within the circuit but has transferable noise from the input. The ratio of the input S/N ratio to the output S/N ratio.
- Permittivity:** A ratio of the electric flux density to the electric field strength.
- Partition noise:** Electrical noise generated within a vacuum tube when the electron stream hits obstacles and is divided.
- Pierce gun:** An electron gun with which the focusing electrode is tilted 67.5° from the axis of the electron beam and the accelerator anode is also tilted forward to produce a rectilinear flow of an electron beam.
- Pitch angle of a helix:** An angle between a tangent to the helix and another tangent to a cylinder that contains the helix and is perpendicular to the cylinder axis at a common tangential point on the helix.
- Power gain:** A ratio of the output power to the input power. The ratio can be expressed by a number, in decibel, or in neper.
- Richardson–Dushman equation:** An equation of electron saturation emission current density from a heated cathode. It states that the emission electron current density is proportional to the square of the cathode temperature and an exponential of negative constant times a reciprocal of the absolute temperature of the cathode. The proportionality constant is 6.02×10^{-3} and the negative constant depends on the cathode material.
- Sensitivity:** Amount of input signal power to a two-port network that produces a designed signal-to-noise ratio at the output.
- Shot noise:** Electrical noise presents an electron current due to stochastic modulation of electronic emission from the source.
- Slow-wave structure:** A short microwave transmission line in a traveling wave tube in which the longitudinal phase velocity of traveling microwave is slowed down to almost equal speed of electrons in the interacting electron beam of the tube.
- Tangential sensitivity:** Amount of input signal power to a two-port network to produce the output signal-to-noise power ratio unity.
- Thermal noise:** Electric noise power that is due to heat. It is equal to the product of Boltzmann's constant, the absolute temperature of the subject, and the operating frequency bandwidth.
- Thermionic emission:** Electron emission from a heated cathode.
- Traveling wave:** Electromagnetic waves propagating into a specified direction coherently.
- Traveling wave tube (TWT):** A microwave amplifier vacuum tube that is based on interaction between the traveling microwave and the electron beam.
- Velocity modulation:** A process that induces variation of velocities to electrons in an electron beam with otherwise uniform velocity.
- Voltage gain:** Ratio of the output voltage of an amplifier to the input voltage to the amplifier. The voltage gain is expressed by a number, in decibel, or in Neper.
- Work function:** Amount of energy necessary to take out an electron from a material.

6.4 Other Microwave Vacuum Devices

T.K. Ishii

6.4.1 Introduction

Thus far in Sections 6.1–6.3 planar microwave tubes, **klystrons**, and traveling wave tubes in microwave vacuum devices have been covered. There are a great number of other microwave devices available, and it is almost impossible to cover every available microwave vacuum device in detail. Therefore, in this chapter, some selected microwave vacuum devices are presented in some detail. These microwave devices include **magnetrons**, **backward wave oscillators (BWO)**, **carcinotrons**, **twystrons**, **laddertrons**, **ubitrons**, **gyrotrons**, **helical beam tubes**, **amplitrons**, and **platinotrons** (Ishii, 1989).

6.4.2 Magnetrons

Magnetrons are used for high-power applications. The device is widely used for radar transmitters and as a power source for microwave heating processes. Though one of the most common types of magnetron is a radial magnetron, the linear magnetrons and inverted magnetrons may also be used depending on the applications. Both magnetrons and inverted magnetrons are oscillators, and the linear magnetron is an amplifier.

Schematic diagrams of cross-sectional views of linear magnetrons are shown in Fig. 6.19(a) and Fig. 6.19(b). In the **O-type linear magnetron** in Fig. 6.19(a), the **electron beam** emitted from the **electron gun** is focused by a longitudinally applied DC magnetic flux density B as is the case in the traveling wave tube. In Fig. 6.19(a), both the anode and the **collector** are electropositive against the electron gun and the **sole**. The sole is a nonemitting cathode. In practice, for safety reasons, the anode block is grounded and the cathode and the sole are biased to a high negative voltage. In this biasing arrangement, the elementary trajectory of an electron in an O-type linear magnetron is a helix. But as a whole, it is considered to be a uniform flow electron beam if there is no microwave excitation. As seen from Fig. 6.19(a), the anode block has a number of slots. These slots are cut one-quarter wavelength deep. The slots are quarter-wavelength cavity resonators. The structure is a series of microwave **cavity resonators** coupling to an electron beam. This is similar to the multicavity klystron presented in Chap. 31. Therefore, the principles of a **linear magnetron** are similar to the principles of a multicavity klystron. The input microwaves impart velocity modulation to the electron beam and distributes microwave energy to the first cavity and following cavities. The **velocity modulated** electrons are bunched, and the tightly bunched electrons induce a large amount of amplified microwave energy at the output cavity. The energy in the output is coupled to the output circuit. Usually a linear magnetron is an amplifier of high gain, but it is also an amplifier of a narrow frequency bandwidth.

When the orientation of the electron gun and the direction of focusing magnetic flux density B are changed, as shown in Fig. 6.19(b), the magnetron is termed as **M-type linear magnetron**. In this arrangement, the elementary trajectory of an electron in the beam is a cycloid.

FIGURE 6.19 Cross-sectional view of linear magnetrons: (a) O-type linear magnetron, (b) M-type linear magnetron.

If the slots in the anode are not resonating, the tube is no longer a linear magnetron. If many nonresonating slots are cut in the anode block, then the device is a traveling wave tube. This type of traveling wave tube is termed a **crossed field amplifier (CFA)** or **crossed field device (CFD)**.

If the anode block of M-type linear magnetron is bent and made re-entrant, in which the end of the structure is connected to the beginning of the structure as shown in Fig. 6.20, then the magnetron is termed a **radial magnetron**. In the radial magnetron, there is no nonemitting sole. The cathode is an emitting hot cathode. Electrons emitted from the hot cathode are pulled toward the anode by the radial electric field. Therefore, the radial force is expressed in a cylindrical coordinate coaxially set up with the radial

FIGURE 6.20 Cross-sectional view of a radial linear magnetron.

magnetron as shown in Fig. 6.20. In Ishii (1989)

$$m \left\{ \frac{\partial^2 r}{\partial t^2} - r \left(\frac{\partial \phi}{\partial t} \right)^2 \right\} = q \left\{ \frac{\partial V}{\partial y} - Br \frac{\partial \phi}{\partial t} \right\} \quad (6.83)$$

where (r, ϕ, z) is a cylindrical coordinate of an electron in a radial magnetron, m is an electronic mass 9.1091×10^{-31} kg, q is the electronic charge 1.6021×10^{-19} C, V is the electric potential in volts at (r, ϕ, z) , and B is the DC magnetic flux density in tesla at (r, ϕ, z) . The first term of Eq. (6.83) is the radial force toward the anode, which inwardly counteracted the centripetal force in the second term of Eq. (6.83). The third term is the electric radial force pushing the electron toward the anode and the fourth term of Eq. (6.83) is the magnetic force counteracting inwardly against the electric force.

The tangential force on the electron at (r, ϕ, z) is (Ishii, 1989)

$$r \left\{ q \frac{1}{r} \frac{\partial V}{\partial \phi} + qB \frac{\partial r}{\partial t} \right\} = \frac{\partial}{\partial t} \left(r m r \frac{\partial \phi}{\partial t} \right) \quad (6.84)$$

The first term on the left-hand side of Eq. (6.84) is the torque due to the tangential electric force of an electron at (r, ϕ, z) against the center axis. The second term on the left-hand side of Eq. (6.84) is the torque against the center axis due to the tangential magnetic force acting on the electron moving radially. The right-hand side of Eq. (6.84) is the time rate of change of the torque of the electron at (r, ϕ, z) against the center axis due to tangential motion of the electron.

The energy of the electron at (r, ϕ, z) is (Ishii, 1989)

$$\frac{1}{2} m \{ \dot{r}^2 + (r \dot{\phi})^2 \} = qV \quad (6.85)$$

The first term on the left-hand side is the radial **kinetic energy** and the second term is the tangential kinetic energy. The right-hand side of Eq. (6.85) is the electric potential energy of the electron at the specific location (r, ϕ, z) . Therefore, the electric potential V in Eqs. (6.83–6.85) should contain a solution of **Poisson's equation** and a solution of **Helmholtz's wave equation**. Since the work is very involved, however, most designers use a solution of **Laplace's equation** only for the first approximation. Solving Eqs. (6.83–6.85), the trajectory of an electron in a radial magnetron will be known. As a result, electrons emitted from the cathode surface in all directions circle around the cathode forming an **electron cloud**. The relationship between the electron cloud and the cavities in the anode of a radial magnetron is similar to the electron beam in the M-type linear magnetron to its cavity resonators. A small microwave voltage induced at the opening of the cavity resonator generated from background electrical noise, such as **thermal noise**, **shot noise**, **partition noise**, and **flicker noise**, produces velocity modulation to the circulating electron cloud. Because of this velocity modulation, **electron bunching** is produced. The bunched electrons in a radial magnetron are termed the **electron pole**. In most magnetrons, the number of electron poles formed is

$$n = \frac{N}{2} \quad (6.86)$$

where N is the number of cavity resonators in the anode block of the radial magnetron.

As the electron poles rotate around the cathode, the electron bunching gets tighter. The high-density electron pole produces a high microwave voltage across the opening or the gap of the cavity resonator. Thus, if an output transmission line such as a coaxial line or a waveguide is connected to one of the cavity resonators as shown in Fig. 6.20, the induced microwave voltage is coupled to the outside of the magnetron. Thus, a radial magnetron is inherently an oscillator. On the other hand, a linear magnetron is inherently an amplifier.

A radial magnetron is, if the axial magnetic field is not applied, just a vacuum diode. If an anode voltage is applied, the anode current flows. If the axial magnetic field is applied, the anode current keeps flowing approximately the same amount as initially, as long as the anode voltage is kept constant. Then, at a certain value of magnetic flux density B_c , the anode current will drop to extremely small value. This indicates that the magnetic force has become so large that the **electron orbit** has been bent excessively. Electrons cannot

reach the anode with this amount of magnetic force. The magnetic flux density that causes the anode current to drop sharply is termed the **cutoff magnetic flux density**. Magnetron oscillation is frequently found near the cutoff magnetic flux density. Oscillation under extremely small anode current is one of the features of a radial magnetron that provides high efficiency. The relationship among the anode voltage V_a , the cutoff magnetic flux density B_c , the radius of the cathode r_c , and the radius of the anode r_a is given by (Ishii, 1989)

$$B_c = \sqrt{45.5V_a} \frac{r_a}{r_a^2 - r_c^2} \quad (6.87)$$

The high efficiency of radial magnetrons stems from this low operating anode current as well as the **re-entrant use** of electron poles. In practice, whenever the high efficiency and high-power generation of microwave power is considered, magnetrons are the first to be considered. Radar and industrial and domestic microwave ovens are examples of applications of radial magnetrons.

In the radial magnetron shown in Fig. 6.20, the output waveguide is connected to only one of the cavity resonators in the anode block. The output transmission line can be connected to all of the cavity resonators if the cavity resonators form a coaxial configuration with the outer jacket to which the output transmission line is connected, as shown in Fig. 6.21(a). This type of magnetron is termed the **coaxial magnetron**. Microwaves generated by the rotating electron poles at the anode vane cavity resonators are coupled to the output coaxial cavity through intervane tip gaps and slits cut on the anode ring between the vane cavities, as shown in Fig. 6.21(a). All vane cavity resonators are thus connected to a coaxial cavity consisting of the conducting outer jacket and the anode ring. Thus, if a transmission line is coupled to this coaxial cavity, generated microwaves are coupled to the output circuit through the output transmission line in a side way as shown in Fig. 6.21(a). An alternate coupling configuration to the output is in the direction perpendicular to the plane of the drawing. The outer jacket is tapered to an outer conductor of the output coaxial line and the slitted anode ring is tapered into the center conductor of the output coaxial line. The side opposite to the output is terminated by a conducting endplate at an impedance matching location, which is approximately one-quarter wavelength from the active part of the coaxial magnetron.

To obtain a large emission current for higher power, the electron emitting hot cathode can be the inside wall of the outermost cylinder as shown in Fig. 6.21(b). This type of coaxial magnetron is termed the **inverted coaxial magnetron**. Microwave cavity resonators formed from a number of anode vanes are tied together with a cylindrical slitted anode ring. Through the slits in the slitted anode ring, microwave power induced in the vane cavity resonators is coupled to the central coaxial cavity, which is formed from the slitted anode ring and the center conductor (which is not emitting electrons). Therefore, if the center conductor is tapered to a center conductor of an output coaxial line and the slitted anode ring is tapered into an outer conductor of the output coaxial line, then the output will be taken from the coaxial line in the direction perpendicular to the plane of the drawing. The side opposite to the output coaxial line of the inverted coaxial magnetron is terminated by a conducting endplate at an impedance matching location, which is approximately one-quarter wavelength away from the active part of the inverted coaxial magnetron.

6.4.3 Backward Wave Oscillators

In a traveling wave tube, if the microwave signal to be amplified is propagating in the slow-wave structure backwardly to the direction of the electron beam, as shown in Fig. 6.22(a), the device is termed a **backward wave oscillator (BWO)**. When the electron beam is focused through the use of longitudinal magnetic flux density as shown in Fig. 6.22(a), the device is *O*-type *BWO*. Regardless the direction of microwave propagation in the slow-wave structure, electrons are velocity modulated in the neighborhood of the electron gun and bunched as the electrons travel toward the collector, and the bunched electrons induce a large microwave voltage in the slow-wave structure at a location near the collector. Microwaves traveling backward carry positive feedback energy toward the electron gun for stronger velocity modulation and bunching. Thus, the system is inherently an oscillator rather than a stable amplifier. It can be used as a high-gain amplifier, but usually it is used as a microwave voltage controlled oscillator (MVCO). The input

FIGURE 6.21 Schematic diagrams of a co-axial magnetron and an inverted coaxial magnetron: (a) coaxial magnetron, (b) inverted coaxial magnetron.

is typically terminated by an impedance-matched reflectionless termination, as shown in Fig. 6.22. The oscillation frequency is determined by the speed of electrons and the time constant of the feedback. The speed of electrons is controlled by the anode voltage.

The BWO can take a form of an *M-type radial BWO* as shown in Fig. 6.22(b). The direction of electron pole motion and the direction of microwave propagation along the annular re-entrant type slow-wave structure are opposite to each other. It should be noted that the depth of the slits cut in the inner surface of the anode is very shallow and it is much less than one-quarter wavelength deep. In other words, the slits are not in resonance or the slits are not cavity resonators as in the case of magnetrons; rather the slits are not resonating, as is in the case of traveling wave tubes. In the *M-type radial BWO*, the electron beam is focused by a magnetic flux density applied perpendicular to the electron beam, as seen from Fig. 6.22(b). Again

FIGURE 6.22 Schematic diagrams of backward wave oscillators: (a) O-type linear BWO, (b) M-type radial BWO.

the input terminal of a M-type radial BWO is usually terminated by an impedance-matched reflectionless termination. An M-type radial BWO is sometime termed the carcinotron by a trade name. A key feature of the carcinotron is its wide voltage tunability over a broad frequency range.

6.4.4 Strap-Fed Devices

In a radial magnetron, sometimes every other pole of the anode resonators is conductively tied for microwave potential equalization, as shown in Fig. 6.23(a). These conducting tie rings are termed **straps**; this technique of using strap rings is termed *strapping*. Strapping ensures good synchronization of microwaves in the magnetron’s resonators with the rotation of electron poles.

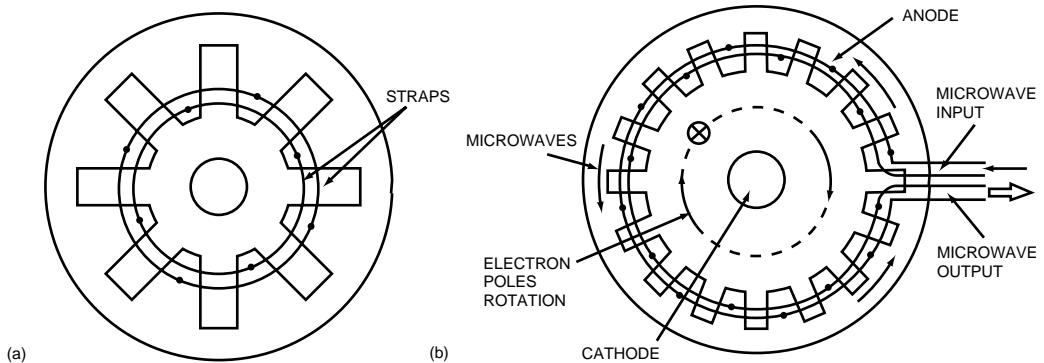

FIGURE 6.23 Strapped devices: (a) strapped radial magnetron, (b) nonre-entrant strapping of a BWO.

The technique of strapping is extended and modified for an M-type radial BWO, as shown in Fig. 6.23(b). Strapping rings tie every other pole of the radial slow wave structure, as in the case of a strapped radial magnetron, but the strapping rings are no longer re-entrant. Microwave energy to be amplified is fed to the strap at one end and the amplified output can be taken out from the other end. This type of electron device is termed the strap-fed device.

If an M-type radial BWO is strapped, usually it does not start oscillation by itself. But if microwaves are fed through the strap from the outside using an external microwave power source to the microwave input, then the oscillation starts and even if the exciter source is turned off, the oscillation continues. This type of M-type radial BWO is termed the **platinotron** (Ishii, 1989).

In a platinotron, if the output of the tube is fed back to the input through a high-Q cavity resonator, it becomes a self-starting oscillator. The oscillation frequency is stabilized by the high-Q cavity resonator. This type of high-power frequency stabilized strapped radial BWO is termed the *stabilotron* (Ishii, 1989). The operating power levels are at kilowatt and megawatt levels.

Performance of a platinotron depends on, among other things, the design of the slow-wave structure. For example, the interdigital slow-wave structure as shown in Fig. 6.23 has a limited power handling capability and frequency bandwidth. Design of a slow-wave structure with greater power handling capacity and stable with broader frequency bandwidth is possible. For example, instead of an anode with an interdigital slow-wave structure, the anode could be made of an annular open conducting duct loading with number of pairs of conducting posts across the open duct. Strapping is done at every other tip of the pairs of conducting posts. This type of strapping loads the slow-wave structure, stabilizing it and preventing oscillation. The structure of the anode with an annular duct and pairs of posts increases the power handling capability. This type of loaded radial BWO is termed the *amplitron* (Ishii, 1989; Liao, 1988). The amplitron is capable of amplifying high-power microwave signals with pulses and **continuous waves**. It is used for long-range pulsed radar transmitter amplifiers and industrial microwave heating generators. The operating power levels are at kilowatt and megawatt levels.

6.4.5 Modified Klystrons

Instead of using a multiple number of cavity resonators as in a multicavity klystron, the cavities may be combined to a single cavity, as shown in Fig. 6.24(a). Multiple cavities are hard to fabricate at millimeter wavelengths. A multimode single cavity as shown in Fig. 6.24(a) is more convenient. Beam coupling is accomplished through the use of ladder-shaped grids, as shown by the dashed lines with the single cavity in Fig. 6.24(a). This type of klystron is termed the laddertron (Ishii, 1989). There will be a standing wave on the ladder line. Velocity modulation is performed in the ladder structure near the electron gun and bunching begins near the middle of the electron stream. Catching is done in the ladder structure near the collector. Since this is only a one-cavity resonator, there is a built-in positive feedback, and the oscillation starts like a reflex klystron, which has a single cavity. At millimeter wavelengths, a dominant mode cavity resonator becomes very small and loses its power handling capability. In a laddertron, the cavity resonator

FIGURE 6.24 Schematic diagrams of modified klystrons: (a) laddertron, (b) twystron.

is a multiple higher mode resonator. Therefore, the quality factor Q of the cavity is high and the size of the cavity resonator is reasonably large. It can handle tens of watts of power at frequency as high as 50 GHz.

The catcher of a two-cavity klystron amplifier can be replaced by the slow-wave structure of a traveling wave tube, as shown in Fig. 6.24(b). This type of tube is termed the *twystron* (Ishii, 1989). The slow-wave structure provides a broader frequency bandwidth than a regular two-cavity klystron. A microwave input fed into the buncher cavity produces velocity modulation to the electron beam. The electron beam is bunched while drifting, and the bunched electrons induce a microwave voltage in the microwave slow-wave structure. The electron beam is focused by the use of longitudinally applied magnetic flux density B .

Commercial twystrons operate in the **S-band** (2.6–3.95 GHz) and **C-band** (3.95–5.85 GHz), and are used for pulsed radar transmitter power amplifiers. The pulsed peak output ranges from 1 to 7 MW with a pulse width of 10–50 μ s. This results in an average output power in the range of 1–28 kW with efficiency of 30–35%. The tube requires a beam voltage of 80–117 kV and a beam current of 45–150 A. The microwave input power to drive the amplifier twystron is in a range of 0.3–3.0 kW (Liao, 1988).

6.4.6 Electron Gyration Devices

As seen in an O-type traveling wave tube, electron trajectory of an electron in an electron beam focused by a longitudinally applied magnetic field is a helix. If the electron velocity, **electron injection angle** and applied longitudinal magnetic flux density are varied, then an electron beam of helical form with different size and pitch will be formed. A coil-shaped electron beam will be produced by adjusting the acceleration voltage, applied magnetic flux density, and the electron injection angle to the focusing magnetic field. The coil of the electron beam can be a simple single coils; or, depending on the adjustment of the aforementioned three parameters, it can be an electron beam of a double coil, or a large coil made of thin small coils. In the case of the double-coil trajectory, the large coil-shaped trajectory is termed the **major orbit** and smaller coil trajectory is termed the **minor orbit**.

If a single coil-shaped electron beam is launched in a waveguide as shown in Fig. 6.25, then microwaves in the waveguide interact with the helical beam. This type of vacuum tube is termed the helical beam tube (Ishii, 1989). A single-coil helical beam is launched into a TE₁₀-mode (Transverse Electric one-zero mode) rectangular waveguide. Inside of the waveguide, microwaves travel from right to left and the helical beam travels in an opposite direction. Therefore, the microwaves–electron beam interaction is the **backward wave interaction**. If the microwave frequency, the focusing magnetic flux density B , and the acceleration voltage V_a are properly adjusted, this device will function as a backward wave amplifier. Electrons in the helical beam interact with the transverse microwave electric fields and velocity modulated at the left-hand side of the waveguide as the beam enters into the wave-guide. The velocity modulated electrons in the helical beam are bunched as they travel toward the right. If the alternating microwave electric field synchronizes its period and phase with the helical motion of bunched electrons so that the electrons always receive retardation from microwave transverse electric fields, then the electrons loose their kinetic energy and microwave gains in the electric field energy by the **kinetic energy conservation principles**. Thus, the amplified microwave power emerges at the waveguide output at the left, since the microwaves travel backward. The amplified microwaves at the left give strong velocity modulation to the helical electron beam at the left.

In Fig. 6.25, if the microwave input port and the output port are interchanged with each other, then the system becomes a forward wave amplifier. Such a forward wave amplifier is termed a peniotron (Ishii, 1990).

FIGURE 6.25 Schematic diagram of a helical beam tube.

FIGURE 6.26 Schematic diagram of gyrotrons: (a) single coiled helical beam gyrotron, (b) electron trajectory of double-coil helical beam gyrotron.

If the electron gun is modified to a side emitting cathode and the waveguide is changed to **TE₁₁-mode** (Transverse Electric one-one mode) oversized circular waveguide as shown in Fig. 6.26(a), this type of tube is termed the gyrotron. In this gyrotron, both ends of the waveguide are open and there are sufficient reflections in the waveguide for positive feedback. The gyrotron is the **forward wave oscillator**. It is capable of generating extremely high power at extremely high frequency. The principles of operation are identical to the helical beam tubes.

If the anode voltage and the focusing flux density are readjusted, the electron beam is made into a double helical coil as shown in Fig. 6.26(b), and the oversized circular waveguide is operated in **TE₀₁ mode** (Transverse Electric zero-one mode), then a *double-coil helical beam gyrotron* is formed. In the TE₀₁ mode, microwave transverse electric fields are concentric circles. Therefore, the tangential electric fields interact with electrons in the small coil trajectory. The alternating tangential microwave electric fields are made to synchronize with the tangential motion of electrons in the minor coil-shaped trajectory. Thus, electron velocity modulation takes place near the cathode and bunching takes place in the middle of the tube. Microwave kinetic energy transfer takes place as beam approaches the right. The focusing magnetic flux density B is applied only in the **interaction region**. Therefore, if electron beam comes out of the interaction region, it is defocused and collected by the anode waveguide as depicted in Fig. 6.26(b). If the circular waveguide is operated in an oversized TE₁₁ mode, with the double-coil helical beam, then it is termed the **tornadotron** (Ishii, 1989). Microwave–electron interaction occurs between the parallel component of tangential motion of the small helical trajectory and the TE₁₁-mode microwave electric field. If the phase of microwave electric field is decelerating bunched electrons, then the lost kinetic energy of the bunched electrons is transferred to the microwave signal and the oscillation starts.

In a single-coiled helical beam gyrotron as shown in Fig. 6.26(a), frequency of the helical motion of electrons is the **cyclotron frequency** and it is given by (Ishii, 1990)

$$f_c = \frac{qB}{2\pi m} \quad (6.88)$$

where q is the charge of the electron, 1.6021×10^{-19} C; B is the longitudinal magnetic flux density in tesla; and m is the mass of an electron, 9.1091×10^{-31} kg. The amount of necessary magnetic flux density

FIGURE 6.27 The gyrokystron amplifier.

to produce desired cyclotron frequency f_c is, then (Ishii, 1990)

$$B = \frac{2\pi m f_c}{q} \tag{6.89}$$

The radius of curvature r of the helical motion is given by (Ishii, 1990)

$$r = \frac{u_\phi}{2\pi f_c} \tag{6.90}$$

where u_ϕ is the tangential velocity of the electron and f_c is the cyclotron-frequency of the electron.

In the double coiled helical beam gyrotron, the cycloidal frequency f of the double coiled trajectory is calculated to be

$$f = \frac{qB}{2\pi mc} \tag{6.91}$$

This cycloidal frequency must be made equal to the operating microwave frequency.

Gyrotrons are capable of producing high microwave power on the order of 100 kW at microwave frequency on the order of 100 GHz.

There are a family of gyrotrons. Gyrotrons with a single waveguide, as shown in Fig. 6.26 are termed **gyromonotron**. There are many other variations in gyrotrons (Coleman, 1982; McCune, 1985).

When the circular waveguide is split as shown in Fig. 6.27, the tube is termed the **gyrokystron amplifier**. Both waveguides resonate to the input frequency. There are strong standing waves in both waveguide resonators. The input microwave signal to be amplified is fed through a side opening to the input waveguide resonator. This is the buncher resonator as in the case of a klystron. This buncher resonator gives velocity modulation to gyrating electrons in the double helical coil-shaped electron beam. There is a **drift space** between the buncher resonator and the **catcher** resonator at the output. While drifting electrons bunch and bunched electrons enter into the output waveguide catcher resonator, electron speed is adjusted in such a way that electrons are decelerated by the resonating microwave electric field. The lost kinetic energy in bunched electrons is transformed into microwave energy and microwaves in catcher resonator are amplified. The amplified power appears at the output of the tube.

If the waveguide is an unsplit one piece waveguide that is impedance matched and not resonating, as shown in Fig. 6.28, the tube is termed the **gyrotron traveling wave tube amplifier**. In this tube the input microwaves are fed through an opening in the waveguide near the electron gun, as shown in Fig. 6.28. Microwaves in the waveguide are amplified gradually as they travel toward the output port by interacting with the double coiled helical electron beam, which is velocity modulated and bunched. There are no significant standing waves in the waveguide. Microwaves grow gradually in the waveguide as they travel toward the output port by interaction with electrons.

If the electron gun is moved to the side of the waveguide and the microwave power is extracted from the wave-guide opening in proximity to the electron gun, as shown in Fig. 6.29, then it is termed a **gyrotron**

FIGURE 6.28 Gyrotron traveling wave tube amplifier.

backward oscillator. The principle is similar to the backward wave oscillator; the process of velocity modulation, drifting, bunching, and catching are similar to the klystron. Microwave energy induced in the waveguide travels in both directions. The circuit is adjusted to emphasize the waves traveling in a backward direction. The backward waves become the output of the tube and, at the same time, they carry the positive feedback energy to the electrons just emitted and to be velocity modulated. Thus, the system goes into oscillation. This is a backward wave oscillator in a gyrotron form.

If the waveguide is split into two again, but this time the input side waveguide is short and the output side waveguide is long, as shown in Fig. 6.30, then the tube is termed a **gyrotwystron** amplifier. The input side waveguide resonator is the same as the input resonator wave-guide of a gyroklystron, as shown in Fig. 6.27. There are strong standing waves in the input bunched **waveguide** resonator. There is no drift space between the two waveguides. The output side waveguide is a long impedance-matched waveguide and there is no microwave standing wave in the waveguide. This is a traveling wave waveguide. As microwaves travel in the waveguide, they interact with bunched electrons and the microwaves grow as they travel toward the output port. This is a combination of the gyroklystron and gyrotron traveling wave tube amplifier. Therefore it is termed the gyrotwystron amplifier.

6.4.7 Quasiquantum Devices

In a gyrotron, if electrons are accelerated by extremely high voltage, electrons become *relativistic*, or the mass of an electron becomes a function of the velocity as

$$m = \frac{m_0}{\sqrt{1 - \left(\frac{c}{v}\right)^2}} \tag{6.92}$$

where m is the relativistic mass of an electron, m_0 the static mass of an electron, c the speed of light in vacuum, and v the speed of the electron in question.

FIGURE 6.29 Gyrotron backward oscillator.

FIGURE 6.30 Gyrotwystron amplifier.

The energy states of electrons are specified by a set of **quantum numbers**, and the transition of energy state occurs only between the energy state described by a set of quantum numbers. The set of quantum numbers specify a high-energy orbit of an electron and a low-energy orbit of an electron. With the interaction with the waveguide or waveguide resonator at the cyclotron frequency, if the electrons are stimulated to induce a downward transition of high-energy orbit electrons to the low-energy orbit, then microwave radiation results. This is a *cyclotron frequency maser* (Ishii, 1989).

Another **quasiquantum vacuum device** is the *free electron laser*, or the *ubitron*. A schematic diagram of a ubitron is shown in Fig. 6.31. A high-speed relativistic electron beam is emitted from an electron gun focused by a longitudinally applied DC magnetic flux density B and periodically deflected by deflection magnetics. These repetitious deflections create among relativistic electrons high-energy states and low-energy states. If the high-energy electrons in the deflection waveguides are stimulated by the resonance frequency of the waveguide resonator, then the downward transition (which is the transition of an energy state of electrons in the high-energy state to the low-energy state) occurs. Then, there will be microwave emissions due to the energy transition at the stimulation frequency. The emission-frequency is

$$f = \frac{\Delta E}{h} \tag{6.93}$$

where ΔE is the energy difference between the high-energy state and the low-energy state in Joule and h is Planck's constant, which is 6.6256×10^{-34} J-s. The operating frequency of ubitrons are in millimeter wave or submillimeter wave frequencies and operate at a high-power level.

FIGURE 6.31 Schematic diagram of a ubitron.

6.4.8 Features of other Microwave Vacuum Devices

It is interesting to note that no matter what kind of microwave vacuum device, most electron devices function based on the principles of velocity modulation, electron bunching, and electrodynamic induction for microwave generation and amplification. The only microwave vacuum devices not based on velocity modulation, electron bunching, and electrodynamic induction are monolithically developed solid-state vacuum diode or triode. These devices are microscopically small and incorporate cathodes. The operating electric fields are strong enough for cold emission from the cathode.

Defining Terms

Amplitron: A strap fed radial crossed field microwave amplifier.

Backward wave interaction: Interaction between backward propagating microwave electric fields against an electron stream and the electron in the electron beam. The direction of propagating microwaves and the direction of motion of electrons in the beam are opposite each other.

Backward wave oscillators (BWO): A microwave oscillator tube that is based on a backward wave interaction.

Carcinotron: A forward radial traveling wave amplifier in which microwave signals are fed to the radial slow-wave structure.

Catcher: A cavity resonator of a multicavity klystron proximate to the collector to catch microwave energy from the bunched electrons.

Cavity resonator: A resonating space surrounded by conducting walls. An electromagnetic wave energy storage device.

C-band: Microwave frequency range, 3.95–5.85 GHz.

Coaxial magnetron: A radial magnetron where the anode and cathode are gradually transformed into a coaxial line.

Continuous wave: A wave of a constant and uninterrupted amplitude, unmodulated waves, carrier waves.

Collector: An electrode at the end of the electron beam in a microwave vacuum tube to collect electrons finished with the electronic processes.

Crossed field amplifier (CFA): Radial or linear traveling wave amplifier where radial or transverse DC accelerating electric fields are perpendicular to axial or longitudinal DC magnetic fields, respectively.

Crossed field devices (CFD): Radial or linear forward traveling wave amplifier or backward wave oscillator where radial or transverse DC accelerating electric fields are perpendicular to axial or longitudinal DC magnetic fields, respectively.

Cutoff magnetic flux density: In magnetrons operated under a constant anode voltage, a value of magnetic flux density at which the anode current decreases abruptly.

Cyclotron frequency: A frequency of electron oscillation in a cyclotron. A frequency of circular motion of an electron under magnetic fields applied perpendicularly to the plane of the circular motion.

Drift space: Space where electrons move only due to their inertia.

Duty cycles: A ratio of activated time duration to the whole period in a periodically activated system.

Electron beam: A focused stream of electrons.

Electron bunching: A gathering of electrons as a result of velocity modulation and drifting.

Electron cloud: A gathering of electrons due to thermionic emission, space charge effect, Coulomb force, and Lorentz force by applied electric and magnetic fields, respectively.

Electron gun: A source of electron beam that shoots out electron beam in a specified direction in a focused and collimated fashion. It contains a hot cathode, accelerating anode, and focusing electrodes.

Electron injection angle: An angle between injected electron beam and focusing magnetic fields.

Electron orbit: Trajectory of an electron motion.

Electron pole: In a radial magnetron, gathering of electrons formed by tangential velocity modulation and the electromagnetic fields. It rotates around the cathode.

- Flicker noise:** An electrical noise current contained in a thermal emission current due to stochastic change on conditions of cathode surface. For example in case of the $1/f$ noise, the noise power is inversely proportional to the operating frequency of interest.
- Forward wave oscillator:** A traveling wave amplifier with a positive feedback.
- Gyroklystron:** A gyrotron with a catcher waveguide and a buncher waveguide.
- Gyromonotron:** A gyrotron with a single resonating waveguide.
- Gyrotron:** A high-power millimeter wave generator based on transverse interaction on helically gyrating electrons against the millimeter wave electric field that is traveling longitudinally in a waveguide.
- Gyrotron backward wave oscillator:** A gyrotron in which the gyrating helical electron beam and traveling millimeter waves in a waveguide are in opposite directions.
- Gyrotron traveling wave amplifier:** A gyrotron with a matched waveguide. The waveguide carried only forward waves. The gyrating electrons interact with forward millimeter waves only.
- Gyrotwystron:** A gyrotron with a resonating buncher waveguide and a nonresonating traveling wave catcher waveguide.
- Helical beam tube:** A backward wave amplifier based on interaction between a forward helical electron beam launched into a waveguide and backward traveling microwave in the waveguide.
- Helmholtz' wave equation:** A second-order linear differential equation of electric potential, magnetic potential, electric field, magnetic field, or any other field quantities associated with propagating waves and/or standing waves.
- Interaction region:** A region where an electron beam and microwaves transfer energy to each other.
- Inverted magnetron:** A radial magnetron in which the anode structure is at inside and the cathode structure is at outside.
- Kinetic energy:** Energy of motion.
- Kinetic energy conservation principle:** Any change of kinetic energy of an electron is transformed into a change in electric potential energy with which the electron is interacting, and vice versa.
- Klystron:** A microwave vacuum tube amplifier or oscillator that contains buncher cavity or cavities, drift space, and a catcher cavity, among other components.
- Laddertron:** A microwave vacuum tube oscillator with a slow-wave structure coupled to a single-cavity resonator.
- Laplace's equation:** A second-order linear homogeneous differential equation of electric potential or any other function.
- Linear magnetron:** A magnetron in which the cavity resonator loaded anode, a sole (nonemitting cathode), and the electron beam are arranged in rectilinear fashion.
- Magnetron:** A microwave vacuum tube oscillator in which microwaves in a number of cavity resonators interact with bunched electrons in motion rotating or rectilinearly. The basic electron motion is formed by the applied accelerating electric fields and the DC magnetic fields.
- Major orbit:** A larger helical orbit of an electron beam in a gyrotron.
- Minor orbit:** A smaller helical orbit of electron beam in a double-coil electron beam gyrotron.
- M-type linear magnetron:** A magnetron in which the cavity loaded anode, the sole (nonemitting cathode), and the electron beam are arranged in a rectilinear fashion. Focusing DC magnetic fields are applied perpendicularly to both the electron beam and the DC electric fields so that the individual electron orbit is a cycloid.
- O-type linear magnetron:** A magnetron in which the cavity loaded anode, the sole (nonemitting cathode), and the electron beam are arranged in a rectilinear fashion. Focusing DC magnetic fields are applied parallel to the electron beam and perpendicularly to the DC electric fields so that the individual electron orbit is a helix.
- Partition noise:** Electrical noise current in an electron stream in an electron device due to separation of electron stream owing to the electron stream striking an obstacle or obstacles in the device.
- Platinotron:** A strap feed starting radial M-type backward wave oscillator.
- Poisson's equation:** Second-order linear inhomogeneous differential equation of electric potential or other electrical or magnetic functions.

Quantum numbers: A group of integrating constants in a solution of Schroedinger's equation.

Quasiquantum devices: Electron devices in which the principle of the device function is more easily explainable by quantum mechanics than by Newtonian classical dynamics.

Radial magnetron: A magnetron in which the anode and the cathode are arranged in a coaxial radial fashion.

Re-entrant use: Operation of a device in which a majority of the output of the device re-enters the input of the device.

S-band: A range of microwave frequency band, 2.6–3.95 GHz.

Shot noise: Electrical noise current in an electron stream in an electron device due to stochastic emission of electrons from the cathode.

Sole: A nonemitting cathode.

Strap: A conducting ring that ties tips of poles of magnetron or magnetronlike devices in a specified fashion for microwave potential and phase equalization.

Strap fed devices: Strapped magnetronlike devices that operate by microwaves fed through the strapping such as amplatron amplifies and platinotron oscillators.

TE₀₁ mode: A mode of circular or rectangular waveguide excitation in which all microwave electric fields are transverse to the direction of microwave propagation and coaxially concentric.

TE₁₁ mode: A mode of a circular or rectangular waveguide excitation in which all microwave electric fields are transverse to the direction of microwave propagation and approximately parallel to each other ending at the waveguide wall.

Thermal noise: Electric noise power of a device or component that is due to thermal vibration of atoms, molecules, and electrons. It is proportional to a product of the frequency bandwidth of interest and the absolute temperature of the device or component. The proportionality constant is Boltzmann's constant.

Tornadotron: A gyrotron with a simple helical beam.

Ubitron: A millimeter wave high-power quasiquantum generator with relativistically high-speed electron beam. Millimeter waves are generated due to quantum transition between two energy states of electrons and amplified due to the velocity modulation and kinetic energy transfer principles.

Velocity modulation: Production of variation of electron speed in a stream of electrons.

Waveguide: A transmission line that guides electromagnetic waves.

6.5 Operational Considerations for Microwave Tubes

Jerry C. Whitaker

6.5.1 Introduction

Long-term reliability of a microwave power tube requires detailed attention to the operating environment of the device, including supply voltages, load point, and cooling. Optimum performance of the system can only be achieved when all elements are functioning within specified parameters.

6.5.2 Microwave Tube Life

Any analysis of microwave tube life must first identify the parameters that define *life*. The primary *wear out* mechanism in a microwave power tube is the electron gun at the cathode. In principle, the cathode will eventually evaporate the activating material and cease to produce the required output power. Tubes, however, rarely fail because of low emission, but for a variety of other reasons that are usually external to the device.

Power tubes designed for microwave applications provide long life when operated within their designed parameters. The point at which the device fails to produce the required output power can be predicted with some accuracy, based on design data and in-service experience. Most power tubes, however, fail because of mechanisms other than predictable chemical reactions inside the device itself. External forces, such as transient overvoltages caused by lightning, cooling system faults, and improper tuning more often than not lead to the failure of a microwave tube.

6.5.3 Life-Support System

Transmitter control logic is usually configured for two states of operation:

- An *operational level*, which requires all of the life-support systems to be present before the high-voltage (HV) command is enabled
- An *overload level*, which removes HV when one or more fault conditions occur

The cooling system is the primary life-support element in most RF generators. The cooling system should be fully operational before the application of voltages to the tube. Likewise, a cool-down period is usually recommended between the removal of beam and filament voltages and shut-down of the cooling system.

Most microwave power tubes require a high-voltage removal time of less than 100 ms from the occurrence of an overload. If the trip time is longer, damage may result to the device. **Arc detectors** are often installed in the cavities of high-power tubes to sense fault conditions, and shut down the high-voltage power supply before damage can be done to the tube. Depending on the circuit parameters, arcs can be sustaining, requiring removal of high voltage to squelch the arc. A number of factors can cause RF arcing, including

- Overdrive condition
- Mistuning of one or more cavities
- Poor cavity fit (applies to external types only)
- Under coupling of the output to the load
- Lightning strike at the antenna
- High voltage standing wave ratio (VSWR)

Regardless of the cause, arcing can destroy internal elements or the vacuum seal if drive and/or high voltage are not removed quickly. A lamp is usually included with each arc detector photocell for test purposes.

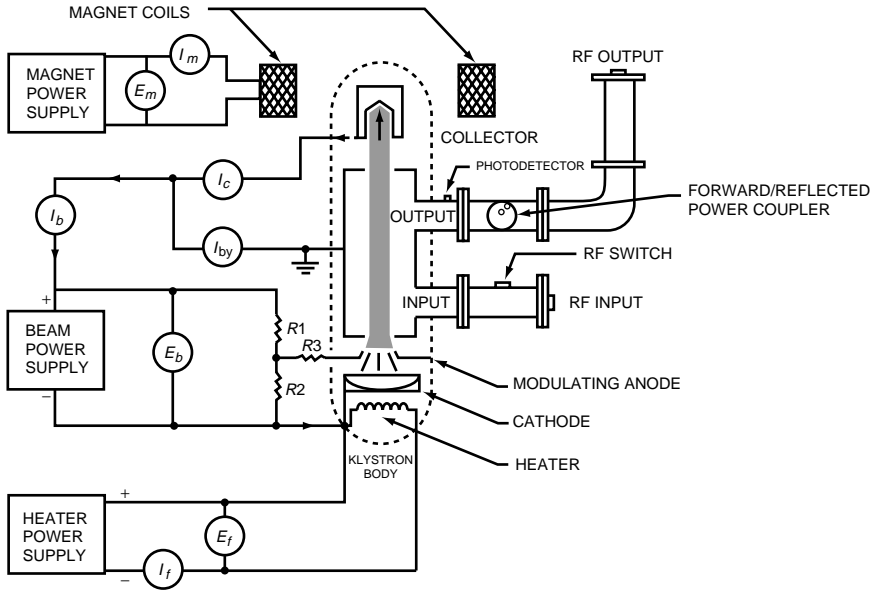

FIGURE 6.32 Protection and metering system for a klystron amplifier.

Protection Measures

A microwave power tube must be protected by control devices in the amplifier system. Such devices offer either visual indications, aural alarm warnings, or actuate interlocks within the system. Figure 6.32 shows a klystron amplifier and the basic components associated with its operation, including metering for each of the power supplies. Other types of microwave power devices use similar protection schemes. Sections of coaxial transmission line, representing essential components, are shown in the figure attached to the RF input and RF output ports of the tube. A single magnet coil is shown to represent any coil configuration that may exist; its position in the drawing is for convenience only and does not represent the true position in the system.

Heater Supply

The heater power supply can be either AC or DC. If it is DC, the positive terminal must be connected to the common heater-cathode terminal and the negative terminal to the heater terminal. The amount of power supplied to the heater is important because it establishes the cathode operating temperature. The temperature must be high enough to provide ample electron emission but not so high that emission life is jeopardized. The test performance sheet accompanying each tube lists the proper operating values of heater voltage and current for that tube. Heater voltage should be measured at the terminals of the device using a true-rms-reading voltmeter.

Because the cathode and heater are connected to the negative side of the beam supply, they must be insulated to withstand the full beam potential.

Beam Supply

The high-voltage **beam supply** furnishes the DC input power to the klystron. The positive side of the beam supply is connected to the body and collector of the klystron. The negative terminal is connected to the common heater-cathode terminal. Never connect the negative terminal of the beam supply to the heater-only terminal because the beam current will then flow through the heater to the cathode and cause premature heater failure. The voltmeter, E_b in Fig. 6.32, measures the beam voltage applied between the cathode and the body of the klystron.

Current meter I_c measures collector current, typically 95% or more of the total device current. Current meter I_{by} measures **body current**. An interlock should interrupt the beam supply if the body current exceeds a specified maximum value.

The sum of the body current I_{by} and collector current I_c is equal to the beam current I_b , which should stay constant as long as the beam voltage and modulating anode voltage are held constant.

Magnet Supply

Electrical connections to the DC magnet include two meters, one for measuring current through the circuit (I_m in Fig. 6.32) and one for measuring voltage (E_m). When the device is first installed in its magnet assembly, both parameters should be measured and recorded for future reference. If excessive body current or other unusual symptoms occur, these data will be valuable for system analysis.

Undercurrent protection should be provided to remove beam voltage if the magnetic circuit current falls below a preset value. The interlock should also prevent the beam voltage from being applied if the magnetic circuit is not energized. This scheme will not, however, provide protection if the coils are shorted. Shorted conditions can be determined by measuring the normal values of voltage and current and recording them for future reference.

The body-current overload protection should actuate if the magnetic field is reduced for any reason.

RF Circuits

In Fig. 6.32, monitoring devices are shown on the RF input and output of the device. These monitors protect the tube should a failure occur in the RF output circuit. Two directional couplers and a photodetector are attached to the output. These components and an RF switching device on the input form a protective network against output transmission line mismatch. The RF switch is activated by the photodetector or the reflected power monitor and must be capable of removing RF drive power from the klystron in less than 10 ms (typically).

In the RF output circuit, the forward power coupler is used to measure the relative power output of the klystron. The reflected power coupler is used to measure the RF power reflected by the output circuit components, or antenna. Damaged components or foreign material in the RF line will increase the RF reflected power. The amount of reflected power should be no more than 5% of the actual forward RF output power of the device in most applications. An interlock monitors the reflected power and removes RF drive to the klystron if the reflected energy reaches an unsafe level. To protect against arcs occurring between the monitor and the output window, a photodetector is placed between the monitor and the window. Light from an arc will trigger the photodetector, which actuates the interlock system and removes RF drive before the window is damaged.

6.5.4 Filament Voltage Control

Extending the life of a microwave tube begins with accurate adjustment of filament voltage. The filament should not be operated at a reduced voltage in an effort to extend tube life. Unlike a thoriated tungsten grid tube, reduced filament voltage may cause uneven emission from the surface of the cathode with little or no improvement in cathode life.

Voltage should be applied to the filament for a specified warm-up period before the application of beam current to minimize thermal stress on the cathode/gun structure. However, voltage normally should not be applied to the filaments for extended periods (2 h or more) if no beam voltage is present. The net rate of evaporation of emissive material from the cathode surface is greater without beam voltage. Subsequent condensation of material on gun components may lead to voltage standoff problems.

6.5.5 Cooling System

The cooling system is vital to any RF generator. In a high-power microwave transmitter, the cooling system may need to dissipate as much as 70% of the input AC power in the form of waste heat. For vapor phase-cooled devices, pure (distilled or demineralized) water must be used. Because the collector is usually only several volts above ground potential, it is generally not necessary to use deionized water.

^cResistivity in Ω · cm.

^dAt 8.5 GHz.

Excessive dissipation is perhaps the single greatest cause of catastrophic failure in a power tube. The critical points of almost every tube type are the metal-to-ceramic junctions or seals. At temperatures below 250°C these seals remain secure, but above that temperature, the bonding in the seal may begin to disintegrate. Warping of internal structures also may occur at temperatures above the maximum operating level of the device. The result of prolonged overheating is shortened tube life or catastrophic failure. Several precautions are usually taken to prevent damage to tube seals under normal operating conditions. Air directors or sections of tubing may be used to provide spot cooling at critical surface areas of the device. Airflow and waterflow sensors typically prevent operation of the RF system in the event of a cooling system failure.

Temperature control is important for microwave tube operation because the properties of many of the materials used to build a device change with increasing temperature. In some applications, these changes are insignificant. In others, however, such changes can result in detrimental effects, leading to, in the worst case, catastrophic failure. Table 6.2 details the variation of electrical and thermal properties with temperature for various substances.

Water Cooling Systems

A water-cooled tube depends on an adequate flow of fluid to remove heat from the device and transport it to an external heat sink. The recommended flow as specified in the technical data sheet should be maintained at all times when the tube is in operation. Inadequate water flow at high temperature may cause the formation of steam bubbles at the collector surface where the water is in direct contact with the collector. This condition can contribute to premature tube failure.

Circulating water can remove about 1.0 kW/cm² of effective internal collector area. In practice, the temperature of water leaving the tube is limited to 70°C to preclude the possibility of spot boiling. The water is then passed through a heat exchanger where it is cooled to 30–40°C before being pumped back to the device.

Cooling System Design

A liquid cooling system consists of the following principal components:

- A source of coolant
- Circulation pump

FIGURE 6.33 Functional schematic of a water-cooling system for a high-power amplifier or oscillator.

- Heat exchanger
- Coolant purification loop
- Various connection pipes, valves, and gauges
- Flow interlocking devices (required to ensure coolant flow anytime the equipment is energized)

Such a system is shown schematically in Fig. 6.33. In most cases the liquid coolant will be water, however, if there is a danger of freezing, it will be necessary to use an antifreeze solution such as ethylene glycol. In these cases, coolant flow must be increased or plate dissipation reduced to compensate for the poorer heat capacity of the ethylene glycol solution. A mixture of 60% ethylene glycol to 40% water by weight will be about 75% as efficient as pure water as a coolant at 25°C. Regardless of the choice of liquid, the system volume must be maintained above the minimum required to insure proper cooling of the vacuum tube(s).

The main circulation pump must be of sufficient size to ensure necessary flow and pressure as specified on the tube data sheet. A filter screen of at least 60 mesh is usually installed in the pump outlet line to trap any circulating debris that might clog coolant passages within the tube.

The heat exchanger system is sized to maintain the outlet temperature such that the outlet water from the tube at full dissipation does not exceed 70°C. Supplementary coolant courses may be connected in parallel or series with the main supply as long as the maximum outlet temperature is not exceeded.

Valves and pressure meters are installed on the inlet lines to the tube to permit adjustment of flow and measurement of pressure drop, respectively. A pressure meter and check valve are employed in the outlet line. In addition, a flow meter, sized in accordance with the tube data sheet, and a thermometer are included in the outlet line of each coolant course. These flow meters are equipped with automatic interlock switches, wired into the system electrical controls, so that the tube will be completely deenergized in the event of a loss of coolant flow in any one of the coolant passages. In some tubes, filament power alone is sufficient to damage the tube structure in the absence of proper water flow.

FIGURE 6.34 Typical configuration of a water purification loop.

The lines connecting the plumbing system to the inlet and outlet ports of tube are made of a flexible insulating material configured so as to avoid excessive strain on the tube flanges. The coolant lines must be of sufficient length to keep electrical leakage below approximately 4 mA at full operating power.

The hoses are coiled or otherwise supported so they do not contact each other or any conducting surface between the high voltage end and ground. Conducting hose *barbs*, connected to ground, are provided at the low-potential end so that the insulating column of water is broken and grounded at the point it exits the equipment cabinet.

Even if the cooling system is constructed using the recommended materials, and is filled with distilled or deionized water, the solubility of the metals, carbon dioxide, and free oxygen in the water make the use of a coolant purification **regeneration loop** essential. The integration of the purification loop into the overall cooling system is shown in Fig. 6.34. The regeneration loop typically taps 5–10% of the total cooling system capacity, circulating it through oxygen scavenging and deionization beds and submicron filters before returning it into the main system. The purification loop can theoretically process water to 18-M Ω resistivity at 25°C. In practice, resistivity will be somewhat below this value.

Figure 6.34 shows a typical purification loop configuration. Packaged systems such as the one illustrated are available from a number of manufacturers. In general, such systems consist of replaceable cartridges that perform the filtering, ion exchange, and organic solid removal functions. The system will usually include flow and pressure gauges and valves and conductivity cells for continuous evaluation of the condition of the water and filters.

Water Purity and Resistivity

The purity of the cooling water is an important operating parameter for any water-cooled amplifier or oscillator. The specific **resistivity** typically must be maintained at 1 M $\Omega \cdot$ cm minimum at 25°C. Distilled or deionized water should be used and the purity and flow protection periodically checked to ensure against degradation.

Oxygen and carbon dioxide in the coolant will form copper oxide, reducing cooling efficiency, and electrolysis may destroy the coolant passages. In addition, a filter screen should be installed in the tube inlet line to trap any circulating debris that might clog coolant passages within the tube.

FIGURE 6.35 The effect of temperature on the resistivity of ultrapure water.

After normal operation for an extended period, the cooling system should be capable of holding 3–4 $M\Omega \cdot \text{cm}$ until the filter beds become contaminated and must be replaced. The need to replace the filter bed resins is indicated when the purification loop output water falls below 5 $M\Omega \cdot \text{cm}$. Although the resistivity measurement is not a test for free oxygen in the coolant, the oxygen filter bed should always be replaced when replacing the deionizing bed.

The resistivity of the coolant is also affected by the temperature of the water. The temperature dependence of the resistivity of pure water is charted in Fig. 6.35.

Generally speaking, it is recommended that the coolant water be circulated at all times. This procedure provides the following benefits:

- Maintains high resistivity
- Reduces bacteria growth
- Minimizes oxidation resulting from coolant stagnation

If it is undesirable to circulate the coolant at the regular rate when the tube is deenergized, a secondary circulating pump can be used to move the coolant at a lower rate to purge any air that might enter the system and to prevent stagnation. Typical recommended minimum circulation rates within the coolant lines are as follows:

- 2 m/s during normal operation
- 30 cm/s during standby

The regeneration loop is typically capable of maintaining the cooling system such that the following maximum contaminant levels are not exceeded:

- Copper: 0.05 PPM by weight
- Oxygen: 0.5 PPM by weight
- CO_2 : 0.5 PPM by weight
- Total solids: 3 PPM by weight

These parameters represent maximum levels; if the precautions outlined in this section are taken, actual levels will be considerably lower.

If the cooling system water temperature is allowed to reach 50°C, it will be necessary to use cartridges in the coolant regeneration loop that are designed to operate at elevated temperatures. Ordinary cartridges will decompose in high temperature service.

Defining Terms

Arc detector: A device placed within a microwave power tube or within one or more of the external cavities of a microwave power tube whose purpose is to sense the presence of an overvoltage arc.

Beam supply: The high-voltage power supply that delivers operating potential to a microwave power tube.

Body current: A parameter of operation for a microwave power tube that describes the amount of current passing through leakage paths within or around the device, principally through the body of the tube. Some small body current is typical during normal operation. Excessive current, however, can indicate a problem condition within the device or its support systems.

Regeneration loop: A water purification system used to maintain proper conditions of the cooling liquid for a power vacuum tube.

Water resistivity: A measure of the purity of cooling liquid for a power tube, typically measured in $M\Omega \cdot \text{cm}$.

7.1 Semiconductors

Sidney Soclof

7.1.1 Introduction

Transistors form the basis of all modern electronic devices and systems, including the integrated circuits used in systems ranging from radio and television to computers. Transistors are solid-state electron devices made out of a category of materials called semiconductors. The mostly widely used semiconductor for transistors, by far, is silicon, although gallium arsenide, which is a compound semiconductor, is used for some very high-speed applications.

Semiconductors

Semiconductors are a category of materials with an electrical conductivity that is between that of conductors and insulators. Good conductors, which are all metals, have electrical resistivities down in the range of 10^{-6} Ω -cm. Insulators have electrical resistivities that are up in the range from 10^6 to as much as about 10^{12} Ω -cm. Semiconductors have resistivities that are generally in the range of 10^{-4} – 10^4 Ω -cm. The resistivity of a semiconductor is strongly influenced by impurities, called **dopants**, that are purposely added to the material to change the electronic characteristics.

We will first consider the case of the pure, or **intrinsic semiconductor**. As a result of the thermal energy present in the material, electrons can break loose from covalent bonds and become free electrons able to move through the solid and contribute to the electrical conductivity. The covalent bonds left behind have an electron vacancy called a **hole**. Electrons from neighboring covalent bonds can easily move into an adjacent bond with an electron vacancy, or hole, and thus the hole can move from one covalent bond to an adjacent bond. As this process continues, we can say that the hole is moving through the material. These holes act as if they have a positive charge equal in magnitude to the electron charge, and they can also contribute to the electrical conductivity. Thus, in a semiconductor there are two types of mobile electrical charge carriers that can contribute to the electrical conductivity, the free electrons and the holes. Since the electrons and holes are generated in equal numbers, and recombine in equal numbers, the free electron and hole populations are equal.

In the **extrinsic** or **doped semiconductor**, impurities are purposely added to modify the electronic characteristics. In the case of silicon, every silicon atom shares its four valence electrons with each of its four nearest neighbors in covalent bonds. If an impurity or dopant atom with a valency of five, such as phosphorus, is substituted for silicon, four of the five valence electrons of the dopant atom will be held in covalent bonds. The extra, or fifth electron will not be in a covalent bond, and is loosely held. At room temperature, almost all of these extra electrons will have broken loose from their parent atoms, and become free electrons. These pentavalent dopants thus donate free electrons to the semiconductor and are called **donors**. These donated electrons upset the balance between the electron and hole populations, so there are now more electrons than holes. This is now called an **N-type semiconductor**, in which the electrons are the **majority carriers**, and holes are the **minority carriers**. In an N-type semiconductor the free electron concentration is generally many orders of magnitude larger than the hole concentration.

If an impurity or dopant atom with a valency of three, such as boron, is substituted for silicon, three of the four valence electrons of the dopant atom will be held in covalent bonds. One of the covalent bonds will be missing an electron. An electron from a neighboring silicon-to-silicon covalent bond, however, can easily jump into this electron vacancy, thereby creating a vacancy, or hole, in the silicon-to-silicon covalent bond. Thus, these trivalent dopants accept free electrons, thereby generating holes, and are called **acceptors**. These additional holes upset the balance between the electron and hole populations, and so there are now more holes than electrons. This is called a **P-type semiconductor**, in which the holes are the majority carriers, and the electrons are the minority carriers. In a P-type semiconductor the hole concentration is generally many orders of magnitude larger than the electron concentration.

Figure 7.1 shows a single crystal chip of silicon that is doped with acceptors to make it P-type on one side, and doped with donors to make it N-type on the other side. The transition between the two sides is

called the *PN junction*. As a result of the concentration difference of the free electrons and holes there will be an initial flow of these charge carriers across the junction, which will result in the N-type side attaining a net positive charge with respect to the P-type side. This results in the formation of an electric potential *hill* or barrier at the junction. Under equilibrium conditions the height of this potential hill, called the **contact potential** is such that the flow of the majority carrier holes from the P-type side up the hill to the N-type side is reduced to the extent that it becomes equal to the flow of the minority carrier holes from the N-type side down the hill to the P-type side. Similarly, the flow of the majority carrier free electrons from the N-type side is reduced to the extent that it becomes equal to the flow of the minority carrier electrons from the P-type side. Thus, the net current flow across the junction under equilibrium conditions is zero.

FIGURE 7.1 PN junction.

7.1.2 Diodes

In Fig. 7.2 the silicon chip is connected as a *diode* or two-terminal electron device. The situation in which a bias voltage is applied is shown. In Fig. 7.2(a) the bias voltage is a **forward bias**, which produces a reduction in the height of the potential hill at the junction. This allows for a large increase in the flow of electrons and holes across the junction. As the forward bias voltage increases, the **forward current** will increase at approximately an exponential rate, and can become very large. The variation of forward current flow with forward bias voltage is given by the diode equation as

FIGURE 7.2 Biasing of a diode: (a) forward bias, (b) reverse bias.

$$I = I_0(\exp(qV/nkT) - 1)$$

where

- I_0 = reverse saturation current, constant
- q = electron charge
- n = dimensionless factor between 1 and 2
- k = Boltzmann’s constant
- T = absolute temperature, K

If we define the **thermal voltage** as $V_T = kT/q$, the diode equation can be written as

$$I = I_0(\exp(V/nV_T) - 1)$$

At room temperature $V_T \cong 26\text{ mV}$, and n is typically around 1.5 for silicon diodes.

In Fig. 7.2(b) the bias voltage is a **reverse bias**, which produces an increase in the height of the potential hill at the junction. This essentially chokes off the flow of electrons from the N-type side to the P-type side, and holes from the P-type side to the N-type side. The only thing left is the very small trickle of electrons from the P-type side and holes from the N-type side. Thus the **reverse current** of the diode will be very small.

In Fig. 7.3 the circuit schematic symbol for the diode is shown, and in Fig. 7.4 a graph of the current vs. voltage curve for the diode is presented. The P-type side of the diode is called the **anode**, and the N-type side is the **cathode** of the diode. The forward current of diodes can be very large, in the case of large power diodes, up into the range of 10–100 A.

FIGURE 7.3 Diode symbol.

The reverse current is generally very small, often down in the low nanoampere, or even picoampere range. The diode is basically a one-way voltage-controlled current switch. It allows current to flow in the forward direction when a forward bias voltage is applied, but when a reverse bias is applied the current flow becomes extremely small. Diodes are used extensively in electronic circuits. Applications include rectifiers to convert AC to DC, wave shaping circuits, peak detectors, DC level shifting circuits, and signal transmission gates. Diodes are also used for the demodulation of amplitude-modulated (AM) signals.

FIGURE 7.4 Current vs. voltage curve for a diode.

Defining Terms

Acceptors: Impurity atoms that when added to a semiconductor contribute holes. In the case of silicon, acceptors are atoms from the third column of the periodic table, such as boron.

Anode: The P-type side of a diode.

Cathode: The N-type side of a diode.

Contact potential: The internal voltage that exists across a PN junction under thermal equilibrium conditions, when no external bias voltage is applied.

Donors: Impurity atoms that when added to a semiconductor contribute free electrons. In the case of silicon, donors are atoms from the fifth column of the periodic table, such as phosphorus, arsenic, and antimony.

Dopants: Impurity atoms that are added to a semiconductor to modify the electrical conduction characteristics.

Doped semiconductor: A semiconductor that has had impurity atoms added to modify the electrical conduction characteristics.

Extrinsic semiconductor: A semiconductor that has been doped with impurities to modify the electrical conduction characteristics.

Forward bias: A bias voltage applied to the PN junction of a diode or transistor that makes the P-type side positive with respect to the N-type side.

Forward current: The large current flow in a diode that results from the application of a forward bias voltage.

Hole: An electron vacancy in a covalent bond between two atoms in a semiconductor. Holes are mobile charge carriers with an effective charge that is opposite to the charge on an electron.

Intrinsic semiconductor: A semiconductor with a degree of purity such that the electrical characteristics are not significantly affected.

Majority carriers: In a semiconductor, the type of charge carrier with the larger population. For example, in an N-type semiconductor, electrons are the majority carriers.

Minority carriers: In a semiconductor, the type of charge carrier with the smaller population. For example, in an N-type semiconductor, holes are the minority carriers.

N-type semiconductor: A semiconductor that has been doped with donor impurities to produce the condition that the population of free electrons is greater than the population of holes.

P-type semiconductor: A semiconductor that has been doped with acceptor impurities to produce the condition that the population of holes is greater than the population of free electrons.

Reverse bias: A bias voltage applied to the PN junction of a diode or transistor that makes the P-type side negative with respect to the N-type side.

Reverse current: The small current flow in a diode that results from the application of a reverse bias voltage.

Thermal voltage: The quantity kT/q where k is Boltzmann's constant, T is absolute temperature, and q is electron charge. The thermal voltage has units of volts, and is a function only of temperature, being approximately 25 mV at room temperature.

7.2 Bipolar Junction and Junction Field-Effect Transistors

Sidney Soclof

7.2.1 Bipolar Junction Transistors

A basic diagram of the bipolar junction transistor (BJT) is shown in Fig. 7.5. Whereas the diode has one PN junction, the BJT has two PN junctions. The three regions of the BJT are the emitter, base, and collector. The middle, or base region, is very thin, generally less than $1 \mu\text{m}$ wide. This middle electrode, or base, can be considered to be the control electrode that controls the current flow through the device between emitter and collector. A small voltage applied to the base (i.e., between base and emitter) can produce a large change in the current flow through the BJT.

FIGURE 7.5 Bipolar junction transistor.

BJTs are often used for the amplification of electrical signals. In these applications the emitter-base PN junction is turned on (forward biased) and the collector-base PN junction is off (reverse biased). For the NPN BJT as shown in Fig. 7.5, the emitter will emit electrons into the base region. Since the P-type base region is so thin, most of these electrons will survive the trip across the base and reach the collector-base junction. When the electrons reach the collector-base junction they will roll downhill into the collector, and thus be collected by the collector to become the collector current I_C . The emitter and collector currents will be approximately equal, so $I_C \cong I_E$. There will be a small base current, I_B , resulting from the emission of holes from the base across the emitter-base junction into the emitter. There will also be a small component

of the base current due to the recombination of electrons and holes in the base. The ratio of collector current to base current is given by the parameter β or h_{FE} , is $\beta = I_C/I_B$, and will be very large, generally up in the range of 50–300 for most BJTs.

In Fig. 7.6(a) the circuit schematic symbol for the NPN transistor is shown, and in Fig. 7.6(b) the corresponding symbol for the PNP transistor is given. The basic operation of the PNP transistor is similar to that of the NPN, except for a reversal of the polarity of the algebraic signs of all DC currents and voltages.

FIGURE 7.6 BJT schematic symbols: (a) NPN BJT, (b) PNP BJT.

In Fig. 7.7 the operation of a BJT as an amplifier is shown. When the BJT is operated as an amplifier the emitter-base PN junction is turned on (forward biased) and the collector-base PN junction is off (reverse biased). An AC input voltage applied between base and emitter, $v_{in} = v_{be}$, will produce an AC component, i_c , of the collector current. Since i_c flows through a load resistor, R_L , an AC voltage, $v_o = v_{ce} = -i_c \cdot R_L$ will be produced at the collector. The AC small-signal voltage gain is $A_V = v_o/v_{in} = v_{ce}/v_{be}$.

FIGURE 7.7 A BJT amplifier.

The collector current I_C of a BJT when operated as an amplifier is related to the base-to-emitter voltage V_{BE} by the exponential relationship $I_C = I_{CO} \cdot \exp(V_{BE}/V_T)$, where I_{CO} is a constant, and $V_T = \text{thermal voltage} = 25 \text{ mV}$. The rate of change of I_C with respect to V_{BE} is given by the *transfer conductance*, $g_m = dI_C/dV_{BE} = I_C/V_T$. If the net load driven by the collector of the transistor is R_L , the AC small-signal voltage gain is $A_V = v_{ce}/v_{be} = -g_m \cdot R_L$. The negative sign indicates that the output voltage will be an amplified, but inverted, replica of the input signal. If, for example, the transistor is biased at a DC collector current level of $I_C = 1 \text{ mA}$ and drives a net load of $R_L = 10 \text{ k}\Omega$, then $g_m = I_C/V_T = 1 \text{ mA}/25 \text{ mV} = 40 \text{ mS}$, and $A_V = v_c/v_{be} = -g_m \cdot R_L = -40 \text{ mS} \cdot 10 \text{ k}\Omega = -400$. Thus we see that the voltage gain of a single BJT amplifier stage can be very large, often up in the range of 100, or more.

The BJT is a three electrode or **triode** electron device. When connected in a circuit it is usually operated as a two-port, or two-terminal, pair device as shown in Fig. 7.8. Therefore, one of the three electrodes of the BJT must be common to both the input and output ports. Thus, there are three basic BJT configurations, common emitter (CE), common base (CB), and common collector (CC), as shown in Fig. 7.8. The most often used configuration, especially for amplifiers, is the common-emitter (CE), although the other two configurations are used in some applications.

7.2.2 Amplifier Configurations

We will first compare the common-emitter circuit of Fig. 7.8(b) to the common-base circuit of Fig. 7.8(c). The AC small-signal voltage gain of the common-emitter circuit is given by $A_V = -g_m R_{NET}$ where

FIGURE 7.8 The BJT as a two-port device: (a) block representation, (b) common emitter, (c) common base, (d) common collector.

g_m is the dynamic forward transfer conductance as given by $g_m = I_C/V_T$, and R_{NET} is the net load resistance driven by the collector of the transistor. Note that the common-emitter circuit is an inverting amplifier, in that the output voltage is an amplified, but inverted, replica of the input voltage. The AC small-signal voltage gain of the common-base circuit is given by $A_V = g_m R_{NET}$, so we see that the common-base circuit is a noninverting amplifier, in that the output voltage is an amplified replica of the input voltage. Note that the magnitude of the gain is given by the same expression for both amplifier circuits.

The big difference between the two amplifier configurations is in the input resistance. For the common-emitter circuit the AC small-signal input resistance is given by $r_{IN} = n\beta V_T/I_C$, where n is the ideality factor, which is a dimensionless factor between 1 and 2, and is typically around 1.5 for silicon transistors operating at moderate current levels, in the 1–10 mA range. For the common-base circuit the AC small-signal input resistance is given by $r_{IN} = V_T/I_E \cong V_T/I_C$. The input resistance of the common-base circuit is smaller than that of the common-emitter circuit by a factor of approximately $n\beta$. For example, taking $n = 1.5$ and $\beta = 100$ as representative values, at $I_C = 1.0$ mA we get for the common-emitter case $r_{IN} = n\beta V_T/I_C = 1.5 \cdot 100 \cdot 25 \text{ mV}/1 \text{ mA} = 3750 \Omega$; whereas for the common-base case, we get $r_{IN} \cong V_T/I_C = 25 \text{ mV}/1 \text{ mA} = 25 \Omega$. We see that r_{IN} for the common emitter is 150 times larger than for the common base. The small input resistance of the common-base case will severely load most signal sources. Indeed, if we consider cascaded common-base stages with one common-base stage driving another operating at the same quiescent collector current level, then we get $A_V = g_m R_{NET} \cong g_m \cdot r_{IN} \cong (I_C/V_T) \cdot (V_T/I_C) = 1$, so that no net voltage gain is obtained from a common-base stage driving another common-base stage under these conditions. For the cascaded common-emitter case, we have $A_V = -g_m R_{NET} \cong -g_m r_{IN} = (I_C/V_T) \cdot (n\beta V_T/I_C) = n\beta$, so that if $n = 1.5$ and $\beta = 100$, a gain of about 150 can be achieved. It is for this reason that the common-emitter stage is usually chosen.

The common-base stage is used primarily in high-frequency applications due to the fact that there is no direct capacitive feedback from output (collector) to input (emitter) as a result of the common or grounded base terminal. A circuit configuration that is often used to take advantage of this, and at the same time to have the higher input impedance of the common-emitter circuit is the *cascode* configuration, as shown in Fig. 7.9. The cascode circuit is a combination of the common-emitter stage directly coupled to a common-base stage. The input impedance is that of the common-emitter stage, and the grounded base of the common-base stage blocks the capacitive feedback from output to input.

FIGURE 7.9 A cascode circuit.

The common-collector circuit of Fig. 7.10 will now be considered. The common-collector circuit has an AC small-signal voltage gain given by

$$A_V = \frac{g_m R_{NET}}{[1 + g_m R_{NET}]} = \frac{R_{NET}}{[R_{NET} + V_T/I_C]}$$

The voltage gain is positive, but will always be less than unity, although it will usually be close to unity. For example if $I_C = 10$ mA and $R_{NET} = 50 \Omega$ we obtain

$$A_V = \frac{R_{NET}}{\left[R_{NET} + \frac{V_T}{I_C} \right]} = \frac{50}{\left[50 + \frac{25 \text{ mV}}{10 \text{ mA}} \right]} = \frac{50}{50 + 2.5} = \frac{50}{52.5} = 0.952$$

Since the voltage gain for the common-collector stage is positive and usually close to unity, the AC voltage at the emitter will rather closely follow the voltage at the base, hence, the name *emitter-follower* that is usually used to describe this circuit.

We have seen that the common-collector or emitter-follower stage will always have a voltage gain that is less than unity. The emitter follower is nevertheless a very important circuit because of its impedance transforming properties. The AC small-signal input resistance is given by $r_{IN} = (\beta + 1)((V_T/I_C) + R_{NET})$, where R_{NET} is the net AC load driven by the emitter of the emitter follower. We see that looking into the base, the load resistance R_{NET} is transformed up in value by a factor of $\beta + 1$. Looking from the load back into the emitter, the AC small-signal output resistance is given by

$$r_O = \frac{1}{g_m} + \frac{R_{SOURCE}}{(\beta + 1)} = \frac{V_T}{I_C} + \frac{R_{SOURCE}}{(\beta + 1)}$$

where R_{SOURCE} is the net AC resistance that is seen looking out from the base toward the signal source. Thus, as seen from the load looking back into the emitter follower, the source resistance is transformed down by a factor of $\beta + 1$. This impedance transforming property of the emitter follower is useful for coupling high-impedance sources to low-impedance loads. For example, if a 1-k Ω source is coupled directly to a 50- Ω load, the transfer ratio will be $T = R_{LOAD}/(R_{LOAD} + R_{SOURCE}) = 50/1050 \cong 0.05$. If an emitter follower with $I_C = 10$ mA and $\beta = 200$ is interposed between the signal source and the load, the input resistance of the emitter follower will be

$$r_{IN} = (\beta + 1) \left[\frac{V_T}{I_C} + R_{NET} \right] = 201 \cdot (2.5 \Omega + 50 \Omega) = 201 \cdot 52.5 \Omega = 10.55 \text{ k}\Omega$$

The signal transfer ratio from the signal source to the base of the emitter follower is now $T = r_{IN}/(r_{IN} + R_{SOURCE}) = 10.55 \text{ k}\Omega/11.55 \text{ k}\Omega = 0.913$. The voltage gain through the emitter follower from base to emitter is

$$A_V = \frac{R_{NET}}{\left[R_{NET} + \frac{V_T}{I_C} \right]} = \frac{50}{\left[50 + \frac{25 \text{ mV}}{10 \text{ mA}} \right]} = \frac{50}{[50 + 2.5]} = \frac{50}{52.5} = 0.952$$

and so the overall transfer ratio is $T_{NET} = 0.913 \cdot 0.952 = 0.87$. Thus, there is a very large improvement in the transfer ratio.

As a second example of the usefulness of the emitter follower, consider a common-emitter stage operating at $I_C = 1.0$ mA and driving a 50 Ω load. We have

$$A_V = -g_m R_{NET} = -\frac{1 \text{ mA}}{25 \text{ mV}} \cdot 50 \Omega = -40 \text{ mS} \cdot 50 \Omega = -2$$

If an emitter follower operating at $I_C = 10$ mA is interposed between the common-emitter stage and the load, we now have for the common-emitter stage a gain of

$$A_V = -g_m R_{NET} = -\frac{1 \text{ mA}}{25 \text{ mV}} \cdot r_{IN} = -40 \text{ mS} \cdot 10.55 \text{ k}\Omega = -422$$

The voltage gain of the emitter follower from base to emitter is 0.952, so the overall gain is now $-422 \cdot 0.952 = -402$, as compared to the gain of only -2 that was available without the emitter follower.

The BJT is often used as a switching device, especially in digital circuits, and in high-power applications. When used as a switching device, the transistor is switched between the *cutoff region* in which both junctions are off, and the *saturation region* in which both junctions are on. In the *cutoff region* the collector current

FIGURE 7.10 Emitter-follower circuit.

is reduced to a small value, down in the low nanoampere range, and so the transistor looks essentially like an open circuit. In the saturation region the voltage drop between collector and emitter becomes small, usually less than 0.1 V, and the transistor looks like a small resistance.

7.2.3 Junction Field-Effect Transistors

A junction field-effect transistor or JFET is a type of transistor in which the current flow through the device between the drain and source electrodes is controlled by the voltage applied to the gate electrode. A simple physical model of the JFET is shown in Fig. 7.11. In this JFET an N-type conducting channel exists between *drain* and *source*. The gate is a heavily doped P-type region (designated as P⁺), that surrounds the N-type channel. The gate-to-channel PN junction is normally kept reverse biased. As the reverse bias voltage between gate and channel increases, the depletion region width increases, as shown in Fig. 7.12. The depletion region extends mostly into the N-type channel because of the heavy doping on the P⁺ side. The depletion region is depleted of mobile charge carriers and, thus, cannot contribute to the conduction of current between drain and source. Thus, as the gate voltage increases, the cross-sectional area of the N-type channel available for current flow decreases. This reduces the current flow between drain and source. As the gate voltage increases, the channel becomes further constricted, and the current flow gets smaller. Finally, when the depletion regions meet in the middle of the channel, as shown in Fig. 7.13, the channel is pinched off in its entirety, all of the way between the source and the drain. At this point the current flow between drain and source is reduced to essentially zero. This voltage is called the **pinch-off voltage** V_p . The pinch-off voltage is also represented as $V_{GS}(\text{OFF})$, as being the gate-to-source voltage that turns the drain-to-source current I_{DS} off. We have been considering here an N-channel JFET. The complementary device is the P-channel JFET, which has a heavily doped N-type (N⁺) gate region surrounding a P-type channel. The operation of a P-channel JFET is the same as for an N-channel device, except the algebraic signs of all DC voltages and currents are reversed.

We have been considering the case for V_{DS} small compared to the pinch-off voltage such that the channel is essentially uniform from drain to source, as shown in Fig. 7.14(a). Now let us see what happens as V_{DS} increases. As an example, assume an N-channel JFET with a pinch-off voltage of $V_p = -4$ V. We will see what happens for the case of $V_{GS} = 0$ as V_{DS} increases. In Fig. 7.14(a) the situation is shown for the case of $V_{DS} = 0$ in which the JFET is fully on and there is a uniform channel from source to drain. This is at point A on the I_{DS} vs. V_{DS} curve of Fig. 7.15. The drain-to-source conductance is at its maximum value of $g_{ds}(\text{ON})$, and the drain-to-source resistance is correspondingly at its minimum value of $r_{ds}(\text{ON})$. Now, consider the case of $V_{DS} = +1$ V as shown in Fig. 7.14(b). The gate-to-channel bias voltage at the source end is still $V_{GS} = 0$. The gate-to-channel bias voltage at the drain end is $V_{GD} = V_{GS} - V_{DS} = -1$ V, so the depletion region will be wider at the drain end of the channel than at the source end. The channel will, thus, be narrower at the drain end than at the source end, and this will result in a decrease in the channel conductance g_{ds} , and correspondingly, an increase in the channel resistance r_{ds} . Thus, the slope

FIGURE 7.11 Model of a JFET device.

FIGURE 7.12 JFET with increased gate voltage.

FIGURE 7.13 JFET with pinched-off channel.

FIGURE 7.14 JFET operational characteristics: (a) Uniform channel from drain to source, (b) depletion region wider at the drain end, (c) depletion region significantly wider at the drain, (d) channel near pinchoff, (e) channel at pinchoff.

of the I_{DS} vs. V_{DS} curve, which corresponds to the channel conductance, will be smaller at $V_{DS} = 1\text{ V}$ than it was at $V_{DS} = 0$, as shown at point B on the I_{DS} vs. V_{DS} curve of Fig. 7.15.

In Fig. 7.14(c) the situation for $V_{DS} = +2\text{ V}$ is shown. The gate-to-channel bias voltage at the source end is still $V_{GS} = 0$, but the gate-to-channel bias voltage at the drain end is now $V_{GD} = V_{GS} - V_{DS} = -2\text{ V}$, so the depletion region will be substantially wider at the drain end of the channel than at the source end. This leads to a further constriction of the channel at the drain end, and this will again result in a decrease in the channel conductance g_{ds} , and correspondingly, an increase in the channel resistance r_{ds} . Thus the slope of the I_{DS} vs. V_{DS} curve will be smaller at $V_{DS} = 2\text{ V}$ than it was at $V_{DS} = 1\text{ V}$, as shown at point C on the I_{DS} vs. V_{DS} curve of Fig. 7.15.

In Fig. 7.14(d) the situation for $V_{DS} = +3\text{ V}$ is shown, and this corresponds to point D on the I_{DS} vs. V_{DS} curve of Fig. 7.15.

When $V_{DS} = +4\text{ V}$ the gate-to-channel bias voltage will be $V_{GD} = V_{GS} - V_{DS} = 0 - 4\text{ V} = -4\text{ V} = V_P$. As a result the channel is now pinched off at the drain end, but is still wide open at the source end since $V_{GS} = 0$, as shown in Fig. 7.14(e). It is important to note that channel is pinched off just for a very short distance at the drain end, so that the drain-to-source current I_{DS} can still continue to flow. This is not at all the same situation as for the case of $V_{GS} = V_P$ wherein the channel is pinched off in its entirety, all of the way from source to drain. When this happens, it is like having a big block of insulator the entire distance between source and drain, and I_{DS} is reduced to essentially zero. The situation for $V_{DS} = +4\text{ V} = -V_P$ is shown at point E on the I_{DS} vs. V_{DS} curve of Fig. 7.15.

For $V_{DS} > +4\text{ V}$, the current essentially saturates, and does not increase much with further increases in V_{DS} . As V_{DS} increases above $+4\text{ V}$, the pinched-off region at the drain end of the channel gets wider, which increases r_{ds} . This increase in r_{ds} essentially counterbalances the increase in V_{DS} such that I_{DS} does not increase much. This region of the I_{DS} vs. V_{DS} curve in which the channel is pinched off at the drain end is called the **active region**, also known as the *saturated region*. It is called the active region because when the JFET is to be used as an amplifier it should be biased and operated in this region. The saturated value of drain current up in the active region for the case of $V_{GS} = 0$ is called I_{DSS} . Since there is not really a true saturation of current in the active region, I_{DSS} is usually specified at some value of V_{DS} . For most JFETs, the values of I_{DSS} fall in the range of 1–30 mA. In the current specification, I_{DSS} , the third subscript S refers to I_{DS} under the condition of the gate shorted to the source.

FIGURE 7.15 I_{DS} vs. V_{DS} curve.

The region below the active region where $V_{DS} < +4\text{ V} = -V_P$ has several names. It is called the **non-saturated region**, the **triode region**, and the **ohmic region**. The term triode region apparently originates from the similarity of the shape of the curves to that of the vacuum tube triode. The term ohmic region is due to the variation of I_{DS} with V_{DS} as in Ohm's law, although this variation is nonlinear except for the region of V_{DS} , which is small compared to the pinch-off voltage, where I_{DS} will have an approximately linear variation with V_{DS} .

The upper limit of the active region is marked by the onset of the breakdown of the gate-to-channel PN junction. This will occur at the drain end at a voltage designated as $BV_{DG} = BV_{DS}$, since $V_{GS} = 0$. This breakdown voltages is generally in the 30–150 V range for most JFETs.

Thus far we have looked at the I_{DS} vs. V_{DS} curve only for the case of $V_{GS} = 0$. In Fig. 7.16 a family of curves of I_{DS} vs. V_{DS} for various constant values of V_{GS} is presented. This is called the *drain characteristics*, and is also known as the **output characteristics**, since the output side of the JFET is usually the drain side. In the active region where I_{DS} is relatively independent of V_{DS} , there is a simple approximate equation relating I_{DS} to V_{GS} . This is the square law **transfer equation** as given by $I_{DS} = I_{DSS} [1 - (V_{GS}/V_P)]^2$. In Fig. 7.17 a graph of the I_{DS} vs. V_{GS} *transfer characteristics* for the JFET is presented. When $V_{GS} = 0$, $I_{DS} = I_{DSS}$ as expected, and as $V_{GS} \rightarrow V_P$, $I_{DS} \rightarrow 0$. The lower boundary of the active region is controlled by the condition that the channel be pinched off at the drain end. To meet this condition the basic requirement is that the gate-to-channel bias voltage at the drain end of the channel, V_{GD} , be greater than the pinch-off voltage V_P . For the example under consideration with $V_P = -4\text{ V}$, this means that $V_{GD} = V_{GS} - V_{DS}$ must be more negative than -4 V . Therefore, $V_{DS} - V_{GS} \geq +4\text{ V}$. Thus, for $V_{GS} = 0$, the active region will begin at $V_{DS} = +4\text{ V}$. When $V_{GS} = -1\text{ V}$, the active region will begin at $V_{DS} = +3\text{ V}$, for now $V_{GD} = -4\text{ V}$. When $V_{GS} = -2\text{ V}$, the active region begins at $V_{DS} = +2\text{ V}$, and when $V_{GS} = -3\text{ V}$, the active region begins at $V_{DS} = +1\text{ V}$. The dotted line in Fig. 7.16 marks the boundary between the nonsaturated and active regions. The upper boundary of the active region is marked by the onset of the avalanche breakdown of the gate-to-channel PN junction. When $V_{GS} = 0$, this occurs at $V_{DS} = BV_{DS} = BV_{DG}$. Since $V_{DG} = V_{DS} - V_{GS}$, and breakdown occurs when $V_{DG} = BV_{DG}$, as V_{GS} increases the breakdown voltages decreases as given by $BV_{DG} = BV_{DS} - V_{GS}$. Thus, $BV_{DS} = BV_{DG} + V_{GS}$. For example, if the gate-to-channel breakdown voltage is 50 V, the V_{DS} breakdown voltage will start off at 50 V when $V_{GS} = 0$, but decreases to 46 V when $V_{GS} = -4\text{ V}$. In the nonsaturated region I_{DS} is a function of both V_{GS} and I_{DS} , and in the lower portion of the nonsaturated region where V_{DS} is small compared to V_P , I_{DS} becomes an approximately linear function of V_{DS} . This linear portion of the nonsaturated region is called the *voltage-variable resistance* (VVR) region, for in this region the JFET acts like a linear resistance element between source and drain. The resistance is variable in that it is controlled by the gate voltage.

FIGURE 7.16 JFET drain characteristics.

FIGURE 7.17 JFET transfer characteristic.

When $V_{GS} = -2\text{ V}$, the active region begins at $V_{DS} = +2\text{ V}$, and when $V_{GS} = -3\text{ V}$, the active region begins at $V_{DS} = +1\text{ V}$. The dotted line in Fig. 7.16 marks the boundary between the nonsaturated and active regions. The upper boundary of the active region is marked by the onset of the avalanche breakdown of the gate-to-channel PN junction. When $V_{GS} = 0$, this occurs at $V_{DS} = BV_{DS} = BV_{DG}$. Since $V_{DG} = V_{DS} - V_{GS}$, and breakdown occurs when $V_{DG} = BV_{DG}$, as V_{GS} increases the breakdown voltages decreases as given by $BV_{DG} = BV_{DS} - V_{GS}$. Thus, $BV_{DS} = BV_{DG} + V_{GS}$. For example, if the gate-to-channel breakdown voltage is 50 V, the V_{DS} breakdown voltage will start off at 50 V when $V_{GS} = 0$, but decreases to 46 V when $V_{GS} = -4\text{ V}$. In the nonsaturated region I_{DS} is a function of both V_{GS} and I_{DS} , and in the lower portion of the nonsaturated region where V_{DS} is small compared to V_P , I_{DS} becomes an approximately linear function of V_{DS} . This linear portion of the nonsaturated region is called the *voltage-variable resistance* (VVR) region, for in this region the JFET acts like a linear resistance element between source and drain. The resistance is variable in that it is controlled by the gate voltage.

JFET as an Amplifier: Small-Signal AC Voltage Gain

Consider the common-source amplifier circuit of Fig. 7.18. The input AC signal is applied between gate and source, and the output AC voltage between be taken between drain and source. Thus the source

electrode of this triode device is common to input and output, hence the designation of this JFET as a common-source (CS) amplifier.

A good choice of the DC operating point or quiescent point (Q-point) for an amplifier is in the middle of the active region at $I_{DS} = I_{DSS}/2$. This allows for the maximum symmetrical drain current swing, from the quiescent level of $I_{DSQ} = I_{DSS}/2$, down to a minimum of $I_{DS} \cong 0$ and up to a maximum of $I_{DS} = I_{DSS}$. This choice for the Q-point is also a good one from the standpoint of allowing for an adequate safety margin for the location of the actual Q-point due to the inevitable variations in device and component characteristics and values. This safety margin should keep the Q-point well away from the extreme limits of the active region, and thus insure operation of the JFET in the active region under most conditions. If $I_{DSS} = +10$ mA, then a good choice for the Q-point would thus be around $+5.0$ mA. The AC component of the drain current, i_{ds} is related to the AC component of the gate voltage, v_{gs} by $i_{ds} = g_m \cdot v_{gs}$, where g_m is the *dynamic transfer conductance*, and is given by

$$g_m = \frac{2\sqrt{I_{DS} \cdot I_{DSS}}}{-V_p}$$

If $V_p = -4$ V, then

$$g_m = \frac{2\sqrt{5 \text{ mA} \cdot 10 \text{ mA}}}{4 \text{ V}} = \frac{3.54 \text{ mA}}{\text{V}} = 3.54 \text{ mS}$$

If a small AC signal voltage v_{gs} is superimposed on the quiescent DC gate bias voltage $V_{GSQ} = V_{GG}$, only a small segment of the transfer characteristic adjacent to the Q-point will be traversed, as shown in Fig. 7.19. This small segment will be close to a straight line, and as a result the AC drain current i_{ds} , will have a waveform close to that of the AC voltage applied to the gate. The ratio of i_{ds} to v_{gs} will be the slope of the transfer curve as given by

$$\frac{i_{ds}}{v_{gs}} \cong \frac{dI_{DS}}{dV_{GS}} = g_m$$

Thus $i_{ds} \cong g_m \cdot v_{gs}$. If the net load driven by the drain of the JFET is the drain load resistor R_D , as shown in Fig. 7.18, then the AC drain current i_{ds} will produce an AC drain voltage of $v_{ds} = -i_{ds} \cdot R_D$. Since $i_{ds} = g_m \cdot v_{gs}$, this becomes $v_{ds} = -g_m v_{gs} \cdot R_D$. The AC small-signal voltage gain from gate to drain thus becomes

$$A_V = \frac{v_O}{v_{IN}} = \frac{v_{ds}}{v_{gs}} = -g_m \cdot R_D$$

The negative sign indicates signal inversion as is the case for a common-source amplifier.

If the DC drain supply voltage is $V_{DD} = +20$ V, a quiescent drain-to-source voltage of $V_{DSQ} = V_{DD}/2 = +10$ V will result in the JFET being biased in the middle of the active region. Since $I_{DSQ} = 5$ mA, in the example under consideration, the voltage drop across the drain load resistor R_D is 10 V. Thus $R_D = 10 \text{ V}/5 \text{ mA} = 2 \text{ k}\Omega$. The AC small-signal voltage gain, A_V , thus becomes

$$A_V = -g_m \cdot R_D = -3.54 \text{ mS} \cdot 2 \text{ k}\Omega = -7.07$$

FIGURE 7.18 A common source amplifier.

FIGURE 7.19 JFET transfer characteristic.

Note that the voltage gain is relatively modest, as compared to the much larger voltage gains that can be obtained with the bipolar-junction transistor common-emitter amplifier. This is due to the lower transfer conductance of both JFETs and metal-oxide-semiconductor field-effect transistors (MOSFETs) as compared to BJTs. For a BJT the transfer conductance is given by $g_m = I_C/V_T$ where I_C is the quiescent collector current and $V_T = kT/q \cong 25$ mV is the **thermal voltage**. At $I_C = 5$ mA, $g_m = 5$ mA/25 mV = 200 mS for the BJT, as compared to only 3.5 mS for the JFET in this example. With a net load of 2 k Ω , the BJT voltage gain will be -400 as compared to the JFET voltage gain of only 7.1. Thus FETs do have the disadvantage of a much lower transfer conductance and, therefore, lower voltage gain than BJTs operating under similar quiescent current levels; but they do have the major advantage of a much higher input impedance and a much lower input current. In the case of a JFET the input signal is applied to the *reverse-biased* gate-to-channel PN junction, and thus sees a very high impedance. In the case of a common-emitter BJT amplifier, the input signal is applied to the *forward-biased* base-emitter junction and the input impedance is given approximately by $r_{IN} = r_{BE} \cong 1.5 \cdot \beta \cdot V_T/I_C$. If $I_C = 5$ mA and $\beta = 200$, for example, then $r_{IN} \cong 1500$ Ω . This moderate input resistance value of 1.5 k Ω is certainly no problem if the signal source resistance is less than around 100 Ω . However, if the source resistance is above 1 k Ω , there will be a substantial signal loss in the coupling of the signal from the signal source to the base of the transistor. If the source resistance is in the range of above 100 k Ω , and certainly if it is above 1 M Ω , then there will be severe signal attenuation due to the BJT input impedance, and a FET amplifier will probably offer a greater overall voltage gain. Indeed, when high impedance signal sources are encountered, a multistage amplifier with a FET input stage, followed by cascaded BJT stages is often used.

JFET as a Constant Current Source

An important application of a JFET is as a constant current source or as a current regulator diode. When a JFET is operating in the active region, the drain current I_{DS} is relatively independent of the drain voltage V_{DS} . The JFET does not, however, act as an ideal constant current source since I_{DS} does increase slowly with increases in V_{DS} . The rate of change of I_{DS} with V_{DS} is given by the drain-to-source conductance $g_{ds} = dI_{DS}/dV_{DS}$. Since I_{DS} is related to the channel length L by $I_{DS} \propto 1/L$, the drain-to-source conductance g_{ds} can be expressed as

$$\begin{aligned} g_{ds} &= \frac{dI_{DS}}{dV_{DS}} = \frac{dI_{DS}}{dL} \cdot \frac{dL}{dV_{DS}} \\ &= \frac{-I_{DS}}{L} \cdot \frac{dL}{dV_{DS}} = I_{DS} \left(\frac{-1}{L} \right) \left(\frac{dL}{dV_{DS}} \right) \end{aligned}$$

The channel length modulation coefficient is defined as

$$\text{channel length modulation coefficient} = \frac{1}{V_A} = \frac{-1}{L} \left(\frac{dL}{dV_{DS}} \right)$$

where V_A is the JFET *early voltage*. Thus we have that $g_{ds} = I_{DS}/V_A$. The early voltage V_A for JFETs is generally in the range of 20–200 V.

The *current regulation* of the JFET acting as a constant current source can be expressed in terms of the fractional change in current with voltage as given by

$$\text{current regulation} = \left(\frac{1}{I_{DS}} \right) \frac{dI_{DS}}{dV_{DS}} = \frac{g_{ds}}{I_{ds}} = \frac{1}{V_A}$$

For example, if $V_A = 100$ V, the current regulation will be $1/(100$ V) = 0.01/V = 1%/V, so I_{DS} changes by only 1% for every 1 V change in V_{DS} .

In Fig. 7.20 a diode-connected JFET or *current regulator diode* is shown. Since $V_{GS} = 0$, $I_{DS} = I_{DSS}$. The current regulator diode can be modeled as an ideal constant current source in parallel with a resistance r_O

as shown in Fig. 7.21. The *voltage compliance range* is the voltage range over which a device or system acts as a good approximation to the ideal constant current source. For the JFET this will be the extent of the active region. The lower limit is the point where the channel just becomes pinched off at the drain end. The requirement is, thus, that $V_{DG} = V_{DS} - V_{GS} > -V_P$. For the case of $V_{GS} = 0$, this occurs at $V_{DS} = -V_P$. The upper limit of the voltage compliance range is set by the breakdown voltage of the gate-to-channel PN junction, BV_{DG} . Since V_P is typically in the 2–5 V range, and BV_{DG} is typically >30 V, this means that the voltage compliance range will be relatively large. For example, if $V_P = -3$ V and $BV_{DG} = +50$ V, the voltage compliance range will extend from $V_{DS} = +3$ V up to $V_{DS} = +50$ V. If $V_A = 100$ V and $I_{DSS} = 10$ mA, the current regulator dynamic output conductance will be

$$g_O = \frac{dI_O}{dV_O} = \frac{dI_{ds}}{dV_{ds}} = g_{ds} = \frac{10 \text{ mA}}{100\text{V}} = 0.1 \text{ mA/V} = 0.1 \text{ mS}$$

The current regulator dynamic output resistance will be $r_O = r_{ds} = 1/g_{ds} = 10 \text{ k}\Omega$. Thus, the current regulator diode can be represented as a 10-mA constant current source in parallel with a 10-k Ω dynamic resistance.

In Fig. 7.22 a current regulator diode is shown in which a resistor R_S is placed in series with the JFET source in order to reduce I_{DS} below I_{DSS} . The current I_{DS} flowing through R_S produces a voltage drop $V_{SG} = I_{DS} \cdot R_S$. This results in a gate-to-source bias voltage of $V_{GS} = -V_{SG} = -I_{DS} \cdot R_S$. From the JFET transfer equation, $I_{DS} = I_{DSS}(1 - (V_{GS}/V_P))^2$ we have that $V_{GS} = V_P(1 - \sqrt{I_{DS}/I_{DSS}})$. From the required value of I_{DS} the corresponding value of V_{GS} can be determined, and from that the value of R_S can be found.

With R_S present, the dynamic output conductance, $g_O = dI_O/dV_O$, becomes $g_O = g_{ds}/(1 + g_m R_S)$. The current regulation now given as

$$\text{current regulation} = \left(\frac{1}{I_O} \right) \frac{dI_O}{dV_O} = \frac{g_O}{I_O}$$

Thus R_S can have a beneficial effect in reducing g_O and improving the current regulation. For example, let $V_P = -3$ V, $V_A = 100$ V, $I_{DSS} = 10$ mA, and $I_O = I_{DS} = 1$ mA. We now have that

$$V_{GS} = V_{GS} = V_P \left[1 - \sqrt{\frac{I_{DS}}{I_{DSS}}} \right] = -3 \text{ V} \left[1 - \sqrt{\frac{1 \text{ mA}}{10 \text{ mA}}} \right] = -2.05 \text{ V}$$

and so $R_S = 2.05 \text{ V}/1 \text{ mA} = 2.05 \text{ k}\Omega$. The transfer conductance g_m is given by

$$g_m = \frac{2\sqrt{I_{DS} \cdot I_{DSS}}}{-V_P} = \frac{2\sqrt{1 \text{ mA} \cdot 10 \text{ mA}}}{3 \text{ V}} = 2.1 \text{ mS}$$

and so $g_m R_S = 2.1 \text{ mS} \cdot 2.05 \text{ k}\Omega = 4.32$. Since $g_{ds} = 1 \text{ mA}/100 \text{ V} = 10 \mu\text{S}$, we have

$$g_O = \frac{g_{ds}}{1 + g_m R_S} = \frac{10 \mu\text{S}}{5.32} = 1.9 \mu\text{S}$$

FIGURE 7.20 A current regulator diode

FIGURE 7.21 Model of the current regulator diode.

FIGURE 7.22 A current regulator diode for $I_{DS} < I_{DSS}$.

The current regulation is thus $g_O/I_O = 1.9 \mu\text{S}/1 \text{ mA} = 0.0019/\text{V} = 0.19\%/V$. This is to be compared to the current regulation of $1\%/V$ obtained for the case of $I_{DS} = I_{DSS}$.

Any JFET can be used as a current regulating diode. There are, however, JFETs that are especially made for this application. These JFETs have an extra long channel length, which reduces the channel length modulation effect and, hence, results in a large value for V_A . This in turn leads to a small g_{ds} and, hence, a small g_O and, thus, good current regulation.

Operation of a JFET as a Voltage-Variable Resistor

A JFET can be used as voltage-variable resistor in which the drain-to-source resistance r_{ds} of the JFET can be varied by variation of V_{GS} . For values of $V_{DS} \ll V_P$ the I_{DS} vs. V_{DS} characteristics are approximately linear, and so the JFET looks like a resistor, the resistance value of which can be varied by the gate voltage.

The channel conductance in the region where $V_{DS} \ll V_P$ is given by $g_{ds} = A\sigma/L = WH\sigma/L$, where the channel height H is given by $H = H_0 - 2W_D$. In this equation W_D is the depletion region width and H_0 is the value of H as $W_D \rightarrow 0$. The depletion region width is given by $W_D = K\sqrt{V_J} = K\sqrt{V_{GS} + \phi}$ where K is a constant, V_J is the junction voltage, and ϕ is the PN junction **contact potential** (typical around $0.8\text{--}1.0 \text{ V}$). As V_{GS} increases, W_D increases and the channel height H decreases as given by $H = H_0 - 2K\sqrt{V_{GS} + \phi}$. When $V_{GS} = V_P$, the channel is completely pinched off, so $H = 0$.

The drain-to-source resistance r_{ds} is given approximately by $r_{ds} \cong r_{ds}(\text{ON})/[1 - \sqrt{V_{GS}/V_P}]$. As $V_{GS} \rightarrow 0$, $r_{ds} \rightarrow r_{ds}(\text{ON})$ and as $V_{GS} \rightarrow V_P$, $r_{ds} \rightarrow \infty$. This latter condition corresponds to the channel being pinched off in its entirety, all of the way from source to drain. This is like having big block of insulator (i.e., the depletion region) between source and drain. When $V_{GS} = 0$, r_{ds} is reduced to its minimum value of $r_{ds}(\text{ON})$, which for most JFETs is in the $20\text{--}4000 \Omega$ range. At the other extreme, when $V_{GS} > V_P$, the drain-to-source current I_{DS} is reduced to a small value, generally down into the low nanoampere, or even picoampere range. The corresponding value of r_{ds} is not really infinite, but is very large, generally well up into the gigaohm ($1000 \text{ M}\Omega$) range. Thus, by variation of V_{GS} , the drain-to-source resistance can be varied over a very wide range. As long as the gate-to-channel junction is reverse biased, the gate current will be very small, generally down in the low nanoampere, or even picoampere range, so that the gate as a control electrode draws little current. Since V_P is generally in the $2\text{--}5 \text{ V}$ range for most JFETs, the V_{DS} values required to operate the JFET in the VVR range is generally $< 0.1 \text{ V}$. In Fig. 7.23 the VVR region of the JFET I_{DS} vs. V_{DS} characteristics is shown.

FIGURE 7.23 Voltage-variable resistor characteristics of the JFET.

Voltage-Variable Resistor Applications

Applications of VVRs include automatic gain control (AGC) circuits, electronic attenuators, electronically variable filters, and oscillator amplitude control circuits.

When using a JFET as a VVR it is necessary to limit V_{DS} to values that are small compared to V_P to maintain good linearity. In addition, V_{GS} should preferably not exceed $0.8V_P$ for good linearity, control, and stability. This limitation corresponds to an r_{ds} resistance ratio of about 10:1. As V_{GS} approaches V_P , a small change in V_P can produce a large change in r_{ds} . Thus, unit-to-unit variations in V_P as well as changes in V_P with temperature can result in large changes in r_{ds} as V_{GS} approaches V_P .

The drain-to-source resistance r_{ds} will have a temperature coefficient TC due to two causes: (1) the variation of the channel resistivity with temperature and (2) the temperature variation of V_P . The TC of the channel resistivity is positive, whereas the TC of V_P is positive due to the negative TC of the contact potential ϕ . The positive TC of the channel resistivity will contribute to a positive TC of r_{ds} . The negative TC of V_P will contribute to a negative TC of r_{ds} . At small values of V_{GS} , the dominant contribution to

the TC is the positive TC of the channel resistivity, and so r_{ds} will have a positive TC . As V_{GS} gets larger, the negative TC contribution of V_p becomes increasingly important, and there will be a value of V_{GS} at which the net TC of r_{ds} is zero and above this value of V_{GS} the TC will be negative. The TC of $r_{ds(ON)}$ is typically $+0.3\%/^{\circ}C$ for N-channel JFETs, and $+0.7\%/^{\circ}C$ for P-channel JFETs. For example, for a typical JFET with an $r_{ds(ON)} = 500\ \Omega$ at $25^{\circ}C$ and $V_p = 2.6\ V$, the zero temperature coefficient point will occur at $V_{GS} = 2.0\ V$. Any JFET can be used as a VVR, although there are JFETs that are specifically made for this application.

Example of VVR Application

A simple example of a VVR application is the electronic gain control circuit of Fig. 7.24. The voltage gain is given by $A_V = 1 + (R_F/r_{ds})$. If, for example, $R_F = 19\ k\Omega$ and $r_{ds(ON)} = 1\ k\Omega$, then the maximum gain will be $A_{VMAX} = 1 + [R_F/r_{ds(ON)}] = 20$. As V_{GS} approaches V_p , the r_{ds} will increase and become very large such that $r_{ds} \gg R_F$, so that A_V will decrease to a minimum value of close to unity. Thus, the gain can be varied over a 20:1 ratio. Note that $V_{DS} \cong V_{IN}$, and so to minimize distortion, the input signal amplitude should be small compared to V_p .

FIGURE 7.24 An electronic gain control circuit.

Defining Terms

Active region: The region of transistor operation in which the output current is relatively independent of the output voltage. For the BJT this corresponds to the condition that the emitter-base junction is on, and the collector-base junction is off. For the FETs this corresponds to the condition that the channel is on, or open, at the source end, and pinched off at the drain end.

Contact potential: The internal voltage that exists across a PN junction under thermal equilibrium conditions, when no external bias voltage is applied.

Ohmic, nonsaturated, or triode region: These three terms all refer to the region of FET operation in which a conducting channel exists all of the way between source and drain. In this region the drain current varies with both the gate voltage and the drain voltage.

Output characteristics: The family of curves of output current vs. output voltage. For the BJT this will be curves of collector current vs. collector voltage for various constant values of base current or voltage, and is also called the collector characteristics. For FETs this will be curves of drain current vs. drain voltage for various constant values of gate voltage, and is also called the drain characteristics.

Pinch-off voltage, V_p : The voltage that when applied across the gate-to-channel PN junction will cause the conducting channel between drain and source to become pinched off. This is also represented as $V_{GS(OFF)}$.

Thermal voltage: The quantity kT/q where k is Boltzmann's constant, T is absolute temperature, and q is electron charge. The thermal voltage has units of volts, and is a function only of temperature, being approximately 25 mV at room temperature.

Transfer conductance: The AC or dynamic parameter of a device that is the ratio of the AC output current to the AC input voltage. The transfer conductance is also called the *mutual transconductance*, and is usually designated by the symbol g_m .

Transfer equation: The equation that relates the output current (collector or drain current) to the input voltage (base-to-emitter or gate-to-source voltage).

Triode: A three-terminal electron device, such as a bipolar junction transistor or a field-effect transistor.

7.3 Metal-Oxide-Semiconductor Field-Effect Transistor

John R. Brews

7.3.1 Introduction

The metal-oxide-semiconductor field-effect transistor (MOSFET) is a transistor that uses a control electrode, the **gate**, to capacitively modulate the conductance of a surface **channel** joining two end contacts, the **source** and the **drain**. The gate is separated from the semiconductor **body** underlying the gate by a thin *gate insulator*, usually silicon dioxide. The surface channel is formed at the interface between the semiconductor body and the gate insulator, see [Fig. 7.25](#).

The MOSFET can be understood by contrast with other field-effect devices, like the junction field-effect transistor (JFET) and the metal-semiconductor field-effect transistor (MESFET) (Hollis and Murphy, 1990). These other transistors modulate the conductance of a *majority-carrier* path between two *ohmic* contacts by capacitive control of its cross section. (Majority carriers are those in greatest abundance in

FIGURE 7.25 A high-performance n -channel MOSFET. The device is isolated from its neighbors by a surrounding thick *field oxide* under which is a heavily doped *channel stop* implant intended to suppress accidental channel formation that could couple the device to its neighbors. The drain contacts are placed over the field oxide to reduce the capacitance to the body, a parasitic that slows response times. These structural details are described later. (Source: After Brews, J.R. 1990. The submicron MOSFET. In *High-Speed Semiconductor Devices*, ed. S.M. Sze, pp. 139–210. Wiley, New York.)

field-free semiconductor, electrons in n -type material and holes in p -type material.) This modulation of the cross section can take place at any point along the length of the channel, and so the gate electrode can be positioned anywhere and need not extend the entire length of the channel.

Analogous to these field-effect devices is the *buried-channel*, *depletion-mode*, or *normally on* MOSFET, which contains a surface layer of the same doping type as the source and drain (opposite type to the semiconductor body of the device). As a result, it has a built-in or normally on channel from source to drain with a conductance that is reduced when the gate depletes the majority carriers.

In contrast, the true MOSFET is an *enhancement-mode* or *normally off* device. The device is normally off because the body forms p - n junctions with both the source and the drain, so no majority-carrier current can flow between them. Instead, *minority-carrier* current can flow, provided minority carriers are available. As discussed later, for gate biases that are sufficiently attractive, above **threshold**, minority carriers are drawn into a surface channel, forming a conducting path from source to drain. The gate and channel then form two sides of a capacitor separated by the gate insulator. As additional attractive charges are placed on the gate side, the channel side of the capacitor draws a balancing charge of minority carriers from the source and the drain. The more charges on the gate, the more populated the channel, and the larger the conductance. Because the gate *creates* the channel, to insure electrical continuity the gate must extend over the entire length of the separation between source and drain.

The MOSFET channel is created by attraction to the gate and relies on the insulating layer between the channel and the gate to prevent leakage of minority carriers to the gate. As a result, MOSFETs can be made only in material systems that provide very good gate insulators, and the best system known is the

silicon-silicon dioxide combination. This requirement for a good gate insulator is not as important for JFETs and MESFETs where the role of the gate is to *push away* majority carriers, rather than to *attract* minority carriers. Thus, in GaAs systems where good insulators are incompatible with other device or fabrication requirements, MESFETs are used.

A more recent development in GaAs systems is the heterostructure field-effect transistor (HFET) (Pearson and Shah, 1990) made up of layers of varying compositions of Al, Ga, and As or In, Ga, P, and As. These devices are made using molecular beam epitaxy or by organometallic vapor phase epitaxy. HFETs include a variety of structures, the best known of which is the modulation doped FET (MODFET). HFETs are field-effect devices, not MOSFETs, because the gate simply modulates the carrier density in a pre-existent channel between ohmic contacts. The channel is formed spontaneously, regardless of the quality of the gate insulator, as a condition of equilibrium between the layers, just as a depletion layer is formed in a p - n junction. The resulting channel is created very near to the gate electrode, resulting in gate control as effective as in a MOSFET.

The silicon-based MOSFET has been successful primarily because the silicon-silicon dioxide system provides a stable interface with low trap densities and because the oxide is impermeable to many environmental contaminants, has a high breakdown strength, and is easy to grow uniformly and reproducibly (Nicollian and Brews, 1982). These attributes allow easy fabrication using lithographic processes, resulting in integrated circuits (ICs) with very small devices, very large device counts, and very high reliability at low cost. Because the importance of the MOSFET lies in this relationship to high-density manufacture, an emphasis of this chapter is to describe the issues involved in continuing miniaturization.

An additional advantage of the MOSFET is that it can be made using either electrons or holes as channel carrier. Using both types of devices in so-called complementary MOS (CMOS) technology allows circuits that draw no DC power if current paths include at least one series connection of both types of device because, in steady state, only one or the other type conducts, not both at once. Of course, in exercising the circuit, power is drawn during switching of the devices. This flexibility in choosing n - or p -channel devices has enabled large circuits to be made that use low-power levels. Hence, complex systems can be manufactured without expensive packaging or cooling requirements.

7.3.2 Current-Voltage Characteristics

The derivation of the current-voltage characteristics of the MOSFET can be found in (Annaratone, 1986; Brews, 1981; and Pierret, 1990). Here a qualitative discussion is provided.

Strong-Inversion Characteristics

In Fig. 7.26 the source-drain current I_D is plotted vs. drain-to-source voltage V_D (the I - V curves for the MOSFET). At low V_D the current increases approximately linearly with increased V_D , behaving like a simple resistor with a resistance that is controlled by the gate voltage V_G : as the gate voltage is made more attractive for channel carriers, the channel becomes stronger, more carriers are contained in the channel, and its resistance R_{ch} drops. Hence, at larger V_G the current is larger.

At large V_D the curves flatten out, and the current is less sensitive to drain bias. The MOSFET is said to be in *saturation*. There are different reasons for this behavior, depending on the field along the channel caused by the drain voltage. If the source-drain

FIGURE 7.26 Drain current I_D vs. drain voltage V_D for various choices of gate bias V_G . The dashed-line curves are for a *long-channel* device for which the current in saturation increases quadratically with gate bias. The solid-time curves are for a *short-channel* device that is approaching *velocity saturation* and thus exhibits a more linear increase in saturation current with gate bias, as discussed in the text.

separation is short, near, or below a micrometer, the usual drain voltage is sufficient to create fields along the channel of more than a few $\times 10^4$ V/cm. In this case the carrier energy is sufficient for carriers to lose energy by causing vibrations of the silicon atoms composing the crystal (optical phonon emission). Consequently, the carrier velocity does not increase much with increased field, saturating at a value $v_{\text{sat}} \approx 10^7$ cm/s in silicon MOSFETs. Because the carriers do not move faster with increased V_D , the current also saturates.

For longer devices the current-voltage curves saturate for a different reason. Consider the potential along the insulator-channel interface, the surface potential. Whatever the surface potential is at the source end of the channel, it varies from the source end to a value larger at the drain end by V_D because the drain potential is V_D higher than the source. The gate, on the other hand, is at the same potential everywhere. Thus, the difference in potential between the gate and the source is larger than that between the gate and drain. Correspondingly, the oxide field at the source is larger than that at the drain and, as a result, less charge can be supported at the drain. This reduction in attractive power of the gate reduces the number of carriers in the channel at the drain end, increasing channel resistance. In short, we have $I_D \approx V_D/R_{\text{ch}}$ but the channel resistance $R_{\text{ch}} = R_{\text{ch}}(V_D)$ is increasing with V_D . As a result, the current-voltage curves do not continue along the initial straight line, but bend over and saturate.

Another difference between the current-voltage curves for short devices and those for long devices is the dependence on gate voltage. For long devices, the current level in saturation $I_{D,\text{sat}}$ increases quadratically with gate bias. The reason is that the number of carriers in the channel is proportional to $V_G - V_{\text{TH}}$ (where V_{TH} is the *threshold voltage*) as is discussed later, the channel resistance $R_{\text{ch}} \propto 1/(V_G - V_{\text{TH}})$, and the drain bias in saturation is approximately V_G . Thus, $I_{D,\text{sat}} = V_D/R_{\text{ch}} \propto (V_G - V_{\text{TH}})^2$, and we have quadratic dependence. When the carrier velocity is saturated, however, the dependence of the current on drain bias is suppressed because the speed of the carriers is fixed at v_{sat} , and $I_{D,\text{sat}} \propto v_{\text{sat}}/R_{\text{ch}} \propto (V_G - V_{\text{TH}})v_{\text{sat}}$, a linear gate-voltage dependence. As a result, the current available from a short device is not as large as would be expected if we assumed it behaved like a long device.

Subthreshold Characteristics

Quite different current-voltage behavior is seen in **subthreshold**, that is, for gate biases so low that the channel is in *weak inversion*. In this case the number of carriers in the channel is so small that their charge does not affect the potential, and channel carriers simply must adapt to the potential set up by the electrodes and the dopant ions. Likewise, in subthreshold any flow of current is so small that it causes no potential drop along the interface, which becomes an equipotential.

As there is no lateral field to move the channel carriers, they move by diffusion only, driven by a gradient in carrier density setup because the drain is effective in reducing the carrier density at the drain end of the channel. In subthreshold the current is then independent of drain bias once this bias exceeds a few tens of millivolts, enough to reduce the carrier density at the drain end of the channel to near zero.

In short devices, however, the source and drain are close enough together to begin to share control of the potential with the gate. If this effect is too strong, a drain-voltage dependence of the subthreshold characteristic then occurs, which is undesirable because it increases the MOSFET off current and can cause a drain-bias dependent threshold voltage.

Although for a well-designed device there is no drain-voltage dependence in subthreshold, gate-bias dependence is exponential. The surface is lowered in energy relative to the semiconductor body by the action of the gate. If this *surface potential* is ϕ_S below that of the body, the carrier density is enhanced by a Boltzmann factor $\exp(q\phi_S/kT)$ relative to the body concentration, where kT/q is the thermal voltage, ≈ 25 mV at 290 K. As ϕ_S is roughly proportional to V_G , this exponential dependence on ϕ_S leads to an exponential dependence on V_G for the carrier density and, hence, for the current in subthreshold.

7.3.3 Important Device Parameters

A number of MOSFET parameters are important to the performance of a MOSFET. In this section some of these parameters are discussed, particularly from the viewpoint of digital ICs.

Threshold Voltage

The threshold voltage is vaguely defined as the gate voltage V_{TH} at which the channel begins to form. At this voltage devices begin to switch from off to on, and circuits depend on a voltage swing that straddles this value. Thus, threshold voltage helps in deciding the necessary supply voltage for circuit operation and it also helps in determining the leakage or off current that flows when the device is in the off state.

We now will make the definition of threshold voltage precise and relate its magnitude to the doping profile inside the device, as well as other device parameters such as oxide thickness and flatband voltage.

Threshold voltage is controlled by oxide thickness d and by body doping. To control the body doping, ion implantation is used, so that the dopant-ion density is not simply a uniform extension of the bulk, background level N_B ions/unit volume, but has superposed on it an implanted ion density. To estimate the threshold voltage, we need a picture of what happens in the semiconductor under the gate as the gate voltage is changed from its off level toward threshold.

If we imagine changing the gate bias from its off condition toward threshold, at first the result is to repel majority carriers, forming a surface *depletion layer*, refer to Fig. 7.25. In the depletion layer there are almost no carriers present, but there are dopant ions. In n -type material these dopant ions are positive donor impurities that cannot move under fields because they are locked in the silicon lattice, where they have been deliberately introduced to replace silicon atoms. In p -type material these dopant ions are negative acceptors. Thus, each charge added to the gate electrode to bring the gate voltage closer to threshold causes an increase in the depletion-layer width sufficient to balance the gate charge by an equal but opposite charge of dopant ions in the silicon depletion layer.

This expansion of the depletion layer continues to balance the addition of gate charge until threshold is reached. Then this charge response changes: above threshold any additional gate charge is balanced by an increasingly strong inversion layer or channel. The border between a depletion-layer and an inversion-layer response, threshold, should occur when

$$\frac{dq N_{inv}}{d\phi_S} = \frac{dQ_D}{d\phi_S} \quad (7.1)$$

where $d\phi_S$ is the small change in surface potential that corresponds to our incremental change in gate charge, $q N_{inv}$ is the inversion-layer charge/unit area, and Q_D the depletion-layer charge/unit area. According to Eq. (7.1), the two types of response are equal at threshold, so that one is larger than the other on either side of this condition. To be more quantitative, the rate of increase in $q N_{inv}$ is exponential, that is, its rate of change is proportional to $q N_{inv}$, and so as $q N_{inv}$ increases, so does the left side of Eq. (7.1). On the other hand, Q_D has a square-root dependence on ϕ_S , which means its rate of change becomes smaller as Q_D increases. Thus, as surface potential is increased, the left side of Eq. (7.1) increases $\propto q N_{inv}$ until, at threshold, Eq. (7.1) is satisfied. Then, beyond threshold, the exponential increase in $q N_{inv}$ with ϕ_S swamps Q_D , making change in $q N_{inv}$ the dominant response. Likewise, below threshold, the exponential decrease in $q N_{inv}$ with decreasing ϕ_S makes $q N_{inv}$ negligible and change in Q_D becomes the dominant response. The abruptness of this change in behavior is the reason for the term threshold to describe MOSFET switching.

To use Eq. (7.1) to find a formula for threshold voltage, we need expressions for N_{inv} and Q_D . Assuming the interface is held at a lower energy than the bulk due to the charge on the gate, the minority-carrier density at the interface is larger than in the bulk semiconductor, even below threshold. Below threshold and even up to the threshold of Eq. (7.1), the number of charges in the channel/unit area N_{inv} is given for n -channel devices approximately by (Brews, 1981)

$$N_{inv} \approx d_{INV} \frac{n_i^2}{N_B} e^{q(\phi_S - V_S)/kT} \quad (7.2)$$

where the various symbols are defined as follows: n_i is the intrinsic carrier density/unit volume $\approx 10^{10}/\text{cm}^3$ in silicon at 290 K and V_S is the body reverse bias, if any. The first factor, d_{INV} , is an effective depth of

minority carriers from the interface given by

$$d_{\text{INV}} = \frac{\varepsilon_s kT/q}{Q_D} \quad (7.3)$$

where Q_D is the depletion-layer charge/unit area due to charged dopant ions in the region where there are no carriers and ε_s is the dielectric permittivity of the semiconductor.

Equation (7.2) expresses the net minority-carrier density/unit area as the product of the bulk minority-carrier density/unit volume n_i^2/N_B , with the depth of the minority-carrier distribution d_{INV} multiplied in turn by the customary Boltzmann factor $\exp(q(\phi_S - V_S)/kT)$ expressing the enhancement of the interface density over the bulk due to lower energy at the interface. The depth d_{INV} is related to the carrier distribution near the interface using the approximation (valid in weak inversion) that the minority-carrier density decays exponentially with distance from the oxide-silicon surface. In this approximation, d_{INV} is the *centroid* of the minority-carrier density. For example, for a uniform bulk doping of 10^{16} dopant ions/cm³ at 290 K, using Eq. (7.2) and the surface potential at threshold from Eq. (7.7) ($\phi_{\text{TH}} = 0.69$ V), there are $Q_D/q = 3 \times 10^{11}$ charges/cm² in the depletion layer at threshold. This Q_D corresponds to a $d_{\text{INV}} = 5.4$ nm and a carrier density at threshold of $N_{\text{inv}} = 5.4 \times 10^9$ charges/cm².

The next step in using the definition of threshold, Eq. (7.1), is to introduce the depletion-layer charge/unit area Q_D . For the ion-implanted case, Q_D is made up of two terms (Brews, 1981)

$$Q_D = qN_B L_B (2(q\phi_{\text{TH}}/kT - m_1 - 1))^{\frac{1}{2}} + qD_I \quad (7.4)$$

where the first term is Q_B , the depletion-layer charge from bulk dopant atoms in the depletion layer with a width that has been reduced by the first moment of the implant, namely, m_1 given in terms of the centroid of the implant x_C by

$$m_1 = \frac{D_I x_C}{N_B L_B^2} \quad (7.5)$$

The second term is the additional charge due to the implanted-ion density within the depletion layer, D_I /unit area. The Debye length L_B is defined as

$$L_B^2 \equiv \left[\frac{kT}{q} \right] \left[\frac{\varepsilon_s}{qN_B} \right] \quad (7.6)$$

where ε_s is the dielectric permittivity of the semiconductor. The Debye length is a measure of how deeply a variation of surface potential penetrates into the body when $D_I = 0$ and the depletion layer is of zero width.

Approximating qN_{inv} by Eq. (7.2) and Q_D by Eq. (7.4), Eq. (7.1) determines the surface potential at threshold ϕ_{TH} to be

$$\phi_{\text{TH}} = 2(kT/q)\ell_n(N_B/n_i) + (kT/q)\ell_n \left[1 + \frac{qD_I}{Q_B} \right] \quad (7.7)$$

where the new symbols are defined as follows: Q_B is the depletion-layer charge/unit area due to bulk body dopant N_B in the depletion layer, and qD_I is the depletion-layer charge/unit area due to implanted ions in the depletion layer between the inversion-layer edge and the depletion-layer edge. Because even a small increase in ϕ_S above ϕ_{TH} causes a large increase in qN_{inv} , which can balance a rather large change in gate charge or gate voltage, ϕ_S does not increase much as $V_G - V_{\text{TH}}$ increases. Nonetheless, in strong inversion $N_{\text{inv}} \approx 10^{12}$ charges/cm², and so in **strong inversion** ϕ_S will be about $7kT/q$ larger than ϕ_{TH} .

Equation (7.7) indicates for uniform doping (no implant, $D_I = 0$) that threshold occurs approximately for $\phi_S = \phi_{\text{TH}} = 2(kT/q)\ell_n(N_B/n_i) \equiv 2\phi_B$, but for the nonuniformly doped case, a larger surface potential is needed, assuming the case of a normal implant where D_I is positive, increasing the dopant density. The implant increases the required surface potential because the field at the surface is larger, narrowing the inversion layer and reducing the channel strength for $\phi_S = 2\phi_B$. Hence, a somewhat larger

surface potential is needed to increase qN_{inv} to the point that Eq. (7.1) is satisfied. Equation (7.7) would not apply if a significant fraction of the implant were confined to lie within the inversion layer itself. No realistic implant can be confined within a distance comparable to an inversion-layer thickness (a few tens of nanometers), however, and so Eq. (7.7) covers practical cases.

With the surface potential ϕ_{TH} known, the potential on the gate at threshold Φ_{TH} can be found if we know the oxide field F_{ox} by simply adding the potential drop across the semiconductor to that across the oxide. That is, $\Phi_{\text{TH}} = \phi_{\text{TH}} + F_{\text{ox}}d$, where d is the oxide thickness and F_{ox} is given by Gauss' law as

$$\varepsilon_{\text{ox}}F_{\text{ox}} = Q_D \quad (7.8)$$

There are two more complications in finding the threshold voltage. First, the gate *voltage* V_{TH} usually differs from the gate *potential* Φ_{TH} at threshold because of a work-function difference between the body and the gate material. This difference causes a spontaneous charge exchange between the two materials as soon as the MOSFET is placed in a circuit allowing charge transfer to occur. Thus, even before any voltage is applied to the device, a potential difference exists between the gate and the body due to spontaneous charge transfer. The second complication affecting threshold voltage is the existence of charges in the insulator and at the insulator–semiconductor interface. These nonideal contributions to the overall charge balance are due to traps and fixed charges incorporated during the device processing.

Ordinarily interface-trap charge is negligible ($< 10^{10}/\text{cm}^2$ in silicon MOSFETs) and the other nonideal effects on threshold voltage are accounted for by introducing the *flatband voltage* V_{FB} , which corrects the gate bias for these contributions. Then, using Eq. (7.8) with $F_{\text{ox}} = (V_{\text{TH}} - V_{\text{FB}} - \phi_{\text{TH}})/d$ we find

$$V_{\text{TH}} = V_{\text{FB}} + \phi_{\text{TH}} + Q_D \frac{d}{\varepsilon_{\text{ox}}} \quad (7.9)$$

which determines V_{TH} even for the nonuniformly doped case, using Eq. (7.7) for ϕ_{TH} and Q_D at threshold from Eq. (7.4). If interface-trap charge/unit area is not negligible, then terms in the interface-trap charge/unit area Q_{IT} must be added to Q_D in Eq. (7.9).

From Eqs. (7.4) and (7.7), the threshold voltage depends on the implanted dopant-ion profile only through two parameters, the net charge introduced by the implant in the region between the inversion layer and the depletion-layer edge qD_I , and the centroid of this portion of the implanted charge x_C . As a result, a variety of implants can result in the same threshold, ranging from the extreme of a δ -function spike implant of dose D_I /unit area located at the centroid x_C , to a box type rectangular distribution with the same dose and centroid, namely, a rectangular distribution of width $x_W = 2x_C$ and volume density D_I/x_W . (Of course, x_W must be no larger than the depletion-layer width at threshold for this equivalence to hold true, and x_C must not lie within the inversion layer.) This weak dependence on the details of the profile leaves flexibility to satisfy other requirements, such as control of off current.

As already stated, for gate biases $V_G > V_{\text{TH}}$, any gate charge above the threshold value is balanced mainly by inversion-layer charge. Thus, the additional oxide field, given by $(V_G - V_{\text{TH}})/d$, is related by Gauss' law to the inversion-layer carrier density approximately by

$$\varepsilon_{\text{ox}}(V_G - V_{\text{TH}})/d \approx qN_{\text{inv}} \quad (7.10)$$

which shows that channel strength above threshold is proportional to $V_G - V_{\text{TH}}$, an approximation often used in this chapter. Thus, the switch in balancing gate charge from the depletion layer to the inversion layer causes N_{inv} to switch from an exponential gate-voltage dependence in subthreshold to a linear dependence above threshold.

For circuit analysis Eq. (7.10) is a convenient *definition* of V_{TH} because it fits current-voltage curves. If this definition is chosen instead of the charge-balance definition Eq. (7.1), then Eqs. (7.1) and (7.7) result in an *approximation* to ϕ_{TH} .

Driving Ability and $I_{D,sat}$

The driving ability of the MOSFET is proportional to the current it can provide at a given gate bias. One might anticipate that the larger this current, the faster the circuit. Here this current is used to find some response times governing MOSFET circuits.

MOSFET current is dependent on the carrier density in the channel, or on $V_G - V_{TH}$, see Eq. (7.10). For a long-channel device, driving ability depends also on channel length. The shorter the channel length L , the greater the driving ability, because the channel resistance is directly proportional to the channel length. Although it is an oversimplification, let us suppose that the MOSFET is primarily in saturation during the driving of its load. This simplification will allow a clear discussion of the issues involved in making faster MOSFETs without complicated mathematics. Assuming the MOSFET to be saturated over most of the switching period, driving ability is proportional to current in saturation, or to

$$I_{D,sat} = \frac{\epsilon_{ox} Z \mu}{2dL} (V_G - V_{TH})^2 \quad (7.11)$$

where the factor of two results from the saturating behavior of the I - V curves at large drain biases, and Z is the width of the channel normal to the direction of current flow. Evidently, for long devices driving ability is quadratic in $V_G - V_{TH}$ and inversely proportional to d .

The result of Eq. (7.11) holds for long devices. For short devices, as explained for Fig. 7.26, the larger fields exerted by the drain electrode cause *velocity saturation* and, as a result, $I_{D,sat}$ is given roughly by (Einspruch and Goldenblat, 1989)

$$I_{D,sat} \approx \frac{\epsilon_{ox} Z v_{sat}}{d} \frac{(V_G - V_{TH})^2}{V_G - V_{TH} + F_{sat} L} \quad (7.12)$$

where v_{sat} is the carrier saturation velocity, about 10^7 cm/s for silicon at 290 K, and F_{sat} is the field at which velocity saturation sets in, about 5×10^4 V/cm for electrons and not well established as $\gtrsim 10^5$ V/cm for holes in silicon MOSFETs. For Eq. (7.12) to agree with Eq. (7.11) at long L , we need $\mu \approx 2v_{sat}/F_{sat} \approx 400$ cm²/V · s for electrons in silicon MOSFETs, which is only roughly correct. Nonetheless, we can see that for devices in the submicron channel length regime, $I_{D,sat}$ tends to become independent of channel length L and becomes more linear with $V_G - V_{TH}$ and less quadratic, see Fig. 7.26. Equation (7.12) shows that velocity saturation is significant when $(V_G - V_{TH})/L \gtrsim F_{sat}$, for example, when $L \lesssim 0.5$ μm if $V_G - V_{TH} = 2.3$ V.

To relate $I_{D,sat}$ to a gate response time τ_G , consider one MOSFET driving an identical MOSFET as load capacitance. Then the current from (Eq. 7.12) charges this capacitance to a voltage V_G in a gate response time τ_G given by (Shoji, 1988)

$$\begin{aligned} \tau_G &= C_G V_G / I_{D,sat} \\ &= \left[\frac{L}{v_{sat}} \right] \left[1 + \frac{C_{par}}{C_{ox}} \right] \frac{V_G (V_G - V_{TH} + F_{sat} L)}{(V_G - V_{TH})^2} \end{aligned} \quad (7.13)$$

where C_G is the MOSFET gate capacitance $C_G = C_{ox} + C_{par}$, with $C_{ox} = \epsilon_{ox} ZL/d$ the MOSFET oxide capacitance, and C_{par} the parasitic component of the gate capacitance (Chen, 1990). The parasitic capacitance C_{par} is due mainly to overlap of the gate electrode over the source and drain and partly to fringing-field and channel-edge capacitances. For short-channel lengths, C_{par} is a significant part of C_G , and keeping C_{par} under control as L is reduced is an objective of gate-drain alignment technology. Typically, $V_{TH} \approx V_G/4$, so that

$$\tau_G = \left[\frac{L}{v_{sat}} \right] \left[1 + \frac{C_{par}}{C_{ox}} \right] \left[1.3 + 1.8 \frac{F_{sat} L}{V_G} \right] \quad (7.14)$$

Thus, on an intrinsic level, the gate response time is a multiple of the transit time of an electron from source to drain, which is L/v_{sat} in velocity saturation. At shorter L , a linear reduction in delay with L is predicted, whereas for longer devices the improvement can be quadratic in L , depending on how V_G is scaled as L is reduced.

The gate response time is not the only delay in device switching, because the drain-body p - n junction also must charge or discharge for the MOSFET to change state (Shoji, 1988). Hence, we must also consider a *drain* response time τ_D . Following Eq. (7.13), we suppose that the drain capacitance C_D is charged by the supply voltage through a MOSFET in saturation so that

$$\tau_D = C_D V_G / I_{D,\text{sat}} = \left[\frac{C_D}{C_G} \right] \tau_G \quad (7.15)$$

Equation (7.15) suggests that τ_D will show a similar improvement to τ_G as L is reduced, provided that C_D/C_G does not increase as L is reduced. However, $C_{\text{ox}} \propto L/d$, and the major component of C_{par} , namely, the overlap capacitance contribution, leads to $C_{\text{par}} \propto L_{\text{ovlp}}/d$ where L_{ovlp} is roughly three times the length of overlap of the gate over the source or drain (Chen, 1990). Then $C_G \propto (L + L_{\text{ovlp}})/d$ and, to keep the C_D/C_G ratio from increasing as L is reduced, either C_D or oxide thickness d must be reduced along with L .

Clever design can reduce C_D . For example, various *raised-drain* designs reduce the drain-to-body capacitance by separating much of the drain area from the body using a thick oxide layer. The contribution to drain capacitance stemming from the sidewall depletion-layer width next to the channel region is more difficult to handle, because the sidewall depletion layer is deliberately reduced during miniaturization to avoid *short-channel* effects, that is, drain influence on the channel in competition with gate control. As a result, this sidewall contribution to the drain capacitance tends to increase with miniaturization unless junction depth can be shrunk.

Equations (7.14) and (7.15) predict reduction of response times by reduction in channel length L . Decreasing oxide thickness leads to no improvement in τ_G , but Eq. (7.15) shows a possibility of improvement in τ_D . The *ring oscillator*, a closed loop of an odd number of inverters, is a test circuit the performance of which depends primarily on τ_G and τ_D . Gate delay/stage for ring oscillators is found to be near 12 ps/stage at 0.1- μm channel length, and 60 ps/stage at 0.5 μm .

For circuits, interconnection capacitances and fan out (multiple MOSFET loads) will increase response times beyond the device response time, even when parasitics are taken into account. Thus, we are led to consider interconnection delay τ_{INT} . Although a lumped model suggests, as with Eq. (7.15), that $\tau_{\text{INT}} \approx (C_{\text{INT}}/C_G)\tau_G$, the length of interconnections requires a *distributed* model. Interconnection delay is then

$$\tau_{\text{INT}} = R_{\text{INT}} C_{\text{INT}}/2 + R_{\text{INT}} C_G + (1 + C_{\text{INT}}/C_G)\tau_G \quad (7.16)$$

where R_{INT} is the interconnection resistance, C_{INT} is the interconnection capacitance, and we have assumed that the interconnection joins a MOSFET driver in saturation to a MOSFET load, C_G . For small R_{INT} , the τ_{INT} is dominated by the last term, which resembles Eqs. (7.13) and (7.15). Unlike the ratio C_D/C_G in Eq. (7.15), however, it is difficult to reduce or even maintain the ratio C_{INT}/C_G in Eq. (7.16) as L is reduced. Remember, $C_G \propto Z(L + L_{\text{ovlp}})/d$. Reduction of L , therefore, tends to increase C_{INT}/C_G , especially because interconnect cross sections cannot be reduced without impractical increases in R_{INT} . What is worse, along with reduction in L , chip sizes usually increase, making line lengths longer, increasing R_{INT} even at constant cross section. As a result, interconnection delay becomes a major problem as L is reduced. The obvious way to keep C_{INT}/C_G under control is to increase the device width Z so that $C_G \propto Z(L + L_{\text{ovlp}})/d$ remains constant as L is reduced. A better way is to cascade drivers of increasing Z (Chen, 1990; Shoji, 1988). Either solution requires extra area, however, reducing the packing density that is a major objective in decreasing L in the first place. An alternative is to reduce the oxide thickness d , a major technology objective.

Transconductance

Another important device parameter is the small-signal transconductance g_m (Malik, 1995; Sedra and Smith, 1991; Haznedar, 1991) that determines the amount of output current swing at the drain that results from a given input voltage variation at the gate, that is, the small-signal gain

$$g_m = \left. \frac{\partial I_D}{\partial V_G} \right|_{V_D=\text{const}} \quad (7.17)$$

Using the chain rule of differentiation, the transconductance in saturation can be related to the small-signal *transition* or *unity-gain frequency* that determines at how high a frequency ω the small-signal current gain $|t_{\text{out}}/t_{\text{in}}| = g_m/(\omega C_G)$ drops to unity. Using the chain rule

$$g_m = \frac{\partial I_{D,\text{sat}}}{\partial Q_G} \frac{\partial Q_G}{\partial V_G} = \omega_T C_G \quad (7.18)$$

where C_G is the oxide capacitance of the device, $C_G = \partial Q_G/\partial V_G|_{V_D}$, where Q_G is the charge on the gate electrode. The frequency ω_T is a measure of the small-signal, high-frequency speed of the device, neglecting parasitic resistances. Using Eq. (7.12) in Eq. (7.18) we find that the transition frequency also is related to the transit time L/v_{sat} of Eq. (7.14), so that both the digital and small-signal circuit speeds are related to this parameter.

Output Resistance and Drain Conductance

For small-signal circuits the output resistance r_o of the MOSFET (Malik, 1995; Sedra and Smith, 1991) is important in limiting the gain of amplifiers. This resistance is related to the small-signal drain conductance in saturation by

$$r_o = \frac{1}{g_D} = \left. \frac{\partial V_D}{\partial I_{D,\text{sat}}} \right|_{V_G=\text{const}} \quad (7.19)$$

If the MOSFET is used alone as a simple amplifier with a load line set by a resistor R_L , the gain becomes

$$\left| \frac{v_o}{v_{\text{in}}} \right| = g_m \frac{R_L r_o}{R_L + r_o} \leq g_m R_L \quad (7.20)$$

showing how gain is reduced if r_o is reduced to a value approaching R_L .

As devices are miniaturized, r_o is decreased and g_D increased, due to several factors. At moderate drain biases, the main factor is channel-length modulation, the reduction of the channel length with increasing drain voltage that results when the depletion region around the drain expands toward the source, causing L to become drain-bias dependent. At larger drain biases, a second factor is drain control of the inversion-layer charge density that can compete with gate control in short devices. This is the same mechanism discussed later in the context of subthreshold behavior. At rather high drain bias, carrier multiplication further lowers r_o .

In a digital inverter, a lower r_o widens the voltage swing needed to cause a transition in output voltage. This widening increases power loss due to current spiking during the transition and reduces noise margins (Annaratone, 1986). It is not, however, a first-order concern in device miniaturization for digital applications. Because small-signal circuits are more sensitive to r_o than digital circuits, MOSFETs designed for small-signal applications cannot be made as small as those for digital applications.

7.3.4 Limitations on Miniaturization

A major factor in the success of the MOSFET has been its compatibility with processing useful down to very small dimensions. Today channel lengths (source-to-drain spacings) of $0.5 \mu\text{m}$ are manufacturable, and further reduction to $0.1 \mu\text{m}$ has been achieved for limited numbers of devices in test circuits, such as ring oscillators. In this section some of the limits that must be considered in miniaturization are outlined (Brews, 1990).

Subthreshold Control

When a MOSFET is in the off condition, that is, when the MOSFET is in subthreshold, the off current drawn with the drain at supply voltage must not be too large in order to avoid power consumption and discharge of ostensibly isolated nodes (Shoji, 1988). In small devices, however, the source and drain are closely spaced, and so there exists a danger of direct interaction of the drain with the source, rather than an interaction mediated by the gate and channel. In an extreme case, the drain may draw current directly

from the source, even though the gate is off (*punchthrough*). A less extreme but also undesirable case occurs when the drain and gate jointly control the carrier density in the channel (*drain-induced barrier lowering*, or drain control of threshold voltage). In such a case, the on-off behavior of the MOSFET is not controlled by the gate alone, and switching can occur over a range of gate voltages dependent on the drain voltage. Reliable circuit design under these circumstances is very complicated, and testing for design errors is prohibitive. Hence, in designing MOSFETs, a drain-bias independent subthreshold behavior is necessary.

A measure of the range of influence of the source and drain is the depletion-layer width of the associated p - n junctions. The depletion layer of such a junction is the region in which all carriers have been depleted, or pushed away, due to the potential drop across the junction. This potential drop includes the applied bias across the junction and a spontaneous built-in potential drop induced by spontaneous charge exchange when p - and n -regions are brought into contact. The depletion-layer width W of an abrupt junction is related to potential drop V and dopant-ion concentration/unit volume N by

$$W = \left[\frac{2\epsilon_s V}{qN} \right]^{\frac{1}{2}} \quad (7.21)$$

To avoid subthreshold problems, a commonly used rule of thumb is to make sure that the channel length is longer than a minimum length L_{\min} related to the junction depth r_j , the oxide thickness d , and the depletion-layer widths of the source and drain W_S and W_D by (Brews, 1990)

$$L_{\min} = A[r_j d (W_S W_D)^2]^{\frac{1}{3}} \quad (7.22)$$

where the empirical constant $A = 0.88 \text{ nm}^{-1/3}$ if r_j , W_S , and W_D are in micrometers and d is in nanometers.

Equation (7.22) shows that smaller devices require shallower junctions (smaller r_j), or thinner oxides (smaller d), or smaller depletion-layer widths (smaller voltage levels or heavier doping). These requirements introduce side effects that are difficult to control. For example, if the oxide is made thinner while voltages are not reduced proportionately, then oxide fields increase, requiring better oxides. If junction depths are reduced, better control of processing is required, and the junction resistance is increased due to smaller cross sections. To control this resistance, various *self-aligned contact* schemes have been developed to bring the source and drain contacts closer to the gate (Brews, 1990; Einspruch and Gildenblat, 1989), reducing the resistance of these connections. If depletion-layer widths are reduced by increasing the dopant-ion density, the *driving ability* of the MOSFET suffers because the threshold voltage increases. That is, Q_D increases in Eq. (7.9), reducing $V_G - V_{\text{TH}}$. Thus, increasing V_{TH} results in slower circuits.

As secondary consequences of increasing dopant-ion density, channel conductance is further reduced due to the combined effects of increased scattering of electrons from the dopant atoms and increased oxide fields that pin carriers in the inversion layer closer to the insulator-semiconductor interface, increasing scattering at the interface. These effects also reduce driving ability, although for shorter devices they are important only in the linear region (that is, below saturation), assuming that mobility μ is more strongly affected than saturation velocity v_{sat} .

Hot-Electron Effects

Another limit on how small a MOSFET can be made is a direct result of the larger fields in small devices. Let us digress to consider why proportionately larger voltages, and thus larger fields, are used in smaller devices. First, according to Eq. (7.14), τ_G is shortened if voltages are increased, at least so long as $V_G/L \lesssim F_{\text{sat}} \approx 5 \times 10^4 \text{ V/cm}$. If τ_G is shortened this way, then so are τ_D and τ_{INT} , Eqs. (7.15) and (7.16). Thus, faster response is gained by increasing voltages into the velocity saturation region. Second, the fabrication control of smaller devices has not improved proportionately as L has shrunk, and so there is a larger percentage variation in device parameters with smaller devices. Thus, disproportionately larger voltages are needed to insure all devices operate in the circuit, to overcome this increased fabrication *noise*. Thus, to increase speed and to cope with fabrication variations, fields get larger in smaller devices.

As a result of these larger fields along the channel direction, a small fraction of the channel carriers have enough energy to enter the insulating layer near the drain. In silicon-based p -channel MOSFETs,

energetic holes can be trapped in the oxide, leading to a positive oxide charge near the drain that reduces the strength of the channel, degrading device behavior. In *n*-channel MOSFETs, energetic electrons entering the oxide create interface traps and oxide wear out, eventually leading to gate-to-drain shorts (Pimbley et al., 1989).

To cope with these problems *drain engineering* has been tried, the most common solution being the *lightly doped drain* (Chen, 1990; Einspruch and Gildenblat, 1989; Pimbley et al., 1989; Wolf, 1995). In this design, a lightly doped extension of the drain is inserted between the channel and the drain proper. To keep the field moderate and reduce any peaks in the field, the lightly doped drain extension is designed to spread the drain-to-channel voltage drop as evenly as possible. The aim is to smooth out the field at a value close to F_{sat} so that energetic carriers are kept to a minimum. The expense of this solution is an increase in drain resistance and a decreased gain. To increase packing density, this lightly doped drain extension can be stacked vertically alongside the gate, rather than laterally under the gate, to control the overall device area.

Thin Oxides

According to Eq. (7.22), thinner oxides allow shorter devices and, therefore, higher packing densities for devices. In addition, driving ability is increased, shortening response times for capacitive loads, and output resistance and transconductance are increased. There are some basic limitations on how thin the oxide can be made. For instance, there is a maximum oxide field that the insulator can withstand. It is thought that the intrinsic break-down voltage of SiO_2 is of the order of 10^7 V/cm, a field that can support $\approx 2 \times 10^{13}$ charges/cm², a large enough value to make this field limitation secondary. Unfortunately, as they are presently manufactured, the intrinsic breakdown of MOSFET oxides is much less likely to limit fields than defect-related leakage or breakdown, and control of these defects has limited reduction of oxide thicknesses in manufacture to about 5 nm to date.

If defect-related problems could be avoided, the thinnest useful oxide would probably be about 3 nm, limited by direct tunneling of channel carriers to the gate. This tunneling limit is not well established and also is subject to oxide-defect enhancement due to tunneling through intermediate defect levels. Thus, defect-free manufacture of thin oxides is a very active area of exploration.

Dopant-Ion Control

As devices are made smaller, the precise positioning of dopant inside the device is critical. At high temperatures during processing, dopant ions can move. For example, source and drain dopants can enter the channel region, causing position-dependence of threshold voltage. Similar problems occur in isolation structures that separate one device from another (Pimbley et al., 1989; Einspruch and Gildenblat, 1989; Wolf, 1995).

To control these thermal effects, process sequences are carefully designed to limit high-temperature steps. This design effort is shortened and improved by the use of computer modeling of the processes. Dopant-ion movement is complex, however, and its theory is made more difficult by the growing trend to use *rapid thermal processing* that involves short-time heat treatments. As a result, dopant response is not steady state, but transient. Computer models of transient response are primitive, forcing further advance in small device design to be more empirical.

Other Limitations

Besides limitations directly related to the MOSFET, there are some broader difficulties in using MOSFETs of smaller dimension in chips involving even greater numbers of devices. Already mentioned is the increased delay due to interconnections that are lengthening due to increasing chip area and increasing complexity of connection. The capacitive loading of MOSFETs that must drive signals down these lines can slow circuit response, requiring extra circuitry to compensate.

Another limitation is the need to isolate devices from each other (Brews, 1990; Chen, 1990; Einspruch and Gildenblat, 1989; Pimbley et al., 1989; Wolf, 1995), so that their actions remain uncoupled by parasitics. As isolation structures are reduced in size to increase device densities, new parasitics are discovered. A solution to this problem is the manufacture of circuits on insulating substrates, *silicon-on-insulator*

technology (Colinge, 1991). To succeed, this approach must deal with new problems, such as the electrical quality of the underlying silicon-insulator interface, and the defect densities in the silicon layer on top of this insulator.

Acknowledgments

The author is pleased to thank R.D. Schrimpf and especially S.L. Gilbert for suggestions that clarified the manuscript.

Defining Terms

Channel: The conducting region in a MOSFET between source and drain. In an *enhancement*-mode, or normally off MOSFET the channel is an inversion layer formed by attraction of minority carriers toward the gate. These carriers form a thin conducting layer that is prevented from reaching the gate by a thin *gate-oxide* insulating layer when the gate bias exceeds *threshold*. In a *buried-channel* or *depletion*-mode, or normally on MOSFET, the channel is present even at zero gate bias, and the gate serves to increase the channel resistance when its bias is nonzero. Thus, this device is based on majority-carrier modulation, like a MESFET.

Gate: The control electrode of a MOSFET. The voltage on the gate capacitively modulates the resistance of the connecting *channel* between the *source* and *drain*.

Source, drain: The two output contacts of a MOSFET, usually formed as *p-n* junctions with the *substrate* or *body* of the device.

Strong inversion: The range of gate biases corresponding to the on condition of the MOSFET. At a fixed gate bias in this region, for low drain-to-source biases the MOSFET behaves as a simple gate-controlled resistor. At larger drain biases, the channel resistance can increase with drain bias, even to the point that the current *saturates*, or becomes independent of drain bias.

Substrate or body: The portion of the MOSFET that lies between the *source* and *drain* and under the *gate*. The gate is separated from the body by a thin *gate insulator*, usually silicon dioxide. The gate modulates the conductivity of the body, providing a gate-controlled resistance between the source and drain. The body is sometimes DC biased to adjust overall circuit operation. In some circuits the body voltage can swing up and down as a result of input signals, leading to body-effect or back-gate bias effects that must be controlled for reliable circuit response.

Subthreshold: The range of gate biases corresponding to the off condition of the MOSFET. In this regime the MOSFET is not perfectly off, but conducts a leakage current that must be controlled to avoid circuit errors and power consumption.

Threshold: The gate bias of a MOSFET that marks the boundary between on and off conditions.

Further Information

The references given in this section have been chosen to provide more detail than is possible to provide in the limited space of this article. In particular, Annaratone (1986) and Shoji (1988) provide much more detail about device and circuit behavior. Chen (1990), Pimbley (1989), and Wolf (1995) provide many technological details of processing and its device impact. Haznedar (1991), Sedra and Smith (1991), and Malik (1995) provide much information about circuits. Brews (1981) and Pierret (1990) provide good discussion of the derivation of the device current-voltage curves and device behavior in all bias regions.

7.4 Image Capture Devices

Edward J. Delp, III

7.4.1 Image Capture

A digital image is nothing more than a matrix of numbers. The question is how does this matrix represent a real image that one sees on a computer screen?

Like all imaging processes, whether they are analog or digital, one first starts with a sensor (or transducer) that converts the original imaging energy into an electrical signal. These sensors, for instance, could be the photomultiplier tubes used in an X-ray system that convert the X-ray energy into a *known* electrical voltage. The transducer system used in ultrasound imaging is an example where sound pressure is converted to electrical energy; a simple TV camera is perhaps the most ubiquitous example. An important fact to note is that the process of conversion from one energy form to an electrical signal is not necessarily a *linear* process. In other words, a proportional change in the input energy to the sensor will not always cause the same proportional change in the output electrical signal. In many cases calibration data are obtained in the laboratory so that the relationship between the input energy and output electrical signal is known. These data are necessary because some transducer performance characteristics change with age and other usage factors.

The sensor is not the only thing needed to form an image in an imaging system. The sensor must have some spatial extent before an image is formed. By spatial extent we mean that the sensor must not be a simple point source examining only one location of energy output. To explain this further, let us examine two types of imaging sensors used in imaging: a charge-coupled device (CCD) video camera and the ultrasound transducer used in many medical imaging applications.

The CCD camera consists of an *array* of light sensors known as charge-coupled devices. The image is formed by examining the output of each sensor in a preset order for a finite time. The electronics of the system then forms an electrical signal, which produces an image that is shown on a cathode-ray tube (CRT) display. The image is formed because there is an array of sensors, each one examining only one spatial location of the region to be sensed.

The process of **sampling** the output of the sensor array in a particular order is known as *scanning*. Scanning is the typical method used to convert a two-dimensional energy signal or image to a one-dimensional electrical signal that can be handled by the computer. (An image can be thought of as an energy field with spatial extent.) Another form of scanning is used in ultrasonic imaging. In this application there is only one sensor instead of an array of sensors. The ultrasound transducer is moved or steered (either mechanically or electrically) to various spatial locations on the patient's chest or stomach. As the sensor is moved to each location, the output electrical signal of the sensor is sampled and the electronics of the system then form a television-like signal, which is displayed. Nearly all of the transducers used in imaging form an image by either using an array of sensors or a single sensor that is moved to each spatial location.

One immediately observes that both of the approaches discussed are equivalent in that the energy is sensed at various spatial locations of the object to be imaged. This energy is then converted to an electrical signal by the transducer. The image formation processes just described are classical analog image formation, with the distance between the sensor locations limiting the spatial resolution in the system. In the array sensors, resolution is also determined by how close the sensors are located in the array. In the single-sensor approach, the spatial resolution is limited by how far the sensor is moved. In an actual system spatial resolution is also determined by the performance characteristics of the sensor. Here we are assuming for our purposes *perfect* sensors.

In digital image formation one is concerned about two processes: *spatial sampling* and **quantization**. Sampling is quite similar to scanning in analog image formation. The second process is known as *quantization* or *analog-to-digital conversion*, whereby at each spatial location a *number* is assigned to the amount of energy the transducer observes at that location. This number is usually proportional to the electrical signal at the output of the transducer. The overall process of sampling and quantization is known as *digitization*. Sometimes the digitization process is just referred to as analog-to-digital conversion, or A/D conversion; however, the reader should remember that digitization also includes spatial sampling.

The digital image formulation process is summarized in Fig. 7.27. The spatial sampling process can be considered as overlaying a grid on the object, with the sensor examining the energy output from each grid box and converting it to an electrical signal. The quantization process then assigns a number to the electrical signal; the result, which is a *matrix* of numbers, is the digital representation of the image. Each spatial location in the image (or grid) to which a number is assigned is known as a *picture element* or **pixel** (or pel). The size of the sampling grid is usually given by the number of pixels on each side of the grid, for examples, 256×256 , 512×512 , 640×480 .

The quantization process is necessary because all information to be processed using computers must be represented by numbers. The quantization process can be thought of as one where the input energy to the transducer is represented by a finite number of energy values. If the energy at a particular pixel location does not take on one of the finite energy values, it is assigned to the closest value. For instance, suppose that we assume *a priori* that only energy values of 10, 20, 50, and 110 will be represented (the units are of no concern in this example). Suppose at one pixel an energy of 23.5 was observed by the transducer. The A/D converter would then assign this pixel the energy value of 20 (the closest one). Notice that the quantization process makes mistakes; this error in assignment is known as *quantization error* or *quantization noise*.

In our example, each pixel is represented by one of four possible values. For ease of representation of the data, it would be simpler to assign to each pixel the index value 0, 1, 2, 3, instead of 10, 20, 50, 110. In fact, this is typically done by the quantization process. One needs a simple table to know that a pixel assigned the value 2 corresponds to an energy of 50. Also, the number of possible energy levels is typically some integer power of two to also aid in representation. This power is known as the number of *bits* needed to represent the energy of each pixel. In our example each pixel is represented by 2 b.

One question that immediately arises is how accurate the digital representation of the image is when one compares the digital image with a corresponding analog image. It should first be pointed out that after the digital image is obtained one requires special hardware to convert the matrix of pixels back to an image that can be viewed on a CRT display. The process of converting the digital image back to an image that can be viewed is known as *digital-to-analog conversion*, or *D/A conversion*.

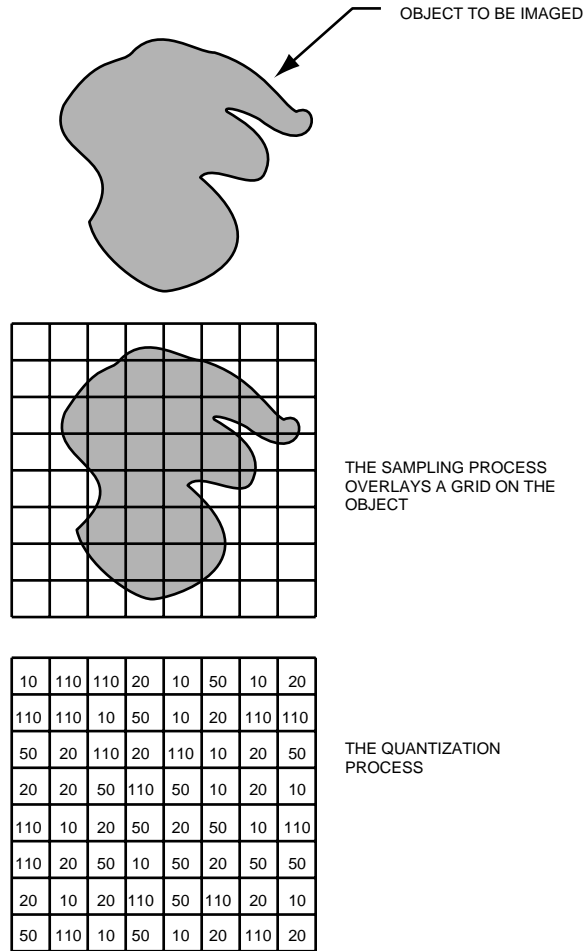

FIGURE 7.27 Digital image formation: sampling and quantization.

The quality of representation of the image is determined by how close spatially the pixels are located and how many levels or numbers are used in the quantization, that is, how coarse or fine is the quantization. The sampling accuracy is usually measured in how many pixels there are in a given area and is cited in pixels/unit length, e.g., pixels/cm. This is known as *the spatial sampling rate*. One would desire to use the lowest rate possible to minimize the number of pixels needed to represent the object. If the sampling rate is too low, then obviously some details of the object to be imaged will not be represented very well. In fact, there is a mathematical theorem that determines the lowest sampling rate possible to preserve details in the object. This rate is known as the *Nyquist* sampling rate. The theorem states that the sampling rate must be *twice* the highest possible detail one expects to image in the object. If the object has details closer than, say, 1 mm, one must take at least 2 pixels/mm. (The Nyquist theorem actually says more than this, but a discussion of the entire theorem is beyond the scope of this chapter). If we sample at a lower rate than the theoretical lowest limit, the resulting digital representation of the object will be distorted. This type of distortion or sampling error is known as *aliasing* errors. Aliasing errors usually manifest themselves in the image as moire patterns (Fig. 7.28). The important point to remember is that there is a *lower limit* to the spatial sampling rate such that object detail can be maintained. The sampling rate can also be stated as the total number of pixels needed to represent the digital image, that is, the matrix size (or grid size). One often sees these sampling rates cited as 256×256 , 512×512 , and so on. If the same object is imaged with a large matrix size, the sampling rate has obviously increased. Typically, images

FIGURE 7.28 This image shows the effects of aliasing due to sampling the image at too low a rate. The image should be straight lines converging at a point. Because of undersampling, it appears as if there are patterns in the lines at various angles. These are known as moiré patterns.

are sampled on 256×256 , 512×512 , or 1024×1024 grids, depending on the application and type of modality. One immediately observes an important issue in digital representation of images: that of the large number of pixels needed to represent the image. A 256×256 image has 65,536 pixels and a 512×512 image has 262,144 pixels. We shall return to this point later when we discuss processing or storage of these images.

The quality of the representation of the digital image is also determined by the number of levels or shades of gray that are used in the quantization. If one has more levels, then fewer mistakes will be made in assigning values at the output of the transducer. Figure 7.29 demonstrates how the number of gray levels affects the digital representation of an artery. When a small number of levels are used, the quantization is coarse and the quantization error is large. The quantization error usually manifests itself in the digital image by the appearance of *false contouring* in the picture. One usually needs at least 6 b or 64 gray levels to represent an image adequately. Higher quality imaging systems use 8 b (256 levels) or even as many as 10 b (1024 levels) per pixel. In most applications, the human observer cannot distinguish quantization error when there are more than 256 levels. (Many times the number of gray levels is cited in bytes. One byte is 8 b, that is, high-quality monochrome digital imaging systems use one byte per pixel.)

One of the problems briefly mentioned previously is the large number of pixels needed to represent an image, which translates into a large amount of digital data needed for the representation. A 512×512 image with 8 b/pixel (1 byte/pixel) of gray levels representation requires 2,097, 152 b of computer data to describe it. A typical computer file that contains 1000 words usually requires only about 56,000 b to describe it. The 512×512 image is 37 times larger! (A picture is truly worth more than 1000 words.) This data requirement is one of the major problems with digital imaging, given that the storage of digital images in a computer file system is expensive. Perhaps another example will demonstrate this problem. Many computers and word processing systems have the capability of transmitting information over telephone lines to other systems at data rates of 14,400 b/s. At this speed it would require nearly 2.5 min to transmit a 512×512 image! Moving objects are imaged digitally by taking *digital snapshots* of them, that is, digital video. True digital imaging would acquire about 30 images/s to capture all of the important motion in a scene.

FIGURE 7.29 This image demonstrates the effects of quantization error. The upper left image is a coronary artery image with 8 b (256 levels or shades of gray) per pixel. The upper right image has 4 b/pixel (16 levels). The lower left image has 3 b/pixel (8 levels). The lower right image has 2 b/pixel (4 levels). Note the false contouring in the images as the number of possible levels in the pixel representation is reduced. This false contouring is the quantization error, and as the number of levels increases the quantization error decreases because fewer mistakes are being made in the representation.

At 30 images/s, with each image sampled at 512×512 and with 8 b/pixel, the system must handle 62,914,560 b/s. Only very expensive acquisition systems are capable of handling these large data rates.

The greatest advantage of digital images is that they can be processed on a computer. Any type of operation that one can do on a computer can be done to a digital image. Recall that a digital image is just a (huge) matrix of numbers. Digital image processing is the process of using a computer to extract useful information from this matrix. Processing that cannot be done optically or with analog systems (such as early video systems) can be easily done on computers. The disadvantage is that a large amount of data needs to be processed, and on some small computer systems this can take a long time (hours).

7.4.2 Point Operations

Perhaps the simplest image processing operation is that of modifying the values of individual pixels in an image. These operations are commonly known as **point operations**. A point operation might be used to highlight certain regions in an image. Suppose one wished to know where all of the pixels in a certain gray level region were *spatially* located in the image. One would modify all those pixel values to 0 (black) or 255 (white) such that the observer could see where they were located.

Another example of a point operation is *contrast enhancement* or *contrast stretching*. The pixel values in a particular image may occupy only a small region of gray level distribution. For instance, the pixels in an image may only take on values between 0 and 63, when they could nominally take on values between 0 and 255. This is sometimes caused by the way the image was digitized and/or by the type of transducer used. When this image is examined on a CRT display the contrast looks washed out. A simple point operation that multiplies each pixel value in the image by four will increase the apparent contrast in the image; the new image now has gray values between 0 and 252. This operation is shown in Fig. 7.30. Possibly the most

FIGURE 7.30 Contrast stretching. The image on the left has gray values between 0 and 63, causing the contrast to look washed out. The image on the right has been contrast enhanced by multiplying the gray levels by four.

widely used point operation in medical imaging is *pseudocoloring*. In this point operation all of the pixels in the image with a particular gray value are assigned a *color*. Various schemes have been proposed for appropriate pseudocolor tables that assign the gray values to colors. It should be mentioned that point operations are often cascaded, that is, an image undergoes contrast enhancement and then pseudocoloring.

The operations just described can be thought of as operations (or *algorithms*) that modify the range of the gray levels of the pixels. An important feature that describes a great deal about an image is the *histogram* of the pixel values. A histogram is a table that lists how many pixels in an image take on a particular gray value. These data are often plotted as a function of the gray value. Point operations are also known as *histogram modification* or *histogram stretching*. The contrast enhancement operation shown in Fig. 7.30 modifies the histogram of the resultant image by stretching the gray values from a range of 0–63 to a range of 0–252. Some point operations are such that the resulting histogram of the processed image has a particular shape. A popular form of histogram modification is known as *histogram equalization*, whereby the pixel are modified such that the histogram of the processed image is almost flat, that is, all of the pixel values occur equally.

It is impossible to list all possible types of point operations; however, the important thing to remember is that these operations process one pixel at a time by modifying the pixel based only on its gray level value and not where it is distributed spatially (i.e., location in the pixel matrix). These operations are performed to enhance the image, to make it easier to see certain structures or regions in the image, or to force a particular shape to the histogram of the image. They are also used as initial operations in a more complicated image processing algorithm.

7.4.3 Image Enhancement

Image enhancement is the use of image processing algorithms to remove certain types of distortion in an image. The image is enhanced by removing noise, by making the edge structures in the image stand out, or by any other operation that makes the image *look* better.¹ Point operations just discussed are generally

¹Image enhancement is often confused with *image restoration*. Image enhancement is the *ad hoc* application of various processing algorithms to enhance the appearance of the image. Image restoration is the application of algorithms that use knowledge of the degradation process to enhance or restore the image, that is, deconvolution algorithms used to remove the effect of the aperture point spread function in blurred images. A discussion of image restoration is beyond the scope of this section.

considered to be enhancement operations. Enhancement also includes operations that use groups of pixels and the spatial location of the pixels in the image.

The most widely used algorithms for enhancement are based on pixel functions that are known as *window operations*. A window operation performed on an image is nothing more than the process of examining the pixels in a certain region of the image, called the window region, and computing some type of mathematical function derived from the pixels in the window. In most cases the windows are square or rectangle, although other shapes have been used. After the operation is performed, the result of the computation is placed in the center pixel of the window. As an example of a window operation, suppose we compute the average value of the pixels in the window. This operation is known as *smoothing* and will tend to reduce noise in the image, but unfortunately it will also tend to blur edge structures in the image.

It is possible to compute a nonlinear function of the pixels in the window. One of the more powerful nonlinear window operations is that of *median filtering*. In this operation all of the pixels in the window are listed in descending magnitude and the middle, or *median*, pixel is obtained. The median pixel then is used to replace the center pixel. The median filter is used to remove noise from an image and at the same time preserve the edge structure in the image. More recently, there has been a great deal of interest in *morphological operators*. These are also nonlinear window operations that can be used to extract or enhance shape information in an image.

Defining Terms

Image enhancement: An image processing operation that is intended to improve the visual quality of the image or to emphasize certain features.

Pixel: A single sample or picture element in the digital image, which is located at specific spatial coordinates.

Point operation: An image processing operation in which individual pixels are mapped to new values irrespective of the values of any neighboring pixels.

Quantization: The process of converting from a continuous-amplitude image to an image that takes on only a finite number of different amplitude values.

Sampling: The process of converting from a continuous-parameter image to a discrete-parameter image by discretizing the spatial coordinate.

Further Information

A number of textbooks are available that cover the broad area of image processing and several that focus on more specialized topics within this field. The texts by Gonzalez and Wintz (1991), Jain (1989), Pratt (1991), and Rosenfeld and Kak (1982, Vol. 1) are quite broad in their scope. Gonzalez and Wintz's treatment is written at a somewhat lower level than that of the other texts. Current research and applications of image processing are reported in a number of journals. Of particular note are the *IEEE Transactions on Image Processing*; the *IEEE Transactions on Pattern Analysis and Machine Intelligence*; the *IEEE Transactions on Geoscience and Remote Sensing*; the *IEEE Transactions on Medical Imaging*; the *Journal of the Optical Society of America, A: Optical Engineering*; the *Journal of Electronic Imaging*; and *Computer Vision, Graphics, and Image Processing*.

7.5 Image Display Devices

Jerry C. Whitaker

7.5.1 Introduction

Information display is a key element in the advancement of electronics technology. The continued rapid growth of computer applications and embedded computer controllers in a wide variety of products have pushed forward the requirements for display components of all types. The basic display technologies in common use include the following:

- Cathode ray tube (CRT)
- CRT-based large screen projection
- Light valve-based large screen projection
- Light emitting diode (LED)
- Plasma display panel (PDP)
- Electroluminescence (EL)
- Liquid crystal display (LCD)

These technologies find use in a broad spectrum of applications, including

- Consumer television
- Computer display
- Medical imaging
- Industrial process control
- Test and measurement
- Automotive instrumentation
- Aerospace instrumentation
- Military devices and systems
- Camera imaging
- Printing
- Textiles
- Office equipment
- Telecommunications systems
- Advertising and point-of-purchase

CRT-based display technologies are covered in Chapter 28. Solid-state display systems will be addressed in this chapter.

Flat Panel Display Systems

Flat panel display systems are of interest to design engineers because of their favorable operational characteristics relative to CRT devices. These advantages include

- Portability
- Low occupied volume
- Low weight
- Modest power requirements

Within the last few years, a great deal of progress has been made on improving the performance of FPDs.

Advanced Display Applications

The applications for information display technologies are wide and varied. Aerospace is one area where different display technologies must be merged and where significant development is being conducted on an on-going basis. More information must be presented in the cockpit than ever before, and in greater varieties as well. The glass cockpit has already become a reality, with electronic displays replacing electromechanical devices. With the need for more detailed information, the size and resolution of the display devices must increase. Full-color plates and multilevel gray scales are a definite requirement. Reliability, naturally, is of the utmost importance.

The cockpit will grow into an interactive space that may include a heads-up display and/or helmet visor display. Alternatively, a big picture approach has been suggested in which the entire cockpit display area is one large reconfigurable element that integrates system readouts and controls. Reconfiguration is important where flight mode determines the cockpit display needs.

Multisensor Environment

Many different types of imaging sensors exist, each sensitive to a different portion of the electromagnetic spectrum (Foyle, 1992). Passive sensors, which collect energy transmitted by or reflected from a source, include television (visible light), night-vision devices (intensified visible and near-infrared light), passive millimeter wave sensors, and thermal imaging (infrared sensors). Active sensors, when objects are irradiated and the energy reflected from those objects is collected, include the various types of radar.

Each of these systems was developed because of their ability to increase the probability of identification, or detection of objects under difficult environment conditions. To best present this information to an operator, image processing algorithms have been developed that *fuse* the information into a single coherent image containing information from more than one sensor. Such systems are referred to as *multisensor displays*. The process of combining the display data is known as **sensor fusion**. New sensor integration hardware and software can be evaluated both relatively, by determining which combinations are better than others, and absolutely, by comparing operator performance to theoretical expectations.

Typically, as the environmental conditions change in which an individual sensor operators, so does the information content of that image. The information content of the image can further be *scaled* by the operator's ability to perform a target identification or discrimination task. It is reasonable to expect task performance with a sensor fusion display formed from two low-information content (and, hence, poor performance) images to still be relatively poor. Similarly, two high-information content (high-performance) sensor images should yield good performance when combined into a sensor fusion display. Assuming that there was some independent information in the two individual sensor images, it is logical to expect performance with the sensor fusion display to be better than either of the two individual sensors alone. This property results in a three-dimensional performance space.

The greater the number of sensor inputs, the greater the overall performance of the fusion display. However, as the number of inputs grows, the task of designing a display that provides coherent information to the operator is significantly increased. This area of display technology represents perhaps the greatest single technical challenge for the display industry. Although a wealth of sensor data is available in a tactical situation, the ability of the operator to integrate the data on a split-second basis remains limited. As the computer industry has already discovered, gathering data is relative easy—determining how to display the data so that the operator can understand it is the real challenge.

7.5.2 LCD Projection Systems

Liquid crystal displays have been widely employed in high-information content systems and high-density projection devices. The steady progress in active-matrix liquid crystal displays, in which each pixel is addressed by means of a thin film transistor (TFT), has led to the development of full-color video TFT-addressed liquid crystal light valve (LCLV) projectors. Compared with conventional CRT-based projectors.

FIGURE 7.31 Structure of a liquid-cooled LC panel.

LCLV systems have a number of advantages, including

- Compact size
- Light weight
- Low cost
- Accurate color registration

Total light output (brightness) and contrast ratio, however, have remained a challenge. Improvements in the transmittance of polarizer elements have helped increase display brightness. By arrangement of the direction of the polarizers, the LCD can be placed in either the *normally black* (NB) or *normally white* (NW) mode. In the NW mode, light will be transmitted through the cell at V_{off} and will be blocked at V_{on} . The opposite situation applies for the NB mode. A high contrast display cannot be obtained without a satisfactory dark state.

Cooling the LC panels represents a significant technical challenge as the light output of projection systems increases. The contrast ratio of the displayed image will decrease as the temperature of the LC panels rises. Furthermore, long-term operation under conditions of elevated temperature will result in shortened life for the panel elements.

The conventional approach to cooling has been to circulate forced air over the LC panels. This approach is simple and works well for low- to medium-light-output systems. Higher power operation, however, may require liquid cooling. One approach incorporates a liquid-cooled heat exchanger to maintain acceptable contrast ratio on a high-output HDTV projector. The structure of the cooling system is shown in Fig. 7.31. The cooling unit, mounted behind the LC panel, is made of frame glass and two glass panels. The coolant is a mixture of water and ethylene glycol, which prevents the substance from freezing at low temperatures.

Figure 7.32 compares the temperature in the center of the panel for conventional air cooling and for liquid cooling. Because LC panel temperature is a function of the brightness distribution of the light source, the highest temperature is at the center of the panel, where most of the light is usually concentrated. As the amount of light from the lamp increases, the cooling activity the liquid-based system accelerates. Waste heat is carried away from the projector by directing cooling air across the heat reduction fins.

FIGURE 7.32 LC panel temperature dependence on lamp power in a liquid crystal projector.

Application Examples

The numerous recent improvements in LC display technology have permitted significant advances in LC projection techniques. One common approach incorporates three 5.5-in. 1.2 million pixel TFT active matrix LCD panels as light valves to project onto a 110-in. (or larger) screen. A simplified block diagram of the system is shown in Fig. 7.33. A short-arc, single jacket type 250-W high-intensity metal halide lamp is used as the light source. A parabolic cold mirror is utilized that reflects only the visible spectrum of the light beam to the front of the projector, allowing the infrared and ultraviolet spectrum rays to pass behind the mirror. Such rays have a harmful effect on the LC panels. The white light from the lamp is separated into the primary colors by dichroic mirrors. Each of the three primary color beams are regulated as they pass through their respective LC panels.

FIGURE 7.33 LC projection system for HDTV applications.

FIGURE 7.34 Optical system for an NTSC LC projector.

The LC system offers good signal clarity, compared to other projection systems. A single lens optical system is used; the primary colors are combined before entering the projection lens. The convergence of the picture projected, therefore, is unaffected by changes in the distance between the projector and the screen. Furthermore, changes in the viewing position relative to the center axis of the display screen will not adversely affect color purity.

Figure 7.34 illustrates the optical system of an LC projector designed for National Television Systems Committee (NTSC) applications. The TFT active matrix LC panels contain 211,000 pixels. Vertical resolution of 440 television lines is achieved through the use of noninterlaced progressive scanning. Interpolative picture processing techniques render the scanning lines essentially invisible. As shown in the figure, white light is separated into red, green, and blue (RGB) light by dichroic mirrors. Light of each color is directed to its corresponding RGB LC imaging panel. The LC panels are mounted to a dichroic prism for fixed convergence. The RGB images are combined into a single full-color image in the dichroic prism and projected by the lens onto the screen.

Homeotropic LCLV

The *homeotropic* (perpendicular alignment) LCLV² (Hughes) is based on the optical switching element shown in Fig. 7.35. Sandwiched between two transparent indium-tin oxide electrodes are a layer of cadmium sulfide photoconductor, a cadmium telluride light blocking layer, a dielectric mirror, and a 6- μm -thick layer of liquid crystal. An AC bias voltage connects the transparent electrodes. The light blocking layer and the dielectric mirror are thin and have high dielectric constants, and so the AC field is primarily across the photoconductor and the liquid crystal layer. When there is no writing light impinging on the photoconductor, the field or voltage drop is primarily across the photoconductor and not across the liquid crystal. When a point on the photoconductor is activated by a point of light from an external writing CRT, the impedance at that point drops and the AC field is applied to the corresponding point in the liquid crystal layer. The lateral impedances of the layers are high, and so the photocarriers generated at the point of exposure do not spread to adjacent points. Thus, the image from the CRT that is exposing

²This section is based on: Fritz, V.J. 1990. Full-color liquid crystal light valve projector for shipboard use. In *Large Screen Projection Displays II*, ed. W.P. Bleha, Jr., pp. 59–68. SPIE 1255.

FIGURE 7.35 Layout of a homeotropic liquid crystal light valve.

the photoconductor is reproduced as a voltage image across the liquid crystal. The electric field causes the liquid crystal molecules to rotate the plane of polarization of the projected light that passes through the liquid crystal layer.

The homeotropic LCLV provides a perpendicular alignment in the *off* state (no voltage across the liquid crystal) and a pure optical birefringence effect of the liquid crystal in the *on* state (voltage applied across the liquid crystal). To implement this electro-optical effect, the liquid crystal layer is fabricated in a perpendicular alignment configuration; the liquid crystal molecules at the electrodes are aligned with their long axes perpendicular to the electrode surfaces. In addition, they are aligned with their long axes parallel to each other along a preferred direction that is fabricated into the surface of the electrodes.

A conceptual drawing of an LCLV projector using this technology is shown in Fig. 7.36. Light from a xenon arc lamp is polarized by a polarized beamsplitting prism. The prism is designed to reflect S polarized light (the polarization axis, the *E*-field vector, is perpendicular to the plane of incidence) and transmit

FIGURE 7.36 Block diagram of an LCLV system.

FIGURE 7.37 Functional optical system diagram of an LCLV projector.

P polarized light (the polarization axis, the E -field vector, is parallel to the plane of incidence). The S polarization component of the light is reflected to the light valve. When the light valve is activated by an image from the CRT, the reflecting polarized light is rotated 90° and becomes P polarized. The P polarization component transmits through the prism to the projection lens. In this type of system the prism functions as both a polarizer and analyzer. Both monochrome and full-color versions of this design have been implemented. Figure 7.37 shows a block diagram of the color system.

The light valve is coupled to the CRT assembly by a fiber optic backplate on valve and a fiber optic faceplate on the CRT.

The heart of this system is the fluid filled prism assembly. This device contains all of the fillers and beamsplitter elements that separate the light into different polarizations and colors (for the full-color model). Figure 7.38 shows the position of the beamsplitter elements inside the prism assembly.

The light that exits the arc lamp housing enters the prism through the ultraviolet (UV) filter. The UV filter is a combination of a UV reflectance dichroic on a UV absorption filter. The UV energy below 400 nm can be destructive to the life of the LCLV. Two separate beamsplitters *prepolarize* the light: the green prepolarizer and the red/blue prepolarizer. Prepolarizers are used to increase the extinction ratio of the two polarization states. The green prepolarizer is designed to reflect only the S polarization component of green light. The P polarization component of green and both the S and P polarizations of red and blue are transmitted through the green prepolarizer. The green prepolarizer is oriented 90° with respect to the other beamsplitters in the prism. This change of orientation means that the transmitted P component of the green light appears to be S polarized relative to the other beamsplitters in the prism assembly. The red/blue prepolarizer is designed to reflect the S polarization component of red and blue. The remaining green that is now S polarized and the red and blue P polarized components are transmitted to the main beamsplitter.

The main beamsplitter is a broadband polarizer designed to reflect all visible S polarized light and transmit all visible P polarized light. The S polarized green light is reflected by the main beamsplitter to the green mirror. The green mirror reflects the light to the green LCLV. The P polarized component of red and blue transmits through the main polarizer. The red/blue separator reflects the blue light and transmits the red to the respective LCLVs.

Image light is rotated by the light valve and is reflected to the prism. The rotation of the light or phase change (P polarization to S polarization) allows the image light from the red and blue LCLVs to reflect off the main beamsplitter toward the projection lens. When the green LCLV is activated, the green image light is transmitted through the main beamsplitter.

FIGURE 7.38 Layout of the fluid filled prism assembly for an LCLV projector.

The fluid filled prism assembly is constructed with thin-film coatings deposited on quartz plates and immersed in an index matching fluid. Because polarized light is used, it is necessary to eliminate stress birefringence in the prism, which, if present, would cause contrast degradation and background nonuniformity in the projected image. Using a fluid filled prism effectively eliminates mechanically and thermally induced stress birefringence as well as any residual stress birefringence. Expansion of the fluid with temperature is compensated for by using a bellows arrangement.

The color projector described in this section is capable of light output of over 1300 lumens with a contrast ratio of 200:1 or greater. The projector uses a 750-W xenon arc lamp as the light source. The video resolution is 1600 (H) \times 1200 (V).

Laser-Addressed LCLV

The laser-addressed liquid crystal light valve is a variation on the CRT-addressed LCLV discussed in the previous section. Instead of using a CRT to write the video information on the LC element, a laser is used.³ The principle advantages of this approach is the small spot size possible with laser technology, thereby increasing the resolution of the displayed image. In addition, a single beam from a laser scanner can be directed to three separate RGB light valves, reducing potential convergence problems by having only one source for the image.

³Portions of this section are based on: Phillips, T.E. et al. 1992. 1280 \times 1024 video rate laser-addressed liquid crystal light valve color projection display. *Optical Engineering* 31(11):2300–2312.

FIGURE 7.39 Block diagram of a color laser-addressed light valve display system.

A block diagram of the laser-addressed LCLV is shown in Fig. 7.39. Major components of the system include

- Laser
- Video raster scanner
- Polarizing multiplexing switches
- LCLV assemblies
- Projection optics

Projector operation can be divided into two basic subsystems:

- Input subsystem, which includes the laser, scanning mechanism, and polarizing beamsplitters
- Output subsystem, which includes the LCLV assemblies, projection optics, and light source

The output subsystem is similar in nature to the homeotropic LCLV discussed in the previous section.

The heart of the input subsystem is the *laser raster scanner* (LRS). The X-Y deflection system incorporated into the LRS uses four acousto-optic devices to achieve all solid-state modulation and scanning. A diode-pumped Nd:YAG, doubled to 535 nm (18 mW at 40:1 polarization ratio), is used as the laser source for the raster scan system.

Because only a single-channel scanner is used to drive the LCLV assemblies, a method is required to sequence the RGB video fields to their respective light valves. This sequencing is accomplished through the use of LC polarization switches. These devices act in a manner similar to the LCLV in that they change the polarization state of incident light. In this case the object is to rotate the polarization by 0° or 90° and exploit the beam steering capabilities of polarizing beamsplitters to direct the image field to the proper light valve at the proper time.

As shown in Fig 7.39, each switch location actually consists of a pair of individual switches. This was incorporated to achieve the necessary fall time required by the LRS to avoid overlapping of the RGB fields. Although these devices have a short rise time (approximately 100 μ s), their decay time is relatively long (approximately 1 ms). By using two switches in tandem, compensation for the relatively slow relaxation

FIGURE 7.40 DC plasma display panel for color video.

time is accomplished by biasing the second switch to relax in an equal, but opposite, polarization sense. This causes the intermediate polarization state that is present during the switch-off cycle to be nulled out, allowing light to pass through the LC switch during this phase of the switching operation.

Luminescent Panels

The prevalent technology of large screen luminescent panels employs plasma excitation of phosphors overlying each display cell. The plasma is formed in low-pressure gas that may be excited by either AC or DC fields. Figure 7.40 depicts a color DC plasma panel. Such devices have been constructed in a variety of sizes and cell structures. Color rendition requires red/green/blue trios that are excited preferentially or proportionally, as in a color CRT, which triples the number of actual cells (three cells comprise one picture element).

Because of their favorable size and weight considerations, PDP systems are well suited to large screen (40-in. diagonal) full-color emissive display applications.

Both AC and DC PDPs have been used to produce full-color, flat-panel large area dot-matrix devices. PDP systems operate in a memory mode. Memory operation is achieved through the use of a thick-film current-limiting series capacitor at each cell site. The internal cell memory capability eliminates the need for a refresh scan. The cell memory holds an image until it is erased. This eliminates flicker because each cell operates at a duty cycle of one. The series cell capacitor in an AC-PDP is fabricated using a thick-film screen-printed dielectric glass, as illustrated in Fig. 7.41. The gap separation between the two substrates is typically 4 mil. The surface of the thick-film dielectric is coated with a thin-film dielectric material such as magnesium oxide.

Matrix Addressing

Provision for individual control of each element of a discrete element display implies a proliferation of electrical connections and, therefore, rapidly expanding cost and complexity. These factors are minimized in discrete-element displays through *matrixing* techniques wherein a display element must receive two or more gating signals before it is activated. Geometric arrangements of the matrixing connectors guarantee that only the appropriate elements are activated at a given time.

FIGURE 7.41 Cross section of an AC-PDP cell capacitor.

Matrix addressing requires that the picture elements of a panel be arranged in rows and columns, as illustrated in Fig. 7.42 for a simplified 4×4 matrix. Each element in a row or column is connected to all other elements in that row or column by active devices (typically transistors). Thus, it is possible to select the drive signals so that when only a row or column is driven, no elements in that row or column will be activated. However, when both the row and column containing a selected element are driven, the sum of the two signals will activate a given element. The resulting reduction in the number of connections required, compared to a discrete-element drive, is significant because the number of lines is reduced from one-per-element to the sum of the number of rows and columns in the panel.

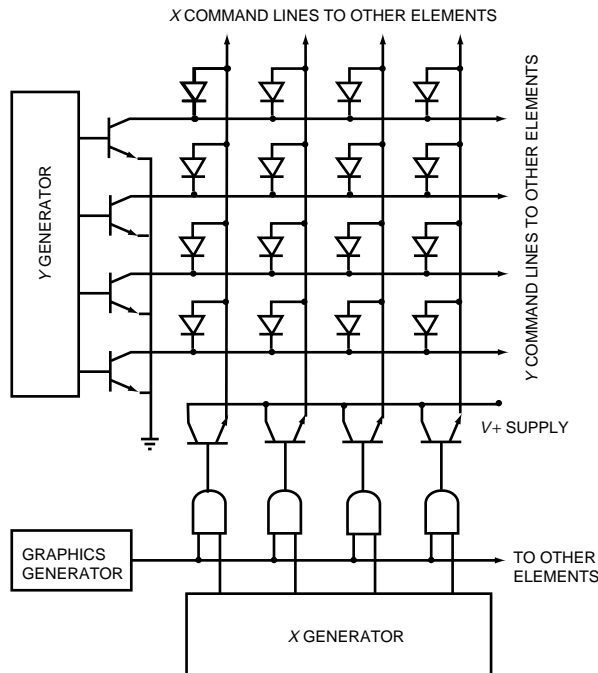

FIGURE 7.42 Matrix addressing for flat-panel display.

For active matrix addressing to work properly, it is necessary to have a sharp discontinuity in the transfer characteristic of the device at each pixel at the intersection of the row and column address lines. In some cases, the characteristics of the display device itself can be used to provide this discontinuity. The breakdown potential of a gas discharge can be used (for plasma displays) or alternatively, liquid crystals can be made to have a reasonably sharp transfer curve.

Defining Terms

- Darkfield performance:** The amount of light that is blocked in a light valve projector when a totally dark scene is being displayed. This parameter is critical to good contrast ratio.
- Front projection system:** A projection device where the image is viewed from the same side of the screen as that on which it is projected.
- Light valve:** A projection device that employs a fixed light source modulated by an optical-valve intervening the source and projection optics.
- Matrix addressing:** The control of a display panel consisting of individual light-producing elements by arranging the control system to address each element in a row/column configuration.
- Rear projection system:** A projection device where the image is viewed from the opposite side of the screen from that on which it is projected.
- Sensor fusion:** The combining of multiple sensor inputs into a single output display that is optimized for operator interpretation through manipulation of data and, if applicable, pre-programmed decision making processes.

Further Information

The SPIE (the international optical technology society) offers a wide variety of publications on the topic of display systems engineering. The organization also holds technical seminars on this and other topics several times each year. SPIE is headquartered in Bellingham, WA. The Society for Information Display (SID) also holds regular technical seminars and offers a number of publications on the topic of projection display systems. SID is headquartered in Santa Ana, CA.

Two books on the topic of display systems are recommended:

Whitaker, Jerry C.: “Video Display Engineering,” McGraw-Hill, New York, N.Y., 2001.

Whitaker, Jerry C., and K. Blair Benson: “Standard Handbook of Video and Television Engineering” McGraw-Hill, New York, N.Y., 2003.

7.6 Solid-State Amplifiers

Timothy P. Hulick

7.6.1 Introduction

Amplifiers are used in all types of electronic equipment and form the basis from which other active circuits are derived. Designing an oscillator would be impossible without an amplifier built in. Without amplifiers, any generated signal (if a meaningful signal could be generated without one) would only suffer loss after loss as it passed through a circuit to the point where it would become immeasurably small and useless. In fact, amplifiers are designed and built to counter loss so that deterioration of a signal as it passes through a medium is restored to its former or even greater level while allowing it to do something to the circuit that it just passed through. An amplified signal does not have to be a greater reproduction of itself, although this may be desirable, but only has to be bigger in some way than the one it came from. The form of an amplified signal may not resemble the signal from which it came, but must be controlled by it. The controlling of a big signal by a smaller one defines the notion of **gain**. All useful amplifiers have a gain magnitude equal to or greater than one which counters the effect of gain less than one (or loss) by passive elements of a circuit. Gain of an amplifier is defined to be the ratio of output power level to a load, divided by input power level driving the amplifier. In general, those devices that have a gain magnitude greater than one are considered to be *amplifiers*, whereas those of the other case are considered to be *attenuators*. The universally accepted electronic symbol for an amplifier is the triangle, however oriented, and it may or may not have more than one input or output or other connection(s) made to it. A simple amplifier is shown in Fig. 7.43.

Technically speaking, active logic gates found in the various types of logic families are also amplifiers since they offer power gain in their ability to drive relatively low-impedance loads, while not acting as a significant load themselves.

Amplifiers discussed in this chapter are limited to those that use solid-state devices as the active element since other types are discussed in Sections 7.7 and 7.8. In addition, amplifiers discussed in this section are presented in a way leading the reader to think that it is a section on *RF* amplifiers. This could not be further from the truth. Examples and presentations made here are meant to be *general*, using the general case where carrier frequencies are not zero. The same rules apply to amplifiers, whether they are used for baseband purposes, in which case the carrier frequency is zero, or are used as *RF* amplifiers, in which case the carrier frequency is not zero.

FIGURE 7.43 Any amplifier is universally symbolically represented as a triangle.

7.6.2 Linear Amplifiers and Characterizing Distortion

Amplifiers overcome loss and may or may not preserve the amplitude-time-frequency attributes of the signal to be amplified. Those that do come under the broad category known as **linear** amplifiers, whereas those that do not come under the category called *nonlinear* amplifiers. A linear amplifier has a frequency domain transfer function so that each point along the time-domain curve that defines the input signal perfectly maps into the output signal in direct proportion with constant time delay. This can only happen if a plot of output vs. input is a straight line, hence, the term linear. Since a straight line function represents only the ideal case, there are degrees of linearity that define the usefulness of such a thing in a particular application. What is considered linear in one application may not be linear enough in another. Linearity is measured in the amount of distortion of many different kinds, again, according to the application.

Compression

For an amplifier to be considered linear, the amplified signal output must be a faithful reproduction of the input signal. Without any *fixes* applied, such as negative feedback, the basic linear amplifier has limitations that are functions of its load impedance, supply voltage, input bias current (or voltage depending on device type), and its ability to just make the power asked of it. With sufficiently large drive, any device can be driven beyond its limits to the point of burnout, and so it is important to know the limitations of any amplifier. The onset of output signal compression is the first sign that a linear amplifier is being driven beyond its linear limits, that is, the transfer function curve is beginning to slope away from a straight line such that the output *compresses* compared to what it should be. Figure 7.44 illustrates the normal straight line path compared to the **compression** taking place when the amplifier is being driven too hard.

FIGURE 7.44 In the normalized plot of power output vs. power input, the amplifier is seen to be linear in the region from 0 to 1.0. Beyond this point, the output becomes compressed and finally flattens.

Linear amplifiers are characterized according to their 1-dBm power gain compression point. Simply put, the 1-dBm compression point is that power output from which a 9-dBm decrease is realized when the drive level is decreased by 10 dBm. A single-frequency continuous wave (CW) signal is usually used as the driving signal. When performing this test it is best to begin with a low-level signal far away from the compression region. The drive level is increased in 1-dBm steps while monitoring the linear tracking of input and output powers. Steps taken in 1-dBm increments are adequate and beneficial when looking for less than a 1-dBm increase in output power as the compression region is reached. At the onset of compression, the drive should be increased by 1 dBm more. At this point drive may be decreased by 10 dBm. If the output power decreases by more than 9 dBm, the 1-dBm compression point is still higher. Increase drive by a few tenths of a decibel and try again. Finding the 1-dBm compression point should be done by decreasing drive, not increasing it. Not knowing where it is, an increase this large could put the amplifier well into saturation (compression) and perhaps permanent damage may result.

The 1-dBm compression point should be noted. Generally, excellent linear operation will be 10 dBm or more below this point, but more power may be gotten from an amplifier if the compression point is approached more closely and compensated for by a low-level precorrector (expander) circuit before the input to the amplifier.

Odd Order Intermodulation Distortion

Another very important measure of linearity is the relative level of generated odd order intermodulation products in the amplifier. For intermodulation to take place, two or more signals must exist at the same time as a combined input signal. They must be at different frequencies, but near enough to each other so that they both fit within the passband of the amplifier. A suitable example input signal is of the form of Eq. (7.23)

$$S_i(t) = A \cos(2\pi f_1 t) + B \cos(2\pi f_2 t) \quad (7.23)$$

where A and B are the amplitudes of the independent input signals of frequencies f_1 and f_2 , respectively.

In the absence of any nonlinearity in the amplifier transfer function, the output is of the same form as the input, and there is no change except that A and B are multiplied by the gain of the amplifier G

$$S_0(t) = G A \cos(2\pi f_1 t) + G B \cos(2\pi f_2 t) \quad (7.24)$$

If the transfer function is not perfectly linear, the input components are also multiplied together within the amplifier and appear at the output. The amplifier actually behaves like an ideal amplifier shunted (input to output) by a mixer, as shown in Fig. 7.45. The expression showing all frequency components out of the amplifier is

$$\begin{aligned} S_0(t) &= G A \cos(2\pi f_1 t) + G B \cos(2\pi f_2 t) + \sum_{m=\text{int}} \sum_{n=\text{int}} c_{mn} A B \cos(2\pi m f_1 t) \cos(2\pi n f_2 t) \\ S_0(t) &= G A \cos(2\pi f_1 t) + G B \cos(2\pi f_2 t) \\ &+ \sum_{m=\text{int}} \sum_{n=\text{int}} \left[\frac{1}{2} c_{mn} A B \cos 2\pi(m f_1 + n f_2)t + \frac{1}{2} c_{mn} A B \cos 2\pi(m f_1 - n f_2)t \right] \end{aligned} \quad (7.25)$$

where c_{mn} is the amplitude of the product component at frequency $f_{mn} = (m f_1 + n f_2)$ and is determined by the degree of nonlinearity.

Note that m and n can be any positive or negative integer and that the frequency components f_{mn} closest to the original signal frequencies are for m or n negative, but not both, $|m| + |n| = \text{odd}$ and m and n differ only by one. Generally, the amplitudes of the multiplication (intermodulation product) frequency components at f_{mn} are greater for $|m| + |n| = 3$ than for $|m| + |n| = 5$. Also the magnitudes of the $|m| + |n| = 5$ components are greater than the $|m| + |n| = 7$ components. The difference frequencies for the sum of m and n being odd are special because these frequency components may be difficult to filter out. Even order components, that is, when $|m| + |n| = \text{even}$ and the sum frequencies are far away

FIGURE 7.45 For intermodulation distortion analysis, the amplifier under test may be thought of as an ideal amplifier shunted by a mixer that creates the intermodulation product components. Multiple frequency signal components make up the inputs to the mixer.

FIGURE 7.46 Example output spectral components are shown for a real linear amplifier with odd order intermodulation distortion. A two-frequency (two-tone) input signal is shown amplified at the output along with odd order difference frequencies generated within the amplifier.

in frequency, therefore, are easy to filter and generally are of no consequence. Because of this, odd order **intermodulation distortion** components are of importance to the amplifier linearity whereas even order components are not. Specifically, the third-order components are of concern because they are the closest in frequency to the original signals and are of the greatest amplitude. Figure 7.46 is a view of the relative positions and amplitudes of odd order intermodulation products around the original signals; their frequencies are listed in Table 7.1.

The CW signal used to find the 1-dBm compression point sets the maximum **peak envelope power (PEP)** with which the amplifier should be driven. The PEP of Eq. (7.23) is $(A + B)^2$, whereas the PEP of each frequency component is A^2 or B^2 . The CW signal used in the compression test would be, for

TABLE 7.1 Some Odd Order Intermodulation Distortion Components to the Ninth Order

Third Order	Fifth Order	Seventh Order	Ninth Order	Comment
$2f_1 - f_2$	$3f_1 - 2f_2$	$4f_1 - 3f_2$	$5f_1 - 4f_2$	Near
$2f_2 - f_1$	$3f_2 - 2f_1$	$4f_2 - 3f_1$	$5f_2 - 4f_1$	Near
$f_1 - 2f_2$	$2f_1 - 3f_2$	$3f_1 - 4f_2$	$4f_1 - 5f_2$	Negative
$f_2 - 2f_1$	$2f_2 - 3f_1$	$3f_2 - 4f_1$	$4f_2 - 5f_1$	Negative
$f_1 + 2f_2$	$2f_1 + 3f_2$	$3f_1 + 4f_2$	$4f_1 + 5f_2$	Far away
$f_2 + 2f_1$	$2f_2 + 3f_1$	$3f_2 + 4f_1$	$4f_2 + 5f_1$	Far away

example, C^2 . Using a *two-tone* signal with equal amplitudes such that $A = B$, the PEP becomes $4A^2$ or $4B^2$. The PEP of the two-tone signal should not exceed the PEP of the CW signal, or the output will enter the compressed region more than anticipated. If $4A^2 = C^2$, then the PEP needed in each of the two tones is one-fourth of the equivalent CW PEP of the single-tone compression test signal, or A^2 . For this reason the two-tone test signals are individually 6 dBm below the compression test limit chosen.

The frequencies of the two tones are spaced such that the third-order intermodulation products commonly known as the IM3 products fall within the passband of the amplifier. They are not to be suppressed by means of any filters or bandwidth shaping circuits. As the amplifier is driven by the two-tone test signal, the output is observed on a spectrum analyzer. The transfer function of one of the desired signals is plotted, whereas the level of one of the IM3 signals is also plotted directly below that. The IM3 point plotted in the *power output vs. power input* space indicates that it could have come from an input signal that already had the IM3 component in it and it was just amplified and that the amplifier was not the source of the IM3 component at all. Of course, this is not true, but the IM3 curve, as it is derived along with the real transfer function as points are plotted at other power levels, begins to show itself as an imaginary transfer function. At increasing power levels, the loci of the two curves may be linearly extended to a crossover point where the desired signal output power equals the IM3 level. An example plot is shown in Fig. 7.47. Linear amplifiers are never driven this hard, but this point is specified (usually in dBm) for every linear amplifier and used along with the gain (slope of the real transfer function) to recreate a plot such as that of Fig. 7.47.

The level of IM3 may be related to the PEP of the two tones, in which case it is referred to as $(X)\text{dB}_{\text{PEP}}$, or it may be related to the PEP of either of the two tone levels that are, of course, 6 dB lower than the PEP value. When expressed this way, it is referred to as $(X)\text{dB}_c$, referenced to one of the carrier or tone levels. It is important to know which is being used.

Although the two-tone test has become a standard to determine the third-order intercept point, it does not tell the whole story. The two-tone test applies where only two tones are expected in the signal to be amplified. In the case of an analog television signal, for example, there are three tones of constant amplitude: the picture carrier, commonly called the *visual carrier*; the **color subcarrier**; and the sound carrier, commonly called the **aural subcarrier**. Their respective equivalent CW amplitudes in most television formats around the world are -8 , -17 , and -10 dB, respectively, referenced to the peak of the synchronization (sync) level. The PEP level is the PEP of the peak of sync and is used as the reference, but for common visual/aural amplification, the combined peak of sync value is an additional 73% greater. If the peak of sync level is considered to be normalized to one, and the aural subcarrier is -10 dBm down from that,

FIGURE 7.47 The output power where the IM3 line and the real transfer function line intersect is called the IM3 intercept point. The slope of the IM3 line is twice that of the transfer function so that for every decibel increase in output power, the IM3 level increases by 3 dB.

FIGURE 7.48 A three-tone test is used when evaluating a linear amplifier for television applications. The tones are set to the level of the carriers making up the signal, for example, -8-dB visual, -17-dB color, and -10-dB aural, relative to peak of sync. Some IM3 products fall in between the carriers and, therefore, are in-band and impossible to filter out.

it follows that

$$P_{PEP} = (\sqrt{P_{PEP \text{ VISUAL}}} + \sqrt{P_{PEP \text{ AURAL}}})^2 \tag{7.26}$$

$$P_{PEP} = (\sqrt{1} + \sqrt{0.1})^2 = 1.73$$

The additional PEP of the color subcarrier is insignificant at 17 dBm down from the peak of sync value. In television, however, the level of intermodulation is related to the peak of sync value as if the aural subcarrier were not present. A three-tone test is commonly used in this industry with the tone levels set to their respective values and placed at the proper frequencies. The visual carrier frequency is taken as the reference, whereas the color subcarrier is about 3.579 MHz higher and the aural subcarrier is 4.5 MHz above the visual carrier. When three tones are used for an intermodulation test, it is important to realize that some of the IM products will fall in between the original three signals. This is not the case when only two tones are used. For IM distortion products in between desired signals, filtering these components to an acceptable level is not possible since they fall on top of sideband information of one or more subcarriers. Concentrating on enhanced linearity and precorrection offers the only possible acceptable performance solutions. Generally, in-band IM products, as they are called, are considered acceptable when they are at least -52 dB lower than the peak of sync level using an average gray picture format. Figure 7.48 shows the placement of IM3 products when three tones are present.

Table 7.2 lists the in-band and nearby IM3 products for an amplified three-tone signal where the three carriers (tones) are designated f_V , f_C , and f_A for *visual*, *color*, and *aural*, respectively. One peculiarity is

TABLE 7.2 Some Third-Order Intermodulation Products for a Three-Tone Signal

IM3 In-band	IM3 Out-of-Band	Out-of-Band Comment
$f_V + f_A - f_C$	$f_V + 2f_A$	Far away
$f_V - f_A + f_C$	$f_V + 2f_C$	Far away
	$f_V - 2f_A$	Negative, only exists mathematically
	$f_V - 2f_C$	Negative, only exists mathematically
	$2f_V - f_A$	Sideband Regeneration
	$2f_V - f_C$	Sideband Regeneration

that $2f_v - f_a$ and $2f_v - f_c$ are also IM3 products, but appear to look as if they were lower sideband images of the legitimate signals at f_a and f_c , respectively. Although these components arise due to intermodulation, they were originally present when the color and aural subcarriers modulated the visual carrier before they were filtered out by a vestigial sideband filter to conform to television standards. This reappearance of the lower sidebands is sometimes called *sideband regeneration* because of where they are placed even though they are third-order intermodulation products.

Communications systems, such as those used by the telephone industry, make use of large numbers of carriers through one amplifier placing very demanding requirements on intermodulation performance. For a two-tone application, it was shown that the PEP of the individual carriers is 6 dB down from the PEP of the combined carriers. IM3 levels are 6 dB higher when referenced to either of these two carriers compared to the combined PEP of the two tones. For n equal amplitude carriers of power P , the PEP of the combined carriers is shown to be

$$\text{PEP} = n^2 P$$

or that each carrier's peak envelope power contribution to the total PEP becomes

$$P = \frac{\text{PEP}}{n^2} \quad (7.27)$$

If 16 carriers are used to drive an amplifier capable of 100-W PEP (50 dBm), the individual carriers cannot exceed about 0.4 W (26 dBm). This is a 24-dB degradation in IM3 level relative to the individual carriers. If Δ is the relative increase in IM3 in dB due to a multicarrier signal and n is the number of carriers, it follows that

$$\Delta = 20 \log n$$

For this amplifier passing 16 carriers, requiring the IM3 levels to be 60 dB_c to prevent cross talk, the IM3 level relative to total PEP must be $60 + 20 \log 16 = 84 \text{ dB}_{\text{PEP}}$.

Other Distortions

Odd order intermodulation distortion and 1-dBm gain compression go a long way to characterize the linearity of a linear amplifier, but they are by no means the only ones. Other distortion types tend to be application specific relating to their importance. For video signals other distortion type include the following:

- Differential gain
- Differential phase
- High-frequency to low-frequency delay
- Group delay
- Incidental carrier phase modulation
- Cross modulation (one carrier modulation to another)
- RF harmonic distortion
- Total harmonic distortion

Each of these is briefly discussed, but for a more in-depth understanding, the reader is referred to more specialized sources of information (Craig, 1994).

Differential gain distortion is a distortion of the amplitude information on a subcarrier in the presence of amplitude modulation of another subcarrier or main carrier. *Differential phase distortion* is a distortion of the phase information on a subcarrier in the presence of amplitude modulation of another subcarrier or main carrier. The former is measured in percent whereas the latter in degrees.

High-frequency to low-frequency delay is a distortion caused by the difference in time delay presented to high-frequency sidebands compared to low-frequency sidebands when it is important that their time

relationship not be changed. A distortion of this type causes misalignment of subcarrier information with main carrier or other subcarriers and is measured in time.

Group delay distortion has the same effect as high-frequency to low-frequency delay, but is caused by associated filters (notch, bandpass, etc.) that may be built into an amplifier. Sudden changes of transfer function of a filter such as that near a notch filter frequency will cause sudden changes in group delay for amplifier frequency components nearby. It is also measured in time.

Incidental carrier phase modulation (ICPM) could be characterized as AM to PM conversion taking place within an amplifier. As an amplifier passes an amplitude modulated signal, dynamic capacitances within the amplifying device itself act in conjunction with fixed impedances in the amplifier circuit to cause dynamic time constants leading to carrier phase shift with amplitude modulation. ICPM is measured in degrees relative to some clamped amplitude level.

Cross modulation is a distortion caused by the modulation of one carrier through the amplifier onto another subcarrier or carrier. A cause of cross modulation is the mixer or multiplier behavior of real amplifiers modeled in Fig. 7.45. If two or more carriers are multiplied together, at least one of which is modulated with AM, its modulation sidebands may appear on the other. This is different from intermodulation distortion where sum and difference carrier frequencies arise whether they are modulated or not, but the mechanism is the same. Cross modulation occurs in linear amplifiers when the signal levels at the input are simply too high in amplitude for the amplifier to pass without *mixing*. Cross modulation is also caused when the amplifier modulates the power supply voltage as supply current changes with amplitude modulated signal level. If an AM signal and a frequency modulated (FM) or phase modulated (PM) signal are being amplified simultaneously, the AM signal causes a modulated current draw from the supply in certain classes of linear amplifiers (see Class B and Class AB amplifiers later in this chapter). This in turn causes a corresponding modulated voltage drop across the internal resistance of the supply to the amplifier causing synchronous amplitude modulation of the FM or PM signal. Cross modulation is measured in terms of percent AM in the case where AM is the result, or, frequency deviation in the case where FM is the result.

When the peaks of the instantaneous RF carrier enter the compression region, the RF carrier sinusoidal waveform is compressed to something other than a perfect sinusoid. When this happens, a Fourier series of harmonic components is generated leading to *RF harmonic distortion*. These are far away in frequency and easy to filter out, but may cause significant degradation of power efficiency since it is power that cannot be used and frequently is as high as 10% of the total RF power coming out of the amplifier. With no harmonic filter, a frequency insensitive power meter may indicate 100 W, but only 90 of these 100 W may be at the fundamental frequency.

In RF amplifiers, harmonics of the carrier frequencies are located at integer multiples of those frequencies and are easy to filter out. Harmonics of the modulating (baseband) signals may fall within the passband of the amplifier. Distortion by the appearance of baseband harmonics will arise out of a real amplifier when they did not exist going in. For example, a typical AM radio amplifier needs a passband of 30 kHz to faithfully pass all of the sidebands out to 15 kHz for quality amplification of a music modulated carrier. If just a single note at 1 kHz is the modulating signal, there is room for 15 harmonics to be passed along should the harmonic distortion create them. What an amplifier does to baseband signals is characterized by *total harmonic distortion*, which is expressed as a percent of total harmonic power to fundamental power. It is an envelope or baseband distortion, not an RF distortion.

7.6.3 Nonlinear Amplifiers and Characterizing Distortion

Any amplifier that significantly degrades amplitude modulation is a nonlinear amplifier. Linear amplifiers are supposed to be perfect, whereas nonlinear amplifiers are deliberately not this way. Usually a nonlinear amplifier is optimized in one or more of its characteristics, such as efficiency or ability to make power no matter how distorted. Nonlinear amplifiers have their place where a single tone input signal or one that is not amplitude modulated (except for the case where the modulation is a full on or full off signal) is the signal to be amplified. An example of this is a signal that is only frequency modulated. Specifically, an RF

carrier that is deviated in frequency does not require *amplitude* linearity. Even though a FM signal may be carrying beautiful music, it is always only a single carrier that is moving around in frequency, hopefully symmetrically about the carrier frequency or *rest point*. Instantaneously it is only at one frequency. This is important to understand and often thought of only casually. The instantaneous frequency of a deviated carrier is singular even if there are subcarriers as part of the baseband signal providing the modulation. The fact remains that instantaneously, there is simply no other carrier to intermodulate with. For this reason, intermodulation cannot exist and so there is no intermodulation distortion. There is no distortion of the modulating signal because of amplitude compression. There is even no distortion of the frequency modulation if there is simultaneous amplitude modulation as long as the AM is not near 100% where the carrier is made to *pinch off* or disappear at times. Phase modulation amplification is affected in the same way as frequency modulation amplification through nonlinear amplifiers. Nonlinear amplifiers are also very good at making high power much more efficiently than linear amplifiers. Industrial RF heating applications also do not care about linearity since the purpose is to make high-power RF at a particular frequency in the most efficient way possible. If all these good things are attributable to nonlinear amplifier's amplifying frequency or phase modulated signals why are they not used universally instead of AM? References on the subject of modulation methods will indicate that theoretically FM and PM require infinite bandwidth and practically five or six times the bandwidth of an equivalent AM signal carrying the same information. Amplitude modulation methods have their place, with their linearity requirements, whereas nonamplitude modulation methods have theirs.

Distortions

Just as there are those conditions that cause distortion in linear amplifiers, there are other conditions that cause distortion in nonlinear amplifiers. For example, it was stated that the bandwidth requirement for FM or PM is much greater than for AM. In fact, infinite bandwidth is the ideal case, when in practice, of course, this is not possible. The bandwidth, however, must be wide enough to pass enough of the sideband components so that harmonic distortion of the recovered baseband signal at the receiving end is below a specified limit. Therefore, distortion of the modulated signal can only be avoided by ensuring that the bandwidth of the nonlinear amplifier is sufficient. The bandwidth required is estimated by the well-known *Carson's Rule* (Taub and Schilling, 1986) which states that

$$B = 2(\Delta f + f_m) \quad (7.28)$$

where B is the bandwidth that will carry 98% of the sideband power, Δf is the frequency deviation of the carrier, and f_m is the highest frequency component of the modulating signal.

Other distortions that affect an FM or PM signal take place in the modulator or source of the modulated signal to be amplified, not in the amplifier, thus they will not be discussed in this chapter.

Linear amplifiers are used wherever the integrity of the signal to be amplified must be maintained to the greatest extent possible. Minimizing the distortion types presented in Sec. 7.6.2 will optimize a linear amplifier so that it can be used for its intended purpose, but an amplifier must be classified as a linear amplifier in the first place or it will be impossible to achieve *acceptable linear performance*. Linear is a relative term implying that distortion is imperceivable for the application. Relative linearity is classified alphabetically from A to Z with A being the most linear. Not all letters are used, thus there are enough of them available for future classification as new amplifier types are discovered. The most widely used linear classes of amplifiers are Class A, Class AB, and Class B. Others are classes BD, G, H, and S.

Often while perusing through the literature, two opposing phrases may appear even within the same paragraph. They are *small signal* and *large signal*. Nebulous words such as these are used among amplifier design engineers and appear to be unscientific in a most unlikely place, but they do have definition. These terms are used because active solid-state amplifying devices have a small signal behavior and a large signal behavior. *Small signal* behavior means simply that the signal going through a transistor is small enough in magnitude so that the transistor may be modeled in terms of equivalent linear elements. The signal is not large enough to be noticed by the modeled elements of the transistor to cause them to change value. Using the model provides predictable behavior. In addition, the signal is not large enough to cause departure from

the user's definition of what is linear enough. Best possible linearity requires that the compression region shown in Fig. 7.44 or Fig. 7.47 be avoided, but if it is acceptable, the small signal domain may be extended into this region of the transfer function. The term small signal is confined to Class A amplifiers and has no meaning in the other classes. The dividing line between small and large signals is at the power level below which the transistor equivalent elements are linear components and the amplifier is still considered linear according to the needs of the application.

7.6.4 Linear Amplifier Classes of Operation

Class A Amplifier

The term Class A does not refer to whether an amplifier is used in a small or large signal application even though all small signal amplifiers are Class A amplifiers. A Class A amplifier could also be used for large signals if the linear model no longer applies. Class A refers to the conduction angle of the amplifying device with respect to the driving signal and how it is biased to achieve this. For an amplifying device to be operating in Class A, it must be biased so that it is conducting current throughout the entire swing of the signal to be amplified. In other words, it is biased so that extremes of the amplitude of the driving signal never cause the device to go to zero **current** draw (cut off) and never cause the voltage across the output of the device to go to zero (**saturation**). In this manner, the device is always active to follow the waveform of the driving signal. Intuitively, it has the best chance at being linear compared to other bias conditions to be presented later. Notice that the word *device* is used when addressing the part that does the amplifying. **Class of operation** has nothing to do with the device type. The requirements for Class A operation are the same whether the device is a tetrode vacuum tube, bipolar junction transistor, field effect transistor, klystron, or anything else, and the mathematical behavior and theoretical limits of a device operated in Class A are the same regardless of the device type. It is true, however, that some devices are better than others in practical linearity, which allows variations in power efficiency and other performance parameters, but not in theoretical limits. The more general statement is that class of operation has nothing to do with device type, but only how it is biased, which, in turn, determines the **conduction angle**.

The operation of the Class A amplifier is easily understood if it is analyzed in graphical form. A bipolar junction NPN transistor is assumed. Figure 7.49 is a plot of collector current I_c vs. collector to emitter voltage V_{ce} for various values of constant base current I_b for a common emitter configuration. There is no resistor in the collector bias circuit so that the transistor quiesces at the supply voltage V_{CC} . To allow a symmetrical current and voltage swing about the quiescent point, the quiescent point is chosen at $\frac{1}{2}(2V_{CC})$ or V_{CC} and $\frac{1}{2}\hat{I}_c$, the peak value of collector current. I_{CQ} is the quiescent collector current. Collector-emitter saturation voltage is assumed to be zero. The negative reciprocal of the correct *load*

FIGURE 7.49 The I_c vs. V_{ce} plot for a bipolar junction transistor biased for Class A operation is shown with the static quiescent point halfway between voltage and current limits for symmetrical excursions along the loadline. Strict Class A operation requires that the ends of the loadline not be exceeded.

resistance is the slope of the loadline plotted to allow maximum power transfer to the load. The loadline must, therefore, connect $2V_{CC}$ at $I_c = 0$ with \hat{I}_c at $V_{ce} = 0$. Class A operation dictates that the ends of the loadline cannot be exceeded, but approaching the ends while maintaining linearity is possible if the harmonic power generated is filtered out so that it does not reach the load. If the peak of the AC component of the collector-emitter voltage is \hat{V}_{ac} and the load resistance is R , then the output power P_{out} , may be calculated to be

$$P_{out} = \frac{\hat{V}_{ac}^2}{2R} \quad (7.29)$$

The DC input power from the power supply P_{in} , is calculated from

$$P_{in} = V_{CC} I_{CQ} = \frac{V_{CC}^2}{R} \quad (7.30)$$

Comparing Eq. (7.29) with Eq. (7.30), it is obvious that

$$P_{out} = \frac{1}{2} P_{in} \quad (7.31)$$

when $\hat{V}_{ac} = V_{CC}$. This occurs when the collector current and collector-emitter voltage are driven to the limits. The maximum theoretical power efficiency η_{max} is

$$\eta_{max} = \frac{P_{out}}{P_{in}} = \frac{1}{2} \quad (7.32)$$

And, of course, this number decreases from the maximum value as \hat{V}_{ac} is decreased from the end limits of the loadline.

In practice, the limits imposed on \hat{V}_{ac} are usually much less than that to provide an efficiency of 50%. A Class A amplifier used as a power amplifier typically operates at 10–20% efficiency in order to maintain third-order intermodulation distortion down to required levels for most communications applications. Since the Class A stage is usually used as the driver in a cascaded series of power amplifiers, the Class A stage must be very clean. The IM3 distortion products that the Class A stage produces are amplified by follow-on stages and the distortion only gets worse as more IM3 is produced. At UHF, or more it is practical to design and construct Class A power amplifiers using one bipolar junction NPN transistor that will provide 13 dBm of gain at 40-W PEP with -30 dBm IM3 performance using the two-tone test. Of course, any number of these may be power combined to produce hundreds of watts. After combining four or eight Class A stages, it is no longer practical to continue, since power combining losses become significant and adding stages only serves to cancel out losses.

Looking at the amplifier as a whole and not just the transistor, the input and output impedances are designed to be some value: 50Ω for power RF amplifiers, 75Ω for video, 600Ω for audio or some other standard value for interfacing with the outside world. Whatever value the amplifier is designed for, it must be a good resistive load to whatever is driving it, and it must work into a load designed to be its load resistance. The actual impedances of the transistor input and the load presented to its output usually are much different than the external impedances, called the **standard**. In fact, for a power amplifier these actual impedances could be a fraction of an ohm. Input and output matching circuits connect these very low-impedance values to the standard. Looking into either port of a Class A amplifier with an impedance measuring device such as an impedance bridge or network analyzer will allow the impedance standard to be measured when the amplifier supply voltages are applied and the transistor is operating at its quiescent point. A return loss of 20 dBm or more across the frequency band of interest signifies a *good* amplifier. In the case of Class A, the entire amplifier may be modeled to be a resistor of the chosen standard value at the input $R_{StandardIn}$ and a current controlled current source shunted by the standard resistance value $R_{StandardLoad(SL)}$ at the output. These are the measured values. A model of the Class A transistor (neglecting the effects of capacitances and stray inductances that are *tuned out* by the matching circuits) is presented

FIGURE 7.50 The Class A amplifier transistor can be modeled as a current controlled current source with internal output resistance R . When $R = R_L$, half of the collector power is dissipated in R and the other half in R_L , providing a maximum efficiency η_{\max} of 50%. This agrees with Eq. (7.31). Not shown are the matching circuits transforming r_{be} and R_L to a standard impedance, such as 50 Ω .

in Fig. 7.50, whereas the model for the transistor amplifier with internal impedance matching circuits modeled is shown in Fig. 7.51.

Class B Amplifier

At high-power levels not practical for Class A, the Class B amplifier is used. Class B is more power efficient than Class A and unlike Class A, a transistor (or other amplifying device) conducts for precisely half of the drive cycle or π radians. It is biased precisely at collector current cutoff. As stated previously, the class of operation has nothing to do with the device type, but rather its bias condition and its conduction angle. Since Class B operation means that the device is only conducting half of the time, a single ended amplifier may only be used at narrow bandwidths where the tuned output network provides the missing half-cycle by storing the energy presented to it by the active half-cycle, then returning it to the circuit when the device is off. For untuned applications, such as audio amplifiers and wideband RF amplifiers, a push-pull pair of devices operate during their respective half-cycles causing the amplifier to be active all of the time. In this situation, the point on the loadline halfway between the ends is at zero supply current for both devices and driven away from zero with drive. Figure 7.52 shows a graphical presentation of the Class B push-pull configuration.

FIGURE 7.51 The Class A transistor amplifier is modeled as a resistive load to its driver whereas the output impedance seen at the output port is equal to the standard load resistance. The input and output impedances may be measured from the outside looking in with a network analyzer or impedance bridge.

FIGURE 7.52 The graphical solution to the push-pull Class B amplifier configuration is shown. The quiescent point is midway between the ends of the loadline as in Class A, but unlike Class A, the quiescent current is zero. Each transistor output sees R_L at the collector since the center-tapped primary transformer has a 1:1 turns ratio from R_L to each transistor even though it has a 2:1 primary (end-to-end) to secondary turns ratio.

Because the phase of one transistor is of the opposite phase of the other, a center tapped transformer is needed to combine the two halves properly. This may be done without the use of a transformer if complementary pairs of transistors are available (one NPN and one PNP). Both cases are presented in Fig. 7.53.

To find the maximum linear output power and maximum theoretical power efficiency of a Class B push-pull amplifier, the loadline in Fig. 7.52 provides the information for the following analysis. Let

- $\hat{V}_{ac} =$ maximum peak-to-peak voltage swing along the loadline, $\leq 2V_{CC}$
- $\hat{I}_{ac} =$ maximum peak-to-peak current swing along the loadline, $\leq 2\hat{I}_c$
- $\hat{V}_{ac} =$ maximum peak voltage swing along the loadline from the quiescent point, $\leq V_{CC}$
- $\hat{I}_{ac} =$ maximum peak current swing along the loadline from the quiescent point, $\leq \hat{I}_c$

It follows that

$$2\hat{V}_{ac} = \hat{V}_{ac} \leq 2V_{CC}$$

$$2\hat{I}_{ac} = \hat{I}_{ac} \leq 2\hat{I}_c$$

FIGURE 7.53 Push-pull amplifier: (a) like transistors are configured in push-pull Class B. An input and an output transformer are needed to invert the phase of one transistor with respect to the other. The turns ratio of T1 is chosen so that the standard load impedance R_{SL} is transformed to the load impedance R_L presented to each collector. Their graphical solution is shown in Fig. 7.52. (b) The phase of one transistor with respect to the other is inverted without transformers since one transistor is NPN whereas the other is PNP.

For a sinusoidal signal

$$P_{\text{out,max}} = \left(\frac{\hat{V}_{\text{ac}}}{\sqrt{2}} \right) \left(\frac{\hat{I}_{\text{ac}}}{\sqrt{2}} \right) = \left(\frac{\hat{I}_{\text{ac}}}{2} \right) \hat{V}_{\text{ac}} \quad (7.33)$$

For simplicity, assume that the output transformer primary to secondary turns ratio is 2:1 so that either active-half has a 1:1 turns ratio with the secondary. For a load at the secondary winding R_L , the primary *end-to-end* load is $4R_L$, but each transistor works into R_L for each half-cycle. The load presented to each transistor is, therefore, R_L . It follows that

$$\hat{I}_{\text{ac}} = 2\hat{I}_{\text{ac}} = \frac{\hat{V}_{\text{ac}}}{R_L} = \frac{2\hat{V}_{\text{ac}}}{R_L} \Rightarrow \left(\frac{\hat{I}_{\text{ac}}}{2} \right) = \frac{\hat{V}_{\text{ac}}}{4R_L} = \frac{2\hat{V}_{\text{ac}}}{4R_L} = \frac{\hat{V}_{\text{ac}}}{2R_L}$$

Substituting for $\hat{I}_{\text{ac}}/2$ into Eq. (7.33) gives

$$P_{\text{out,max}} = \frac{\hat{V}_{\text{ac}}^2}{2R_L} \leq \frac{V_{\text{CC}}^2}{2R_L} \quad (7.34)$$

The center tap current of the transformer is half-wave DC at twice the frequency of the drive signal so that

$$I_{\text{ct}}(\theta) = \hat{I}_{\text{ac}} |\sin \theta|$$

The DC component of I_{ct} is found from

$$I_{\text{DC}} = \frac{1}{2\pi} \int_0^{2\pi} \hat{I}_{\text{ac}} |\sin \theta| d\theta = \frac{1}{2\pi} \int_0^{\pi} \hat{I}_{\text{ac}} \sin \theta d\theta - \frac{1}{2\pi} \int_{\pi}^{2\pi} \hat{I}_{\text{ac}} \sin \theta d\theta = \frac{2\hat{I}_{\text{ac}}}{\pi}$$

and

$$I_{\text{DC}} = \frac{2\hat{V}_{\text{ac}}}{\pi R_L} \leq \frac{2V_{\text{CC}}}{\pi R_L}$$

The DC input power is found from

$$P_{\text{in}} = I_{\text{DC}} V_{\text{CC}} = \frac{2\hat{V}_{\text{ac}} V_{\text{CC}}}{\pi R_L} \leq \frac{2V_{\text{CC}}^2}{\pi R_L} \quad (7.35)$$

The power efficiency becomes (from Eqs. (7.34) and (7.35))

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{\hat{V}_{\text{ac}}^2}{2R_L} \frac{\pi R_L}{2\hat{V}_{\text{ac}} V_{\text{CC}}} = \frac{\pi \hat{V}_{\text{ac}}}{4V_{\text{CC}}} \quad (7.36)$$

whereas the maximum theoretical power efficiency (when $\hat{V}_{\text{ac}} = V_{\text{CC}}$) becomes

$$\eta_{\text{max}} = \frac{\pi}{4} = 78.5\% \quad (7.37)$$

The upper limit of Class B power efficiency is considerably higher than that of Class A at 50%. The power dissipated in each of the two transistors P_{Dis} , is half of the total. The total power dissipated in the case of maximum efficiency is

$$\begin{aligned} 2P_{\text{Dis}} &= P_{\text{in}} - P_{\text{out}} \\ &= \frac{2V_{\text{CC}}^2}{\pi R_L} - \frac{V_{\text{CC}}^2}{2R_L} \\ 2P_{\text{Dis}} &= \frac{V_{\text{CC}}^2}{R_L} \left(\frac{2}{\pi} - \frac{1}{2} \right) \end{aligned} \quad (7.38)$$

and

$$P_{\text{Dis}} = \frac{V_{\text{CC}}^2}{R_L} \left(\frac{1}{\pi} - \frac{1}{4} \right) \quad (7.39)$$

In Fig. 7.52 the loadline passes through the zero collector current point of each transistor where one device is turning off and the other is turning on. At this precise point both amplifier devices could be *off* or *on*. To avoid this *glitch* or *discontinuity*, strict Class B is never really used, but instead, each transistor is biased on to a small value of current to avoid this *crossover distortion*. The choice of bias current has an affect on IM3 so that it may be adjusted for best IM performance under a multitone test condition. The quiescent bias current is usually set for about 1–10% of the highest DC collector current under drive. Biased under this condition, the active devices are not operating in strict Class B, but rather, in a direction toward Class A, and is usually referred to as Class AB.

Since the quiescent point of a Class AB or B amplifier is near or at zero, looking into the input port or output port expecting to measure the standard impedance to which the amplifier was designed is not possible. Large signal behavior comes into play in power amplifiers other than Class A and only exists under drive. Without drive, the amplifier is cut off in the case of Class B or near cut off in the case of Class AB. With drive, the input return loss may be measured as in the case of Class A, but a directional coupler is used to sense the incident and reflected power. Forward output power is also measured with a directional coupler and compared with theoretical efficiency to determine the worth of the output matching circuit. Efficiency should be in the 40–60% range for good linearity, staying away from the ends of the loadline. Frequently, impedance information about the input and output of a transistor used in Class AB or B is for large signal (power) applications and arrived at experimentally by beginning with a best guess set of parameters about the transistor, then designing a matching circuit and optimizing it for best performance under power. When the goal is reached, the transistor is removed, and the input and output impedances of the circuit are measured at the points where the transistor was connected. These points may then be plotted on a Smith chart. If the input impedance to the transistor is called Z_{in} , the complex conjugate of what the circuit measured is Z_{in} of the transistor. If the output impedance of the transistor is called Z_{out} , then this is the complex conjugate of that measured for the output circuit. If, however, the output impedance is called Z_{load} , then it is not the complex conjugate of what was measured, but the load impedance that the transistor is working into. There is some ambiguity about the output impedance among the stated parameters of many manufacturers of devices. Some call it Z_{out} when they really mean Z_{load} . A general guide is that the load that a power transistor wants to work into for best overall performance is capacitive, so if Z_{load} is specified to be $R + jX$, this is probably Z_{out} and not Z_{load} . Z_{load} would be the complex conjugate of this or $R - jX$.

Third-order intermodulation performance for Class AB or B is generally worse than Class A, and harmonic distortion is better in the sense that even harmonics are canceled to a large degree in the primary of the output transformer. These currents flow in opposite directions at the same time and net to zero, whereas odd order harmonic currents do not. An amplifier model for a Class AB or B amplifier is shown in Fig. 7.54. Its topology is the same as that for the Class A in Fig. 7.51 except that $R_{\text{StandardLoad(SL)}}$ *inside* the amplifier is replaced by R_{Internal} or R_{Int} . For a maximum power efficiency, $\eta_{\text{max}} = 78.5\%$,

$$\begin{aligned} \eta_{\text{max}} &= \frac{P_{\text{outmax}}}{P_{\text{in}}} = \frac{R_{\text{Intmax}}}{R_{\text{Intmax}} + R_{\text{SL}}} \\ &= 0.785 \end{aligned} \quad (7.40)$$

and

$$R_{\text{Intmax}} = 3.6512 R_{\text{SL}}$$

so that for efficiency figures less than the theoretical maximum

$$R_{\text{Int}} \leq 3.6512 R_{\text{SL}} \quad (7.41)$$

FIGURE 7.54 The Class AB or B amplifier may be modeled as having a measurable input resistance when driven and an internal output resistance that maintains the power efficiency at or below the theoretical maximum of 78.5%. For this, $R_{Int} \leq 3.6512R_{SL}$.

Deleting max from Eq. (7.40)

$$\eta = \frac{R_{Int}}{R_{Int} + R_{SL}} \tag{7.42}$$

R_{Int} may be measured indirectly by knowing the efficiency of the amplifier and the standard load resistance

$$R_{Int} = R_{SL} \left(\frac{\eta}{1 - \eta} \right) \tag{7.43}$$

An enhancement to the efficiency of the Class B amplifier makes use of the addition of a third harmonic component of the right amount to the collector-emitter voltage waveform to cause near square-wave flattening when it is near zero (where the collector current is greatest). This modification alters the amplifier enough so that it enjoys a different classification called Class F. Flattening enhances efficiency by as much as one-eighth so that

$$\eta_{ClassF} = \frac{9}{8} \eta_{ClassB}$$

From Eq. (7.37)

$$\eta_{ClassFmax} = \frac{9}{8} \left(\frac{\pi}{4} \right) = 0.884$$

7.6.5 Nonlinear Amplifier Classes of Operation

If the Class A amplifier is biased to cause device current for the entire drive cycle, and Class B is biased to cause device current for precisely half of the cycle, then it is logical to assign the Class C designation to that bias condition that causes less than half-cycle device current. There are two types of Class C amplifiers: nonsaturated and saturated.

Nonsaturated Class C Amplifier

It is not convenient to analyze the Class C amplifier by means of the loadline argument as in the cases of Classes A or B, but rather, a time- or phase-domain analysis proves to be more workable. The reason is that in the other classes conduction time is fixed at full time or half. In Class C, the conduction time is variable so that a general analysis must be performed where time or phase is the independent variable, not collector-emitter voltage. A time or phase analysis for Classes A or B could have been done, but then only one method would be presented here and the intention is to present another way. The results are the same and comparisons presented at the end of this section.

A phase domain diagram of the nonsaturated Class C amplifier is shown in Fig. 7.55 along with a representative schematic diagram. The term nonsaturated means that the active device is not driven to the point where the collector-emitter voltage is at the lowest possible value. The curve of $V_{ce}(\theta)$ in Fig. 7.55(a) does not quite touch the zero line. Another way of saying this is that the transistor is always active or never conducts like a switch. It is active in the same way as Classes A and B, and because of this similarity, it may be modeled in the same way, that is, as a dependent current source.

FIGURE 7.55 The phase- or time-domain diagrams of all significant voltages and currents of the nonsaturated Class C amplifier are shown: (a) a representative NPN transistor, (b) schematic diagram.

In an amplifier where the drive signal causes the onset of conduction so that the conduction angle is less than π , it is important to realize the following.

1. The transistor will not conduct until its base-emitter junction self-reverse bias voltage of about 0.7 V is overcome. With no external base bias applied, the conduction angle will be less than π and the quiescent collector current fixed at a negative default value I_{CQ} . If this default value is acceptable in the outcome, then no external bias needs to be applied and the design becomes simpler. Applying a DC base current will allow control over I_{CQ} .
2. The collector current $I_c(\theta)$, is sinusoidal in shape when it exists.
3. The collector-emitter voltage $V_{ce}(\theta)$, is sinusoidal, but π radians out of phase with the collector current.

Some definitions are in order.

$I_c(\theta)$ = instantaneous collector current

\hat{I}_c = peak value of collector current

I_{CQ} = negative self bias collector current

$I_{CC}(\theta)$ = positive net value of $I_c(\theta)$ and I_{CQ}

$I_c(\theta) = I_{CQ} - I_{CC} \sin \theta$ when the net collector current $I_c(\theta) \geq 0$; it is zero elsewhere

I_{DC} = DC current draw from the collector power supply

$I_{acH}(\theta)$ = harmonic current shunted to ground by the tank circuit capacitor

\hat{I}_{ac1} = peak current amplitude of the fundamental frequency component in the load; it is the first harmonic amplitude coefficient of the Fourier series of the collector current with the conduction angle establishing the limits of integration

$I_{ac1}(\theta) = \hat{I}_{ac1} \sin \theta$

$V_{ce}(\theta)$ = collector-emitter voltage

V_{CC} = collector supply voltage

2χ = conduction angle of the transistor collector current

\hat{V}_{ac1} = peak voltage amplitude across the load

$V_{ac1}(\theta) = \hat{V}_{ac1} \sin \theta$

By the definition of the Class C amplifier and analysis of Fig. 7.55, $I_c(\theta)$ is found to be

$$\begin{aligned} I_c(\theta) &= I_{CQ} - I_{CC} \sin \theta \geq 0 \\ &= 0, \text{ elsewhere} \end{aligned} \quad (7.44)$$

and

$$I_{CQ} = -I_{CC} \cos \chi \quad (7.45)$$

The DC current from the power supply is found by averaging $I_c(\theta)$

$$\begin{aligned} I_{DC} &= \frac{1}{2\pi} \int_0^{2\pi} I_c(\theta) d\theta \\ I_{DC} &= \frac{1}{2\pi} \int_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}+\chi} (I_{CQ} - I_{CC} \sin \theta) d\theta \\ I_{DC} &= \frac{2\chi}{2\pi} I_{CQ} + \frac{I_{CC}}{2\pi} \left[\cos \left(\frac{3\pi}{2} + \chi \right) - \cos \left(\frac{3\pi}{2} - \chi \right) \right] \end{aligned}$$

However

$$\cos \left(\frac{3\pi}{2} + \chi \right) = \sin \chi \quad \text{and} \quad -\cos \left(\frac{3\pi}{2} - \chi \right) = \sin \chi$$

so that

$$I_{DC} = \frac{\chi}{\pi}(-I_{CC}\cos\chi) + \frac{I_{CC}}{\pi}\sin\chi$$

and

$$I_{DC} = \frac{I_{CC}}{\pi}(\sin\chi - \chi\cos\chi) \quad (7.46)$$

Also,

$$I_{CC} = \frac{\pi I_{DC}}{(\sin\chi - \chi\cos\chi)} \quad (7.47)$$

DC power supplied to the collector is found to be

$$P_{in} = I_{DC}V_{CC} = \frac{I_{CC}V_{CC}}{\pi}(\sin\chi - \chi\cos\chi) \quad (7.48)$$

The peak current value of the fundamental frequency component in the load, \hat{I}_{ac1} is the coefficient of the fundamental frequency component of the Fourier series of the collector current $I_c(\theta)$. All harmonic current is shunted to ground by the tank circuit capacitor and assumed to be zero. The tank circuit is resonant at the fundamental frequency.

\hat{I}_{ac1} is found from

$$\begin{aligned} \hat{I}_{ac1} &= -\frac{1}{\pi} \int_0^{2\pi} I_c(\theta)\sin\theta d\theta \\ \hat{I}_{ac1} &= -\frac{1}{\pi} \int_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}+\chi} (I_{CQ} - I_{CC}\sin\theta)\sin\theta d\theta \\ \hat{I}_{ac1} &= -\frac{I_{CQ}}{\pi} \int_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}+\chi} \sin\theta d\theta + \frac{I_{CC}}{\pi} \int_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}+\chi} \sin^2\theta d\theta \\ \hat{I}_{ac1} &= \frac{I_{CQ}}{\pi} \cos\theta \Big|_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}+\chi} + \frac{I_{CC}}{\pi} \left(\frac{\theta}{2} + \frac{\sin 2\theta}{4} \right) \Big|_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}+\chi} \\ \hat{I}_{ac1} &= \frac{I_{CQ}}{\pi} \left[\cos\left(\frac{3\pi}{2} + \chi\right) - \cos\left(\frac{3\pi}{2} - \chi\right) \right] + \frac{I_{CC}}{\pi} \left[\chi - \frac{-\sin 2\chi - \sin 2\chi}{4} \right] \\ \hat{I}_{ac1} &= \frac{2I_{CQ}}{\pi}\sin\chi + \frac{I_{CC}}{\pi}\chi + \frac{I_{CC}}{2\pi}\sin 2\chi \end{aligned}$$

Since $I_{CQ} = -I_{CC}\cos\chi$

$$\begin{aligned} \hat{I}_{ac1} &= -\frac{2I_{CC}}{\pi}\sin\chi\cos\chi + \frac{I_{CC}}{\pi}\chi + \frac{I_{CC}}{2\pi}\sin 2\chi \\ \hat{I}_{ac1} &= \frac{I_{CC}}{2\pi}(-4\sin\chi\cos\chi + 2\chi + \sin 2\chi) \end{aligned}$$

rearranging and making use of the identity, $\sin 2x = 2\sin x \cos x$

$$\hat{I}_{ac1} = \frac{I_{CC}}{\pi}(\chi - \sin\chi\cos\chi) \quad (7.49)$$

The peak voltage across the load becomes

$$\hat{V}_{ac1} = \frac{RI_{CC}}{\pi}(\chi - \sin\chi\cos\chi) \quad (7.50)$$

The output power in the load is

$$P_{\text{out}} = P_{\text{ac1}} = \frac{\hat{V}_{\text{ac1}}^2}{2R} = \frac{RI_{\text{CC}}^2}{2\pi^2} (\chi - \sin \chi \cos \chi)^2 \quad (7.51)$$

Substituting Eq. (7.47) for I_{CC}

$$P_{\text{out}} = \frac{RI_{\text{DC}}^2}{2} \left(\frac{\chi - \sin \chi \cos \chi}{\sin \chi - \chi \cos \chi} \right)^2 \quad (7.52)$$

Dividing Eq. (7.51) by Eq. (7.52) the power efficiency η is

$$\begin{aligned} \eta &= \frac{P_{\text{out}}}{P_{\text{in}}} = \frac{RI_{\text{CC}}^2}{2\pi^2} \frac{\pi}{I_{\text{CC}} V_{\text{CC}}} \frac{(\chi - \sin \chi \cos \chi)^2}{(\sin \chi - \chi \cos \chi)} \\ \eta &= \frac{R}{2\pi} \frac{I_{\text{CC}}}{V_{\text{CC}}} \frac{(\chi - \sin \chi \cos \chi)^2}{(\sin \chi - \chi \cos \chi)} \end{aligned} \quad (7.53)$$

Here η_{max} occurs when $\hat{V}_{\text{ac1}} = V_{\text{CC}}$. Setting Eq. (7.50) equal to V_{CC} , solving for I_{CC} , and substituting into Eq. (7.53), $\eta \rightarrow \eta_{\text{max}}$

$$\begin{aligned} \eta_{\text{max}} &= \frac{\chi - \sin \chi \cos \chi}{2(\sin \chi - \chi \cos \chi)} \\ V_{\text{ce}}(\theta) &= V_{\text{CC}} + \hat{V}_{\text{ac1}} \sin \theta \end{aligned} \quad (7.54)$$

and in the case of maximum efficiency where $\hat{V}_{\text{ac1}} = V_{\text{CC}}$

$$V_{\text{ce}}(\theta) = V_{\text{CC}}(1 + \sin \theta)|_{\eta=\eta_{\text{max}}} \quad (7.55)$$

The collector-emitter voltage $V_{\text{ce}}(\theta)$ swings from $2V_{\text{CC}}$ to zero and differs from the voltage across the load R by the DC component V_{CC} . Stated before, $I_{\text{acH}}(\theta)$, the harmonic currents, do not enter the equations because these currents do not appear in the load.

The first thing to note about Eq. (7.54) is that the theoretical maximum efficiency is not limited to a value less than one. The second thing is that it is only a function of conduction angle, 2χ . Here, $\eta_{\text{max}} \rightarrow 1$ as $\chi \rightarrow 0$. For $\chi \rightarrow 0$, Eq. (7.54) becomes

$$\lim_{\chi \rightarrow 0} \eta_{\text{max}} = \frac{\chi - \sin \chi \cos \chi}{2(\sin \chi - \chi \cos \chi)} \quad (7.56)$$

For small χ

$$\sin \chi \rightarrow \chi, \quad \sin 2\chi \rightarrow 2\chi, \quad -4 \sin \chi \rightarrow -4\chi \quad \text{and} \quad \cos \chi \rightarrow (< 1)$$

It follows that

$$\lim_{\chi \rightarrow 0} \eta_{\text{max}} = \frac{2\chi - 2\chi(< 1)}{4\chi - 4\chi(< 1)} = 1 \quad (7.57)$$

To achieve 100% power efficiency, the collector current pulse $I_c(\theta)$ would become infinitesimal in width, carry no energy, and make no power. Even though the amplifier would produce no power, it would consume no power, and so it would be 100% efficient. In real applications, power efficiency can be in the 80s of percent.

Power dissipated as heat in the transistor is

$$P_{\text{Dis}} = (1 - \eta)P_{\text{in}} \quad (7.58)$$

Furthermore, the resistance represented by the transistor collector-emitter path, that is, that which is represented by the internal shunt resistance of the current-dependent current source, is found by dividing Eq. (7.58) by I_{DC}^2 . This resistance may be called R_{Dis} and shares the input power with the load according

FIGURE 7.56 The nonsaturated Class C amplifier may be modeled as a current controlled current source with a measurable input resistance when driven, and an internal output resistance determined by the power efficiency, $\eta \cdot R_{Int}$ shares power with R_{SL} , but $R_{Int} \rightarrow \infty$ when $\eta \rightarrow 1$.

to Eq. (7.58)

$$R_{Dis} = \frac{P_{Dis}}{I_{DC}^2} = \frac{V_{CC}}{I_{DC}} - \frac{R}{2} \left(\frac{\chi - \sin \chi \cos \chi}{\sin \chi - \chi \cos \chi} \right)^2 \tag{7.59}$$

For the amplifier (not the transistor), the equivalent internal resistance may be found referenced to the standard amplifier load resistance by simply scaling $R \rightarrow R_{StandardLoad(SL)}$ and

$$R_{int} = R_{Dis} \frac{R_{SL}}{R} \tag{7.60}$$

The nonsaturated Class C amplifier, like the linear classes, may be modeled as a current controlled current source. Figure 7.56 is a representation of the amplifier and is very similar to Fig. 7.54.

Measuring port impedances without drive and making output power is senseless because the transistor is biased off without drive. Input resistance, $R_{StandardIn}$ may only be measured when the transistor is driven to full power. For nonsaturated Class C, $R_{int} \rightarrow \infty$ as $\eta \rightarrow 1$.

The transistor impedances within the amplifier may be measured by removing the transistor after matching circuit adjustments are made for best specified performance and connecting the impedance measuring instrument, such as a network analyzer, to the input and output connections left open by the transistor. Figure 7.57 illustrates the same concept as that presented in Fig. 7.53(a) for the Class B amplifier except that the latter is for a push-pull configuration and the former is for the single ended.

A measuring instrument will give the complex conjugate of the transistor input impedance Z_{in} . Measuring the impedance seen at the input of the output matching network will give Z_{load} , which will be of the form $R - jX$. R is the same R used in the equations derived for the transistor. There may be a small jX component for best operation of a particular transistor type.

An $I_c(\theta)$ vs. $V_{ce}(\theta)$ loadline representation of the nonsaturated Class C amplifier is shown in Fig. 7.58 and is based on the derived results of the given equations.

The greatest P_{out} is obtained when the conduction angle 2χ is near π in width, that is, where the breakpoint in the loadline is just below V_{CC} . The greatest power efficiency occurs where the breakpoint is far to the left near $V_{ce}(\theta) = 0$ and the conduction angle is near zero. The load R presented to a Class C amplifier is usually chosen to be

$$R = \frac{V_{CC}^2}{2P_{out}} \tag{7.61}$$

FIGURE 7.57 For the nonsaturated Class C amplifier, input and load impedances seen by the transistor may be measured after its removal. The input and output ports must be terminated in the standard impedance for this static measurement. This figure also applies to the saturated Class C amplifier.

for a practical design giving a high conduction angle and power making capability using the simple default base bias current. This is where the drive signal must overcome the base-emitter reverse bias voltage of about 0.7 V. A base bias source is not needed and the base is simply grounded for DC.

Saturated Class C Amplifier

The saturated Class C amplifier allows the collector **voltage** (in the case of the bipolar junction transistor) to be driven into **saturation** for a portion of the active time. Figures 7.44 and 7.47 show this as the compression region, but in Class C with no regard to amplitude linearity, power efficiency is increased when the transistor is driven into hard saturation so that further increases in drive yield little, if any, increase in output power. The collector-emitter voltage is as low as it can be. The variable in this approach is the length of time or phase that the transistor is saturated compared to the conduction angle. With the nonsaturated Class C transistor, there is a sequence of three changes of collector current behavior, that is, cutoff, linear, and cutoff. With the saturated transistor, there are five: cutoff, linear, saturated, linear, and cutoff. The mathematical expressions for each change are necessary to completely describe the transistor behavior, and this involves the introduction of another variable, **saturation angle** $2\chi_s$ to those described for the nonsaturated case.

When using a bipolar junction transistor in the saturated mode, the saturation voltage must be taken into account. It cannot be ignored as in the previously discussed classifications because, in those, V_{Sat} was never reached. Also when saturated, collector current is not infinite. It is limited by an equivalent **on resistance** so that $I_{cSat} = V_{Sat}/R_{on}$.

In addition to the definitions described for the nonsaturated case, the following are also appropriate for the saturated case:

- $2\chi_s$ = saturation angle of the transistor collector current
- V_{Sat} = saturation voltage of the transistor collector-emitter path
- I_{cSat} = saturated collector current when $V_{ce} = V_{Sat}$
- R_{on} = equivalent collector-emitter resistance during saturation

FIGURE 7.58 The nonsaturated Class C amplifier is shown graphically with trends as a function of 2χ , P_{out} , and η . The intersection of the loadline with the $I_c(\theta) = 0$ line at a point lower than V_{CC} accounts for higher efficiency than classes A or B. Quiescent point I_{CQ} is negative.

FIGURE 7.59 Phase- or time-domain diagrams of all significant voltages and currents of the saturated Class C amplifier: (a) representative NPN transistor (b) circuit diagram.

Figure 7.59(a) illustrates the collector current vs. collector-emitter voltage behavior of the saturated transistor. Of course, the saturation angle is always contained within the conduction angle. The circuit diagram in Fig. 7.59(b) is the same as Fig. (7.55 b).

Certain assumptions are made regarding the ideal behavior of a transistor in the saturated Class C mode:

1. The transistor has no dynamic collector-emitter or collector-base capacitances associated with it, which in reality it has.
2. The transistor collector current and collector-emitter voltage waveforms are sinusoidal, which they are not.
3. The saturated collector current is constant, which it is not.
4. Saturation on-resistance is constant, which it is not.
5. There is no parasitic inductance or capacitance associated with the circuit, which there is.
6. There are no harmonic currents flowing in the load, which there are.

The precise saturated Class C amplifier is nearly impossible to analyze for a number of reasons:

1. The transistor has dynamically changing capacitances from collector to base and collector to emitter as functions of dynamic voltages.
2. The current and voltage waveforms are anything but sinusoidal.
3. The saturated collector current has peaks and dips.
4. The saturated on-resistance has peaks and dips.
5. There may be significant parasitic inductances and capacitances at VHF and UHF.
6. There are some harmonic currents in the load.

Because of these things, the assumptions are used in the analysis of the saturated Class C amplifier and in the associated figures to make it manageable.

By definition of saturated Class C transistor operation and analysis of Fig. 7.59, $I_c(\theta)$ is found to be

$$I_c(\theta) = \begin{cases} 0, & \text{when } 0 < \theta < \frac{3\pi}{2} - \chi, \text{ and } \frac{3\pi}{2} + \chi < \theta < 2\pi \\ I_{CQ} - I_{CC} \sin \theta, & \text{when } \frac{3\pi}{2} - \chi \leq \theta \leq \frac{3\pi}{2} - \chi_s, \text{ and } \frac{3\pi}{2} + \chi_s \leq \theta \leq \frac{3\pi}{2} + \chi, \\ \frac{V_{Sat}}{R_{on}}, & \text{when } \frac{3\pi}{2} - \chi_s < \theta < \frac{3\pi}{2} + \chi_s \end{cases} \quad (7.62)$$

The onset of saturation occurs when the collector-emitter voltage equals the saturation voltage. R_{on} is finite allowing V_{Sat} to be greater than zero so that the saturated collector current is finite during saturation.

Also, as in the nonsaturated case

$$I_{CQ} = -I_{CC} \cos \chi \quad (7.63)$$

The DC from the power supply is found by averaging $I_c(\theta)$, therefore

$$\begin{aligned} I_{DC} &= \frac{1}{2\pi} \int_0^{2\pi} I_c(\theta) d\theta \\ I_{DC} &= \frac{1}{2\pi} \int_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}-\chi_s} (I_{CQ} - I_{CC} \sin \theta) d\theta + \frac{1}{2\pi} \int_{\frac{3\pi}{2}+\chi_s}^{\frac{3\pi}{2}+\chi} (I_{CQ} - I_{CC} \sin \theta) d\theta + \frac{1}{2\pi} \int_{\frac{3\pi}{2}-\chi_s}^{\frac{3\pi}{2}+\chi_s} \frac{V_{Sat}}{R_{on}} d\theta \\ I_{DC} &= \frac{I_{CQ}}{\pi} (\chi - \chi_s) + \frac{I_{CC}}{\pi} (\sin \chi - \sin \chi_s) + \frac{V_{Sat} \chi_s}{\pi R_{on}} \end{aligned}$$

Substituting Eq. (7.63) for I_{CQ}

$$I_{DC} = \frac{I_{CC}}{\pi} [(\sin \chi - \sin \chi_s) - (\chi - \chi_s) \cos \chi] + \frac{V_{Sat} \chi_s}{\pi R_{on}} \quad (7.64)$$

Compare Eq. (7.64) with Eq. (7.46). Solving (7.64) for I_{CC}

$$I_{CC} = \frac{\pi I_{DC} - \frac{V_{Sat} \chi_s}{\pi R_{on}}}{(\sin \chi - \sin \chi_s) - (\chi - \chi_s) \cos \chi} \quad (7.65)$$

Compare Eq. (7.65) with Eq. (7.47). DC power supplied to the collector is found to be

$$P_{in} = I_{DC} V_{CC} = \left\{ \frac{I_{CC}}{\pi} [(\sin \chi - \sin \chi_s) - (\chi - \chi_s) \cos \chi] + \frac{V_{Sat} \chi_s}{\pi R_{on}} \right\} V_{CC} \quad (7.66)$$

Compare Eq. (7.65) with Eq. (7.66).

As in the nonsaturated case, the peak current value of the fundamental frequency component in the load, \hat{V}_{ac1} , is the coefficient of the fundamental frequency component of the Fourier series of the collector current $I_c(\theta)$. All harmonic current is shunted to ground by the tank circuit capacitor and *assumed* to be zero. The tank circuit is resonant at the fundamental frequency. \hat{I}_{ac1} is found from

$$\begin{aligned} \hat{I}_{ac1} &= -\frac{1}{\pi} \int_0^{2\pi} I_c(\theta) \sin \theta d\theta \\ \hat{I}_{ac1} &= -\frac{1}{\pi} \int_{\frac{3\pi}{2}-\chi}^{\frac{3\pi}{2}-\chi_s} (I_{CQ} - I_{CC} \sin \theta) \sin \theta d\theta \\ &\quad - \frac{1}{\pi} \int_{\frac{3\pi}{2}+\chi_s}^{\frac{3\pi}{2}+\chi} \frac{V_{Sat}}{R_{on}} \sin \theta d\theta - \frac{1}{\pi} \int_{\frac{3\pi}{2}+\chi_s}^{\frac{3\pi}{2}+\chi} (I_{CQ} - I_{CC} \sin \theta) \sin \theta d\theta \end{aligned}$$

After much painful integration

$$\hat{I}_{ac1} = \frac{2I_{CQ}}{\pi} (\sin \chi - \sin \chi_s) + \frac{I_{CC}}{\pi} (\chi - \chi_s) - \frac{I_{CC}}{2\pi} (\sin 2\chi_s - \sin 2\chi) + \frac{2V_{Sat}}{\pi R_{on}} \sin \chi_s$$

Rearranging

$$\hat{I}_{ac1} = \frac{2I_{CQ}}{\pi} (\sin \chi - \sin \chi_s) + \frac{I_{CC}}{4\pi} (4\chi - 4\chi_s + 2 \sin 2\chi - 2 \sin 2\chi_s) + \frac{2V_{Sat}}{\pi R_{on}} \sin \chi_s$$

And again applying Eq. (7.63)

$$\hat{I}_{ac1} = \frac{I_{CC}}{2\pi} [2(\chi - \chi_s) - 4 \cos \chi (\sin \chi - \sin \chi_s) + (\sin 2\chi - \sin 2\chi_s)] + \frac{2V_{Sat}}{\pi R_{on}} \sin \chi_s \quad (7.67)$$

Compare Eq. (7.67) with Eq. (7.49).

Hypothetically, if $\chi = \chi_s$, then the transistor is immediately saturated and there is no linear region. This can only happen if V_{ce} never is higher than V_{Sat} . Having no linear region, the peak current in the load becomes

$$\hat{I}_{ac1} = \frac{2V_{Sat}}{\pi R_{on}} \sin \chi_s$$

The entire term within the brackets in Eq. (7.67) is zero, meaning that I_{CC} could be very large, approaching ∞ . To find the voltage across the load R , under this condition, \hat{I}_{ac1} is multiplied by R , so that

$$\hat{V}_{ac1} = \frac{2RV_{Sat}}{\pi R_{on}} \sin \chi_s$$

Now, hypothetically suppose that very hard limiting is maintained to ensure that $\chi = \chi_s$, but that the supply voltage is allowed to increase from V_{Sat} to some higher V_{CC} , so that V_{Sat} is replaced by $(V_{CC} - V_{Sat})$. It follows that

$$\hat{V}_{ac1} = \frac{2R(V_{CC} - V_{Sat})}{\pi R_{on}} \sin \chi_s$$

for very hard limiting. The voltage across the load is proportional to supply voltage and can be much greater than it as a function of R/R_{on} and χ_s , and this is the case as will be shown.

Finding \hat{V}_{ac1} by multiplying Eq. (7.67) by R ,

$$\hat{V}_{ac1} = \frac{RI_{CC}}{2\pi} [2(\chi - \chi_s) - 4 \cos \chi (\sin \chi - \sin \chi_s) + (\sin 2\chi - \sin 2\chi_s)] + \frac{2RV_{Sat}}{\pi R_{on}} \sin \chi_s \quad (7.68)$$

Compare Eq. (7.68) with Eq. (7.50).

To make things a bit easier, let

$$\Psi = [2(\chi - \chi_s) - 4 \cos \chi (\sin \chi - \sin \chi_s) + (\sin 2\chi - \sin 2\chi_s)] \quad (7.69)$$

and it has no unit.

Let

$$\Upsilon = \frac{2RV_{Sat}}{\pi R_{on}} \sin \chi_s \quad (7.70)$$

and it has the unit of current.

Let

$$\Gamma = \frac{V_{Sat}}{\pi R_{on}} \chi_s \quad (7.71)$$

and it has the unit of current.

Let

$$\Lambda = [(\sin \chi - \sin \chi_s) - (\chi - \chi_s) \cos \chi] \quad (7.72)$$

and it has no unit.

Rewriting Eq. (7.68)

$$\hat{V}_{ac1} = \frac{RI_{CC}}{2\pi} \Psi + \Upsilon R \quad (7.73)$$

Rewriting Eq. (7.65)

$$I_{CC} = \frac{\pi I_{DC} - \Gamma}{\Lambda} \quad (7.74)$$

Output power is

$$P_{out} = \frac{\hat{V}_{ac1}^2}{2R} = \frac{1}{2R} \left[\frac{RI_{CC}}{2\pi} \Psi + \Upsilon R \right]^2 \quad (7.75)$$

Substituting Eq. (7.74) into Eq. (7.75), we get

$$P_{out} = \frac{R}{2} \left[\frac{1}{2\pi} \left(\frac{\pi I_{DC} - \Gamma}{\Lambda} \right) \Psi + \Upsilon \right]^2 \quad (7.76)$$

Rewriting Eq. (7.66)

$$P_{in} = \left(\frac{I_{CC}}{\pi} \Lambda + \Gamma \right) V_{CC} \quad (7.77)$$

Efficiency η is found by dividing Eq. (7.75) by Eq. (7.77), so that

$$\eta = \frac{P_{out}}{P_{in}} = \frac{\left[\frac{RI_{CC}}{2\pi} \Psi + \Upsilon R \right]^2}{2RV_{CC} \left[\frac{I_{CC}}{\pi} \Lambda + \Gamma \right]} \quad (7.78)$$

Compare Eq. (7.78) with Eq. (7.53).

At this point, η appears to be a function of both I_{CC} and V_{CC} . Equation (7.74) may be used to rid Eq. (7.78) of I_{CC} , but this will only introduce I_{DC} into the equation. Instead, let $\hat{V}_{ac1} = \alpha V_{CC}$, where α is a constant of proportionality greater than one. (This has been shown to be the case for hard saturation.) This will allow expressing Eq. (7.78) only in terms of one voltage αV_{CC} , and no current variable. Being simplified in this way provides for a more meaningful analysis. It also forces the case for hard saturation so that Eq. (7.78) becomes an expression for η_{max} . Setting Eq. (7.73) equal to αV_{CC} , solving for I_{CC} ; and substituting into Eq. (7.78) gives

$$\eta_{max} = \frac{1}{4} \frac{\alpha^2 \Psi V_{CC}}{(\alpha V_{CC} - R\Upsilon)\Lambda + \frac{1}{2} R\Gamma\Psi} \quad (7.79)$$

We dare to expand Eq. (7.79) so that

$$\eta_{max} = \frac{\frac{1}{4} \alpha^2 V_{CC} [2(\chi - \chi_s) - 4\cos \chi (\sin \chi - \sin \chi_s) + (\sin 2\chi - \sin 2\chi_s)]}{\alpha V_{CC} [(\sin \chi - \sin \chi_s) - (\chi - \chi_s)\cos \chi] - \left[\frac{R}{R_{ON}} \frac{2V_{Sat}}{\pi} \sin \chi_s \right] [X]} \quad (7.80)$$

$$\frac{\text{Numerator}}{[(\sin \chi - \sin \chi_s) - (\chi - \chi_s)\cos \chi] + \frac{R}{R_{ON}} \left[\frac{V_{Sat}}{2\pi} \chi_s \right] [X]}$$

$$\frac{\text{Numerator}}{[2(\chi - \chi_s) - 4\cos \chi (\sin \chi - \sin \chi_s) + (\sin 2\chi - \sin 2\chi_s)]}$$

Although this equation is lengthy, it offers some intuitive feel for those things that affect efficiency. At first, the casual reader would expect that efficiency would not depend on V_{CC} because the efficiency of the nonsaturating Class C case does not depend on anything but 2χ . There is conduction angle dependency because, in saturation, the transistor collector equivalent circuit is a voltage source, not a current source. Efficiency is high as long as V_{CC} is much larger than V_{Sat} . Intuitively, efficiency is high because the collector current is highest when the collector-emitter is in saturation. As V_{CC} is made to approach V_{Sat} , there is less voltage to appear across the load and more current flows through R_{on} . When V_{CC} is made equal to V_{Sat} , all of the current flows through R_{on} , none to the load, and $\eta \rightarrow 0$. Other important conclusions may be

drawn by verifying that Eq. (7.80) collapses to η_{\max} predicted for the following:

1. Nonsaturated Class C case, where $2\chi_s = 0$ and $\alpha \rightarrow 1$
2. Linear Class B case, where $2\chi = \pi$
3. Linear Class A case, where $2\chi = 2\pi$

For the nonsaturated Class C case, Eq. (7.80) reduces to

$$\eta_{\max} = \frac{1}{4} \frac{\alpha^2 V_{CC} [2\chi - 4\cos \chi \sin \chi + \sin 2\chi]}{\alpha V_{CC} [\sin \chi - \chi \cos \chi]}$$

and realizing the identity, $\sin 2\chi = 2\sin \chi \cos \chi$

$$\eta_{\max} = \frac{1}{2} \frac{(\chi - \cos \chi \sin \chi)}{(\sin \chi - \chi \cos \chi)} \tag{7.81}$$

which agrees with Eq. (7.54)

For Class B, Eq. (7.81) reduces to

$$\eta_{\max} = \frac{\frac{\pi}{2} - \cos \frac{\pi}{2} \sin \frac{\pi}{2}}{2 \left(\sin \frac{\pi}{2} - \frac{\pi}{2} \cos \frac{\pi}{2} \right)} = \frac{\frac{\pi}{2} - 0}{2(1 - 0)} = \frac{\pi}{4} \tag{7.82}$$

which agrees with Eq. (7.37).

For Class A, Eq. (7.81) reduces to

$$\eta_{\max} = \frac{\pi - 2\sin \pi \cos \pi}{2(\sin \pi - \pi \cos \pi)} = \frac{\pi - 0}{2(1 - 0)} = \frac{1}{2} \tag{7.83}$$

which agrees with Eq. (7.32).

In saturated Class C, the voltage across the load is proportional to the supply voltage V_{CC} . Because of this it may be *high-level modulated* by connecting a baseband modulation signal voltage, $V_m(\theta)$, in series with the supply line. V_{CC} then becomes $V_{CC}(\varphi)$ so that

$$V_{CC}(\varphi) = V_{CC} + V_m(\varphi)$$

Assuming that $V_m(\varphi)$ is sinusoidal and that \hat{V}_m is made equal to V_{CC} , the amplifier will be modulated 100%, that is, $V_{CC}(\varphi)$ will swing from V_{Sat} to $2V_{CC}$. The amplifier is modeled in Fig. 7.60 and transistor,

FIGURE 7.60 The saturated Class C amplifier may be modeled as a current controlled voltage source with a measurable input resistance when driven, and an amplifier output resistance determined by the power efficiency $\eta \cdot R_{\text{Int}}$ shares power with R_{SL} , but $R_{\text{Int}} \rightarrow 0$ when $\eta \rightarrow 1$.

circuit, and standard impedances are measured in the same way as the nonsaturated amplifier. The loadline representation is given in Fig. 7.61 and should be compared with Fig. 7.58.

Referring to Fig. 7.60, R_{Int} is contained in

$$P_{out} = P_{in} \frac{R_{SL}}{R_{SL} + R_{Int}} \tag{7.84}$$

and along with R_{SL} , determines efficiency. In fact

$$\eta = \frac{R_{SL}}{R_{SL} + R_{Int}} \tag{7.85}$$

and should be compared with the complexity of Eq. (7.80). It is much easier to measure efficiency than it is to calculate it analytically.

Power dissipated in the transistor P_{Dis} , is found from

$$P_{Dis} = P_{in} - P_{out} = P_{in} \left(1 - \frac{R_{SL}}{R_{SL} + R_{Int}} \right) = P_{in}(1 - \eta) \tag{7.86}$$

Although Class C amplifiers, saturated or not, cannot perform as linear amplifiers, they are almost always used to amplify phase or frequency modulated signals to higher levels where high-power efficiency is important. Since the saturated Class C amplifier may be V_{CC} modulated, it is often used as the output stage of high-power high-level modulated full carrier AM transmitters. And since the Class C amplifier output tank circuit is high in harmonic current, the amplifier is useful as a frequency multiplier by resonating the tank to a harmonic so that only harmonic energy is passed to the load. An undesirable trait of the Class C is that the transistor collector current *snaps on* as drive appears and cannot be controlled with drive signal if it is saturated. Only V_{CC} will control collector current.

Because of the assumptions made about the saturated Class C amplifier before its mathematical analysis, it must be realized that the final circuit will need *adjusting* to get it to work right. Large signal behavior is only defined for a single set of values, such as supply voltage, load resistance, saturated currents, tank circuit Q, and other parameters. Change one thing and everything else changes! The idealized analysis presented here can only be viewed for basic theoretical understanding and initial design and test. Experience has shown many times that the actual power (O'Reilly, 1975) available from a saturated Class C amplifier is closer to

$$P_{out} \approx 0.625 \frac{(V_{CC} - V_{Sat})^2}{2R} \tag{7.87}$$

rather than

$$P_{out} = \frac{(V_{CC} - V_{Sat})^2}{2R}$$

since reality does not agree with the assumptions of this analysis. Particularly troublesome are the parasitic impedances associated with the emitter ground connection where frequently fractions of an ohm are involved and in bypassing supply lines with real capacitors and decoupling chokes that allow more than zero RF current to flow where in the ideal case, should not.

FIGURE 7.61 The saturated Class C amplifier is shown graphically with trends as a function of $2\chi, 2\chi_s, P_{out}$, and η . The intersection of the loadline with I_{cQ} is negative current, whereas saturation occurs where the loadline meets the transistor curve.

FIGURE 7.62 The half-wave Class D switch-mode pair in (a) produce power at the fundamental component of the switching frequency. Near-100% efficiency may be achieved when the transistors are modeled as ideal switches. The on-resistance of the transistors and drain-source capacitance prevents 100% efficient operation. Drive waveform may be of any shape, but must transition through the on-off threshold region (+4 V) very fast to avoid the active region. (b) The drain-source voltage of Q2.

Class D Voltage Switch-Mode Amplifier

Switch-mode amplifiers comprise a special class unlike Classes A, B, or C or their derivatives. Switch mode implies that something is on or off, but not in between. In switch mode there is no linear region as there is in Class A, B, or C. In fact, the active device is modeled as a switch. Insulated gate bipolar junction transistors (IGBJT) are used in switch-mode amplifiers up to a few hundred kilohertz whereas field effect transistors (FETs) are used to about 10 MHz. IGBJTs are advanced in their voltage and current capability, but are slower to switch on and off than FETs. Device development has advanced in these areas over the past few years at such a rapid rate that it is difficult to predict current, voltage, and switching speed limits with any degree of accuracy. For this discussion, the depletion type power FET is used, but it is only representative. Typically, a power FET has several thousand picofarads of gate-source capacitance, a saturation resistance R_{on} , of tenths or hundredths of an ohm, and snaps closed (to R_{on}) whenever gate-source voltage exceeds about +4 V for an N-channel type. Likewise, it snaps open whenever gate-source voltage falls below this same threshold. For the following discussion it is assumed that the time to pass through +4 V in either direction is zero and independent of drive signal shape. Except for R_{on} , it is close to being an ideal switch. In many ways it is better than a real switch because it is faster, does not bounce, and does not wear out like a real mechanical switch. Moreover, for this discussion, drain-source capacitance when the FET switch is open is also considered to be zero.

Figure 7.62(a) shows the schematic diagram of a half-wave depletion type FET Class D amplifier and the drain-source voltage of Q2 is shown in Fig. 7.62(b). The purpose of the amplifier is to produce a sinusoid output voltage across the load R at the switching frequency. The driving signal may be any shape, but a square voltage drive is preferred so that passage of the gate drive voltage through the threshold voltage is fast. As stated, R_{on} is assumed to be zero, as is any drain-source capacitance.

Because the drain-source voltage of Q2 is square, it contains only odd harmonics according to the nonzero Fourier series coefficients.

$$V_{DS2}(\theta) = V_{DD} \left[\frac{1}{2\pi} \int_0^\pi d\theta + \left(\frac{1}{\pi} \int_0^\pi \sin \theta d\theta \right) \sin \theta + \left(\frac{1}{\pi} \int_0^\pi \sin 2\theta d\theta \right) \sin 2\theta + \dots \left(\frac{1}{\pi} \int_0^\pi \sin 3\theta d\theta \right) \sin 3\theta + \dots \right] \tag{7.88}$$

$$V_{DS2}(\theta) = V_{DD} \left[\frac{1}{2} - \frac{1}{\pi} \cos \theta \Big|_0^\pi \sin \theta - \frac{1}{2\pi} \cos 2\theta \Big|_0^\pi \sin 2\theta - \frac{1}{3\pi} \cos 3\theta \Big|_0^\pi \sin 3\theta + \dots \right] \tag{7.89}$$

$$V_{DS2}(\theta) = V_{DD} \left[\frac{1}{2} + \frac{2}{\pi} \sin \theta + \frac{2}{3\pi} \sin 3\theta + \frac{2}{5\pi} \sin 5\theta + \frac{2}{7\pi} \sin 7\theta + \dots \right]$$

If L and C are resonant at the fundamental frequency of the Fourier series, the load R only sees the fundamental frequency component of the drain-source voltage of Q_2 , $V_{ac1}(\theta)$

$$V_{ac1}(\theta) = \frac{2V_{DD}}{\pi} \sin \theta \quad (7.90)$$

and

$$\hat{V}_{ac1} = \frac{2V_{DD}}{\pi}$$

Output power is simply

$$P_{out} = \frac{\hat{V}_{ac1}^2}{2R} = \frac{4V_{DD}^2}{2\pi^2 R} = \frac{2V_{DD}^2}{\pi^2 R} \quad (7.91)$$

The current through Q_1 or Q_2 is a half-sinusoid since each transistor conducts for only half of the time. The average current through Q_1 is the DC supply current I_{DC}

$$\begin{aligned} I_{ac1}(\theta) &= \frac{V_{ac1}(\theta)}{R} = \frac{2V_{DD}}{\pi R} \sin \theta \\ I_{Q1}(\theta) &= \begin{cases} I_{ac1}(\theta), & \text{when } \sin \theta > 0 \\ 0, & \text{when } \sin \theta \leq 0 \end{cases} \\ I_{DC} &= \frac{1}{2\pi} \int_0^\pi I_{Q1}(\theta) d\theta \\ I_{DC} &= \frac{-V_{DD}}{\pi^2 R} \cos \theta \Big|_0^\pi = \frac{2V_{DD}}{\pi^2 R} \end{aligned} \quad (7.92)$$

The DC input power is found from

$$P_{in} = I_{DC} V_{DD} = \frac{2V_{DD}^2}{\pi^2 R} \quad (7.93)$$

Since Eq. (7.93) equals Eq. (7.91), the efficiency η is equal to one.

A nonzero R_{on} is the only resistance preventing perfect efficiency if L and C in Fig. 7.62 are considered ideal. In reality, power efficiency near 98% is possible with very low on-resistance depletion type FETs. C_{block} is necessary because the current through Q_1 has a DC component.

The full-wave depletion type FET Class D amplifier may be configured as a pair of transistors such as the push-pull Class B schematic diagram shown in Fig. 7.53(a). Using a center-tapped primary transformer in the output circuit allows both transistors to conduct to the supply instead of one to the supply and one to ground, hence, full wave. A series tuned L - C resonant circuit in series with the load is necessary to allow only fundamental frequency load current. Full wave may also be achieved by using the four transistor *H-bridge*. It is the configuration of choice here in order to illustrate another way. The H-bridge name is obvious and is shown in Fig. 7.63. As before, R_{on} and drain-source capacitance are assumed to be zero.

The voltage across the series RLC output circuit alternates polarity between $+V_{DD}$ and $-V_{DD}$ so that $V_{ac}(\theta)$ is of the same form as Eq. (7.89). When L and C are tuned to fundamental resonance

$$V_{ac1}(\theta) = 2V_{DD} \left(\frac{2}{\pi} \sin \theta \right) \quad (7.94)$$

and

$$\hat{V}_{ac1} = \frac{4V_{DD}}{\pi}$$

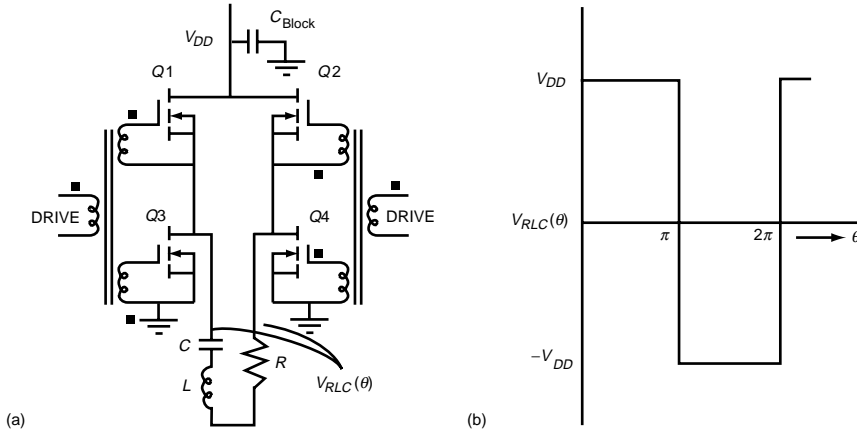

FIGURE 7.63 (a) The H-bridge full-wave Class D amplifier configuration. A diagonal pair of FETs is on, while the opposite pair is off at any instant. The H-bridge provides four times the power as the half-wave configuration. LC is a series resonant circuit at the fundamental frequency so that harmonic currents do not flow in the load R . (b) The waveform is the bridge voltage across the RLC network.

The output power is found from

$$P_{out} = \frac{\hat{V}_{ac1}^2}{2R} = \frac{8V_{DD}^2}{\pi^2 R} \tag{7.95}$$

The current through the load is

$$I_{ac1}(\theta) = \frac{4V_{DD}}{\pi R} \sin \theta$$

and

$$\hat{I}_{ac1} = \frac{4V_{DD}}{\pi R}$$

The currents through $Q1$ – $Q4$ are half-sinusoids since complementary pairs ($Q1$ $Q4$) and/or ($Q2$, $Q3$) only conduct for half of each drive cycle. Over 2π , the pulsating DC from the supply consists of two half-sinusoids so that C_{block} is needed and

$$\begin{aligned} I_{DC} &= 2 \left(\frac{1}{2\pi} \int_0^\pi I_{ac1}(\theta) d\theta \right) \\ &= -\frac{4V_{DD}}{\pi^2 R} \cos \theta \Big|_0^\pi = \frac{8V_{DD}}{\pi^2 R} \end{aligned} \tag{7.96}$$

Input power is

$$P_{in} = I_{DC} V_{DD} = \frac{8V_{DD}^2}{\pi^2 R} \tag{7.97}$$

Since Eq. (7.95) equals Eq. (7.97), power efficiency is equal to one as long as the transistors act as ideal switches with $R_{on} = 0$ and drain-source capacitance is also equal to zero. Four times the power is available from the full-wave H-bridge compared to the two transistor half-wave circuit of Fig. 7.62 because twice V_{DD} is the voltage swing across RLC .

Either the full-wave or half-wave Class D amplifier may be transformer coupled to R . It is only necessary to consider the turns ratio, but P_{out} and P_{in} remain the same.

FIGURE 7.64 The full-wave H-bridge is represented by a voltage source with no internal output resistance, assuming that the on-resistance and drain-source capacitance are zero. The input circuit must be a good load to the driving source, but usually is driven by a low impedance source capable of driving the capacitive input. R_{in} is high.

Modeling the entire switch mode amplifier in Fig. 7.64 shows that R_{Int} of the output circuit of the amplifier is zero. It must be since power efficiency is 100%, and the output circuit is a voltage source. It may be a current controlled voltage source if the switching devices are bipolar function transistors (BJTs), or voltage controlled if FETs or IGBTs are used. Although not much attention is given to the drive input circuit, it must be designed to present itself as some standard impedance at the operating frequency and, perhaps, very broadband if the drive signal is square. With no tuned circuits in the way and a very low source impedance, the drive signal should remain square.

In practice, each transistor in the full-wave or half-wave case is shunted by a *fast recovery diode* placed in the reverse direction from drain to source. The diode provides a path for current to flow when the load R is better represented by a complex impedance, $Z = R \pm jX$. A reactive component in the load causes out-of-phase currents to want to flow backward through any off transistor. Without the diode, the output capacitance of an off transistor will develop a spike of voltage due to the out-of-phase current charging the capacitance, and permanent damage will result. The diodes must be fast enough to conduct or not conduct dictated by the switching phase. Ordinary 60-Hz diodes imitate a resistor at 100 kHz.

In the case of the FET, drive power is derived by charging and discharging the gate-source capacitance. The amount of energy required to charge it is

$$E = \frac{1}{2}CV^2 \tag{7.98}$$

For example, at 10 MHz, the period, τ is 10^{-7} s. A half-period (charge time) is $\tau = 0.5(10)^{-7}$ s. If gate capacitance is 2000 pF, $2(10)^{-9}$ F, for each transistor charging to 10 V, then the energy needed to charge each gate becomes

$$E = \frac{1}{2}(2)(10)^{-9}(10)^2 = (10)^{-7} \text{ J}$$

The same energy must be taken out and dissipated (during the off half-period) at a rate of 10 MHz. The power needed to do this is

$$P = \frac{dE}{dt} = \frac{E}{\frac{\tau}{2}} = 2Ef = 2(10)^{-7}(10)^7 = 2 \text{ watts per gate} \tag{7.99}$$

This may or may not be a large amount of power, but it is not insignificant and must be taken into consideration when designing the overall amplifier. Furthermore, drive power is proportional to carrier frequency.

A potential for disaster exists if a set of on transistors does not turn off as quickly as it should and, instead, remains on while the opposite phase set is turning on. Should this happen, a momentary short circuit appears across the supply, and the transistors are history. A solution is to relatively slowly charge the gates and relatively rapidly discharge them to prevent on-state overlap. The charge path is slow, whereas the discharge path is fast. An effective circuit is shown in Fig. 7.65.

FIGURE 7.65 Slow charge and rapid discharge of the gate-source capacitance prevents possible transistor on-state overlap, which places a short circuit across the supply and destroys transistors.

An enhancement to Class D makes use of the real drain-source capacitance previously ignored. It is a

source of inefficiency and takes energy to charge, which is dissipated as heat during discharge much like the gate-source capacitance. In the Class E enhancement mode (modified Class D), the capacitance is used as part of the output network, and an additional external capacitance is selected so that the total is the correct amount to cause the drain voltage to reach zero at the instant the transistor turns off. In this way no discharge of the capacitance takes place and efficiency approaches unity.

The switch-mode Class D amplifier can be used as a baseband linear amplifier by applying a square gate signal, the pulse width (duty cycle) of which is proportional to the amplitude of the signal to be amplified.

Assume that a 25% duty cycle represents the halfway point between off and full on (50%) for each transistor set. Modulating up or down from 25% drives the amplifier to zero and 50% duty cycle for each set (100% total). The average of the output voltage across R will follow the pulse width represented drive signal. The output must be low-pass filtered to obtain the average, which is a reproduction of the signal to be amplified. (Use of the Class D amplifier in this way is sometimes referred to as Class S.)

Applying a pulse width modulated baseband amplifier like this as the power supply for a switch-mode RF amplifier (same configuration) provides a high-level amplitude modulated RF signal. After bandpass filtering at its output, it is suitable for transmission as a full carrier double sideband signal.

There are many variations of the amplifier classes presented in this section and most are *enhancements* of the basic ones.

Defining Terms

Amplifier class of operation: An alphabetical tag associated with an amplifier configuration describing its bias condition (which, in turn, determines its conduction angle) and sometimes its external circuit configuration.

Attenuation: For a signal passing through a circuit, the ratio of the signal power level at the output of the circuit to the signal power level at the input to the circuit when the output signal is of less power than the input. Usually expressed in decibels

$$\text{attenuation} = -10 \log \frac{P_{\text{out}}}{P_{\text{in}}} \geq 0$$

Aural subcarrier: In a composite television signal, the frequency division multiplexed carrier placed outside the visual passband that carries the audio modulation. In the NTSC (United States) system, it is placed 4.5 MHz higher than the visual carrier.

Color subcarrier: In a composite television signal, the frequency division multiplexed carrier placed within the visual passband which carries the color modulation. In the National Television Systems Committee (NTSC) (United States) system, it is placed approximately 3.579 MHz higher than the visual carrier.

Compression: For the transfer function of an amplifier, the relatively higher power region where the output power is less than proportional to the input power. The 1-dBm compression point is that output power level that decreases by 9 dBm when the input power decreases by 10 dBm.

Conduction angle: The drive or input signal phase angle over which an amplifier conducts current from its output power supply. It is expressed mathematically by 2χ .

Gain: For a signal passing through a circuit, the ratio of the signal power level at the output of the circuit to the signal power level at the input to the circuit when the output signal is of greater power than the input. This can only occur when the circuit is an amplifier. Usually expressed in decibels

$$\text{gain} = 10 \log \frac{P_{\text{out}}}{P_{\text{in}}} \geq 0$$

Intermodulation distortion: The result of two or more time-domain signals being multiplied together when they were intended to be only added together. Undesirable multiplication takes place in every amplifier amplifying multiple signals yielding sum and difference frequency components that are not present at the input to the amplifier.

Linear: Refers to the ability of an amplifier to maintain the integrity of the signal being amplified. A perfectly linear amplifier causes no distortion to the signal while making it greater in amplitude. The output vs. input transfer function plots as a straight line.

On-resistance: The collector-emitter resistance of a bipolar junction transistor or the drain-source resistance of a field effect transistor when driven to saturation. In the case of the BJT, it is equal to the collector-emitter saturation voltage divided by the collector current and is a function of both. In the case of the FET, it is equal to the saturated drain-source voltage divided by the drain current, but is not a function of either one.

Peak envelope power: The average power of the peak value of a signal.

Saturation angle: The drive or input signal phase angle over which an amplifying device is driven into saturation thereby resulting in a flat maximum of amplifying device supply current. Even though drive level may continue to increase, output circuit current does not. It is expressed mathematically by $2\chi_s$.

Saturation current: The collector current of a bipolar junction transistor or the drain current of a field effect transistor during the time of the saturation angle.

Standard load: Refers to the resistance of a load that is a standard established by an organization or committee commissioned to decide standards. Input, output, and interstage resistance in RF circuits is established to be 50 Ω unbalanced. Input, output, and interstage resistance in video circuits is established to be 75 Ω unbalanced, and that for audio circuits is 300 Ω balanced and sometimes 600 Ω balanced or 8 Ω unbalanced.

7.7 Operational Amplifiers

Peter Aronhime

7.7.1 Introduction

The name *operational amplifier* was originally applied to the high-gain voltage amplifiers that were employed in analog computers. When operational amplifiers were used with feedback circuits they could perform mathematical operations such as addition and integration on input signals. In the context of analog computers, operational amplifiers were most often used to solve differential equations.

The first commercially successful *integrated* operational amplifier (op-amp) was the Fairchild Company's μ A702, which was available in 1963. The first practical integrated op-amp was the μ A709, which was available in 1965. National Semiconductor Company's LM101 followed soon after. These three op-amps were designed by Bob Widlar (*Electronic Design*, 1992).

Probably the most widely used op-amp, the μ A741, was designed by Dave Fullagar and became available in 1967. This op-amp has relatively good characteristics, is easy to use, and is very inexpensive. It is an indication of the commercial success of the 741 that many of the more recently designed op-amps still have the same pin-outs as the 741 so that newer op-amps can replace 741s in a circuit board without redesigning the circuit board.

7.7.2 The Ideal Op-Amp

The ideal op-amp is an abstraction that is useful in the design and analysis of active circuits. A design can be formulated in terms of ideal op-amps, and later, if the design shows promise, the circuit can be analyzed in more detail to make sure it works in all circumstances. Figure 7.66 shows a schematic representation of an ideal op-amp. The presence of the *infinity* on the op-amp symbol indicates that this is an ideal op-amp representation.

Terminal 2 in this figure is denoted as the inverting input terminal, and a minus sign is marked next to this terminal on the op-amp symbol. Terminal 3 is called the noninverting input terminal, and a plus sign is placed next to this terminal. Terminal 6 is the output terminal, and terminals 4 and 7 are used to supply power to the device. Power is provided by a split supply consisting of two DC voltage sources with a ground between them. This ground is the electronic ground of the circuit, and all signals are referenced to this ground. Thus, the inverting input port exists between terminals 2 and 2' in Fig. 7.66, the noninverting input port exists between terminals 3 and 3' in the figure, and the output port exists between terminals 6 and 6'. In a physical circuit, terminals 2', 3', and 6' should be electrically the same as the ground point between the power supplies. Although an op-amp will not operate properly and may even be damaged if signals are applied to the op-amp while no

FIGURE 7.66 A schematic representation of an ideal op-amp shown with required power supplies and bypass capacitors. Not shown is the feedback network. The terminal numbers correspond to those used for the 741 op-amp in the minidip configuration.

FIGURE 7.67 Ideal op-amp models: (a) model with note stating that $v_a = 0$, (b) model with note that $i = 0$, (c) model consisting of a nullator and a grounded norator.

power connections are made to it, the power connections will not be shown in the schematics that follow. It is assumed that the op-amps shown are properly powered.

Figure 7.66 shows bypass capacitors connected between the power supply leads and ground at the op-amp. Values for these capacitors typically range between 0.1 and 1 μF , and they may be necessary to prevent the op-amp from oscillating or latching up even when negative feedback is connected around it. The phrase latching up refers to op-amp behavior characterized by the output voltage heading quickly to the maximum or minimum value that the op-amp can sustain and remaining at that level. Some op-amps may require more elaborate power supply bypass circuits, but generally speaking, individual capacitors connected as shown in the figure will suffice. However, a circuit designer should consult the manufacturer's specification sheet for a specific op-amp.

Ideal op-amps have the following properties:

- The voltage gain from the inverting input port to the output port is $-\infty$ over all frequencies, and the voltage gain from the noninverting port to the output port is $+\infty$.
- No current is drawn by the input leads. Thus, i_2 and i_3 in Fig. 7.66 are zero.
- The voltage between the input leads of the ideal op-amp is zero. Thus, v_a in Fig. 7.66 is zero.
- The output voltage can change in zero time in response to an input voltage that changes in zero time.
- The output resistance is zero. Thus, the output voltage of an ideal op-amp is independent of the current drawn from the output.
- Ideal op-amps generate no noise.

No real op-amp has these properties, but the properties of real op-amps approach the ones listed for many applications.

Three circuit models, which summarize the properties of ideal op-amps, are shown in Fig. 7.67. These models are equivalent, and the choice of which one to use in the analysis of a linear op-amp circuit is merely a matter of convenience. The model shown in Fig. 7.67(a) includes the note $v_a = 0$. The connection between terminals 2 and 3 in this figure is sometimes called a **virtual connection** or, if terminal 3 is connected to ground, a **virtual ground**. No current flows through this connection, and there is zero voltage between terminals 2 and 3.

In Fig. 7.67(b), the virtual connection between terminals 2 and 3 is realized by a short circuit with the additional note $i = 0$. In the third model, the virtual connection is represented by a **nullator**, which is an element defined to have zero current through it and zero volts across it (Bruton, 1980).

The output circuits of the models in Fig. 7.67(a) and Fig. 7.67(b) are ideal voltage sources, and the output circuit of the model in Fig. 7.67(c) is a **norator** with one end grounded. A norator is an element in which both the current through it and the voltage across it are arbitrary (Bruton, 1980), where arbitrary in the context of circuit analysis means that the current and voltage are determined by external circuitry.

The use of the model in Fig. 7.67(b) is illustrated in Fig. 7.68. Figure 7.68(a) shows an amplifier circuit consisting of an ideal op-amp and two resistors. The ideal op-amp symbol is replaced by a model in Fig. 7.68(b). A node equation written at node X yields

$$\frac{v_i}{R_1} + \frac{v_O}{R_2} = 0 \quad (7.100)$$

FIGURE 7.68 Inverting amplifier: (a) schematic, (b) a model for the ideal op-amp has been substituted into the circuit.

from which we obtain

$$\frac{v_O}{v_i} = -\frac{R_2}{R_1} \tag{7.101}$$

This amplifier configuration is called an inverting amplifier. The input resistance of this amplifier is easily determined from Fig. 7.68(b) to be \$R_1\$.

In most applications, external circuit elements such as resistors and capacitors must be connected to the terminals of an op-amp to obtain a useful circuit. Very few practical applications exist in which the op-amp is used alone.

7.7.3 A Collection of Functional Circuits

A medley of op-amp circuits is presented in this section. Table 7.3 shows some basic op-amp circuits and lists the chief characteristics of each one. The power supply connections are not shown for these circuits (except for circuits 10 and 11), but it is understood that they are present. Power supply bypass capacitors are also not shown but are assumed to be connected. Circuit 2 in the table is a voltage buffer. It is an example of one of the few applications that require no external components except for a wire connecting the output to the inverting input terminal of the op-amp.

The adder, shown as circuit 4 in Table 7.3, can be expanded into an adder/subtractor as depicted in Fig. 7.69. In this circuit, we have \$(n + Z)\$ voltage sources labeled \$v_1, v_2, \dots, v_n\$ and \$v_A, v_B, \dots, v_Z\$. The output voltage of the circuit is

$$v_O = -\sum_{i=1}^n M_i v_i + \sum_{k=A}^Z M_k v_k \tag{7.102}$$

where the \$M\$ are gain magnitudes. The variable \$S\$ in the figure is

$$S = S_n - S_p \tag{7.103}$$

where

$$S_n = 1 + \sum_{i=1}^n M_i = 1 + |(\text{sum of negative gains})|$$

$$S_p = \sum_{k=A}^Z M_k = \text{sum of positive gains}$$

We require that \$S \ge 0\$ so that the resistor \$R_F/S\$ is not negative. As an example, suppose we have four voltage sources labeled \$v_1, v_2, v_A\$, and \$v_B\$, and we want

$$v_O = -6v_1 - 3v_2 + 5v_A + \frac{1}{2}v_B$$

TABLE 7.3 Op-amp Circuits

No.	Type of Circuit	Schematic	Circuit Gain or Variable of Interest	Input Resistance or Input Currents or Voltages	Special Requirements or Remarks
1	Noninverting amplifier		$\frac{v_O}{v_i} = 1 + \frac{R_2}{R_1}$	$R_{in} = \infty$ (ideally)	
2	Buffer		$\frac{v_O}{v_i} = 1$	$R_{in} = \infty$ (ideally)	Special case of circuit 1
3	Difference amplifier		$v_O = \frac{R_2}{R_1}(v_2 - v_1)$	$i_1 = \frac{v_1 - v_2 \frac{R_b}{(R_a + R_b)}}{R_1}$ $i_2 = \frac{v_2}{R_a + R_b}$	$\frac{R_1}{R_2} = \frac{R_a}{R_b}$
4	Adder		$v_O = -\left\{v_1 \frac{R_f}{R_1} + v_2 \frac{R_f}{R_2} + \dots + v_n \frac{R_f}{R_n}\right\}$	$i_1 = \frac{v_1}{R_1}$ $i_2 = \frac{v_2}{R_2}$ \vdots $i_n = \frac{v_n}{R_n}$	

5 Variable gain circuit

$$\frac{v_O}{v_i} = (2Kx - K)$$

$$0 \leq x \leq 1, \quad K > 1$$

$$i = \frac{v_i}{R_3} + \frac{K v_i (1 - x)}{R}$$

Potentiometer R_3 adjusts the gain over the range $-K$ to $+K$.

6 Voltage-to-current converter

$$i = \frac{v_i}{R_1}$$

The current through R_L is independent of R_L

7 Voltage-to-current converter with grounded load

$$i = \frac{v_i}{R}$$

$$i_s = \frac{v_i}{R} \left(1 - \frac{R_L}{R} \right)$$

$v_O = v_i(2R_L/R)$
The current i is independent of R_L
Circuit has wide band-width for $R_L \ll R$.

8 Current-to-voltage converter

$$v_O = -R i_i$$

$$v = 0$$

The voltage v_O is independent of R_L and R_i

(Continued)

TABLE 7.3 Op-amp Circuits (Continued)

No.	Type of Circuit	Schematic	Circuit Gain or Variable of Interest	Input Resistance or Input Currents or Voltages	Special Requirements or Remarks
9	Current-to-voltage converter		$v_O = -2i R_1 \frac{R_4}{R_3}$	$v = 0$	
10	Inverting amplifier with single supply		$v_O = 7.5 - v_i \frac{R_2}{R_1}$		$R = 3.9 \text{ k}\Omega$
11.	Noninverting amplifier with single supply		$v_O = 7.5 + v_i \left(1 + \frac{R_2}{R_1} \right)$		$R = 3.9 \text{ k}\Omega$

12 Integrator

$$v_o = -V(0) - \frac{1}{RC} \int_0^t v_i(t) dt$$

$V(0)$ is the initial voltage across the capacitor. RC is very large.

$$i = \frac{v_i}{R}$$

Negative feedback is required at DC. A large value of R_C can be used or a feedback path can be established through an external circuit.

13. De Boo integrator

$$v_o = 2V(0) + \frac{2}{RC} \int_0^t v_i(t) dt$$

$$i = \frac{v_i}{R} - \frac{v_o}{2R}$$

One end of capacitor is physically grounded.

14. Differentiator

$$v_o = -RC \frac{dv_i}{dt}$$

$$i = C \frac{dv_i}{dt}$$

Differentiators are usually avoided in the design of circuits because they accentuate noise.

15. Generalized impedance converter (GIC)

$$Z_{in} = \frac{Z_1 Z_3 Z_5}{Z_2 Z_4}$$

FIGURE 7.69 Single op-amp adder/subtractor circuit.

We note that $S_n = 1 + (6 + 3) = 10$ and $S_p = 5.5$ so that $S = 4.5$, which is not negative. The resulting circuit is shown in Fig. 7.70.

However, suppose we require a different circuit in which

$$v_O = -v_1 - 2v_2 + 3v_A + 4v_B$$

In this case, S is negative. So we append a fictitious source v_3 and require that the gain from v_3 to v_O be -3 . Now $S_n = 1 + (1 + 2 + 3) = 7$. The sum of positive gains, S_p , remains equal to 7. Thus $S = 0$, and the resistor R_F/S in Fig. 7.69 is replaced by an open circuit. Of course, we set $v_3 = 0$. The resulting circuit is shown in Fig. 7.71.

Another useful circuit, based on a single op-amp, is shown in Fig. 7.72. The schematic depicts a rendering of the Burr-Brown RCV420 4–20 mA current loop receiver, a circuit which converts a 4–20 mA input signal to a 0–5 V output signal.

The circuit realizes a transresistance R_T given by

$$R_T = \frac{\Delta V_O}{\Delta I_N} = \frac{5 \text{ V}}{16 \text{ mA}} = 0.3125 \text{ V/mA}$$

Also, the output voltage of the circuit must be offset by -4 mA (0.3125 V/mA) = -1.25 V so that 0 V will be obtained when 4 mA is applied to the input. Thus, the output voltage is given by

$$V_O = -1.25 \text{ V} + I_N(\text{mA}) [0.3125 \text{ (V/mA)}] \tag{7.104}$$

FIGURE 7.70 Adder/subtractor that provides gains: -6 , -3 , $+5$, and $+\frac{1}{2}$.

FIGURE 7.71 Adder/subtractor with gains equal to -1 , -2 , $+3$, and $+4$.

FIGURE 7.72 A 4–20 mA current loop receiver shown with a positive input current signal. This signal returns to ground through terminal CT. The terminal labeled $-I_N$ is left open. If the signal is a negative current signal, then it is applied to the terminal labeled $-I_N$ and the terminal $+I_N$ is left open.

To verify Eq. (7.104), we reduce the circuit in Fig. 7.72 to that shown in Fig. 7.73(a) using the techniques described in Aronhime (1995). Further reduction yields the circuit in Fig. 7.73(b) from which we obtain Eq. (7.104). Note that if $+I_N$ were zero (open circuit) in Fig. 7.72, then from Eq. (7.105), V_O would be -1.25 V. This voltage can be easily sensed and used as an indicator that the signal line is open.

Op-amps can be advantageously combined with analog switches to create innovative and useful circuits. For example, Fig. 7.74 shows a representation of a programmable-gain amplifier composed of a dual 4-to-1 analog multiplexer and a difference amplifier. The positions of the switches in the multiplexer are selected digitally by means of leads A_0 and A_1 and yield amplifier gains according to Table 7.4.

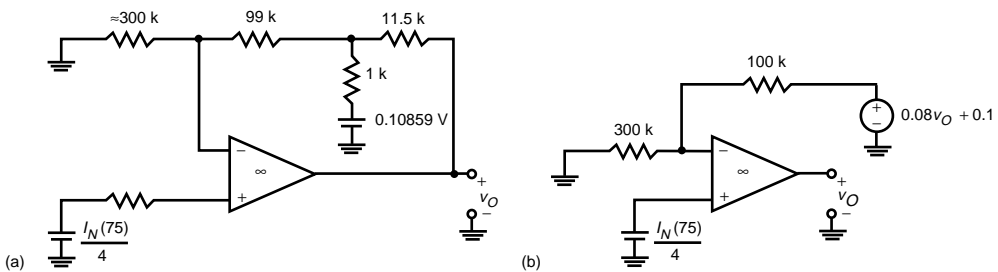

FIGURE 7.73 Steps in the analysis of the current loop receiver.

FIGURE 7.74 Programmable gain amplifier consisting of a dual 4-to-1 analog multiplexer and a difference amplifier. The op-amps are ideal.

The resistors labeled R_M represent parasitic resistances of the analog switches used in the multiplexer. These resistances can range in value from 35 Ω to several kilohms.

To verify the second entry in Table 7.4, suppose A_1 is low and A_0 is high. The resulting connections to op-amps 1 and 2 are shown in Fig. 7.75. Since the op-amps are considered to be ideal, no currents flow through the resistors labeled R_M , and so these resistors do not enter into the calculations. Using superposition and the results previously given for the ideal inverting amplifier, we can write

$$v_{O1} = v_1 \left(1 + \frac{R_F}{2R_A + R_B + R_C} \right) - v_2 \left(\frac{R_F}{2R_A + R_B + R_C} \right) \tag{7.105}$$

and

$$v_{O2} = -v_1 \left(\frac{R_F}{2R_A + R_B + R_C} \right) + v_2 \left(1 + \frac{R_F}{2R_A + R_B + R_C} \right) \tag{7.106}$$

TABLE 7.4 Amplifier Gains (for Fig. 7.74)

A_1	A_0	Amplifier Gain
0	0	1
0	1	10
1	0	100
1	1	1000

FIGURE 7.75 Reduced circuit corresponding to the programmable gain amplifier in Fig. 7.74 with both switches set to position 1 ($A_1 = 0$ and $A_0 = 1$). Op-amp 3 and its associated resistors are not shown.

The difference of the two voltages v_{O1} and v_{O2} is formed by the difference amplifier composed of op-amp 3 and the four 10-k Ω resistors in Fig. 7.74 (see circuit 3 in Table 7.3). Thus, v_O is given by

$$v_O = v_{O2} - v_{O1} = (v_2 - v_1) \left(1 + \frac{2R_F}{2R_A + R_B + R_C} \right) = 10.0(v_2 - v_1) \quad (7.107)$$

At low frequencies, the resistances of the switches used to create the analog multiplexers have no effect on the output voltage, but they may affect the results at higher frequencies if parasitic capacitances are not kept to low values. However, the properties of real or tangible op-amps (as opposed to ideal op-amps) will most likely impose tighter limits on the range of frequencies over which this circuit and any of the circuits in this section can be used. Furthermore, real op-amp characteristics will affect gain accuracies. In the next section, we discuss the characteristics of real op-amps and show how these characteristics can be modeled.

7.7.4 Op-Amp Limitations

Real, tangible op-amps differ from ideal op-amps in the following ways:

- The gain of a real op-amp is neither infinite nor constant. It is a function of frequency.
- A real op-amp has an offset voltage and nonzero bias current.
- Input resistances are not infinite and output resistance is not zero. Input capacitance is not zero as well.
- The output voltage is limited in amplitude, and it is slew-rate limited. The output current is also limited in amplitude.
- A tangible op-amp has nonzero **common-mode gain**.
- Real op-amps generate noise.

In this section we discuss these properties of real op-amps and compare them with the specifications of the commercial version of the $\mu\text{A}741$ op-amp. Although the list above is somewhat lengthy, in many applications only one or two properties of real op-amps matter. For this reason, we develop a series of models for the real op-amp. Each model accounts for only one or two departures from ideal behavior. Thus, the effects of a particular property of an op-amp on a circuit can be ascertained.

Op-Amp Gain

For many applications, the most important departure from ideal behavior is the finite, frequency-dependent gain of real op-amps. Figure 7.76 shows an op-amp model which is useful for determining the effects of

nonideal gain on a circuit. In this figure, the pin numbers correspond to those of the $\mu A741$ in the 8-pin minidip (see Fig. 7.66), and pin 2 is the *inverting* terminal of the op-amp. The variables $V_a(s)$ and $V_O(s)$ are Laplace transforms of the corresponding functions of time v_a and v_O . The variable s is the Laplace transform variable, which is set to $j\omega$ for the sinusoidal steady-state analysis of strictly stable networks. Unlike the ideal model in Fig. 7.67 in which v_a is zero, v_a is not zero in the model in Fig. 7.76, although it is quite small for linear applications of an op-amp. Typically, v_a is of the order of a few millivolts.

FIGURE 7.76 Op-amp model which accounts for the finite, frequency-dependent gain of a real op-amp. Pin numbers in the figure correspond to those used on the 741 minidip.

$A(s)$ represents the gain of the op-amp. For most modern general-purpose op-amps, this frequency-dependent gain is closely approximated by

$$A(s) = \frac{A_o \omega_a}{(s + \omega_a)} \tag{7.108}$$

where A_o is the gain of the op-amp at DC and ω_a is the (radian) frequency at which the magnitude of the gain has decreased 3.01 dB from its DC value. The frequency-dependent gain given in Eq. (7.108) is termed the **open-loop gain** of the op-amp, and the schematic in Fig. 7.76 with $A(s)$ given by Eq. (7.108) is termed the **one-pole model** or the one-pole rolloff model.

A_o is very large. Even an inexpensive op-amp such as the $\mu A741$ has a gain at DC of 100 dB or more. However, ω_a is only 10–20 rad/s, which corresponds to only a few hertz. Figure 7.77 shows sketches of the magnitude and phase of Eq. (7.108). Note that the magnitude of the **open-loop gain** equals one at $\omega = A_o \omega_a$.

If A_o is 105 dB and ω_a is 10 rad/s, the magnitude of the gain is reduced to about 85 dB at $\omega = 100$ rad/s. The question arises: Why are op-amps designed to exhibit the characteristics of this one-pole model? A brief answer to this question begins with the fact that an op-amp consists of many transistors and, therefore, there are many parasitic capacitances, which in turn create many poles in $A(s)$. Suppose the op-amp is used to make an amplifier such as the one shown as circuit 1 in Table 7.3. As the gain of this amplifier is reduced by, say, decreasing R_2 , the poles of the transfer function of the *amplifier* move in the s plane. Some of these poles move toward the imaginary axis and may even cross over into the right-half s plane if the gain is reduced to a low value. This would cause the amplifier to be unstable. The poles of the amplifier exist because $A(s)$ has poles (and zeros), but the poles of the amplifier are different from the poles of $A(s)$. To ensure that the amplifier remains stable while providing a gain that is accurately modeled by $1 + (R_2/R_1)$, it can be shown that $A(s)$

FIGURE 7.77 (a) Magnitude and (b) phase of the open-loop gain $A(s)$ of an op-amp.

should have one dominant pole close to the origin of the s plane (Budak, 1974; Geiger, Allen, and Strader, 1990; Franco, 1988). This discussion has assumed that the feedback around the op-amp is purely resistive and has ignored stray capacitance that might be associated with a load on the op-amp. If the feedback network around the op-amp is not purely resistive and/or there are capacitors (or inductors) in the load, then an analysis must be performed to determine whether the amplifier is stable or not. The one-pole model developed here can be used for this analysis.

The **gain-bandwidth product** GB of the op-amp is $GB = A_o\omega_a$, and the **op-amp time constant** is denoted as $\tau = 1/GB$. For analyses in which the frequencies of interest are much greater than ω_a , $A(s)$ is usually approximated as

$$A(s) \approx \frac{GB}{s} = \frac{1}{s\tau} \tag{7.109}$$

Ideally, GB is infinite and τ is zero.

Applying the one-pole model to the noninverting amplifier shown as circuit 1 in Table 7.3, we obtain the circuit shown in Fig. 7.78.

Since $V_O = A(s)V_a$, we obtain

$$V_i - \frac{V_O}{A(s)} = V_O \frac{R_1}{R_1 + R_2}$$

Using $A(s) = GB/s$ and letting $K = 1 + R_2/R_1$, we get

$$\frac{V_O}{V_i} = K \left[\frac{\frac{GB}{K}}{s + \frac{GB}{K}} \right] \tag{7.110}$$

The gain of the amplifier in Eq. (7.110) is referred to as the closed-loop gain. Examination of Eq. (7.110) shows that the gain consists of the ideal gain K (gain obtained with an ideal op-amp) multiplied by a first-order function of the Laplace variable s . This first-order function causes the magnitude of the amplifier gain to fall off for higher frequencies, a behavior that is readily observed in the laboratory. Figure 7.79

FIGURE 7.78 Noninverting amplifier schematic including one-pole model of Fig. 7.76.

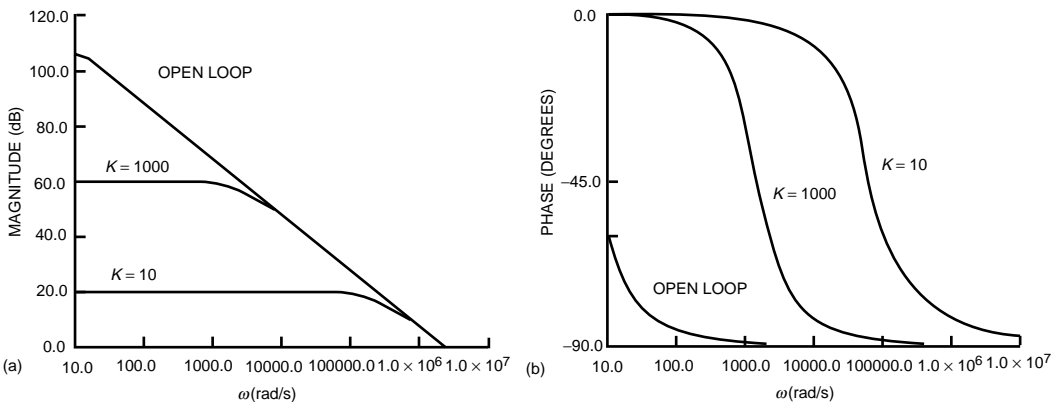

FIGURE 7.79 (a) Bode plots of the closed-loop gain of the noninverting amplifier for $K = 1000$ and for $K = 10$. The magnitude of the op-amp gain is also shown. (b) Plots of phase are shown for $K = 1000$ and $K = 10$, as well as for the op-amp gain.

shows Bode plots of the amplifier gain and phase for two different gain settings. The magnitude of the open-loop gain is also shown in Fig. 7.79(a), and we see that the magnitude of the open-loop gain sets a bandwidth limit on the closed-loop gain. Let ω_{CL} be the frequency at which the closed loop gain is down 3.01 dB from its low-frequency level of $20 \log(K)$. From Eq. (7.110), we have $\omega_{CL} = GB/K$. Thus

$$\omega_{CL}K = A_o\omega_a \quad (7.111)$$

The quantity $\omega_{CL}K$ is the **closed-loop gain-bandwidth product**, and so Eq. (7.111) shows that the closed-loop gain-bandwidth product for this amplifier equals the open-loop gain-bandwidth product.

The finite gain-bandwidth product of the op-amp also manifests itself in other ways in addition to causing the gain of op-amp amplifiers to fall off at higher frequencies. For example, it can cause the pole and zero placements in active filter circuits to be inaccurate, it can cause active filters to be unstable, and it can limit the **rise time** of an amplifier's response to a step. For example, suppose the buffer shown as circuit 2 in Table 7.3 is excited by a step of voltage of small amplitude V . Small amplitude is needed so that we avoid slew rate limiting which is discussed in a later section. The rise time t_r of the response is defined as the time required for the output voltage to go from 10 to 90% of the final value V . If we use the one-pole model given in Fig. 7.76 in the buffer circuit and solve for t_r , we obtain

$$t_r = \tau \ln 9 = 2.2\tau$$

where τ is the time constant of the op-amp. Thus, in response to the step excitation, the output voltage has a nonzero rise time. Clearly, the rise time is improved for smaller τ .

Offset Current and Voltage

An op-amp must be permitted to conduct DC currents through its input leads in order to operate properly. These currents are small and range from picoamps to nanoamps for an IGFET-input op-amp such as a CA3140. For a $\mu A741$, they range from nanoamps to a microamp. In an ideal op-amp, they are taken as zero. But these small currents cause the output voltage of an op-amp amplifier to be nonzero when the signals applied to the amplifier are zero. In applications such as instrumentation amplifiers or a track-and-hold circuits, these currents can cause appreciable error.

As in Fig. 7.66, we denote these currents as I_2 and I_3 . The term **bias current** or *input bias current* on the specification sheets of op-amps from most semiconductor manufacturers is the *average* of I_2 and I_3 . That is, the bias current I_B is

$$I_B = \frac{I_2 + I_3}{2} \quad (7.112)$$

In addition, the *difference* between I_2 and I_3 is termed the **input offset current** I_{OS} , and its magnitude is usually provided on op-amp specification sheets. Thus

$$|I_{OS}| = |I_2 - I_3| \quad (7.113)$$

We note that I_2 and I_3 can be expressed in terms of I_B and I_{OS} as

$$I_2 = I_B + \frac{I_{OS}}{2} \quad \text{and} \quad I_3 = I_B - \frac{I_{OS}}{2} \quad (7.114)$$

All of these currents drift with temperature and with time.

Input offset voltage V_{OS} also causes the output voltage of an op-amp amplifier to be nonzero when the input signals are zero. This voltage exists because of small mismatches in the base-emitter voltages or gate-source voltages of the transistors in the input differential stage of an op-amp. It is defined as the voltage that must be applied to the input of a noninverting amplifier to drive the output voltage to zero with no load on the output. It is assumed that the feedback resistors are chosen so that negligible current is drawn from the output, and currents flowing in the input leads of the op-amp cause insignificant voltages. Offset voltage also drifts with temperature and time.

FIGURE 7.80 (a) Model showing DC input currents and DC offset voltage. (b) Model which incorporates specification sheet parameters for the input currents.

Figure 7.80(a) shows a model for an op-amp that incorporates I_2 , I_3 , and V_{OS} . Using Eq. (7.114) we obtain the model shown in Fig. 7.80(b) in which the currents are given in terms of I_B and I_{OS} . For both schematics in Fig. 7.80, the nonideal op-amp, depicted with dotted lines, is modeled with independent sources and an op-amp, shown with solid lines, which has zero input currents and zero offset voltage.

To assess the effects of nonzero I_B , I_{OS} , and V_{OS} on the output voltage of the noninverting amplifier, we employ the circuit shown in Fig. 7.81. Note that no external signals are applied and that an extra resistor R_C has been included in the noninverting input lead of the amplifier. The DC output voltage can be written as

FIGURE 7.81 Noninverting amplifier schematic incorporating the op-amp model shown in Fig. 7.80(b).

$$V_O = I_B \left[R_2 - R_C \left(1 + \frac{R_2}{R_1} \right) \right] + \frac{I_{OS}}{2} \left[R_2 + R_C \left(1 + \frac{R_2}{R_1} \right) \right] + V_{OS} \left(1 + \frac{R_2}{R_1} \right) \quad (7.115)$$

Ideally, V_O should be zero. If

$$R_C = \frac{R_2}{1 + \frac{R_2}{R_1}} = R_1 \parallel R_2$$

then V_O becomes independent of I_B and can be expressed as

$$V_O = I_{OS} R_2 + V_{OS} \left(1 + \frac{R_2}{R_1} \right)$$

Since I_B is typically 5–10 times larger than I_{OS} , the resistor R_C should be included if the voltage $I_B R_2$ is significant in comparison with the expected range of input signal amplitudes.

Although R_C can be selected to make the output of the noninverting amplifier (and other amplifiers as well) independent of I_B , it cannot be used to eliminate the effects of the other error terms in Eq. (7.115). The reason for this is that the polarities of I_{OS} and V_{OS} , shown with specific polarities in Fig. 7.80(b), are not really known in practice. In fact, these offsets may change polarities as temperature is changed. On the other hand, most integrated op-amps have provision for the connection of an external circuit that can be used to adjust the effects of the offset sources to zero. For a $\mu A741$, the external circuit consists of a 10-k Ω potentiometer connected between pins 1 and 5 (on the minidip)

FIGURE 7.82 Op-amp model suitable for computer simulations. The two batteries in the output circuit of the model account for the clipping levels of the op-amp. $R_{IN} = 2 \text{ M}\Omega$, $A_o = 200,000$, $R_p = 10 \text{ k}\Omega$, $C_p = 5.0 \mu\text{F}$, and $A_1 = 1$. R_p and C_p set the pole of the one-pole rolloff model. For the values indicated, ω_a is 20. The two batteries are each set to 14 V (with the polarities indicated in the figure). N for the diodes (emission coefficient) is set to 0.001, which yields almost ideal diodes. Thus, the clipping levels for this model are set to $\pm 14 \text{ V}$. R_o is 75Ω .

with the wiper connected to the negative supply. The range of adjustment for this circuit is typically $\pm 15 \text{ mV}$ at the input. In use, the signals to the op-amp amplifier are set to zero, and the output of the amplifier is then adjusted to zero with the potentiometer. As ambient temperature changes or if the power to the amplifier is removed and then reapplied, this adjustment procedure should be performed again.

Output Voltage and Current Limits

If an amplifier containing a typical $\mu\text{A}741$ op-amp is driven by a sine wave of sufficient amplitude to cause clipping and the op-amp is powered by $\pm 15\text{-V}$ power supplies, the voltage amplitudes at which clipping occurs are approximately $+14.3 \text{ V}$ and -13.8 V for a light load ($R_L \geq 10 \text{ k}\Omega$). Thus, the clipping levels are slightly unsymmetrical. If the load is increased, the magnitudes of the clipping levels are decreased. During the time the op-amp is clipping the output signal, the input voltage $v_a(t)$ is not held to approximately 0 V , and the models shown in Fig. 7.67 are not valid. Figure 7.82 shows a model that accounts for clipping levels, incorporates the one-pole open-loop gain model, and includes input and output resistances. This model is suitable for use in computer simulations of op-amp circuits. Input and output resistances are discussed in a later section.

The output current is also limited. The output current for a $\mu\text{A}741$ op-amp is limited to about 25 mA by internal protection circuitry. Thus, the current demanded from the output of this op-amp should be kept below 25 mA to avoid distortion of the output waveform. In fact, the output current demand should be kept small for best results because most parameters of an op-amp, such as gain-bandwidth product, degrade as output current demand is increased. Also, the op-amp output must supply current to the feedback network, and this current is included as part of the output current demand. For example, the op-amp in the circuit shown in Fig. 7.83 supplies current to both $1\text{-k}\Omega$ resistors. This op-amp will current limit if $|v_{O1}| \geq 12.5 \text{ V}$.

If more current is needed, a power op-amp or a power buffer can be employed.

FIGURE 7.83 Op-amp 1 supplies current from its output terminal to both $1\text{-k}\Omega$ resistors shown.

Slew Rate

For large signal excitations, a nonlinear phenomenon called **slew rate (SR)** limiting imposes an upper limit on how fast the output voltage can change with time. If the input voltage signal is a sine wave given by $V \sin(\omega t)$, and if the gain of the amplifier is G , then the output voltage becomes slew rate limited if

$$\left. \frac{d[GV \sin(\omega t)]}{dt} \right|_{\max} > SR \quad (7.116)$$

Since the maximum slope of the output voltage occurs when the sine wave goes through zero, we have slew rate limiting for

$$GV\omega > SR$$

Thus, if the product of the output voltage amplitude, GV , and frequency ω is too large, then the output waveform becomes distorted as shown in Fig. 7.84. To avoid slew rate distortion for a given op-amp, one must reduce either the amplitude or the frequency of the sinusoidal input waveform so that the product is less than the SR of the op-amp.

Slew rate limiting begins abruptly as the amplitude and frequency of the output voltage are increased. The cause of slew rate limiting is illustrated by the circuit diagram shown in Fig. 7.85. This diagram represents an op-amp as a three-stage amplifier. The compensation capacitor, which sets the position of the dominant pole, is represented by C_c . The first stage is a transconductance amplifier and its maximum output current is limited to $I_{O1\max}$. Stage 2 is a voltage amplifier with a high-input resistance and low-output resistance, and stage 3 is a voltage amplifier with a gain approximately equal to one. For a $\mu A741$, $I_{O1\max}$ is approximately $18 \mu A$ and C_c is about 30 pF . If the input signal is large enough in frequency or amplitude to cause SR limiting, then I_{O1} is constant at $I_{O1\max}$. From $I = CdV/dt$, we obtain $SR = 0.6 \times 10^6 \text{ V/s}$ or $0.6 \text{ V}/\mu s$. The typical value for SR for a $\mu A741$ is given as $0.5 \text{ V}/\mu s$, a result that compares favorably with the outcome of this simple calculation. Op-amps are available having slew rates greater than hundreds of volts per microsecond.

The magnitude of the SR of the $\mu A741$ is approximately the same whether the output voltage is increasing or decreasing. Some op-amps slew faster in one direction than in the other. As a result, when the output

FIGURE 7.84 Desired output and slew rate limited output for an op-amp amplifier.

FIGURE 7.85 A three-stage representation for an op-amp that emphasizes the causes of slew rate limiting.

voltage is slew rate limited, a DC offset voltage is created, and the magnitude of this DC voltage increases as the input voltage amplitude and frequency are increased.

Another specification for op-amps that pertains to *SR* is **full power bandwidth**. Suppose the sinusoidal output voltage of an op-amp amplifier is to be, say, 10-V peak. How high can the frequency ω be increased while avoiding distortion due to *SR*? This question is answered by the calculation: $10\omega \leq SR$. If *SR* is $0.5 \text{ V}/\mu\text{s}$, then $\omega = 2\pi f \leq 0.05 \text{ rad}/\mu\text{s}$ or $f \leq 8 \text{ kHz}$.

Input and Output Impedances

An ideal op-amp has infinite-input and zero-output impedances. Figure 7.86 shows a model for an op-amp, which accounts for the finite- (but large) input resistances and the low- (but not zero) output resistance of a real op-amp. For a $\mu\text{A}741$, the differential input resistance R_{id} is about $2 \text{ M}\Omega$, the common-mode input resistance R_{iCM} is $100 \text{ M}\Omega$, the input capacitance C_i is $4\text{--}7 \text{ pF}$ (including the capacitance of the op-amp package), and the output resistance R_o is about 75Ω . There are other parasitic capacitances such as capacitance between input and output that are not shown, but for many applications, C_i is the most significant capacitance.

Although the input resistances are in the megohm range and the output resistance is 75Ω , it appears that the input and output resistances depart considerably from the ideal values of infinity and zero, respectively. However, negative feedback around the op-amp in an op-amp voltage amplifier increases the input resistance and reduces the output resistance. For example, let us determine the output

FIGURE 7.86 A model for the op-amp which accounts for input impedances and output resistance.

FIGURE 7.87 (a) Inverting amplifier whose output impedance Z_o is to be found. (b) Amplifier schematic prepared for analysis.

impedance of the inverting amplifier shown in Fig. 7.87(a). Figure 7.87(b) shows the resulting schematic after:

- The model in Fig. 7.86 has been substituted into Fig. 7.87(a). The resistances and C_i at the input of the model have been neglected since they are in parallel with R_1 .
- The independent source v_i has been set to 0 V.
- An independent source $I_o(s)$ where s is the Laplace variable has been applied to the output port.

The output impedance is given by $Z_o = V_o/I_o$, and the result is

$$Z_o = \frac{R_o(R_1 + R_2)}{R_o + R_1 + R_2} \left[\frac{1}{1 + \frac{AR_1}{R_o + R_1 + R_2}} \right] \tag{7.117}$$

Thus, the output impedance is given by $R_o \parallel (R_1 + R_2) = R_{pas}$ modified by the terms in the braces. Note that R_{pas} is merely the output resistance of the passive network that is obtained when A is set to zero. We also note that Z_o approaches zero as GB of the op-amp approaches infinity and that for noninfinite GB , Z_o is a function of frequency since A is given by Eq. (7.108).

The output impedance can be expressed in terms of loop gain. If the circuit in Fig. 7.87(b) is broken at point X , the current source I_o removed, and the circuit excited with a voltage source V_X , we obtain the circuit shown in Fig. 7.88. The output of the circuit is V_L and the loop gain is V_L/V_X . The loop gain is found as

FIGURE 7.88 Finding the loop gain of the inverting amplifier shown in Fig. 7.87.

$$\frac{V_L}{V_X} = \text{loop gain} = \frac{-AR_1}{R_o + R_1 + R_2} \tag{7.118}$$

Thus

$$Z_o = \frac{R_{pas}}{1 - \text{loop gain}} \tag{7.119}$$

If $R_o = 75 \Omega$, $R_1 = 1 \text{ k}\Omega$, $R_2 = 10 \text{ k}\Omega$, $A_o = 200,000$, and $\omega_a = 20 \text{ rad/s}$, then substituting the expression for A from Eq. (7.108) into Eq. (7.117) and setting $s = 0$ yields the output resistance at DC as

$$Z_o|_{s=0} \approx 4.13 \text{ m}\Omega$$

This value is very near the ideal value of zero.

FIGURE 7.89 Plot of $|Z_o(j\omega)|$ of an inverting amplifier vs. ω on a log-log scale.

Z_O is a function of frequency. Again, substituting the expression for A from Eq. (7.108) into Eq. (7.117) and neglecting ω_a in comparison with $A_o\omega_a R_1/(R_o + R_1 + R_2)$, we obtain

$$Z_O \approx R_{pas} \left[\frac{s + \omega_a}{s + \frac{A_o\omega_a R_1}{R_o + R_1 + R_2}} \right]$$

We note that $Z_O(s)$ has one zero and one pole, that both the zero and the pole are located on the negative real axis of the s plane, and that the zero is closer to the origin than the pole for reasonable values of R_1 and R_2 . Thus $Z_O(s)$ is an RL driving point impedance. That is, the output impedance of the inverting amplifier is RL. Since Z_O is RL, $|Z_o(j\omega)|$ increases with frequency, and, although it has a low value of a few milliohms at DC, at high frequencies it eventually reaches the value of R_{pas} . Figure 7.89 shows a plot on a log-log scale of $|Z_o(j\omega)|$ vs. ω .

Next, we examine the input impedance of the noninverting amplifier shown as circuit 1 in Table 7.3. Ideally, this impedance should be infinite. Figure 7.90 shows the noninverting amplifier with the model shown in Fig. 7.86 substituted for the op-amp. The upper resistor $2R_{iCM}$ in Fig. 7.90 is ignored since it is parallel with R_1 and $R_1 \ll 2R_{iCM}$. The lower resistor $2R_{iCM}$ is temporarily removed because it is in parallel with the impedance of the remainder of the circuit. Let the impedance of the remainder of the circuit be denoted as Z' so that the input impedance of the noninverting amplifier is $Z_{IN} = (2R_{iCM}) \parallel Z'$. Figure 7.91 shows the circuit used to determine $Z' = V_i/I_i$. The results are

FIGURE 7.90 Noninverting amplifier with op-amp modeled by circuit of Fig. 7.86.

FIGURE 7.91 Circuit used to determine Z' .

$$Z' = R_1 \parallel R_2 + R_{id} \left\{ \frac{s + \omega_a + A_o\omega_a \frac{R_1}{(R_1 + R_2)}}{(sC_i R_{id} + 1)(s + \omega_a)} \right\} \tag{7.120}$$

FIGURE 7.92 Inverting amplifier with the op-amp modeled by the essential components in the model in Fig. 7.86.

If Eq. (7.120) is rewritten with a common denominator, it is noticed that the poles and zeros of the results are located on the negative real axis of the s plane, and the lowest critical frequency is a pole (at $s = -\omega_a$). But the poles and zeros may or may not be interlaced depending on the values chosen. Thus, Z' may be an RC or an RLC driving point impedance. Nevertheless, $|Z'|$ falls off more or less uniformly until it levels out at high frequency. At DC, Z' is given by

$$Z' |_{s=0} = R_1 \parallel R_2 + R_{id} \left(1 + \frac{A_o R_1}{R_1 + R_2} \right) \approx R_{id} \left(\frac{A_o R_1}{R_1 + R_2} \right) \tag{7.121}$$

If $A_o = 200,000$, $R_1 = 1 \text{ k}\Omega$, $R_2 = 10 \text{ k}\Omega$, and $R_{id} = 2 \text{ M}\Omega$, then $Z' = 3.6 \times 10^{10} \Omega$ for $s = 0$. Thus, $Z_{IN} = 2R_{iCM}$ at DC. Although Z_{IN} is about $200 \text{ M}\Omega$ at low frequencies, its magnitude decreases with increasing frequency toward a value of $R_1 \parallel R_2$.

The model in Fig. 7.86 can explain an instability that sometimes occurs when an op-amp amplifier drives a capacitive load. Figure 7.92 shows the inverting amplifier with the op-amp replaced by the essential components of the model in Fig. 7.86. For convenience, the resistors of the circuit have been replaced by their corresponding conductances. Thus, $G_1 = 1/R_1$, $G_o = 1/R_o$, etc. We have neglected the resistors ($2R_{iCM}$) as well as R_{id} because they are large. However, we have included C_i . C_L at the output of the circuit represents a capacitive load. The transfer function of the circuit is given by

$$\frac{V_o}{V_i} = \frac{-G_1(G_o - s\tau G_2)}{s^3\tau C_i C_L + s^2\tau(C_L(G_1 + G_2) + C_i(G_o + G_2)) + s\tau(G_o(G_1 + G_2) + G_1 G_2) + G_o G_2} \tag{7.122}$$

where $\tau = 1/GB$. We have employed the simplified expression for A given in Eq. (7.109) for this analysis. Note that if $\tau = 0$, then Eq. (7.122) reduces to

$$\frac{V_o}{V_i} = -\frac{G_1}{G_2} = -\frac{R_2}{R_1}$$

as we would expect for an ideal op-amp.

The characteristic polynomial of the amplifier, given by the denominator of Eq. (7.122), is third order, and it is not difficult to find a set of values of the components and parameters of the amplifier that causes two roots of the denominator to be in the right-half s plane. That is, sets of reasonable component and parameter values can be found that make the circuit unstable. The instability in this circuit arises from a combination of nonzero τ and nonzero C_i , R_o , and C_L . We have already shown that when $\tau = 0$, the transfer function reduces to a constant, which has no poles. Setting the other components to zero one at a time reduces the characteristic polynomial to one of second order in which all of the coefficients are positive. For example, if $R_o = 0$ ($G_o = \text{infinity}$), then the transfer function reduces to

$$\frac{V_o}{V_i} = \frac{-G_1}{s^2\tau C_i + s\tau(G_1 + G_2) + G_2}$$

A second-order polynomial (unlike some third- and higher-order polynomials) in which all of the coefficients are positive has its roots located in the open left-half s plane, and so an analysis without R_o would indicate erroneously that the amplifier is always stable.

If a load is capacitive, how can it be driven without risking amplifier instability? Figure 7.93 shows a commonly used solution to this problem (Franco, 1988). The inverting amplifier has been modified in two ways. First, a resistor R , which is approximately the same value as R_o , is connected to the output of the op-amp, and, second, a small capacitor C_c is connected around the op-amp as shown. The value of this capacitor is determined by $C_c = (R_1/R_2)C_i$.

FIGURE 7.93 Driving a capacitive load with a modified inverting amplifier.

Common-Mode Rejection Ratio

Common-mode rejection ratio (CMRR) and its companion, common-mode gain, are concepts developed for difference amplifiers. They are important in the design of amplifiers for sensors and transducers since, in many such applications, it is necessary to determine the difference of two voltages. Consider the generic difference amplifier represented in Fig. 7.94. This amplifier consists of one or more op-amps and associated external resistors. Circuit number three in Table 7.3 is an example of a difference amplifier that uses one op-amp and four external resistors.

FIGURE 7.94 Generic difference amplifier with arbitrary excitations V_1 and V_2 .

The input voltages V_1 and V_2 are assumed to be of reasonable amplitude and frequency, but otherwise they are arbitrary. These arbitrary signals can be expressed in terms of common-mode and difference-mode excitations. The arithmetic average of the two excitations is the common-mode voltage. That is

$$V_{CM} = \frac{V_1 + V_2}{2} \tag{7.123}$$

The difference of the two arbitrary excitations is the difference-mode voltage V_D . That is

$$V_D = V_1 - V_2 \tag{7.124}$$

Thus, the excitations in Fig. 7.94 can be written as

$$V_1 = \frac{V_D}{2} + V_{CM} \quad V_2 = -\frac{V_D}{2} + V_{CM} \tag{7.125}$$

and Fig. 7.94 can be redrawn as shown in Fig. 7.95. If $V_D = 0$, the output voltage of the difference amplifier V_O should be zero. But due to the amplifier's common-mode gain G_{CM} , there is an output voltage that depends on V_{CM} . Ideally, G_{CM} should be zero, but mismatches among the external components as well as the common-mode gain of the op-amps contribute to nonzero G_{CM} .

Let the voltage gain from port X (terminal X to ground in Fig. 7.95) to the output port be $-G_X$, and let the gain from port Y to the output port be

FIGURE 7.95 Difference amplifier with excitations expressed as difference-mode and common-mode voltages.

G_Y . Then we can express V_O as

$$V_O = -V_D \left(\frac{G_X + G_Y}{2} \right) + V_{CM}(G_Y - G_X) \tag{7.126}$$

Nonzero common-mode gain is caused by the two gains being unequal. If $G_X = G_Y = G$, then $V_O = -G V_D$, and there is no common-mode contribution to the output voltage. The term $(G_Y - G_X) = G_{CM}$, and $(G_X + G_Y)/2$ is the **difference-mode gain** of the amplifier. The ratio of the difference-mode gain to the common-mode gain is the common-mode rejection ratio. Thus, CMRR can be expressed as

$$CMRR = \frac{G_X + G_Y}{2(G_Y - G_X)}$$

and ideally, this ratio should be infinity. CMRR is a useful parameter because it permits us to rewrite Eq. (7.126) in the form

$$V_O = \frac{G_X + G_Y}{2} \left(-V_D + \frac{V_{CM}}{CMRR} \right)$$

which emphasizes the error caused by V_{CM} and noninfinite CMRR.

An op-amp is also a difference amplifier although the box representing a difference amplifier in Fig. 7.94 cannot be replaced directly by an op-amp because there would be no negative feedback around the op-amp. Thus, the op-amp would not operate properly. Figure 7.96 shows a specific difference amplifier based on a single op-amp. We assume the resistors R_1, R_2, R_a , and R_b are identical. Thus, error in the output voltage is caused by the op-amp alone. For the purpose of developing a *general* model that accounts for the op-amp's common-mode gain, we assume the op-amp has no imperfections except for common-mode gain and noninfinite open-loop gain. The voltages at the inverting and noninverting input leads of the op-amp are labeled V_n and V_p , respectively. Let the gain of the op-amp from the inverting input port to the output port be A_1 , and let A_2 be the gain from the noninverting input port to the output port. The op-amp exhibits nonzero common-mode gain because the magnitudes of A_1 and A_2 are not exactly equal, the phase of A_1 is not exactly π , and the phase of A_2 is not zero.

FIGURE 7.96 A specific difference amplifier.

The output voltage of the op-amp can be expressed as

$$V_O = V_n A_1 + V_p A_2 \tag{7.127}$$

If $A_1 = -A_2 = -A$, then $V_O = (V_p - V_n)A = V_a A$. That is, the results correspond to the op-amp model shown in Fig. 7.76.

The common-mode voltage applied to the op-amp in Fig. 7.96 is

$$V_{CM} = \frac{V_n + V_p}{2} \tag{7.128}$$

and the difference-mode voltage is $V_D = V_p - V_n$. Then Eq. (7.127) can be rewritten as

$$V_O = V_D \left(\frac{A_2 - A_1}{2} \right) + V_{CM}(A_1 + A_2) \tag{7.129}$$

The difference-mode gain is

$$A_D = \frac{V_O}{V_D} \Big|_{V_{CM}=0} = \frac{A_2 - A_1}{2} \tag{7.130}$$

and the common-mode gain is

$$A_c = \frac{V_O}{V_{CM}} \Big|_{V_D=0} = A_1 + A_2 \tag{7.131}$$

Common-mode rejection ratio for the op-amp is given by

$$\text{CMRR} = \frac{A_D(s)}{A_c(s)} \tag{7.132}$$

Often, CMRR is expressed in decibels as

$$\text{CMRR}_{\text{dB}} = 20 \log \left| \frac{A_D(j\omega)}{A_c(j\omega)} \right| \tag{7.133}$$

CMRR for an op-amp is a function of frequency, and its magnitude decreases as frequency increases. The value of CMRR given in an op-amp specification sheet is usually the low-frequency (large) value, although a plot of the magnitude of CMRR vs. frequency is sometimes provided. CMRR for a $\mu A741$ is listed as typically 90 dB.

Rewriting Eq. (7.129) using CMRR, we obtain

$$V_O = A_D \left(V_p - V_n + \frac{V_n + V_p}{2} \frac{1}{\text{CMRR}} \right) \tag{7.134}$$

The development of the expression for V_O for the op-amp has paralleled the derivation of V_O for the entire difference amplifier in Fig. 7.94. However, by means of the negative feedback around the op-amp, the voltages V_n and V_p are nearly equal. Thus, we approximate $(V_n + V_p)/2$ as V_p . We also approximate A_D as the open-loop gain $A(s)$ given in Eq. (7.107). With these approximations, Eq. (7.134) becomes

$$V_O \approx A \left[V_p \left(1 + \frac{1}{\text{CMRR}} \right) - V_n \right] \tag{7.135}$$

Equation (7.135) indicates that to account for noninfinite CMRR, we increase the input signal at the noninverting input lead of the op-amp by V_p/CMRR as shown in Fig. 7.97.

As an example of the application of this model, we analyze the difference amplifier in Fig. 7.96 with $V_1 = 5.000$ and $V_2 = 5.002$ V DC. Let us assume the resistors are equal and find V_O for infinite CMRR and for $\text{CMRR} = 1000$. Let us also assume $A(s)$ is infinite and that op-amp offsets are zero. For infinite

FIGURE 7.97 Model for op-amp which accounts for noninfinite CMRR.

CMRR, we immediately have

$$V_O = V_1 \left(-\frac{R_2}{R_1} \right) + V_2 \frac{R_b}{R_a + R_b} \left(1 + \frac{R_2}{R_1} \right)$$

If the resistors are equal, $V_O = 2$ mV, and the difference amplifier is able to discern a 2-mV difference in the two input signals. However, if $\text{CMRR} = 1000$, using Fig. 7.97 and Eq. (7.135), we have

$$V_O = -5.000 + \frac{5.002}{2} \left(1 \pm \frac{1}{\text{CMRR}} \right) 2 = (2 \pm 5) \text{ mV DC} \quad (7.136)$$

Thus, the desired output voltage is obscured by the error introduced by the low CMRR of the op-amp. Note that the sign of the CMRR term in Eq. (7.136) is not really known, and so a \pm is used.

Suppose the input voltages to the difference amplifier in Fig. 7.96 are 100 and 102 mV DC. Again, we take CMRR to be 1000. In this case, we have $V_O = (2 \pm 0.1)$ mV DC. Thus, the output voltage is very nearly the desired value with only $\pm 5\%$ error. The reason for this improvement is that the common-mode excitation has been reduced from about 5 V to 100 mV.

There is one other consideration that must be kept in mind when contending with common-mode gain. That is, the specification sheets for most op-amps specify a *range* of V_{CM} over which the published CMRR specifications apply. For a $\mu\text{A}741$, this range is ± 12 V when the op-amp is powered by ± 15 -V power supplies. If the input voltage is outside this range, the CMRR specification does not apply.

Noise

An op-amp generates noise currents and voltages, and the resulting noise at the output of an op-amp amplifier degrades and may entirely obscure a useful output signal. In this section, we briefly review some noise concepts and provide a noise model for the op-amp.

Noise is a random phenomenon; its instantaneous value cannot be known. Thus, statistical concepts are employed to determine the effects of noise on a circuit. If $e_n(t)$ is a noise voltage, then its root-mean-square (rms) value E_n is given by

$$E_n = \left[\frac{1}{T} \int_0^T e_n^2(t) dt \right]^{\frac{1}{2}} \quad (7.137)$$

where T is a specified time interval over which the average of $e_n^2(t)$ is taken. E_n^2 , denoted as the mean square value of the noise, represents the average power a $1\text{-}\Omega$ resistor dissipates when $e_n(t)$ is applied across it. If E_n is known and if its amplitude distribution is Gaussian, then it is common engineering practice to calculate the peak-to-peak value of noise as $6E_n$. That is, the **crest factor** of Gaussian noise is considered to be 3 where crest factor is defined as the ratio of the peak value of the noise to its rms value.

If we have two noise sources $e_{n1}(t)$ and $e_{n2}(t)$, to determine the rms value of the sum, we have

$$\begin{aligned} E_n &= \left[\frac{1}{T} \int_0^T [e_{n1}(t) + e_{n2}(t)]^2 dt \right]^{\frac{1}{2}} \\ &= \left[E_{n1}^2 + E_{n2}^2 + \frac{2}{T} \int_0^T [e_{n1}(t)e_{n2}(t)] dt \right]^{\frac{1}{2}} \end{aligned} \quad (7.138)$$

The average of the product of two uncorrelated noise sources is zero. Thus, if $e_{n1}(t)$ and $e_{n2}(t)$ are uncorrelated, then

$$E_n = (E_{n1}^2 + E_{n2}^2)^{\frac{1}{2}} \quad (7.139)$$

Since noise power E_n^2 is spread over all parts of the spectrum, we must specify the frequency band over which we are performing measurements or making calculations. In general, the noise power depends on the width of the frequency band specified and on the location of the band within the frequency spectrum. A useful concept here is **noise power density**, which is the rate of change of noise power with frequency. It is denoted as $e_n^2(f)$, its units are volts squared per hertz, and it is defined as

$$e_n^2(f) = \frac{dE_n^2}{df} \tag{7.140}$$

Noise power density represents the average noise power over a 1-Hz bandwidth as a function of frequency. A companion quantity is *noise spectral density* denoted by $e_n(f)$ with units given by volts/ $\sqrt{\text{hertz}}$.

If the noise power density is known over a specified frequency band, then the rms value of the noise can be obtained by integrating Eq. (7.140). Thus

$$E_n = \left[\int_{f_L}^{f_U} e_n^2(f) df \right]^{\frac{1}{2}} \tag{7.141}$$

where f_L and f_U are the lower and upper limits of the frequency band, respectively.

Two common varieties of noise power densities are white noise and $1/f$ noise. The spectral density of white noise is a constant e_{nW} , and its rms value, from Eq. (7.141), is

$$E_n = e_{nW} \sqrt{f_U - f_L} \tag{7.142}$$

From Eq. (7.142) we see that the power of white noise, E_n^2 , is proportional to the bandwidth no matter where this bandwidth is located in the frequency spectrum.

The noise power density of $1/f$ noise has the form $e_n^2(f) = K_v^2/f$ where K_v is a constant representing the extrapolated value of the noise spectral density at $f = 1$ Hz. The spectral density of $1/f$ noise is K_v/\sqrt{f} indicating that on a log-log plot the spectral density has a slope of -0.5 decades/decade. The rms value of $1/f$ noise, obtained from Eq. (7.141), is

$$E_n = K_v \left[\ln \frac{f_U}{f_L} \right]^{\frac{1}{2}} \tag{7.143}$$

and the power of $1/f$ noise is given by

$$E_n^2 = K_v^2 \ln \left(\frac{f_U}{f_L} \right) \tag{7.144}$$

which indicates that the power is proportional to the log ratio of the band-edge frequencies independent of the band's placement in the frequency spectrum.

The noise sources in the noise model for an op-amp are composed of a mixture of white and $1/f$ noise as shown for a voltage noise source in Fig. 7.98. At low frequencies, $1/f$ noise dominates, and at high frequencies, white noise dominates. The boundary is called the *corner frequency* and is denoted as f_{cv} in Fig. 7.98. A similar plot applies to the noise spectral density of current noise sources in the op-amp model. The corner frequency for a noise current source is denoted as f_{ci} .

The power density of the noise represented in Fig. 7.98 can be expressed analytically as

$$e_n^2 = e_{nW}^2 \left(\frac{f_{cv}}{f} + 1 \right) \tag{7.145}$$

FIGURE 7.98 Spectral noise density plot of noise consisting of a mixture of white and $1/f$ noise.

and the rms value corresponding to Eq. (7.145), from Eq. (7.141), is

$$E_n = e_{nW} \left[f_{cv} \ell_n \frac{f_U}{f_L} + f_U - f_L \right]^{\frac{1}{2}} \tag{7.146}$$

The corresponding rms value for a noise current source is

$$I_n = i_{nW} \left[f_{ci} \ell_n \frac{f_U}{f_L} + f_U - f_L \right]^{\frac{1}{2}}$$

For a $\mu A741$ op-amp, $e_{nW} \approx 20 \text{ nV}/\sqrt{\text{Hz}}$, $f_{cv} \approx 200 \text{ Hz}$, $i_{nW} \approx 0.5 \text{ pA}/\sqrt{\text{Hz}}$, and $f_{ci} \approx 2 \text{ kHz}$. As another point of comparison, a low-noise op-amp such as an OP-27F has typical noise specifications given by $e_{nW} = 3.0 \text{ nV}/\sqrt{\text{Hz}}$ and $i_{nW} = 0.5 \text{ pA}/\sqrt{\text{Hz}}$ with corner frequencies $f_{cv} = 2.7 \text{ Hz}$ and $f_{ci} = 140 \text{ Hz}$.

Figure 7.99 shows the op-amp noise model. A noisy op-amp is modeled by three noise generators and a noiseless op-amp. Polarities and reference directions are not shown since noise generators do not have true polarity or reference direction assignments. The spectral densities of the current sources are listed as i_{nn} and i_{np} in the model in order to keep track of the effects of these generators. Op-amp data sheets list information for or provide graphs for a single current spectral density i_n . At the end of our analysis, we set $i_{nn} = i_{np} = i_n$ and consider the sources to be uncorrelated.

FIGURE 7.99 Noise model for an op-amp consisting of two current noise generators, a voltage noise generator, and a noiseless op-amp.

To analyze an op-amp circuit with resistive feedback, we also need noise models for resistors. Two models for a noisy resistor are shown in Fig. 7.100. The thermal noise (Johnson noise) of the resistor is modeled by a voltage noise source with spectral density e_R as shown in Fig. 7.100(b). The power density of this source is $e_R^2 = 4kTR \text{ V}^2/\text{Hz}$ where R is in ohms, k is Boltzmann’s constant $= 1.38 \times 10^{-23} \text{ J/K}$, and T is temperature in degrees Kelvin. Thus, thermal noise is white. At 25°C , the noise spectral density is approximately $e_R \approx 4\sqrt{R} \text{ nV}/\sqrt{\text{Hz}}$ where R is expressed in kilohms. Figure 7.100(c) shows an equivalent resistor noise model that includes a current noise source having power density $i_R^2 = 4kT/R \text{ A}^2/\text{Hz}$.

As an example of the application of the op-amp noise model we find the noise power output of the circuit shown in Fig. 7.101. The steps followed to perform this analysis are

- Substitute noise models for the op-amp and resistors. This step yields six noise sources for this circuit.
- Reduce the number of sources where possible by combining power densities.
- If the circuit is linear and the noise sources are uncorrelated, then superposition can be used. Thus, the contribution to the output power density is found by multiplying each source power density

FIGURE 7.100 (a) The noisy resistor R is modeled by (b) a voltage noise source in series with a noiseless resistor or by (c) a current noise source in parallel with a noise-free resistor.

FIGURE 7.101 Example circuit for noise calculations.

by the magnitude squared of the transfer function from that source to the output. The total output voltage noise power density is obtained by adding all the contributions together.

- The rms value of the output noise can be found by integrating over a specified bandwidth and taking the square root of the result.

We assume the op-amp is ideal except for its noise sources. Figure 7.102 shows the results obtained after the second step. Then using superposition, we have

$$e_{nO}^2 = (e_n^2 + i_{np}^2 + i_3^2 R_3^2) \left(1 + \frac{R_2}{R_1}\right)^2 + (i_1^2 + i_{nn}^2) R_1^2 \left(\frac{R_2}{R_1}\right)^2 + i_2^2 R_2^2 (1)^2 \tag{7.147}$$

where $i_j^2 = 4kT/R_j$, $j = 1, 2, 3$. Note that the transfer function from the generator associated with R_2 to the output is 1. Rewriting Eq. (7.147) with $i_{nn} = i_{np} = i_n$, we have

$$e_{nO}^2 = \left(1 + \frac{R_2}{R_1}\right)^2 \left\{ e_n^2 + i_n^2 [R_3^2 + (R_1 \parallel R_2)^2] \right. \\ \left. + 4kT [R_3 + (R_1 \parallel R_2)] \right\} \tag{7.148}$$

Equation (7.148) has the form

$$e_{nO}^2 = |A_n|^2 e_{ni}^2 \tag{7.149}$$

where A_n is the noise gain of the circuit and e_{ni} is the equivalent input noise spectral density. This result can be represented by the schematic shown in Fig. 7.103 in which the op-amp and the resistors are noiseless.

Using Eq. (7.145) for e_n^2 (and a corresponding expression for i_n^2), we can integrate e_{nO}^2 as in Eq. (7.141) to obtain the rms value of the output noise. An estimate of the peak-to-peak output noise is found by multiplying the results of Eq. (7.141) by 6.

Purely reactive elements do not generate noise, but they affect frequency characteristics of the noise gain of the circuit as does the open-loop gain of the op-amp. These topics are beyond the scope of the brief review of noise concepts given here, but the interested reader is referred to Franco (1988) for a more complete discussion and some useful examples.

This completes the discussion of op-amp limitations. Not every op-amp departure from the ideal has been discussed, but the ones presented here are

FIGURE 7.102 Results after the second step: combining noise sources.

FIGURE 7.103 Equivalent representation for circuit shown in Fig. 7.102.

important in many applications. There is ample literature on op-amps, and the reader is urged to consult the listings in Further Information following Section 7.8.

Types and Values of Elements

In this section we discuss briefly the ranges of values and types of passive components that are normally used in discrete design. As a rule of thumb, resistors most often employed in op-amp circuits range between a few hundred ohms to several hundred kilohms. Resistors of value below a few hundred ohms may be too much of a load, and most op-amps are low-power devices whose parameters degrade as they are required to supply more current to load and feedback circuits. At the high end of the range, resistors larger in value than several hundred kilohms generate more noise and allow stray pickup signals to couple into the circuit more easily. This rule of thumb is probably broken as often as it is observed, but it serves notice that a circuit requiring resistors outside the range indicated should be examined carefully.

Carbon composition, carbon film, metal oxide film, and metal film resistors are the usual resistors employed at the design and prototyping stage. Wire-wound resistors should be avoided because of their inductive traits which can affect the frequency characteristics of circuits even at low frequencies. Resistors used in finished products must be flame retardant.

Mica and plastic film (polycarbonate, polyester, or polystyrene) are most often the types of capacitors used to determine the frequency characteristics or timing behavior of discrete op-amp circuits. Ceramic disc or electrolytic capacitors should generally not be used in these applications. Ceramic disc capacitors are sensitive to temperature and humidity, and electrolytic capacitors are sensitive to temperature and conduct small amounts of DC current. However, ceramic disc and electrolytic capacitors are used for power supply bypassing duties.

Values of capacitors used in discrete design range from tens of picofarads to a few microfarads. Capacitor values should not be so small that parasitic capacitances, which may range up to 10 pF or more, will have an appreciable effect.

Plastic film capacitors for electronic applications can be obtained with values up to about 10 μF , but these capacitors are bulky and expensive, and the use of capacitors this large in value should be avoided if possible. Film capacitors that range in value from nanofarads to microfarads perform nicely in most op-amp circuits.

Acknowledgments

The author wishes to express his gratitude to Dr. Jacek Zurada, Mr. Zbigniew J. Lata, Mr. Damon Miller, Mr. A. Wisen, Mr. Peichu (Peter) Sheng, and Mr. KeChang Wang for their help and encouragement.

Defining Terms

Bias Current (I_B): The arithmetic average of the currents that flow in the input leads of an op-amp.

Closed loop gain-bandwidth product: The product of the magnitude of low-frequency gain and the 3.01 dB bandwidth of an op-amp amplifier.

Common-mode gain: The gain given to a common-mode input signal by a difference amplifier. Ideally, this gain should be zero.

Common-mode rejection ratio: The ratio of the difference-mode gain to the common-mode gain. Ideally, this ratio should be infinite. This quantity is often expressed in decibels.

Common-mode signal: If two arbitrary signals v_1 and v_2 are applied to the inputs of a difference amplifier, then the common-mode signal is the arithmetic average of the two signals. That is, the common-mode signal is $(v_1 + v_2)/2$.

Crest factor: The ratio of the peak value of a signal to its rms value.

Difference-mode gain: The gain given to a difference-mode input signal by a difference amplifier.

Difference-mode signal: If two arbitrary signals v_1 and v_2 are applied to the inputs of a difference amplifier, then the difference-mode signal is the difference of the two signals.

Driving point function: The ratio of the transform of the time-domain response of a linear network to the transform of the excitation causing the response. Both the excitation and the response are at the same

port of the network. In determining a driving point function, all independent sources associated with the network are set to zero except the excitation. Dependent sources remain operating.

Dynamic range: The dynamic range of a filter is the ratio of the largest undistorted output signal amplitude and the noise floor.

Full power bandwidth: The frequency at which a sinusoidal signal having large amplitude begins to become distorted at the output of an op-amp due to the slew rate limitation. Full power bandwidth, ω_{FB} in rad/s, is related to SR by $\omega_{FB} = SR/V_{Omax}$, where V_{Omax} is the peak value of output voltage.

Gain-bandwidth product (GB): The product of the magnitude of op-amp gain at DC and its open loop bandwidth.

Input offset current (I_{OS}): The difference between the currents that flow in the input leads of an op-amp. Usually only the magnitude of this difference is known.

Input offset voltage (V_{OS}): The small DC voltage that must be applied at the input of a noninverting amplifier to drive the output voltage to zero with no load on the output. It is assumed that the feedback resistors are chosen so that no appreciable current is drawn from the output, and currents flowing in the input leads of the op-amp cause insignificant voltages.

Loop gain: If a feedback network is cut and a signal is applied at one side of the cut so as to maintain impedance levels, then the loop gain is the gain experienced by that signal as it traverses the circuit to the other side of the cut.

Noise power density: The rate of change of noise power with frequency. The units are volt squared per hertz or ampere squared per hertz.

Norator: An idealized two-terminal network element for which the voltage across it and the current through it are determined by the network to which it is connected.

Nullator: An idealized two-terminal network element that conducts no current and yet maintains zero volts across itself. This element is often used to represent a virtual connection.

One-pole model: An approximation for the open-loop gain of an op-amp. This approximation represents the frequency behavior of most general purpose op-amps fairly well and has only one pole.

Op-amp time constant (τ): The reciprocal of the gain-bandwidth product of the op-amp.

Open-loop gain [$A(s)$]: In the context of this chapter, this term refers to the gain of the op-amp itself without a feedback network.

Port: Two terminals of a network that are considered to be associated.

Rise time (t_r): The time required for the response of a network to go from 10% to 90% of its final value when the network is excited by a step.

Slew rate (SR): A nonlinear phenomenon in which the rate of change of output voltage in response to a large-amplitude step of input voltage is internally limited.

Small signal: A level of signal applied to an amplifier or filter so that the circuit retains linear behavior.

Virtual connection: A representation of the circuit between the input leads of an ideal op-amp. The voltage across and the current through a virtual connection are both zero. If one input lead of an ideal op-amp is connected to ground, the virtual connection is often termed a virtual ground.

7.8 Applications of Operational Amplifiers

Peter Aronhime

7.8.1 Instrumentation Amplifiers

Instrumentation amplifiers are, generally, high-performance differential input voltage amplifiers that have high-gain accuracy, high-input resistance, low-output resistance, high common-mode rejection ratio (CMRR), low noise, and low offsets with low offset drift with temperature. Differential input current instrumentation amplifiers have low-input resistance and high-output resistance. Most applications of instrumentation amplifiers are based on amplifying the signal of a transducer to an amplitude that can be accurately converted to a digital signal without introducing significant errors. Thus, instrumentation amplifiers are used with strain gauge bridges, with thermocouples and other types of thermosensors, and with precision semiconductor gas sensors. In some applications such as medical instrumentation, an instrumentation amplifier may be required to operate with high common-mode signals. Gains of instrumentation amplifiers are often preset by internal, precision trimmed resistors.

Circuit three in Table 7.3 (see Section 7.7) is a simple example of an instrumentation amplifier that utilizes four resistors and a single op-amp. It has many drawbacks, not the least of which is that the input currents are generally different and depend on the input voltages. This defect could be remedied by using gain-of-one buffers (circuit two in Table 7.3) between the signals and the input leads of the difference amplifier, but this modification would require two more op-amps to fix one problem. Figure 7.104 shows a difference amplifier that employs two op-amps and four resistors (Wojslaw and Moustakas, 1986). The input resistances are, ideally, infinite. The output voltage of the circuit is given by

$$v_O = \left(1 + \frac{R_4}{R_3}\right) \left[v_2 - v_1 \left(1 + \frac{R_2}{R_1}\right) \left(\frac{R_4}{R_3 + R_4}\right) \right]$$

(See Section 7.7 for definitions of parameters.) If we impose the requirement that $R_2/R_1 = R_3/R_4$, then the output voltage of the amplifier can be expressed as

$$v_O = \left(1 + \frac{R_1}{R_2}\right) (v_2 - v_1)$$

For a gain of 101, typical values for resistors are $R_1 = R_4 = 100 \text{ k}\Omega$ and $R_2 = R_3 = 1 \text{ k}\Omega$.

The most common three-op-amp configuration is shown in Fig. 7.105. The CMRR of this instrumentation amplifier can be quite large, over 110 dB. Minus and plus signs in parentheses at the inputs denote inverting and noninverting inputs of the amplifier. Op-amps (1) and (2) are best matched, and a Linear Technology LT1002 can be used for this application. To analyze the circuit, we let $R_{2A} + R_{2B} = R_2$, and

FIGURE 7.104 Difference amplifier which ideally draws no current from the input signal sources.

FIGURE 7.105 Instrumentation amplifier with high CMRR.

$R_{7A} + R_{7B} = R_7$, and ignore C and R_8 . Also, we assume the op-amps are ideal. Using superposition and making liberal use of the virtual connections between the input leads of op-amps (1) and (2), we obtain

$$v_{o1} = v_{i1} \left(1 + \frac{R_1}{R_2} \right) + v_{i2} \left(-\frac{R_1}{R_2} \right) \tag{7.150}$$

and

$$v_{o2} = v_{i1} \left(-\frac{R_3}{R_2} \right) + v_{i2} \left(1 + \frac{R_3}{R_2} \right) \tag{7.151}$$

Op-amp (3) and its associated resistors R_5 – R_7 are recognized as the simple difference amplifier from Table 7.3 (see Section 7.7). Here, it forms the difference between v_{o1} and v_{o2} . The result is

$$v_O = v_{o1} \left(-\frac{R_6}{R_4} \right) + v_{o2} \left(\frac{R_7}{R_5 + R_7} \right) \left(1 + \frac{R_6}{R_4} \right) \tag{7.152}$$

Normally, $R_4 = R_5$ and $R_6 = R_7$ so that we have

$$\begin{aligned} v_O &= (v_{o2} - v_{o1}) \frac{R_6}{R_4} \\ &= (v_{i2} - v_{i1}) \left(1 + \frac{R_1 + R_3}{R_2} \right) \frac{R_6}{R_4} \end{aligned} \tag{7.153}$$

Typical values of the components used for this circuit are shown in Fig. 7.105. With these values, the differential voltage gain of the circuit is about 1000. To adjust the circuit, a low-frequency signal (with low-common-mode voltage) is applied to the inputs, and R_{2B} is tuned to obtain a gain of 1000. Then the inputs of the amplifier are tied together, and a DC common-mode voltage is applied. R_{7B} is adjusted so that the output voltage is minimized. Finally, an AC common-mode voltage is applied having a frequency of 10–20 kHz or a frequency that is pertinent to a particular application, and R_8 is adjusted to minimize the AC output voltage.

As an example of the application of an instrumentation amplifier we consider the bridge circuit shown in Fig. 7.106(a), which is formed by two 350-Ω strain gauges and two other 350-Ω precision resistors, each

FIGURE 7.106 (a) Bridge circuit with instrumentation amplifier, (b) location of strain gauges on a bar which is subjected to uniaxial force F in the direction shown.

labeled R . A $2\text{-}\Omega$ potentiometer R_a is included in the bridge between the gauges with the wiper connected to the noninverting input of the amplifier. One gauge is a dummy gauge, which is included to compensate for environmental factors such as temperature. It is mounted as shown in Fig. 7.106(b) so that it is not subjected to strain. The other strain gauge is termed the active gauge. An excitation v_i , which may be DC or AC, is applied, and the bridge is balanced using R_a with no force applied to the bar.

A uniaxial force is then applied to the bar. The output voltage of the bridge v_{OB} is amplified by an instrumentation amplifier with gain $G = 1000$. What is the strain measured in the bar if v_O of the amplifier equals v_i and the **gauge factor (GF)** of the strain gauge is 2.05? The resistance of the active gauge increases to $R + \Delta R$ when force is applied to the bar. We assume that R_a is zero and obtain

$$v_{OB} = v_i \left(\frac{R + \Delta R}{2R + \Delta R} - \frac{1}{2} \right) = v_i \left(\frac{\frac{\Delta R}{R}}{4 + 2 \left(\frac{\Delta R}{R} \right)} \right)$$

For $\Delta R \ll 2R$,

$$v_{OB} \approx \frac{v_i}{4} \frac{\Delta R}{R}$$

Thus, $\Delta R/R = 0.004$. The gauge factor is defined as

$$GF = \frac{\frac{\Delta R}{R}}{\frac{\Delta L}{L}} \tag{7.154}$$

where L is the active length of the gauge, and $\Delta L/L$ is the strain ϵ . Since GF for these strain gauges is 2.05, we have $\epsilon = 0.002$ in/in.

In this application, the instrument amplifier is required to have high-common-mode rejection ratio because the common-mode voltage at its input is $v_i/2$. If the bridge excitation is DC, low-offset voltage is required because v_{OB} is about 1 mV. The large gain of the amplifier is an aid in initially balancing the bridge by adjusting R_a .

7.8.2 Active Filter Circuits

A primary incentive for the development of active filters is the elimination of inductors that are required if a filter is to be realized only with passive elements. Especially for low frequencies, the inductors required for filter realizations are large, heavy, expensive, and not standardized. Other advantages of active filters are that they are versatile, easily constructed, easily tuned, and inexpensive. Over the years several approaches to the design of active filters have been developed. Each approach has its advantages and disadvantages, and these will become evident for the design approaches presented in this section. The common theme for the

FIGURE 7.107 Passive circuit realizations of the transfer function given in Eq. (7.155): (a) double terminated circuit employing two inductors and three capacitors, (b) circuit formed by replacing the voltage source by a short circuit, forming the dual, and then reinserting the voltage source.

filters discussed in this section is that they are continuous time as opposed to digital or switched-capacitor filters. Continuous-time filters are often referred to as analog filters.

The **transfer function** $T(s)$ of a fifth-order low-pass Butterworth filter with (3.01-dB) cutoff frequency $\omega_c = 1 \text{ rad/s}$ is

$$T(s) = \frac{1}{s^5 + 3.2361s^4 + 5.2361s^3 + 5.2361s^2 + 3.2361s + 1} \tag{7.155}$$

If the denominator of Eq. (7.155) is factored, we have

$$T(s) = \frac{1}{(s + 1)(s^2 + 0.618s + 1)(s^2 + 1.618s + 1)} \tag{7.156}$$

Figure 7.107 shows double-terminated LC ladder realizations of $T(s)$. One circuit can be obtained from the other by replacing the voltage excitation by a short circuit, forming the dual, and then inserting the voltage source using the pliers technique.

Cascade Design

The cascade design procedure begins with a transfer function in factored form such as is shown in Eq. (7.156) and realizes the transfer function as a product of second-order transfer functions and, if the order is odd, a first-order transfer function. These constituent transfer functions are termed *sections*. For the transfer function in Eq. (7.156), we have three sections so that $T = T_1 T_2 T_3$ where $T_1 = 1/(s + 1)$, and T_2 and T_3 have the form $1/(s^2 + s(\omega_0/Q) + \omega_0^2) = 1/((s + \alpha)^2 + \beta^2)$. In the expressions for T_2 and T_3 , ω_0 and Q are used to describe the locations of the poles in a polar manner, and α and β describe pole locations in a rectangular manner. The quantity ω_0 is termed the *undamped natural frequency* and is the radius of the circle centered at the origin of the s -plane on which the pair of complex poles lie. To have poles that are complex and in the open left-half s -plane, $1/2 < Q < \infty$. A circuit representation of the product of transfer functions is shown in Fig. 7.108; the individual blocks representing T_j , $j = 1, 2, 3$, are said to be connected in cascade. It is assumed that there is no loading between the blocks in the figure. From a purely mathematical point of view, the order of the blocks in the figure does not make a difference. But from a practical view, the order of placement may be important. If the input signal to the filter is of sufficient amplitude, then, usually, the sections are cascaded in the order of increasing Q in order to prevent clipping in the high Q stages. However, if the input signal is small, a higher Q stage may be placed at the beginning of the cascade in order to amplify the signal over some portion of its frequency range.

FIGURE 7.108 Cascade connection of circuits realizing transfer function T_j , $j = 1, 2, 3$. The overall transfer function of the circuit is $T = \Pi T_j$. It is assumed there is no loading between the blocks shown.

The issues in the cascade design of an active filter, once a desired overall transfer function has been determined, are the selection of appropriate circuits to realize each section, especially the second-order sections, and the determination of the values for the resistors and capacitors for each section. Factors that influence the selection of active **filter sections** are the sensitivity of the section to the gain-bandwidth

product (GB) of the op-amp(s), the sensitivities to changes in values of the passive elements of the section, and the number of components required. In the following, we provide a representative listing and design information for active filter second-order sections.

Figure 7.109 shows a low-pass Rauch section (Nichols and Rauch, 1956). Its transfer function, assuming the op-amp is ideal, is given by

$$\frac{V_O}{V_i}(s) = \frac{-\left(\frac{1}{C_1 C_2 R_2 R_3}\right)}{s^2 + s \frac{1}{C_1} \left[\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} \right] + \frac{1}{C_1 C_2 R_1 R_2}} \tag{7.157}$$

For the Rauch section

$$\omega_0 = \frac{1}{\sqrt{C_1 C_2 R_1 R_2}} \quad \frac{1}{Q} = \sqrt{\frac{C_2}{C_1}} \left[\sqrt{\frac{R_2}{R_1}} + \sqrt{\frac{R_1}{R_2}} + \frac{\sqrt{R_1 R_2}}{R_3} \right] \tag{7.158}$$

The sensitivities of ω_0 and Q to the passive elements, where the sensitivity of Q and of ω_0 to element x are defined as

$$\frac{Q}{x} = \frac{x}{Q} \frac{\delta Q}{\delta x} \quad \frac{\omega_0}{x} = \frac{x}{\omega_0} \frac{\delta \omega_0}{\delta x} \tag{7.159}$$

are given by

$$\frac{\omega_0}{R_1} = \frac{\omega_0}{R_2} = \frac{\omega_0}{C_1} = \frac{\omega_0}{C_2} = -\frac{1}{2}; \quad \frac{\omega_0}{R_3} = 0; \quad \frac{Q}{C_1} = -\frac{Q}{C_2} = \frac{1}{2}$$

and

$$\frac{Q}{R_1} = -\frac{1}{2} + Q \sqrt{\frac{C_2 R_2}{C_1 R_1}}; \quad \frac{Q}{R_2} = -\frac{1}{2} + Q \sqrt{\frac{C_2 R_1}{C_1 R_2}}; \quad \frac{Q}{R_3} = Q \sqrt{\frac{C_2}{C_1} \frac{\sqrt{R_1 R_2}}{R_3}}$$

To realize a second-order section, values must be chosen for the five unknowns, $R_1, R_2, R_3, C_1,$ and C_2 . There are only two known quantities, ω_0 and Q , and so, usually, the resistors are chosen to be equal. In this case, the sensitivities to the passive elements are quite low and rival those of a passive RLC circuit realization of a filter section. However, the Rauch circuit is not appropriate for the realization of a high Q section. For example, even to realize $Q = 10$ requires $C_1 = 900C_2$, which is a relatively large spread of capacitor values. Also, for $Q > 5$, the Rauch section is sensitive to GB of the op-amp (Budak, 1974). However, for low Q sections, such as would be needed to realize the transfer function in Eq. (7.156), the Rauch section is a good choice. Finally, we note that if ω_0 is set, then Q can be adjusted using R_3 . However, changing R_3 also changes the gain constant for the section.

FIGURE 7.109 Low-pass Rauch filter section.

Figure 7.110 shows a cascade design for the fifth-order low-pass filter transfer function in Eq. (7.156). Two Rauch sections and a first-order section are utilized. All the resistors are 1Ω , and the values of the capacitors are shown in the figure. These values for the resistors and capacitors are not practical, but the elements would be **magnitude scaled** (resistors multiplied by a scaling factor K_m and all capacitors divided by K_m where K_m can be of the order of 10^5) and **frequency scaled** (all capacitors divided by another scaling factor K_f but the resistors left unchanged) to meet given specifications for the filter. Buffers are employed at the input and output of the circuit so that source and load impedances do not change the frequency characteristics of the filter. The first-order section is placed last in the cascade of sections because if it were placed earlier in the circuit, an additional buffer would be needed.

FIGURE 7.110 Realization for the transfer function in Eq. (7.156). All resistors are 1 Ω. These element values are impractical, but they can be magnitude and frequency scaled to obtain practical values.

Figure 7.111 shows a second-order bandpass section that corresponds to the low-pass Rauch section. The circuit in Fig. 7.111 realizes a transfer function of the form

$$T(s) = \frac{Ks}{s^2 + s\frac{\omega_0}{Q} + \omega_0^2} \tag{7.160}$$

Specifically, the transfer function is

$$\frac{V_O}{V_i} = \frac{-\frac{s}{R_1 C_1}}{s^2 + \frac{s}{R_2} \left(\frac{1}{C_1} + \frac{1}{C_2} \right) + \frac{1}{R_1 R_2 C_1 C_2}} \tag{7.161}$$

and the expressions for ω_0 and $1/Q$ for this circuit are

$$\omega_0 = \frac{1}{\sqrt{R_1 R_2 C_1 C_2}} \quad \frac{1}{Q} = \sqrt{\frac{R_1}{R_2}} \left[\sqrt{\frac{C_1}{C_2}} + \sqrt{\frac{C_2}{C_1}} \right] \tag{7.162}$$

There are four unknowns, R_1 , R_2 , C_1 , and C_2 and often C_1 is set equal to C_2 . The sensitivities of this circuit to its passive elements are low. However, as with the low-pass version, the circuit is not appropriate for the realization of high Q sections because of high element value spread and sensitivity to op-amp GB .

FIGURE 7.111 Bandpass filter section corresponding to the Rauch low-pass section.

Figure 7.112 shows a high-pass version of the Rauch section. Its transfer function is

$$\frac{V_O}{V_i} = \frac{-s^2 \frac{C_3}{C_1}}{s^2 + \frac{s}{R_2} \left(\frac{1}{C_1} + \frac{1}{C_2} + \frac{C_3}{C_1 C_2} \right) + \frac{1}{R_1 R_2 C_1 C_2}} \tag{7.163}$$

with ω_0 and $1/Q$ given by

$$\omega_0 = \frac{1}{\sqrt{R_1 R_2 C_1 C_2}} \quad \frac{1}{Q} = \sqrt{\frac{R_1}{R_2}} \left(\sqrt{\frac{C_1}{C_2}} + \sqrt{\frac{C_2}{C_1}} + \frac{C_3}{\sqrt{C_1 C_2}} \right) \tag{7.164}$$

As with the low-pass and bandpass versions, this high-pass circuit can only realize second-order sections with moderate Q .

A notch filter or a second-order allpass filter can be obtained using the circuit shown in Fig. 7.113. It is based on the fact that a notch or second-order allpass can be realized by subtracting a second-order bandpass transfer function from an appropriate constant. Setting $C_1 = C_2 = C$ in Fig. 7.111 and adding V_i by means of R_A and R_B as shown in Fig. 7.113, we obtain, using superposition,

FIGURE 7.112 High-pass Rauch section.

$$V_O = V_i T_{BP} + k V_i (1 - T_{BP}) \tag{7.165}$$

where $k = R_B / (R_A + R_B)$ and T_{BP} is given by Eq. (7.161). Thus, the transfer function for the circuit in Fig. 7.113 can be rewritten as

$$\frac{V_O}{V_i} = k \left[\frac{s^2 + s\omega_0 \left(\frac{1}{Q} + 2Q \left(1 - \frac{1}{k} \right) \right) + \omega_0^2}{s^2 + s\frac{\omega_0}{Q} + \omega_0^2} \right] \tag{7.166}$$

and a notch filter is realized with

$$k = \frac{2Q^2}{2Q^2 + 1} \tag{7.167}$$

A second-order allpass with complex poles is obtained for

$$k = \frac{Q^2}{Q^2 + 1} \tag{7.168}$$

This circuit is easily adjusted, but it is best used for moderate and low Q sections.

Many other filter sections that employ only one op-amp have been used over the years. Particular mention should be made of the Sallen-Key circuits (Budak, 1974) and J.J. Friend's single-amplifier-biquad (SAB) (Ghausi and Laker, 1981). The Friend SAB can realize second-order notch sections in which the undamped natural frequency of the zeros can differ from that of the poles. This is a feature that is needed if a higher-order bandstop filter is to be realized by cascading second-order notch sections.

The Rauch low-pass section and the other sections derived from it are limited in the Q they can realize. In some instances, a scheme called Q -boosting can be employed to increase Q without additionally burdening the existing op-amp. This scheme is illustrated with the bandpass section of Fig. 7.111. An additional op-amp amplifier is connected into the original circuit as shown in Fig. 7.114. The overall feedback loop through R_5 introduces positive feedback into the circuit. The output voltage of the two-op-amp circuit can be written as

FIGURE 7.113 Circuit used to obtain a second-order notch or a second-order allpass filter.

$$V_O = -T_{BP} \left[V_i \frac{R_4}{R_3} + V_O \frac{R_4}{R_5} \right] \tag{7.169}$$

FIGURE 7.114 Q-boosting applied to the bandpass section in Fig. 7.111.

where T_{BP} is given in Eq. (7.161). After substituting Eq. (7.161) into Eq. (7.167) and rearranging the results we obtain

$$\frac{V_O}{V_i} = \frac{\frac{s}{R_1 C_1} \frac{R_4}{R_3}}{s^2 + s \left[\frac{1}{R_2} \left(\frac{1}{C_1} + \frac{1}{C_2} \right) - \frac{1}{R_1 C_1} \frac{R_4}{R_5} \right] + \frac{1}{R_1 R_2 C_1 C_2}} \tag{7.170}$$

Let Q' be the Q of the complex poles in Eq. (7.170). Then it is easy to show that

$$\frac{1}{Q'} = \frac{1}{Q} - \frac{R_4}{R_5} \sqrt{\frac{R_2 C_2}{R_1 C_1}}$$

and, therefore, $Q' > Q$, and a higher Q can be obtained without as much spread in element values by means of the ratio R_5/R_4 . Also note that ω_0 stays the same as before. However, a penalty in the form of increased sensitivities is exacted when Q is increased by inserting additional terms into the s term in the denominator. This scheme is limited to Q -boosts up to a factor of about five or ten.

As with single op-amp sections, there are many two op-amp sections given in the literature. One very useful two op-amp bandpass section is shown in Fig. 7.115.

FIGURE 7.115 Two op-amp bandpass section.

The transfer function of this circuit is given by

$$\frac{V_O}{V_i} = \frac{s \frac{1 + K_R}{C_1 R_1}}{s^2 + \frac{s}{C_1 R_1} + \frac{K_R}{C_1 C_2 R_2 R_3}} \tag{7.171}$$

where $K_R = R_4/R_5$ and

$$\omega_0 = \sqrt{\frac{K_R}{C_1 C_2 R_2 R_3}} \quad Q = \sqrt{K_R} \sqrt{\frac{C_1}{C_2} \left(\frac{R_1}{\sqrt{R_2 R_3}} \right)}$$

Note that the coefficient of the s term and the constant term in the denominator of Eq. (7.171) can be changed independently. Thus, the coefficient of the s term can be adjusted by R_1 without affecting the constant term, and the constant term can be adjusted by, say, R_3 without affecting the s term. For best results, the two op-amps should be matched (Franco, 1988).

As a final example of a second-order section that can be used in cascade design, we examine the Akerberg-Mossberg low-pass section shown in Fig. 7.116. This section has three op-amps, and, if the op-amps are

FIGURE 7.116 Akerberg-Mossberg low-pass filter section.

ideal, has a transfer function given by

$$\frac{V_O}{V_i} = \frac{-\frac{R_2}{C_1 C_2 r_1 R_1 R_3}}{s^2 + \frac{s}{C_2 r_3} + \frac{R_2}{C_1 C_2 R_1 r_2 R_3}} \tag{7.172}$$

The quantities ω_0 and Q for this circuit are

$$\omega_0 = \sqrt{\frac{R_2}{C_1 C_2 R_1 r_2 R_3}} \quad Q = r_3 \sqrt{\frac{C_2}{C_1}} \sqrt{\frac{R_2}{R_1 r_2 R_3}} \tag{7.173}$$

From Eq. (7.172) and (7.173), it is seen that ω_0 can be adjusted by r_2 , and then Q can be adjusted using r_3 without affecting ω_0 . Finally, the gain constant can be adjusted using r_1 without affecting the previously set variables. This circuit is said to feature orthogonal adjustments. Several three op-amp circuits have this attribute. All five basic second-order filter sections can be realized with modifications to the low-pass circuit (Schaumann, Ghahsi, and Laker, 1990).

The Akerberg-Mossberg section is relatively insensitive to op-amp GB compared with, say, the lossy integrator three op-amp circuit (Aronhime, 1977). To provide a comparison, the effects of op-amp GB are now determined for the Akerberg-Mossberg low-pass section. The one-pole rolloff model given in Eq. (41.109) (see Section 7.7) is used for each op-amp. For the sake of simplicity, we assume GB of the op-amps are equal, that $R_1 = R_2 = R_3 = r_1 = r_2 = R$, and that $C_1 = C_2 = C$. Thus, the expressions for ω_0 and Q simplify to $\omega_0 = 1/(CR)$ and $Q = r_3/R$. Then the characteristic polynomial $D(s)$ of the filter can be written as

$$\begin{aligned} D(s) = & s^2 + s \frac{\omega_0}{Q} + \omega_0^2 + \frac{s}{GB} \left[2s^2 + s \left(3\omega_0 + 2\frac{\omega_0}{Q} \right) + 2\frac{\omega_0^2}{Q} \right] \\ & + \frac{s^2}{GB^2} \left[3s^2 + s \left(7\omega_0 + 3\frac{\omega_0}{Q} \right) + \omega_0^2 \left(2 + \frac{6}{Q} \right) \right] \\ & + \frac{s^3}{GB^3} \left[2s^2 + s \left(6\frac{\omega_0}{Q} + 2\omega_0 \right) + 4\omega_0^2 \left(1 + \frac{1}{Q} \right) \right] \end{aligned} \tag{7.174}$$

Next, we let $s_n = s/\omega_0$ and $GB_n = GB/\omega_0$ where the subscript n indicates normalization with respect to ω_0 . Upon collecting terms, we have

$$\begin{aligned} GB_n^3 \frac{D_n}{2} = & s_n^5 + s_n^4 \left[\frac{3}{2} GB_n + \frac{3}{Q} + 1 \right] + s_n^3 \left[GB_n^2 + GB_n \left(\frac{7}{2} + \frac{3}{2Q} \right) + 2 \left(1 + \frac{1}{Q} \right) \right] \\ & + s_n^2 \left[\frac{GB_n^3}{2} + GB_n^2 \left(\frac{3}{2} + \frac{1}{Q} \right) + GB_n \left(1 + \frac{3}{Q} \right) \right] + s_n \left[\frac{GB_n^3}{2Q} + \frac{GB_n^2}{Q} \right] + \frac{GB_n^3}{2} \end{aligned} \tag{7.175}$$

FIGURE 7.117 Loci of second quadrant dominant pole of Eq. (7.175) for values of Q (ideal) from 10 to 0.5. These loci show how the position of the dominant poles of the Akerberg–Mossberg section are influenced by finite op-amp GB . Each locus corresponds to a single value of the ideal Q . The loci are generated by factoring Eq. (7.175) for values of GB_n in the range $\infty > GB_n \geq 1$, where $GB_n = GB/\omega_0$ and ω_0 is the ideal magnitude of the (dominant) poles. The points on the loci for $GB_n = \infty$ are obtained from the denominator of Eq. (7.172).

From Eq. (7.174), we see that the ideal terms obtained with infinite GB have been corrupted by additional terms caused by finite GB . To see the effects graphically, we select several values of Q and then factor the polynomial in Eq. (7.175) for many values of GB_n in order to draw loci. The polynomial in Eq. (7.175) is fifth order, but three of the roots are in the far left-half normalized s plane. The dominant poles are a pair of complex poles that correspond to the ideal poles in Eq. (7.172) but are shifted because of finite GB . Figure 7.117 shows the family of loci generated, one locus for each value of Q selected. Only the loci of the dominant second quadrant pole are plotted. The other dominant pole is the conjugate.

To interpret the results, let us choose the locus for $Q = 10$. The ideal pole location is at the top end of the locus and corresponds to infinite GB . However, if GB_n equals 35, then the pole, instead of being at the upper end of the locus, is at the point on the locus marked with an unshaded square. This means that if the op-amp GB is 35 times the ω_0 of the pair of complex poles desired, then the actual ω_0 will be less than the desired value by the amount indicated on the locus. As another example, on the same locus, if the GB of the op-amp is only two times the desired ω_0 , then the pole location will be on the imaginary axis at the shaded square, and the filter will be on the verge of oscillation. This set of loci can be compared to the loci of other three op-amp sections given in Aronhime (1977) and to loci for single op-amp sections provided in Budak (1974).

Advantages of cascade design are: each section can be tuned to some extent so that its poles and zeros are at the correct locations, circuit realizations for each section can be selected depending on the Q of the poles to be realized and other factors, and the filters, if properly designed, can be relatively easily tested. However, the main advantage of cascade design, namely, easy tuning, is lost if thousands of filters have to be produced that must meet a particular set of design requirements accurately. Manual tuning of filter sections in this case would be too expensive and time consuming. Many approaches have been employed to eliminate the need to tune filter sections. Since the most important factor causing actual pole and zero locations to differ from the ideal location is finite op-amp GB , there have been several schemes that attempt to compensate for this problem. Predistortion, a technique used with passive filters to account for

parasitic resistance in inductors and capacitors, can be applied. If it is known that finite GB will lower ω_0 and increase Q for a particular section, the section can be designed to have poles with a larger magnitude and lower Q . Then when real op-amps are used, the poles, hopefully, will be near the correct locations. The problem with this and other schemes is that, if they are to be accurate, the user must have some idea of the values of GB of the op-amps being used in the section. But GB is not a controlled parameter of an op-amp.

Automatic tuning is another scheme (Schaumann, Ghausi, and Laker, 1990), but it adds circuit complexity. The best solution is to eliminate the need for tuning without the requirement for knowing op-amp GB . An approach that employs composite op-amps accomplishes this goal.

Composite Op-Amps

Given accurate passive components, the primary reason that the poles and zeros realized by active filter sections are not located where they are supposed to be is the finite GB of the op-amps. How can op-amps be modified, without knowing their GB , so that filter sections are insensitive to op-amp GB ? To answer this question, we consider the circuit shown in Fig. 7.118 which represents an active filter section consisting of an RC network and an op-amp (Budak, Wullink, and Geiger, 1980; Geiger and Budak, 1981). The open loop gain of the op-amp is given in Section 7.7 by Eq. (4.109) and is repeated here for convenience:

FIGURE 7.118 Active filter section consisting of an RC network and an op-amp.

$$\frac{V_O}{V_a} = A(s) \approx \frac{GB}{s} = \frac{1}{\tau s}$$

The transfer function of the entire network in Fig. 7.118 is given by

$$\frac{V_O}{V_i} = T(s) = \frac{-T_{21}}{T_{2F} + \frac{1}{A}} \tag{7.176}$$

where T_{21} and T_{2F} are transfer functions of the RC network given by

$$T_{21} = \left. \frac{-V_a}{V_i} \right|_{V_O=0} \quad \text{and} \quad T_{2F} = \left. \frac{-V_a}{V_O} \right|_{V_i=0}$$

To see the effect of the op-amp on the filter section, we examine

$$\frac{\delta T(s)}{\delta \tau} = \frac{T_{21} \frac{\delta \left(\frac{1}{A} \right)}{\delta \tau}}{\left[T_{2F} + \frac{1}{A} \right]^2} \tag{7.177}$$

If the section is to be insensitive to the time constant of the op-amp, we must have

$$\left. \frac{\delta T(s)}{\delta \tau} \right|_{\tau=0} = 0$$

and from Eq. (7.177) this requires

$$\left. \frac{\delta \left(\frac{1}{A} \right)}{\delta \tau} \right|_{\tau=0} = 0 \tag{7.178}$$

But $1/A = \tau s$, and so Eq. (7.178) yields s instead of zero. The conclusion is that no active filter section employing only a single op-amp (modeled by the one-pole rolloff model) can be made insensitive to the time constant of the op-amp. However, it is possible to devise a composite op-amp consisting of *two* individual op-amps that allows us to synthesize a filter transfer function $T(s)$ that is first-order insensitive to the op-amp time constants. A circuit realized with such a composite op-amp has a transfer function T with Maclaurin series expansion,

FIGURE 7.119 A composite op-amp composed of two individual op-amps.

$$T(\tau_1, \tau_2) = T(0, 0) + \left[\left(\tau_1 \frac{\delta}{\delta \tau_1} + \tau_2 \frac{\delta}{\delta \tau_2} \right) T(\tau_1, \tau_2) \right]_{\tau_1=\tau_2=0} + \dots + \frac{1}{n!} \left[\left(\tau_1 \frac{\delta}{\delta \tau_1} + \tau_2 \frac{\delta}{\delta \tau_2} \right)^n T(\tau_1, \tau_2) \right]_{\tau_1=\tau_2=0} + \dots \tag{7.179}$$

where $T(0, 0)$ corresponds to the ideal transfer function of the circuit. To make the overall transfer function $T(s)$ insensitive to first-order op-amp time constant effects, we devise composite op-amps for which the first partials in Eq. (7.179) are zero. Figure 7.119 shows an example of such an op-amp. The gain of this op-amp is given by

$$\frac{V_O}{V_a} = A(s) = \frac{-1}{s^2 \tau_1 \tau_2} \tag{7.180}$$

Clearly, the composite op-amp in Fig. 7.119 is unstable, but it is not meant to be used by itself. The issue is whether the filter it is used in is stable. Also note that

$$\frac{\delta}{\delta \tau_1} \frac{1}{A} = s^2 \tau_2 \quad \text{and} \quad \frac{\delta}{\delta \tau_2} \frac{1}{A} = s^2 \tau_1 \tag{7.181}$$

Thus, when τ_1 and τ_2 are zero, both partials in Eq. (7.181) are zero. Although the ideal values of τ_1 and τ_2 are zero, the values of these quantities are not required to be equal in the actual composite op-amp. In other words, matching of the time constants of the individual op-amps is not required. If the op-amp in Fig. 7.118 is replaced by the composite amplifier in Fig. 7.119 then $T(s)$ will be, to a first-order approximation, insensitive to the op-amp time constants as they take on values that differ from zero. The values for the passive components of the filter section are obtained assuming the op-amp is ideal. Then, instead of constructing the section with a single op-amp, a composite op-amp is used.

FIGURE 7.120 A representation for a composite op-amp or a composite amplifier composed of a resistor network and two individual one-pole rolloff op-amps.

Figure 7.120 shows a representation for a composite op-amp (or a composite amplifier) employing a resistor network and two one-pole rolloff op-amps. The transfer function of this circuit is

$$\frac{V_O}{V_a} = A(s) = \frac{s \tau_2 t_{13} + t_{14} t_{23} - t_{13} t_{24}}{s^2 \tau_1 \tau_2 - s \tau_1 t_{24} - s \tau_2 t_{15} + t_{15} t_{24} - t_{14} t_{25}} \tag{7.182}$$

where τ_1 and τ_2 are the time constants of the two op-amps, and t_{ij} , $i = 1, 2$ and $j = 3, 4, 5$, are transfer functions of the resistor network. Since the transfer functions of the resistor network are real numbers, we

rewrite Eq. (7.182) as

$$A(s) = \frac{s\tau_2 a_1 + a_0}{s^2\tau_1\tau_2 + s\tau_1 b_1 + s\tau_2 b_2 + b_0} \tag{7.183}$$

The partial derivatives of $1/A$ with respect to the time constants are

$$\frac{\delta}{\delta\tau_1} \frac{1}{A} = \frac{s^2\tau_2 + sb_1}{s\tau_2 a_1 + a_0} \quad \frac{\delta}{\delta\tau_2} \frac{1}{A} = \frac{s^2\tau_1(a_0 - a_1 b_1) + s(a_0 b_2 - a_1 b_0)}{(s\tau_2 a_1 + a_0)^2} \tag{7.184}$$

To make the partial derivative with respect to τ_1 equal to zero when the time constants are zero requires that $b_1 = 0$ and $a_0 \neq 0$. For the other derivative to be zero requires $(a_0 b_2 - a_1 b_0) = 0$ and, again $a_0 \neq 0$. Imposing these requirements on $A(s)$ we obtain

$$A = \frac{s\tau_2 a_1 + a_0}{s^2\tau_1\tau_2 + \frac{b_0}{a_0}(s\tau_2 a_1 + a_0)}, \quad a_0 \neq 0 \tag{7.185}$$

which has the expected form

$$A = \frac{\text{polynomial}}{K_1 s^2 + K_2 (\text{polynomial})} \tag{7.186}$$

Table 7.5 shows several composite devices which meet the requirements given in Eq. (7.184) and thus have the form of Eqs. (7.185) and (7.186). Circuit 1 in this table is a composite op-amp in which b_0 in Eq. (7.185) is zero.

The other two circuits in the table are positive gain, infinite input resistance amplifiers. Note that circuit 3 is obtained from circuit 2 by switching the input leads of op-amp 1. Although circuits two and three in

TABLE 7.5 Composite Op-Amps and Amplifiers

No.	Type of Circuit	Schematic	Gain $A(s)$	Remarks
1	Op-amp		$\frac{V_O}{V_a} = \frac{s\tau_2 + a}{s^2\tau_1\tau_2}$	$a = \frac{R_B}{R_A + R_B}$
2	Amplifier (positive gain)		$\frac{V_O}{V_i} = -\frac{s\tau_2 + \frac{m}{m+1}}{s^2\tau_1\tau_2 - s\tau_2 \frac{1}{m+1} - \frac{m}{(m+1)^2}}$	$m = \frac{R_B}{R_A}$
3	Amplifier (positive gain)		$\frac{V_O}{V_i} = \frac{s\tau_2 + \frac{m}{m+1}}{s^2\tau_1\tau_2 + s\tau_2 \frac{1}{m+1} + \frac{m}{(m+1)^2}}$	$m = \frac{R_B}{R_A}$

FIGURE 7.121 Composite op-amp consisting of three individual op-amps.

Table 7.5 require the matching of resistor ratios, none of the circuits require that op-amp time constants be matched.

These results can be extended so that first and second partials of $1/A$ with respect to the time constants of the op-amps can be made zero when evaluated for values of the time constants equal to zero. Figure 7.121 shows a three op-amp composite operational amplifier. Its transfer function is given by

$$\frac{V_O}{V_a} = -\frac{s^2\tau_2\tau_3 + s\tau_2(1-\theta) + \theta\beta}{s^3\tau_1\tau_2\tau_3} \tag{7.187}$$

Note that this transfer function has the form of Eq. (7.186). Not only are the first partial derivatives of Eq. (7.187) with respect to the op-amp time constants zero when evaluated at zero, but also, the second partials are zero,

$$\frac{\delta^2 \frac{1}{A}}{\delta\tau_j^2} \bigg|_{\tau_1=\tau_2=\tau_3=0} = 0, \quad j = 1, 2$$

and

$$\frac{\delta^2 \frac{1}{A}}{\delta\tau_j\delta\tau_k} \bigg|_{\tau_1=\tau_2=\tau_3=0} = 0, \quad j, k = 1, 2, 3, \quad j \neq k$$

However, as more individual op-amps are combined, the resulting composite op-amp becomes less forgiving. Circuit layout, lead dress, and second-order effects become much more important. The diode D in Fig. 7.121 is included to prevent a large unstable mode of operation due to op-amp nonlinearities that may be excited when power is first applied or when large noise spikes exist (Budak, Wullink, and Geiger, 1980). Normally, the diode is off, and it is not included in the analysis.

The composite op-amp in Fig. 7.121 consists of three one-pole rolloff op-amps, and if it is used in a (nominally) second-order filter section, there are five poles that must be accounted for. Thus, a careful stability analysis must be performed to ensure that the dominant pair of complex poles realized are the ones desired. The resistor ratios in Fig. 7.121 are used as an aid in achieving stability in this application. Usually, the product $\theta\beta$ is set to be less than one, such as 0.2. In this case, θ can be set to 0.2 and β can be set to 1 (no β resistor divider needed).

We end this brief description of composite op-amps and amplifiers with a rule of thumb. To realize second-order filter sections with $Q \leq 10$ using $\mu A741$ op-amps so that f_o is within about 2% of the ideal value and Q is within about 5% of its ideal value *with no tuning*, then for $f_o \leq 2$ kHz, only one op-amp or op-amp amplifier is needed; for $f_o \leq 10$ kHz, a first-order zero sensitivity composite op-amp or amplifier is needed; and for $f_o \leq 50$ kHz, a second-order zero sensitivity composite op-amp or amplifier is required. With higher performance op-amps such as an LF356s, the design of active filter sections that require no tuning can readily be pushed to a value of f_o beyond 150 kHz.

LC Ladder Simulations

Passive circuit realizations of filters have very low sensitivities to element values. Lossless filters designed to maximize power transfer between source and load have the lowest possible sensitivities in the passband (Schaumann, Ghausi, and Laker, 1990). These networks are realized as double-terminated LC ladders as shown in Fig. 7.107, and the corresponding active filter realizations based on ladder simulations begin with the passive filter schematic rather than with the transfer function.

Ladder simulations can be classed into two groups: operational simulations and element simulations. In other words, one class of simulations is focussed on the *equations* of the passive network, and the other class concentrates on the *elements*, especially the inductors.

We first examine an operational simulation. Consider the doubly terminated ladder network shown in Fig. 7.122. This network represents a low-pass filter that has been frequency denormalized (frequency scaled up to the frequencies of interest). Interior node voltage V_1 and branch currents I_1 and I_2 have been identified in the figure. The first step in obtaining the operational simulation of this network is to write the network equations using Kirchhoff's and Ohm's laws. The equations are

FIGURE 7.122 A doubly terminated ladder low-pass filter.

$$I_1 = \frac{K V_{IN} - V_1}{s L_1 + R_S} \tag{7.188a}$$

$$V_1 = \frac{I_1 - I_2}{s C_1} \tag{7.188b}$$

$$I_2 = \frac{V_1 - V_O}{s L_2} \tag{7.188c}$$

$$V_O = I_2 \frac{R_L}{s C_2 R_L + 1} \tag{7.188d}$$

In Eq. (7.188a), V_{IN} has been multiplied by a constant K so that the active circuit can realize the required transfer function with an arbitrary gain factor.

The next step in realizing the operational simulation is to construct a *voltage* signal flow graph. This is done by first converting all currents in Eqs. (7.188) to voltages by the use of an arbitrary scaling resistor R . Thus, the equations in Eqs. (7.188) become

$$I_1 R = \frac{K V_{IN} R - V_1 R}{s L_1 + R_S} \tag{7.189a}$$

$$V_1 = \frac{I_1 R - I_2 R}{s C_1 R} \tag{7.189b}$$

$$I_2 R = \frac{V_1 R - V_O R}{s L_2} \tag{7.189c}$$

$$V_O = \frac{I_2 R}{s C_2 R + \frac{R}{R_L}} \tag{7.189d}$$

The original network has two inductors and two capacitors, and the equations in Eqs. (7.189) can be considered as describing four integrators. Two integrators incorporate a source or a load resistor and are lossy. The other two integrators are lossless. In other words, for an n th-order doubly terminated low-pass LC ladder, the network equations will have the form of n integrators of which two will be lossy, and the remaining integrators will be lossless. To construct the signal flow graph corresponding to Eqs. (7.189), we follow the convention that the voltages associated with the circuit, such as input and output voltages

FIGURE 7.123 Signal flow graph for the low-pass ladder circuit in Fig. 7.122.

and voltage V_1 at the internal node, are represented by nodes at the bottom of the graph. Voltages that represent the branch currents I_1 and I_2 are placed at nodes at the top of the graph. We also adopt the rule: Employ inverting integrators in branches corresponding to the ladder capacitors, and use noninverting integrators to simulate the ladder inductors. The resulting signal flow graph is depicted in Fig. 7.123. We note that the gain around each loop in the figure is negative and independent of R .

The next step in obtaining an operational realization is to substitute appropriate integrators (or summer-integrators) into the signal flow graph. The usual integrators used are the Miller integrator and the noninverting integrator shown in Fig. 7.124(a) and Fig. 7.124(b), respectively. For lossless integration, resistors R_C in the circuits are set open. The output voltages of these circuits can be expressed as

$$V_O = \mp \left[\frac{V_A}{sCR_A + \frac{R_A}{R_C}} + \frac{V_B}{sCR_B + \frac{R_B}{R_C}} \right] \tag{7.190}$$

where the minus sign is used for the Miller integrator, and the plus sign is employed for the noninverting circuit. When the integrators are substituted into the signal flow graph of Fig. 7.123, there will be many more unknown elements than equations. Thus, usually the capacitors are set equal. The resulting operational realization is shown in Fig. 7.125. However, even with equal capacitors, there still remain 10 unknown elements consisting of 9 resistors (excluding r and R) and 1 capacitor value. There are 6 known values in Fig. 7.122. The available degrees of freedom can be used to maximize the dynamic range of the filter or to achieve other design objectives. Here, we will be content merely to equate the time constants in Eq. (7.189) with those of the circuit in Fig. 7.125. Equating CR_3 to L_1/R_s (from Eq. (7.189a)), we obtain

FIGURE 7.124 (a) Lossy inverting integrator (Miller integrator), (b) noninverting lossy integrator, sometimes referred to as the phase lead integrator.

FIGURE 7.125 Operational simulation of ladder network in Fig. 7.122.

$R_3 = L_1/(CR_s)$. Also from Eq. (7.189a) at DC, we obtain $R_3/R_1 = KR/R_s$ and $R_3/R_2 = R/R_s$. Thus

$$R_1 = R_3 \frac{R_s}{KR} = \frac{L_1}{CKR} \quad \text{and} \quad R_2 = R_3 \frac{R_s}{R} = \frac{L_1}{CR}$$

From Eq. (7.189b), we require that $C_1R = CR_4 = CR_5$. Thus

$$R_4 = R_5 = R \frac{C_1}{C}$$

In the same manner from Eq. (7.189c), we have $L_2/R = CR_6 = CR_8$. Thus

$$R_6 = R_8 = \frac{L_2}{CR}$$

Equation (7.189d) yields $C_2R = CR_7$, which produces

$$R_7 = R \frac{C_2}{C}$$

Also, at DC, Eq. (7.189d) yields $R_7/R_9 = R/R_L$ so that

$$R_9 = R_7 \frac{R_L}{R} = R_L \frac{C_2}{C}$$

The scaling resistor R and the capacitor C are arbitrary and can be selected to obtain practical values for the circuit components. In this section, we have obtained an active operational simulation of a double-terminated LC ladder filter. This simulation mimics the equations of the passive network and inherits its low element sensitivities. Although we have only examined a low-pass realization, the basic idea can be extended to rather general LC ladder circuits (Schaumann, Ghausi, and Laker, 1990), and so it can be used with some modifications for the other types of basic filter functions (highpass, bandpass, bandstop) as well as for general filter and signal processing circuits.

We now examine a method of ladder simulation that utilizes element substitution. This is a direct approach in which Antoniou's *generalized impedance converter* (GIC), listed as circuit number 15 in Table 7.3 (see Section 7.7), is used to realize grounded inductors in the passive network. Figure 7.126 shows the GIC

FIGURE 7.126 Antoniou's generalized impedance converter configured to realize an inductor.

arranged for realizing a grounded inductor. The input impedance for this circuit is

$$Z_{IN} = sCR_1R_5 = sL$$

It can be shown (Schaumann, Ghausi, and Laker, 1990) that inductor errors are minimized if $R_5 = 1/(\omega_e C)$ where ω_e is a special frequency of interest such as a filter passband edge. Then the value of R_1 is found from the desired value of the inductor as $R_1 = \omega_e L$.

Figure 7.127(a) shows a passive high-pass ladder network to be simulated. The resulting active network is shown in Fig. 7.127(b) in which the grounded inductors have been replaced by GICs so that $L_1 = R_1 R_5 C_A$ and $L_2 = R_6 R_{10} C_B$. The resistors and capacitors remain unchanged.

This direct method of ladder network simulation is best employed if the inductors to be replaced are grounded. If floating inductors are to be replaced, then $1\frac{1}{2}$ –2 times as many op-amps are needed depending

FIGURE 7.127 (a) Passive ladder network with grounded inductors, (b) active circuit simulation of (a).

TABLE 7.6 Bruton's Transformation

Impedance in Passive Network	Impedance in Transformed Network
$Z = R$	$Z' = R/(ks) = 1/(sC')$
$Z = sL$	$Z' = L/k = R'$
$Z = 1/(sC)$	$Z' = 1/(s^2Ck) = 1/(s^2D')$

on the circuits used to realize the inductors. Also, parasitic capacitors and resistors have significant effects on the resulting networks. Instead, if a network with floating inductors has only grounded capacitors, then Bruton's transformation can be used to advantage. To apply this transformation, each impedance of the passive network is scaled by $1/(ks)$. This amounts to a magnitude scaling of the network, and so the overall transfer function remains unaffected, but the impedances of the resistors, inductors, and capacitors are transformed according to Table 7.6. Primed quantities refer to impedances and element values in the transformed network. We see from Table 7.6 that resistors are transformed to capacitors, inductors become resistors, and capacitors convert to *frequency-dependent negative resistors* (FDNRs) having impedances $Z'(j\omega) = -1/(\omega^2 D')$. The constant k is arbitrary and can be used to obtain practical values of components. Antoniou's GIC is used to realize grounded FDNRs.

Figure 7.127(a) shows the network obtained by applying Bruton's transformation to the low-pass passive network in Fig. 7.122. Note that the FDNRs are denoted in this schematic by a symbol consisting of four parallel bars. The active realization of the network in Fig. 7.128(a) is given in Fig. 7.128(b). Each GIC in this figure requires two capacitors to realize an FDNR, but a smaller number of op-amps is needed than if the floating inductors in Fig. 7.122 were realized directly. The values of the two FDNRs in Fig. 7.128(b) are $D'_1 = C_A^2 R_A$ and $D'_2 = C_B^2 R_B$. It can be shown (Schaumann, Ghausi, and Laker, 1990) that a good

FIGURE 7.128 (a) Transformed circuit containing FDNRs obtained from Fig. 7.122, (b) FDNR symbols replaced by GIC realizations.

choice for R_A is $1/(\omega_e C_A)$ where ω_e is a frequency of interest such as a filter passband edge. This choice minimizes the errors in D' caused by finite GB of the op-amps. The same remarks apply to R_B and C_B .

Examination of the active circuit structure in Fig. 7.128(b) reveals two problems. The first is that, since the entire ladder is transformed, the active structure does not have a true source and load resistor. If the source and load resistors are specified, then gain-of-one buffers should be inserted into the circuit at points X and Y. Then the specified resistors can be connected without changing the overall transfer function.

The second problem is that DC current cannot flow through the noninverting inputs of the upper op-amps unless the extra resistors R_1 and R_2 , shown with dotted lines, are added to the circuit. Recall that a DC current must be allowed to flow through the input leads for an op-amp to operate properly. Thus, there must be a path for DC current to ground, to the output terminal of an op-amp, or to a (DC coupled) input voltage source. The added resistors R_1 and R_2 in Fig. 7.128(b) provide this path at the expense of inaccuracy at low frequency in the transfer function realized. From the figure at DC, we have

$$T(j0) = \frac{R_2}{R_1 + R'_1 + R'_2 + R_2}$$

where $T(j\omega)$ is the transfer function of the overall circuit. From the original circuit in Fig. 7.122, we have at DC

$$T(j0) = \frac{R_L}{R_L + R_S}$$

Thus

$$R_2 = \frac{R_L}{R_S}(R_1 + R'_1 + R'_2)$$

The added resistors R_1 and R_2 represent parasitic inductors in the transformed circuit. To minimize their effects, it can be shown that each resistor should be chosen to be much larger than $R'_1 + R'_2$. As a result

$$\frac{R_2}{R_1} = \frac{R_L}{R_S}$$

Typically, R_1 and R_2 are chosen to be from several hundred thousand ohms to a megohm.

Direct replacement for grounded inductors and Bruton's transformation for networks with floating inductors but only grounded capacitors yield active, inductorless realizations for low-pass, high-pass, and some types of bandpass circuits. These circuits inherit the low sensitivities of the passive realizations. For passive circuits that contain *both* floating inductors and floating capacitors, these methods are inefficient. In such cases, element simulations of the passive network can be accomplished using the Gorski-Popiel embedding technique which also uses a version of Antoniou's GIC. An excellent description of the technique is given in (Schaumann, Ghausi, and Laker, 1990), and the interested reader is urged to consult that reference.

Multiple-Loop Feedback Topologies

Many active filter topologies have been devised that can be classed under the generic term *multiple-loop feedback* (MLF) topologies. These structures were created in the search for higher-order filter active realizations that retained the modularity of cascade design but yielded lower sensitivities to the passive elements. Figure 7.129 shows four of these structures (feedforward paths are added later). Note that each feedback loop includes a minus sign. Figure 7.129(a) shows *follow-the-leader feedback* (FLF), and Fig. 7.129(b) depicts *modified leapfrog feedback* (MLF). Figure 7.129(c) illustrates *inverse follow-the-leader feedback* (IFLF), and Fig. 7.129(d) shows *primary resonator feedback* (PRB). The blocks labeled T_i , $i = 1, 2, 3$, in the figure are, in general, biquads having the form

$$T_i = K_i \frac{s^2 + s \frac{\omega_{Zi}}{Q_{Zi}} + \omega_{Zi}^2}{s^2 + s \frac{\omega_0}{Q} + \omega_0^2}$$

FIGURE 7.129 Multiple-loop feedback topologies: (a) follow-the-leader feedback (FLF), (b) modified leapfrog feedback (MLF), (c) inverse follow-the-leader feedback, (d) primary resonator block feedback (PRB).

except for the PRB in which all of the transfer functions are the same. The circles labeled $B_i, i = 1, 2, 3$, are feedback weighting factors. The configurations shown realize overall sixth-order transfer functions, but the diagrams can be easily extended for the realizations of higher-order filters.

Figure 7.130 illustrates two types of feedforward topologies that can be utilized with any of the four diagrams in Fig. 7.129 with the addition of summers where needed. The individual transfer function blocks in Fig. 7.129 are labeled T_A, T_B , and T_C for generality, and the F_i are feedforward weighting factors. A common pairing of feedback and feedforward topologies is shown in the FLF structure depicted in Fig. 7.131. In this diagram, the feedback and feedforward weighting factors have been combined with the summers. The summer at the input of the diagram also supplies the minus sign needed at the first biquad block. The overall transfer function T is given by

$$T = \frac{V_{OUT}}{V_{IN}} = B_0 \frac{F_0 + \sum_{i=1}^n \left[F_i \prod_{j=1}^i T_j \right]}{1 + \sum_{i=1}^n \left[B_i \prod_{j=1}^i T_j \right]} \quad (7.191)$$

where $B_i = R_{B_i} / R_1$ and $F_i = R_2 / R_{F_i}, i = 0, 1, \dots, n$. From Eq. (7.191), it can be seen that the poles and zeros of the individual transfer function blocks affect the poles and zeros of the overall transfer function T .

FIGURE 7.130 Feedforward topologies: (a) topology usually employed with FLE, (b) another feedforward topology.

FIGURE 7.131 FLF with feedback and feedforward weighting factors.

To realize a general high-order filter with arbitrary zeros using MLF circuit to achieve low sensitivities is difficult. Some simplifications can be made in the design of geometrically symmetrical bandpass filters, but we will leave these procedures to the references (Ghausi and Laker, 1981; Schaumann, Ghausi, and Laker, 1990).

7.8.3 Other Operational Elements

In previous sections, we described the conventional op-amp and examined some of its applications. In this section, we survey other important operational elements—the *current feedback op-amp* (CFB), the *operational transconductance amplifier* (OTA), and the *current conveyor* (CC). All of these other operational elements are available commercially, and all offer advantages and have some disadvantages in comparison with conventional op-amps such as the $\mu A741$. Unlike the conventional op-amp, which is a *voltage-controlled voltage source* (VCVS) operational element, current is the main variable of interest at either an input or an output port of all the other operational elements.

Current Feedback Operational Amplifier

CFBs have large closed-loop bandwidths that range from 3×10^6 rad/s to over 10^9 rad/s, and the bandwidth is relatively independent of closed-loop gain (Soclof, 1991; Franco, 1991). Commercial examples of CFBs include the Analog Devices AD844 and AD9611, the Comlinear CLC220A, and the Burr-Brown OPA603.

Figure 7.132 depicts a small signal model of a CFB together with external feedback resistors R_F and R_1 and an input voltage signal V_i . As is the case for the conventional op-amp, inverting and noninverting

FIGURE 7.132 Model for current feedback op-amp (CFB).

terminals are indicated at the inputs to the CFB. However, the structure of the CFB differs from that of the conventional op-amp. A unity-gain voltage buffer is located between the two input leads which forces the voltage at the inverting input port to equal the voltage at the noninverting input port. Ideally, the input resistance at the noninverting input port is infinite so that no current flows in the lead. However, the input resistance at the inverting port is ideally zero. At the output port of the CFB, the model has an ideal voltage source which depends on the current I_n . The coefficient of the dependent source is Z so that

$$V_O = ZI_n \quad (7.192)$$

where Z is the transimpedance of the CFB. Generally, Z is designed to have a large magnitude at low frequencies, ranging from 300 k Ω to over 3 M Ω . Its magnitude rolls off with a one-pole rolloff characteristic so that we can express Z as

$$Z(j\omega) = \frac{r_T}{1 + j\frac{\omega}{\omega_a}} \quad (7.193)$$

where $r_T = Z(0)$ and ω_a is the frequency at which the magnitude of this impedance has decreased to 0.707 of its low-frequency value. This frequency can also be written as

$$\omega_a = \frac{1}{r_T C_T} \quad (7.194)$$

where C_T is termed the transcapacitance of the CFB. C_T is held to as low a value as possible so that larger values of the feedback resistor R_F can be used while retaining a fast response. Values of C_T typically range from 0.5 to 5 pF, and a typical value of ω_a is about $2\pi(12 \times 10^3)$ rad/s. However, as we shall see, the closed-loop bandwidth is much larger than ω_a .

Consider the noninverting amplifier in Fig. 7.132. The current I_n can be expressed as

$$I_n = \frac{V_i}{R_1 \parallel R_F} - \frac{V_O}{R_F} \quad (7.195)$$

and it is seen from Eq. (7.195) that the feedback signal V_O/R_F is in the form of a current. Then employing Eq. (7.192) and Eq. (7.193) in Eq. (7.195) and solving for V_O/V_i , we obtain

$$\frac{V_O}{V_i} = G = \frac{1 + \frac{R_F}{R_1}}{1 + \frac{R_F}{r_T} \left(1 + j\frac{\omega}{\omega_a}\right)} \quad (7.196)$$

where G is the closed-loop gain of the amplifier. Since R_F/r_T is much less than 1, we can write

$$G \approx \frac{1 + \frac{R_F}{R_1}}{1 + j\frac{R_F\omega}{r_T\omega_a}} \quad (7.197)$$

from which we obtain the closed-loop 3.01-dB bandwidth of the amplifier, BW_{CL} in radians per second, as

$$BW_{CL} = \frac{\omega_a r_T}{R_F} \quad (7.198)$$

For example, if $R_F = 1000 \Omega$, $R_1 = 111 \Omega$, $r_T = 3 \text{ M}\Omega$, and $\omega_a = 2\pi(12 \times 10^3)$ rad/s, then $G(0) = 10$, and $BW_{CL} = 22.6 \times 10^7$ rad/s. The resulting closed-loop gain-bandwidth product is 22.6×10^8 rad/s corresponding to 360 MHz.

A remarkable aspect of these results is that the closed-loop bandwidth does not depend, in this somewhat idealized case, on the closed-loop gain $G(0)$. Figure 7.133 shows plots of the magnitude of the gain vs.

ω obtained from Eq. (7.197). These plots should be compared with the corresponding plots shown in Fig. 7.79 (see Section 7.197), for an amplifier based on a conventional op-amp.

Another interesting aspect of these results concerns the current I_n . Since $I_n = V_O/Z$, the current in the inverting input lead is very small. In the limit as $|Z|$ approaches infinity, I_n approaches zero. Thus, the CFB's output voltage ideally takes on whatever value is required to make I_n equal zero even though the output resistance of the voltage buffer between the input leads ranges from 3 to 50 Ω . As a result, the conditions that apply for an ideal conventional op-amp, namely, zero volts between the two input leads and zero currents drawn by these leads, also hold for the CFB, although for different reasons (Franco, 1991).

CFBs have very large slew rates because of the small size of C_T and because the current available to charge C_T is not limited by the maximum current of a current source. Slew rates of CFBs are one or two orders of magnitude greater than the slew rates of conventional op-amps. Slew rates greater than 6000 V/ μ s are not uncommon (Soclof, 1991).

However, no CFB is ideal, and small departures from ideal characteristics have adverse effects on the performance of these operational elements. For example, the output resistance of the buffer between the input leads causes some dependence of the closed-loop bandwidth on the closed-loop gain. Figure 7.134 shows an amplifier that includes a CFB model that accounts for this resistance which is denoted as r . With r included, the closed-loop gain of the noninverting amplifier becomes

$$\frac{V_O}{V_i} = G = \frac{1 + \frac{R_F}{R_1}}{1 + \frac{R_F}{Z} \left[1 + \frac{r}{R_1 \parallel R_F} \right]} \tag{7.199}$$

Substituting for Z from Eq. (7.193) we have

$$\begin{aligned} G(j\omega) &= \frac{G(0)}{1 + \frac{R_F}{r_T} \left(1 + j \frac{\omega}{\omega_a} \right) \left(1 + \frac{r}{R_1 \parallel R_F} \right)} \\ &\approx \frac{G(0)}{1 + j \frac{\omega R_F}{\omega_a r_T} \left(1 + \frac{r}{R_1 \parallel R_F} \right)} \end{aligned} \tag{7.200}$$

FIGURE 7.134 Noninverting amplifier that includes a CFB model that accounts for the output resistance r of the gain-of-one voltage buffer between the input leads of the CFB. Typical values of this resistance range from 3 to 50 Ω .

FIGURE 7.133 Magnitudes of gain vs. ω obtained from Eq. (7.147) for noninverting CFB amplifier.

TABLE 7.7 Closed-Loop Gains and Bandwidths

Gains [$G(0)$]	Bandwidths (BW_{CL} in M rad/s)
3	377.4
10	333.3
30	250.0
100	133.3

where $G(0) = 1 + R_F/R_1$. The closed-loop bandwidth is

$$BW_{CL} = \frac{\omega_a \left(\frac{r_T}{R_F} \right)}{1 + \frac{r}{R_F} G(0)} \tag{7.201}$$

Here we see that $G(0)$ is present in the denominator of BW_{CL} , and so there is a small decrease in bandwidth as the gain is increased. For example, suppose a CFB has $r = 30 \Omega$, $R_F = 1.5 \text{ k}\Omega$, $r_T = 3 \text{ M}\Omega$, and $\omega_a = 200 \times 10^3 \text{ rad/s}$. The closed-loop bandwidths for various gains are given in Table 7.7, and plots of the magnitudes of the gains vs. frequency are shown in Fig. 7.135. We see that in changing the gain from 10 to 100, the bandwidth is reduced by a factor of 2.5 for the CFB of this example. But the bandwidth of the noninverting amplifier shown as circuit 1 in Table 7.3 (see Section 7.7) would be reduced by a factor of 10.

Equation (7.201) can be used to modify the external resistor of the CFB amplifier of Fig. 7.134 to compensate for bandwidth reduction caused by r . For required closed-loop bandwidth BW_{CL} and low-frequency gain $G(0) = 1 + R_F/R_1$, we obtain

$$R_F = \frac{\omega_a r_T}{BW_{CL}} - r G(0)$$

Suppose a low-frequency gain $G(0)$ equal to 30 is required with a bandwidth of $300 \times 10^6 \text{ rad/s}$. We obtain $R_F = 1100 \Omega$, and $R_1 = 40 \Omega$.

CFBs can be used to realize inverting and noninverting amplifiers, current-to-voltage and voltage-to-current converters, and summing and differencing amplifiers. Thus, they can be utilized in a variety of active filters such as Sallen-Key active filters. However, careful stability analysis must be performed for circuits in which CFBs have reactive components in their feedback networks. For example, the usual Miller

FIGURE 7.135 Plots of the magnitudes of closed loop gains vs. frequency which show dependence of the bandwidth on r .

FIGURE 7.136 A CFB integrator.

FIGURE 7.137 Operational transconductance amplifier: (a) schematic representation, (b) ideal model.

integrator is not often realized with a CFB, although the interested reader should refer to (Mahattanakul and Toumazou, 1996) for a and more thorough discussion of this circuit. Instead, the integrator employed in the Akerberg-Mossberg active filter section, Fig. 7.116, can be used. This integrator is shown in Fig. 7.136. Ideally its transfer function is $V_O/V_i = R_1/(sCR_F R_2)$, and it can be made a lossy integrator by shunting C with a resistor R_C as shown in dotted lines in the figure. Thus, a variety of active filter sections and topologies can be constructed with CFBs.

Operational Transconductance Amplifier

An OTA is an approximation to an ideal voltage-controlled current source. Figure 7.137(a) shows a representation for the device, and Fig. 7.137(b) depicts an ideal model. In Fig. 7.137(a), the DC current I_{ABC} is termed the amplifier bias current. It controls the transconductance, g_m , of the OTA and can vary g_m over several decades. Usually, g_m is proportional to I_{ABC} so that

$$g_m = kI_{ABC} \tag{7.202}$$

where $k = q/(2KT)$ and $KT/q = 26 \text{ mV}$ at 25°C . The typical range of I_{ABC} is $0.1 \mu\text{A}$ to 1 mA .

Ideally, the OTA has infinite input and output impedances, and g_m is assumed to be constant. However, real OTAs have noninfinite input and output impedances and g_m is frequency dependent. Figure 7.138 shows a model that accounts for these imperfections. Input parasitic capacitance C_i typically ranges in

FIGURE 7.138 Model for nonideal OTA.

value from 0.5 to 4 pF, and the output capacitance is typically from 1 to 6 pF. Discrete OTAs such as the CA3080 and the National LM13600 have parasitic capacitances at the higher end of these ranges whereas OTAs that are incorporated on an integrated circuit chip have capacitances at the lower end. The capacitances across the input ports are assumed to be equal. To show the frequency dependence of the transconductance, g_m can be expressed as

$$g_m = \frac{g_{m0}\omega_a}{s + \omega_a} \tag{7.203}$$

where g_{m0} is the low-frequency value of g_m and ω_a is the frequency in radians per second where the transconductance has decreased to 0.707 of its low-frequency value. As I_{ABC} is changed from 0.1 μA to 1 mA, g_{m0} changes from about 2 μS to $20 \times 10^4 \mu\text{S}$. The frequency ω_a is about $2\pi(2 \times 10^6)$ rad/s for a CA3080 operating with $I_{ABC} = 500 \mu\text{A}$. The parasitic resistors R_i in Fig. 7.138 are typically several megohms for lower values of I_{ABC} and R_O typically ranges from several megohms to over 100 M Ω . But all of these parasitic resistances are heavily dependent on I_{ABC} . As I_{ABC} is increased so that g_m is increased, R_i and R_O decrease. For example, if I_{ABC} is 500 μA , R_i is about 30 k Ω for a CA3080. But if I_{ABC} is 5 μA , R_i is about 1.5 M Ω . Also, the peak output current that can be drawn is approximately equal to I_{ABC} . Another aspect of OTAs that must be kept in mind is that $|V_a|$ is limited to about 25-mV peak in order to preserve linearity in the CA3080. However, this limit is being broadened in newer OTAs. Finally, it should be observed that OTAs must be allowed to conduct DC current in their input leads. It is clear that careful attention must be given to the manufacturer’s specification sheets when discrete versions of OTAs are used.

Despite the many departures from ideal behavior exhibited by OTAs, their usefulness for design is not as meager as it first appears. The advantages afforded by OTAs include control of g_m by means of I_{ABC} , good high-frequency performance, greater adaptability to monolithic integrated circuit design than conventional op-amps and elimination of the requirement for negative feedback in order to operate properly, although feedback is often employed to realize particular circuit functions. Also, some commercial OTAs have buffers included on the chip so that a load may be driven without changing the overall transfer function of the circuit.

We next examine some of the basic OTA building blocks for linear signal processing applications. Figure 7.139(a) shows an OTA circuit that realizes a grounded resistor with a value that can be controlled by I_{ABC} . The input impedance is

$$\frac{V_i}{I_i} = Z_{IN} = \frac{1}{g_m + Y_i + Y_O} \tag{7.204}$$

where $Y_i = sC_i + 1/R_i$ and $Y_O = sC_O + 1/R_O$. For frequencies low enough and parasitic resistances large enough, $Z_{IN} \approx 1/g_m$. If the input leads of the OTA are interchanged, the circuit yields a short circuit stable negative resistor with $Z_{IN} \approx -1/g_m$. Figure 7.139(b) shows a circuit that can realize a floating resistor. Using the ideal model and solving for I_1 and I_2 , we obtain $I_1 = (V_1 - V_2)g_{m1}$ and $I_2 = (V_2 - V_1)g_{m2}$. If $g_{m1} = g_{m2} = g_m$, then $I_2 = -I_1$, and the circuit realizes a floating resistor of value $1/g_m$. The two circuits in Fig. 7.139 permit the construction of active filters without the use of resistors. Thus, transconductance-C filters can be realized, and such filters are attractive for monolithic integrated circuit realizations (Schaumann, Ghausi, and Laker, 1990).

FIGURE 7.139 OTA circuits: (a) OTA realization of a grounded resistor, (b) floating resistor realization.

FIGURE 7.140 OTA circuits: (a) OTA summer, (b) OTA lossy integrator.

For active filters, summers and integrators are also needed. Figure 7.140(a) shows a summer circuit for which the output voltage is given by

$$V_O = V_1 \frac{g_{m1}}{G} + V_2 \frac{g_{m2}}{G}$$

where $G = 1/R$. This circuit is versatile because the resistor R can be replaced by the OTA grounded resistor circuit in Fig. 7.139(a) to obtain an all-OTA circuit, more input voltages can be accommodated simply by adding more OTAs at the input, and interchanging the input leads of one of the OTAs at the input side of the summer changes the sign of the corresponding term in the output.

Figure 7.140(b) shows a lossy differential input OTA integrator. The output voltage is

$$V_O = (V_1 - V_2) \frac{g_m R}{sCR + 1}$$

and, again, the resistor can be replaced by the circuit in Fig. 7.139(a). Removal of the resistor results in a lossless integrator.

Grounded and floating realizations of an inductor are shown in Fig. 7.141(a) and Fig. 7.141(b), respectively. These are OTA gyrator realizations of inductors. The first circuit realizes

$$\frac{V_i}{I_i} = Z_{IN} = \frac{sC}{g_{m1}g_{m2}} \tag{7.205}$$

For the second circuit, we can write

$$\begin{aligned} I_1 - g_{m1}g_{m2}(V_2 - V_1) \frac{1}{sC} &= 0 \\ I_2 + g_{m1}g_{m3}(V_1 - V_2) \frac{1}{sC} &= 0 \end{aligned} \tag{7.206}$$

If $g_{m2} = g_{m3} = g_m$, then $I_2 = -I_1$, and the floating inductor realized ideally is $L = C/(g_m g_{m1})$. However, the parasitic resistors and capacitors can seriously influence the floating inductor realized. Unwanted resistance and capacitance will exist across both ports, the inductor itself will be lossy, the

FIGURE 7.141 OTA circuits: (a) OTA realization of a grounded inductor, (b) floating inductor realization.

FIGURE 7.142 OTA circuits: (a) RLC bandpass circuit, (b) OTA realization.

value of the inductor will be changed from its ideal value, and a current source will be included in the overall equivalent circuit of the inductor (Schaumann, Ghahsi, and Laker, 1990). Whether these departures from ideal behavior will prevent the OTA realization from being utilized depends on the particular application.

As a final example of a useful OTA circuit, we examine a bandpass/low-pass OTA circuit based on the passive RLC tuned circuit shown in Fig. 7.142(a). The active circuit, containing three OTAs, is shown in Fig. 7.142(b). Using ideal models for the OTAs, we obtain

$$\frac{V_{BP}}{V_i} = \frac{s \frac{g_{m3}}{C_1}}{s^2 + s \frac{g_{m3}}{C_1} + \frac{g_{m1}g_{m2}}{C_1C_2}} \tag{7.207}$$

As a bonus, if we take an output across C_2 , we obtain a low-pass transfer function given by

$$\frac{V_{LP}}{V_i} = \frac{-\frac{g_{m1}g_{m3}}{C_1C_2}}{s^2 + s \frac{g_{m3}}{C_1} + \frac{g_{m1}g_{m2}}{C_1C_2}} \tag{7.208}$$

In the active circuit, OTA3 converts the input voltage signal to a current source in parallel with a resistor $1/g_{m3}$. Capacitor C_1 realizes the capacitor of the RLC network, and the remaining two OTAs together with C_2 realize the inductor L . This circuit has the advantage that all parasitic capacitors are in parallel with C_1 or C_2 . They do not increase the order of the circuit and can be accounted for in the values chosen for C_1 and C_2 . Also, the output conductances of OTAs 2 and 3 are in parallel with the simulated conductance g_{m3} and can be absorbed into this value. Only the output conductance of OTA1 cannot be lumped directly with a design element of the circuit. Its main effect is to lower the Q and increase ω_0 of the circuit.

This brief catalog of circuits provides an indication of the versatility of OTAs and their usefulness especially in the design of linear integrated circuit signal processors.

Current Conveyor (CC)

Current conveyors (CCs) were first introduced by Smith and Sedra (1968) (see also Sedra (1989)) and have been used in a wide variety of electronic applications.

The current conveyor is a three-port device described by the hybrid equations

$$\begin{bmatrix} i_Y \\ v_X \\ i_Z \end{bmatrix} = \begin{bmatrix} 0 & a & 0 \\ 1 & 0 & 0 \\ 0 & \pm 1 & 0 \end{bmatrix} \begin{bmatrix} v_Y \\ i_X \\ v_Z \end{bmatrix} \tag{7.209}$$

in which the symbols for the port variables represent total instantaneous quantities. If $a = 1$, the first generation current conveyor, denoted as CCI, is described, and if $a = 0$, the second generation current conveyor, CCII, is characterized. Also, if the plus sign is employed in the equation for i_Z in Eq. (7.209), the corresponding current conveyor is termed a *positive* current conveyor, denoted as CCI+ or CCII+. If the minus sign is chosen, a negative current conveyor is described, indicated by CCI- or CCII-.

FIGURE 7.143 (a) Representation for a CCI. (b) Ideal model for a CCI. The downward-pointing arrow in the output current source is used for a CCI+. (c) Representation for a CCII. (d) Ideal model for a CCII. The downward-pointing arrow is used to model a CCII+.

FIGURE 7.144 Ideal models for current conveyors that incorporate nullators and norators: (a) model for a CCI, (b) model for a CCII–, (c) model for a CCII+.

Figure 7.143 shows schematics and ideal models for CCIs and CCII. The current generators driving port Z in the models shown in Fig. 7.43(b) and 7.43(d) have two arrows. The downward-pointing arrows are used for positive CCs, and the upward-pointing arrows are employed for negative CCs. In these models, current is conveyed from the low-impedance input at port X to the high-impedance output at port Z. Note that the CCI has three dependent sources in its model, and the CCII has only two. Because it is easier to make, the CCII is more commonly encountered. If the input to the CCII at port Y is connected to ground, the CCII becomes a gain-of-one current buffer.

Figure 7.144 shows ideal models that incorporate nullors. A CCI is modeled in Fig. 7.144(a), and a CCII– model is shown in Fig. 7.144(b). The simplicity of the model for the CCII– makes it attractive for design, and it should be noted that, unlike the nullor model for the conventional op-amp, the norator is not required to be grounded. Figure 7.144(c) shows the slightly more complicated model for the CCII+.

Figure 7.145 shows a model for a CCII+ that accounts for some of the imperfections of this operational element (Svoboda, 1994). R_X typically ranges from 3 to 50 Ω depending on which commercial current conveyor is being used. R_Y is typically 2 to 10M Ω , R_Z is typically 3 M Ω , and C_Z can range from 3 to 11 pF. Also, i_X and i_Z are not exactly

FIGURE 7.145 Nonideal model for a CCII+.

equal. That is $i_Z = (1 \pm \Delta)i_X$ where Δ is a positive number $\ll 1$. Typically, $\Delta = 0.005$. Finally, the open-loop bandwidth in hertz for a current conveyor with $R_L = 1 \text{ k}\Omega$ at port Z can range from 5 to over 20 MHz depending on the current conveyor used. Similar models apply for the CCII+ and for CCIs.

The input side of the CCII– in Fig. 7.145 is the same as for a CFB (see Fig. 7.134). Thus, a CFB can be obtained by connecting the output port of a CCII– to a voltage buffer to obtain V_O . Then Z for the resulting CFB is $R_Z/(sC_ZR_Z + 1)$. The close relationship between CFBs and CCII and the fact that the input to the voltage buffer at the output is brought out to a pin are the reasons an AD844 CFB can be used as a current conveyor.

Table 7.8 lists some circuit building blocks that are based on current conveyors. In the first four circuits listed, the CCII– can be replaced with a CCII+ yielding an extra minus sign in the result. Note that the results for circuit 4 in the table are the same whether a negative or positive CCII is used for the second current conveyor in the voltage amplifier.

Current conveyors are particularly suited for **current-mode circuits**. Current-mode circuits are circuits in which the internal processing of signals is performed on currents rather than voltages. When the voltages at the nodes of a circuit change, the ever-present parasitic capacitances must be charged or discharged, and this is one cause of reduced circuit bandwidth. However, if signals are processed in the form of currents such that voltage amplitudes in the circuit change relatively little, then an improvement in the bandwidth of the circuit can be obtained if stray inductance is minimized.

Second-order cascadable current-mode filter sections can be constructed from CCIs or CCII (Aronhime and Dinwiddie, 1991; Sedra and Roberts, 1990). However, it is often convenient to derive current-mode circuits directly from **voltage-mode circuits** using the **adjoint network** concept. Given a network N , an adjoint network N' can be obtained having a current ratio transfer function that is the same as the voltage ratio transfer function of the original network N . Figure 7.146 depicts the relations between the transfer functions of N and N' .

To construct N' given N , voltage-controlled-voltage-sources in N are replaced by current-controlled-current-sources in N' with input terminal pairs of the sources exchanged with output terminal pairs as shown in Fig. 7.147. Passive elements R, L , and C are left unchanged. The resulting networks are termed *interreciprocal networks*.

As an example, consider the voltage-mode circuit shown in Fig. 7.148(a) in which two gain-of-one voltage amplifiers are used. The corresponding adjoint network is depicted in Fig. 7.148(b), and its

FIGURE 7.146 (a) Given network N with transfer function V_o/V_i , (b) adjoint network N' with transfer function I_o/I_i . The two transfer functions are equal.

FIGURE 7.147 Voltage-controlled-voltage-sources are replaced by current-controlled-current-sources with input and output terminal pairs exchanged to obtain N' from given network N .

TABLE 7.8 Applications of Current Conveyors

No.	Type of Circuit	Schematic	Gain, Output Current, or Impedance
1	Current amplifier		$\frac{i_z}{i_i} = \frac{R_1}{R_2}$
2	Current adder subtractor		$i_z = (i_A + \dots + i_n)R \left(\frac{1}{R_1} + \dots + \frac{1}{R_n} \right) - (i_1 + \dots + i_n)$
3	Current integrator		$I_z = \frac{I_i}{sCR}$
4	Voltage amplifier		$\frac{v_o}{v_i} = -\frac{R_1}{R_2}$
5	Grounded inductor		$Z_{IN} = sCR^2$
6	Floating FDNR		$Z_{IN} = \frac{R_3}{s^2 C_1 C_2 R_1 R_2}$

FIGURE 7.148 (a) A voltage-mode filter circuit, (b) adjoint network corresponding to (a), (c) realization of adjoint network using current conveyors.

current conveyor realization is shown in Fig. 7.148(c). The transfer functions for the two networks are given by

$$\frac{V_O}{V_i} = \frac{I_O}{I_i} = \frac{1}{s^2 + \frac{s}{R_1 C_1} + \frac{1}{R_1 C_1 R_2 C_2}}$$

Thus, the transfer function for the two networks are the same except that one is a voltage ratio, and the other is a current ratio.

In this example, a voltage-mode low-pass filter section that contained gain-of-one voltage amplifiers was converted to a current-mode filter that could be realized by current conveyors. However, conversion of voltage-mode circuits with voltage amplifiers having gains greater than one requires current amplifiers with corresponding equal gains in the adjoint network. Such current amplifiers can be realized if the required gain is not great by ratioing the areas of the transistors in the output current mirror in the usual realization of current conveyors. In some cases, the current amplifier in Table 7.8 can be used.

The list of operational elements described in this section is by no means a complete list of elements available. Devices such as Norton operational amplifiers, four-terminal floating nullors, and operational floating conveyors are objects of study in the literature (Sedra and Roberts, 1990).

Acknowledgments

The author wishes to express his gratitude to Jacek Zurada, Zbigniew J. Lata, Damon Miller, Peichu (Peter) Sheng, KeChang Wang and A. Wisen for their help and encouragement.

Defining Terms

Adjoint network: A network having a nodal admittance matrix which is the transpose of that of a given network. This concept is useful in deriving current-mode networks from voltage-mode networks.

Critical frequencies: A collective term for the poles and zeros of a transfer function or a driving point function of a network.

Current-mode circuits: Signal processing circuits in which the primary variables of interest are currents.

Filter section: An active circuit with a transfer function that is usually second order that can be used in cascade design to realize higher-order filters.

Frequency scaling: A procedure for changing the cutoff frequency, peaking frequency, or other special frequency of a filter without changing either the filter's topology or types of network elements used. Values of capacitors and inductors are divided by parameter b where $1 < b < \text{infinity}$ if the filter is being scaled *up* in frequency. Resistors are not changed in value.

Gauge factor (GF): The ratio of the per unit change in resistance of a strain gauge to the per unit change in length. Thus, GF is given by $\Delta R/R/\Delta L/L$ where L is the active gauge length.

Magnitude scaling: A procedure for changing the values of network elements in a filter section without affecting the voltage ratio or current ratio transfer function of the section. Resistors and inductors are multiplied by parameter a , while capacitors are divided by a . If $1 < a < \text{infinity}$, then the magnitudes of the impedances are increased.

Transfer function: The ratio of the transform of the time-domain response of a linear circuit to the transform of the excitation causing the response. The response and excitations are applied or exist at different ports of the network. In determining a transfer function for a particular network, all independent sources associated with the network except the excitation are set to zero. Dependent sources remain operating.

Voltage-mode circuits: Signal processing circuits in which the primary variables of interest are voltages.

Further Information

Supplementary data and material about operational amplifiers and their uses can be obtained from the following sources:

EDN magazine, a twice monthly periodical that has a general electronics orientation. The section titled “Design Ideas” is noteworthy. The magazine is published by Cahners Publishing Co., Highlands Ranch, CO, and is free to qualified subscribers.

Electronic Design magazine, a twice monthly periodical that discusses many aspects of electronics. Particularly noteworthy are the column “Pease Porridge” by Bob Pease and the section “Ideas for Design.” This magazine is published by Penton Publishing, Inc., and is free to qualified subscribers.

Applications notes from manufacturers provide another valuable source of information. An alphabetical listing of companies that manufacture integrated operational amplifiers and that provide applications notes follows:

Analog Devices	Maxim Integrated Products
Burr Brown	Motorola
Harris Semiconductor	National Semiconductor
Linear Technology	Texas Instruments

Articles in technical journals are another source of information. New developments and innovative op-amp applications are often first made known in these publications.

7.9 Switched-Capacitor Circuits

Ezz I. El-Masry

7.9.1 Introduction

Implementation of electrical systems has evolved dramatically over the years as a result of numerous developments in technology. Originally, electrical systems had been implemented using passive components such as resistors (R), capacitors (C), and inductors. Because inductors are bulky, noisy, lossy, and unsuitable for miniaturization, tremendous efforts to simulate and/or replace them by circuits containing R , C , and **operational amplifiers (op amps)** had begun following the development of the monolithic op amp by Widlar in 1967 (Graeme, 1973). Most of the resulting analog RC–op amp circuits were constructed in hybrid form with monolithic op amps and chip capacitors soldered on a board containing thick-film resistors.

Practically, to achieve full integration in silicon chips, designer would have to choose between the bipolar or **metal oxide semiconductor (MOS) integrated circuit (IC)** technologies (Grey and Meyer, 1984; Grebene, 1984). Each technology has advantages and disadvantages. Bipolar technology is faster, offers higher transconductance values, and has lower turn-on values (0.5 V for silicon). On the other hand, MOS technology has the ability to store signal-carrying charges at a node for a relatively long period of time, to move the charge between different nodes (under the control of a digital clock), and to continuously, nondestructively, sense these charges. Prior to about 1977, there existed a clear separation of bipolar and MOS technologies, according to the function required. MOS technology, with its superior device density, was used mostly for digital logic and memory applications; on the other hand, bipolar ICs, such as op amps, were used to implement analog filters.

Strong motivation for analog circuits designers to develop techniques that are compatible with the MOS technology came with development of the MOS large scale integration (LSI) microprocessor and other low-cost digital ICs. Currently, MOS technology is the most widely used IC technology for digital **very large scale integration (VLSI)** circuits. In addition, new developments have occurred in communication technology (such as digital telephony, data transmission via telephone lines, etc.) that require mixed analog and digital signal processing circuitry. Therefore, problems of compatibility with digital systems, as well as cost, reliability, weight, and size added greater incentives to the development of analog circuits that can be fabricated using MOS technologies.

There has been long-standing difficulty in producing fully integrated MOS RC–op amp circuits with precise characteristics. This is because the MOS fabrication process does not result in sufficiently precise control over the absolute values of resistance and capacitance (and, hence, the RC product). In addition, MOS integrated (diffused) resistors have poor temperature and linearity characteristics, as well as requiring a large silicon area. Ordinarily the RC values cannot be controlled to better than 20%. This limitation was soon overcome by the development of circuit techniques wherein the resistor is simulated by a capacitor

and MOS switches. Hence, the circuit's frequency response depends on the ratios of MOS capacitors. It has been shown that MOS technology has the capability of realizing capacitor ratios within 0.1% accuracy. This class of circuits is known as **switched-capacitor** (SC) circuits, and they have received considerable attention. In addition to being very accurate, the SC circuit characteristic can be controlled by a precision digital clock. In addition, absolute capacitance values can be sufficiently reduced while maintaining the same capacitance ratios, resulting in circuits that consume a small chip area.

The principle of SC is not new. In fact, it was mentioned in 1873 by Maxwell in his fundamental book on electricity and magnetism. Many years later, Fudem (1984) pointed out that the SC approach to circuit synthesis was introduced in 1962 as was documented in his Ph.D. thesis in 1965 (Fudem is the first to use the name *capacitor switch*). The development of the resonant transfer principle (Boite and Thiran, 1968; Fettweis, 1968) had a great impact on the SC network theory. The use of capacitor and MOS switches to realize digital filters was demonstrated by Kuntz in 1968. More recently, Fried (1972) demonstrated the way to implement active filters using only capacitors, MOS transistors, and a pulse generator. Later, the idea of replacing resistors in RC-op amp filters by capacitors and MOS switches was fully investigated and implemented in the design of **SC filters** by Caves et al. (1977) and Hosticka, Broderon, and Gray (1977). Since then, SC circuit design techniques have made rapid progress and are widely used in many communications and signal processing applications. For almost the last two decades, the most successful realizations of analog filters in MOS technologies have been based on the well-established SC circuit techniques (Allan and Sanchez-Sinencio, 1984; Unbenhauen and Cichocki, 1989; Moschytz, 1984; Ghausi and Laker, 1981; Gregorian and Temes, 1986; Nakayama and Kuraishi, 1987).

7.9.2 Switched-Capacitor Simulation of a Resistor

The recognition that a resistor could be simulated with the combination of a capacitor and MOS switches was the basic theory underlying the operation of SC filters. To illustrate this principle let us consider the SC configuration shown in Fig. 7.149 where the switch is moving back and forth between positions 1 and 2 with frequency f_c Hz. In the analysis to follow, switch position 1 or 2 will be referred to as switch-1 or switch-2, respectively. Assume that v_1 and v_2 are voltage sources (or virtual ground or op amp's output); that is, the values of v_1 and v_2 are not affected by the switch actions. When the switch is in position 1

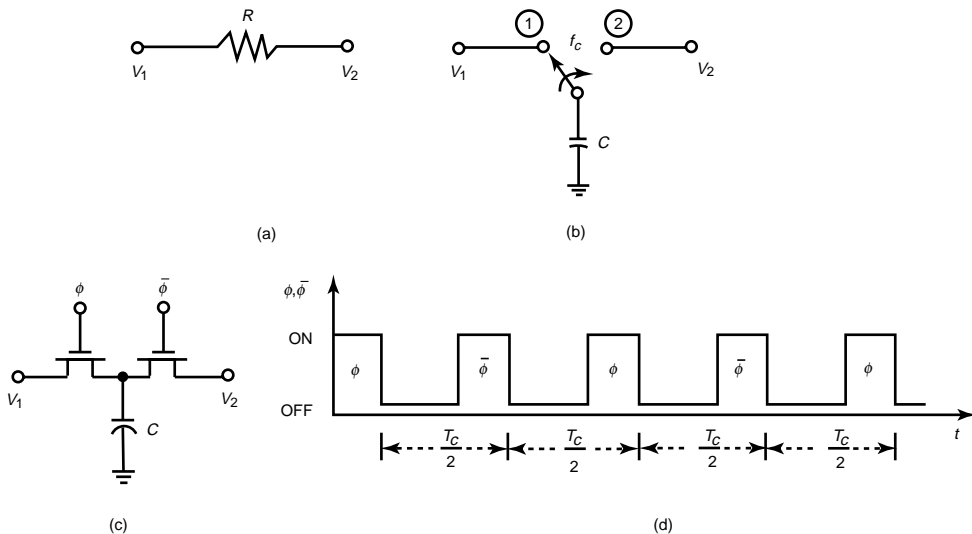

FIGURE 7.149 A switched capacitor circuit: (a) resistor to be simulated by SC, (b) SC simulation of R , (c) MOS implementation of (b), (d) waveforms of the clock signals.

(switch-1 is on) as shown, the capacitor is charging to q_1 given by

$$q_1 = C v_1 \tag{7.210}$$

It is assumed that the switch stays at that position long enough to fully charge the capacitor. Now if the switch moves to position 2 (switch-2 is on), the capacitor will be charging (discharging); if $v_2 > v_1$ ($v_2 < v_1$) at voltage v_2 , then the new charge q_2 is given by

$$q_2 = C v_2 \tag{7.211}$$

Therefore, the transfer of charge Δq is

$$\Delta q = q_1 - q_2 = C(v_1 - v_2) \tag{7.212}$$

and this will be accomplished in $T_c = 1/f_c$ s. The electric current will be, on an average

$$i(t) = \frac{\partial q}{\partial t} = \lim_{\Delta t \rightarrow 0} \frac{\Delta q}{\Delta t} \cong \frac{C(V_1 - V_2)}{T_c}, \quad T_c \ll 1 \tag{7.213}$$

The size of an equivalent resistor that yields the same value of current is then

$$R = \frac{(V_1 - V_2)}{i} \cong \frac{T_c}{C} = \frac{1}{C f_c} \tag{7.214}$$

For this approximation to be valid, it is necessary that the switching frequency f_c be much larger than the frequencies of v_1 and v_2 . This can be easily achieved in the case of audio-frequency filtering, and the SC may be regarded as a direct replacement for the resistor in RC-op amp circuits. This, however, is only valid under the assumption that v_1 and v_2 are not affected by the switch closures. Although this is in effect true in RC-op amp filters that are based on integrators, it is not true in more general circuits. In these cases simple replacement of a resistor by a SC can yield the wrong results. The practicality and technological design considerations of this approach have been discussed in details by many authors (Brodersen, Gray, and Hodges, 1979; Allstot and Black, 1983). MOS realization of the SC resistor, together with the pertinent clock signals, is shown in Fig. 7.149(c) and Fig. 7.149(d).

7.9.3 Switched-Capacitor Integrators

SC integrators are the key elements in the realization of SC filters. A straightforward realization of a SC integrator, Fig. 7.150, is obtained by applying the SC simulation of a resistor, Fig. 7.149, to the RC-op amp inverting integrator. Analysis of this circuit using the preceding approach yields approximate results. Exact results, however, can be achieved by applying a sampled-data analysis technique. Because of the sampled-data nature of SC filters, they are more accurately described, as well as designed, by the use of the z transformation (Jury, 1964). In this formulation the charge distribution in the SC circuit, for one clock

FIGURE 7.150 Realization of a SC integrator: (a) SC integrator, (b) MOS implementation of (a).

cycle, is described by a difference equation. This difference equation is then converted into an algebraic equation employing the z transformation. Moreover, the application of this transformation yields a rational function in z that describes the behavior of the SC circuit. Begin by assuming that switch-1, in Fig. 7.150, is closed (ϕ is high) and C_1 is charged to a value

$$q_1 = C_1 v_{c_1} = C_1 v_1 \quad (7.215)$$

The concept of *discrete time* (DT) is introduced at this point. The simplest way of looking at this concept is to visualize the input voltage as being sampled at some discrete point in time. Mathematically, one can state that the signal is uniformly sampled at times $t + nT_c$ where T_c is the clock period and n is an integer. The choice of values for n is arbitrary and, thus, the value $n = -1$ is chosen for this first phase. Equation (7.215) can now be rewritten as

$$q_1(t - T_c) = C_1 v_1(t - T_c) \quad (7.216)$$

Assume that the input voltage remains constant during this clock phase and C_1 charges instantly to the value in Eq. (7.216) and holds that value for the duration of that phase. This assumption is valid as long as the frequency of the input voltage is smaller than the clock frequency. During the same time interval, C_2 is holding a charge

$$q_2(t - T_c) = C_2 v_2(t - T_c) \quad (7.217)$$

Since both switch-2 and the inverting input of the op amp present infinite impedance, no current is allowed to flow through C_2 . This requires that the voltage across C_2 remains constant or, equivalently, that any charge stored in C_2 during the previous clock phase is held there during this phase. Therefore, v_2 remains constant, due to the virtual ground at the inverting input terminal of the op amp. After half-clock cycle (at the instant $t - (T_c/2)$) switch-1 is opened and switch-2 is closed (ϕ is low) connecting the top plate of C_1 directly to the inverting input of the op amp and disconnecting the input from the rest of the circuit. Because of the virtual ground, C_1 is completely discharged and all of the charge is transferred to C_2 . The net effect of this charge transfer is most easily understood with the aid of the following charge equations for this time instant:

$$\begin{aligned} q_1[t - (T_c/2)] &= 0 \\ q_2[t - (T_c/2)] &= q_2(t - T_c) + C_1 \{v_{c_1}[t - (T_c/2)] - v_{c_1}(t - T_c)\} \end{aligned} \quad (7.218a)$$

Thus

$$C_2 v_2[t - (T_c/2)] = C_2 v_2(t - T_c) + C_1 \{v_{c_1}[t - (T_c/2)] - v_{c_1}(t - T_c)\} \quad (7.218b)$$

with $v_{c_1}[t - (T_c/2)] = 0$ and $v_{c_1}(t - T_c) = v_1(t - T_c)$.

Equations (7.218) make use of the *charge conservation principle* that states that charge is neither created nor destroyed in a closed system. Once the charge transfer has taken place, all currents go to zero, and no further voltage change occur.

After another half-clock cycle (at the instant t), switch-2 is opened (ϕ is high), therefore, no change will occur in the voltage across C_2 , as explained earlier. Thus

$$v_2(t) = v_2[t - (T_c/2)] \quad (7.219)$$

Equations (7.218) and (7.219) may then be combined to form the complete difference equation

$$C_2 v_2(t) = C_2 v_2(t - T_c) - C_1 v_1(t - T_c) \quad (7.220)$$

Implicit in Eq. (7.220) is the assumption that the output of the circuit is sampled at the instants $t + nT_c$ of operation (when ϕ is high). Now applying the z transformation to Eq. (7.220) yields

$$C_2 V_2(z) = C_2 z^{-1} V_2(z) - C_1 z^{-1} V_1(z) \quad (7.221)$$

The transfer function of the integrator is then obtained as

$$\frac{V_2}{V_1}(z) = -\left(\frac{C_1}{C_2}\right) \frac{z^{-1}}{1 - z^{-1}} \tag{7.222}$$

The reader familiar with numerical integration methods can easily recognize that Eq. (7.222) is the forward-Euler numerical integration scheme. Therefore, the integrator in Fig. 7.150 with the output signal sampled when switch-1 is closed (ϕ is high) is known as the **forward-Euler discrete integrator** (FEDI).

7.9.4 Parasitic Capacitors

A major problem with the integrator of Fig. 7.150 is that it suffers from the effect of the inevitable **parasitic capacitors** that are associated with the switches and capacitors due to the MOS fabrication process. These parasitic capacitors have considerable effect on the frequency response of SC filters. It is difficult, if not impossible, to compensate for these parasitics since they do not have specific values but rather they assume a range of values that are poorly controlled. The sources of these parasitics are briefly described next (Ghausi and Laker, 1981; Gregouian and Temes, 1986).

Parasitic Capacitors Associated with the MOS Switch

On a chip associated with every MOS transistor are some undesired capacitances. This is inherent in the MOS technology. Figure 7.151 shows an NMOS switch together with the major parasitic capacitors associated with it. C_{ol} are the gate-diffusion overlap capacitances due to errors in the mask alignment. They are about 0.005 pF each and couple the clock signals into the filter. This clock feedthrough appears at the output as an additional DC offset. These parasitic capacitors can be greatly reduced by using self-alignment MOS technologies that result in very small overlaps between the gate and both the source and drain of a transistor. C_{pn} are the source- (drain-) substrate capacitance due to the reversed-biased pn junctions between the source (drain) and the substrate. They are about 0.02 pF each.

Parasitic Capacitors Associated with the MOS Capacitor

Figure 7.152 shows a cross section of a typical MOS capacitor using double polysilicon MOS technology together with the associated parasitic capacitors and an equivalent circuit model. C_{p1} is a sizable parasitic capacitance that exists from the bottom plate of the MOS capacitor C to the substrate. This is the capacitance of the silicon dioxide layer under the first layer of polysilicon, as shown in Fig. 7.152. Typically, C_{p1} can have a value in the range of 5–20% of C . C_{p2} is a small capacitance from the top plate of C to the substrate,

FIGURE 7.151 NMOS switch and the associated parasitic capacitances: (a) CMOS implementation, (b) symbolic representation.

FIGURE 7.152 Double polysilicon CMOS capacitor and the associated parasitic capacitances: (a) CMOS implementation, (b) symbolic representation

and it is due to the interconnection of C to other circuitry. Typically, values of C_{p2} can be from 0.1–1% of C , depending on the layout technique.

Recognizing that the range of capacitance values of the capacitors used as passive components in SC filters are typically from 0.01 to 100 pF, therefore, the effects of this parasitic on the frequency response should not be ignored. The design of SC filters must be done in such a way that the parasitic capacitors do not degrade the performance of the filter, as will be seen later.

The effect of the parasitic capacitors is shown in Fig. 7.153 for the FEDI. Most of the top and bottom plate parasitic capacitors, shown in Fig. 7.153(a), have no effect on V_2 since they do not deliver any charge to C_2 (C_{p12} , C_{pn22} , and C_{p21} are shorted assuming that the open-loop gain of the op amp is sufficiently high, C_{pn11} and C_{p22} are voltage driven and, therefore, they are insignificant). The overlap capacitance

FIGURE 7.153 Management of parasitic capacitances: (a) SC integrator and the associated parasitic capacitances, (b) effect of the parasitics on the performance of SC integrator.

(C_{ol1} and C_{ol2}) can be drastically reduced in the fabrication process (using the self-alignment techniques), therefore, they are irrelevant. The parasitic capacitors that have direct effect on the output of the integrator are C_{pn12} , C_{p11} , and C_{pn21} . Their parallel combination is represented by C_p as shown in Fig. 7.153(b). C_p is poorly controlled and may be as large as 0.05 pF, making the net value of C_1 uncertain. If, for example, 1% accuracy is required for C_1 , it should have value greater than 5 pF. For practical reasons, the integrating capacitance $C_2 \gg C_1$; therefore, the integrator will consume a large chip area.

7.9.5 Parasitic-Insensitive Switched-Capacitor Integrators

The effect of the parasitic capacitors can be eliminated by the use of the parasitic-insensitive integrator configurations (Hosticka, Brodersen, and Gray, 1977; Mertin and Sedra, 1979), shown in Fig. 7.154. The circuit in Fig. 7.154(a) is the parasitic-insensitive version of the FEDI, where C_1 is charging through the top plate and discharging through the bottom plate. Therefore, the transfer function of this integrator, with v_2 is sampled when ϕ is high, is a noninverting one. It should be noted that if v_1 is sampled and held for a full-clock cycle, then v_2 will also be held constant for a full cycle. The integrator shown in Fig. 7.154(c) has an inverting transfer function. Applying the charge equation method, previously described in Sec. 7.9.3, to the integrator of Fig. 7.154(c) and assuming v_2 is sampled when ϕ is high, one can easily derive the following transfer function:

$$\frac{V_2}{V_1}(z) = -\left(\frac{C_1}{C_2}\right) \frac{1}{1 - z^{-1}} \tag{7.223}$$

It should be noted that the numerical integration in Eq. (7.223) is similar to the backward-Euler numerical integration scheme. Therefore, the integrator in Fig. 7.154(c), with the output signal sampled when ϕ is high, is known as the *backward-Euler discrete integrator (BEDI)*.

The MOS implementations along with the relevant parasitic capacitors, C_{p1} and C_{p2} , are also given in Fig. 7.154(b) and Fig. 7.154(d). Note that C_{p1} and C_{p2} are periodically switched between v_1 ground and the op amp's virtual ground-ground, respectively. Therefore, they do not deliver any charge to C_2 .

FIGURE 7.154 (a) Parasitic-insensitive FEDI, (b) MOS realization of (a), (c) parasitic-insensitive BEDI, (d) MOS realization of (c).

Thus, the integrator's output voltage v_2 is insensitive to these parasitic capacitors. Also, as a result of this insensitivity, the capacitance values C_1 and C_2 need not be much larger than the parasitic. Therefore, the size of the integrator can be made smaller than that of the parasitic-sensitive realization.

7.9.6 Switched-Capacitor Biquad

Switched-capacitor circuits that realize the DT **biquadratic transfer function** of Eq. (7.224) are known in the literature as SC **biquad**. They are useful circuits to filter designers because they form a fundamental building block for the construction of higher order filters in the form of cascade or multiple-loop feedback topologies. In this section we will introduce a SC biquad that will be used later to realize higher order filters. The SC circuit shown in Fig. 7.155 realizes the general discrete-time biquadratic transfer function (El-Masry, 1980)

$$T(z) = \frac{\alpha_0 + \alpha_1 z^{-1} + \alpha_2 z^{-2}}{1 + \beta_1 z^{-1} + \beta_2 z^{-2}} \tag{7.224}$$

with no exceptions. The circuit is based on the two-integrator loop topology and implements the parasitic-insensitive inverting and noninverting BEDI and FEDI, respectively.

FIGURE 7.155 General SC biquad circuit.

Damping is provided, in general, by the SC γ_8C and $\gamma_{15}C$ (resistive damping) and by the SC $\gamma_{10}C$ and $\gamma_{12}C$ (capacitive damping). Usually only one of these four SC schemes is used. The SC γ_7C , $\gamma_{11}C$, and $\gamma_{16}C$ realize positive feedback and the SC γ_7C and $\gamma_{16}C$ provide local positive feedback. Typically, only one of these capacitors is used. Transmission zeros are realized via the *feedforward approach*; that is, the input signal is fed to the input terminal of both integrators through capacitors γ_1C and γ_5C and SCs γ_2C , γ_3C , γ_4C , and γ_6C . Assuming that the switches are operated by nonoverlapping clocks and the input signal is sampled and held for the full period T_c , then the voltage-ratio transfer functions of the circuit are obtained as (El-Masry, 1980, 1983)

$$T_1(z) = \frac{V_1}{V_{in}}(z) = \frac{a_0 + a_1z^{-1} + a_2z^{-2}}{c_0 + c_1z^{-1} + c_2z^{-2}} \tag{7.225a}$$

and

$$T_2(z) = \frac{V_2}{V_{in}}(z) = \frac{b_0 + b_1z^{-1} + b_2z^{-2}}{c_0 + c_1z^{-1} + c_2z^{-2}} \tag{7.225b}$$

where

$$\begin{aligned} a_0 &= (\gamma_4 + \gamma_5)(\gamma_9 + \gamma_{10}) - (\gamma_1 + \gamma_2)(1 + \gamma_{15}) \\ a_1 &= (\gamma_1 + \gamma_2)(1 + \gamma_{16}) + (\gamma_1 + \gamma_3)(1 + \gamma_{15}) \\ &\quad - (\gamma_4 + \gamma_5)(\gamma_9 + \gamma_{11}) - (\gamma_5 + \gamma_6)(\gamma_9 + \gamma_{10}) \\ a_2 &= (\gamma_5 + \gamma_6)(\gamma_9 + \gamma_{11}) - (\gamma_1 + \gamma_3)(1 + \gamma_{16}) \\ b_0 &= (\gamma_1 + \gamma_2)(\gamma_{12} + \gamma_{13}) - (\gamma_4 + \gamma_5)(1 + \gamma_8) \\ b_1 &= (\gamma_4 + \gamma_5)(1 + \gamma_7) + (\gamma_5 + \gamma_6)(1 + \gamma_8) \\ &\quad - (\gamma_1 + \gamma_2)(\gamma_{13} + \gamma_{14}) - (\gamma_1 + \gamma_3)(\gamma_{12} + \gamma_{13}) \\ b_2 &= (\gamma_1 + \gamma_3)(\gamma_{13} + \gamma_{14}) - (\gamma_5 + \gamma_6)(1 + \gamma_7) \\ c_0 &= (1 + \gamma_8)(1 + \gamma_{15}) - (\gamma_9 + \gamma_{10})(\gamma_{12} + \gamma_{13}) \\ c_1 &= (\gamma_9 + \gamma_{11})(\gamma_{12} + \gamma_{13}) + (\gamma_9 + \gamma_{10})(\gamma_{13} + \gamma_{14}) \\ &\quad - (1 + \gamma_7)(1 + \gamma_{15}) - (1 + \gamma_8)(1 + \gamma_{16}) \\ c_2 &= (1 + \gamma_7)(1 + \gamma_{16}) - (\gamma_9 + \gamma_{11})(\gamma_{13} + \gamma_{14}) \end{aligned} \tag{7.225c}$$

By using the bilinear z transformation

$$S = 2f_c [(1 - z^{-1}) / (1 + z^{-1})] \tag{7.226}$$

the equivalent analog pole frequency ω_0 and its Q -factor are obtained as

$$\omega_0 = 2f_c \sqrt{\frac{c_0 + c_1 + c_2}{c_0 - c_1 - c_2}} \quad \text{and} \quad Q = \frac{\sqrt{(c_0 + c_1 + c_2)(c_0 - c_1 + c_2)}}{2(c_0 - c_1)} \tag{7.227}$$

It should be noted that as a result of the sampled and held input, the output voltages V_1 and V_2 will also be held constant for the full period T_c . This feature is very useful for the realization of higher order SC filters in cascade or multiple-loop feedback topologies.

Other popular SC biquads based on the two-integrator loop topology can easily be generated from the circuit of Fig. 7.155. For example, the biquad introduced by Fleisher and Laker (1979) can be obtained from the circuit of Fig. 7.155 by letting $\gamma_1 = \gamma_5 = \gamma_7 = \gamma_8 = \gamma_{11} = \gamma_{12} = \gamma_{13} = \gamma_{16} = 0$. Also, the biquad by Martin and Sedra (1980) can be obtained from Fig. 7.155 by letting $\gamma_3 = \gamma_4 = \gamma_6 = \gamma_7 = \gamma_8 = \gamma_{11} = \gamma_{12} = \gamma_{13} = \gamma_{15} = \gamma_{16} = 0$.

Defining Terms

Biquad: An electronic circuit that realizes a biquadratic transfer function.

Biquadratic transfer function: A rational function that comprises a ratio of second-order numerator and denominator polynomials in the frequency variable.

- Forward-Euler discrete integrator (FEDI):** A discrete-time integrator based on the forward-Euler numerical integration scheme.
- Integrated circuit (IC):** A combination of interconnected circuit elements inseparably associated on or within a continuous substrate.
- Metal oxide semiconductor (MOS):** A popular type of integrated circuit technology used to fabricate chips using silicon. It refers specifically to the layer sequence: metal, silicon-dioxide, and silicon.
- Operational amplifier (op amps):** An amplifier with large gain that has two input terminals (inverting and noninverting) and normally one output terminal.
- Parasitic capacitor:** An unwanted capacitor that is unavoidable adjunct of a wanted circuit element (a capacitor or a transistor). It results from the integrated circuit fabrication process.
- Switched-capacitor filters:** An electronic circuit (fabricated from operational amplifiers, transistors, and capacitors) designed to transmit some range of signal frequencies while discriminating others.
- Very large scale integration (VLSI):** A very dense integrated circuit that contains more than 1000 elements.

7.10 Semiconductor Failure Modes⁴

Victor Meeldijk

7.10.1 Discrete Semiconductor Failure Modes

Failures of semiconductor devices in storage, or dormant applications, are the result of latent manufacturing defects that were not detected during device screening tests. For discrete semiconductors, such as transistors, a large percentage of failures are the result of **die** and **wire bonding** defects and contamination. A common failure mode of spring loaded diodes is the contact material losing its compression strength, or slipping off the die, resulting in an open circuit.

⁴Portions of this chapter were adapted from: Meeldijk, V. 1995. *Electronic Components: Selection and Application Guidelines*, Chaps. 10 and 11. Wiley Interscience, New York. Used with permission.

FIGURE 7.156 Excessive thinning or metallization.

Failure mechanisms can be grouped into three categories:

- Those independent of environment (oxide defects, diffusion defects).
- Failures dependent on environment (wire bond or **metallization** defects, see Fig. 7.156 and Fig. 7.157).
- Failure mechanisms that are time and environment dependent (metal migration, corrosion, inter-metallic compound formulations, such as caused by dissimilar metal use).

Table 7.9 and Sec. 7.10.6 discusses the various screening tests to induce failures prior to components being incorporated in assemblies.

Common failure modes of discrete semiconductors are zener diode: 50% short, 50% open; junction diode: 60–70% high reverse, 20–25% open, 10–15% short; silicon controlled rectifier (SCR): 2% open, 98% short; and transistor: 20% high leakage, 20% low gain, 30% open circuit, 30% short circuit (Fig. 7.158).

Interpretation of failure data by the Reliability Analysis Center (RAC, 1991), Rome, New York (used with permission), has the following failure mode breakdowns:

- General purpose diode: 49% short, 36% open, 15% parameter change
- Diode rectifier: 51% short, 29% open, 20% parameter change
- Small signal diode: 18% short, 24% open, 58% parameter change
- Microwave diode: 50% open, 23% parameter change (drift), 10% short, 17% intermittent
- Zener diode reference: 68% parameter change (drift), 17% open, 13% shorted, 2% intermittent
- Zener diode regulator: 45% open, 35% parameter change (drift), 20% shorted
- Optoelectronic LED: 70% open, 30% short
- Optoelectronic sensor: 50% short, 50% open
- Thyristor: 45% failed off, 40% short, 10% open, 5% failed on
- Triac: 90% failed off, 10% failed on

Further breakdown on transistor failure modes by the Reliability Analysis Center (RAC) are

- Bipolar transistor: 73% shorted, 27% open

(Note these new data contrast with that published in January 1976 by the U.S. Army Material Command (AMCP-706-196), which had 59% high collector to base leakage current, 37% low collector to emitter

FIGURE 7.157 Separation/depression of metallization and thinness of metallization. The second photograph shows an acceptable metallization step.

breakdown (B_{vceo}), and 4% open circuited).

- Field effect transistor (FET): 51% shorted, 22% low output, 17% parameter change, 5% open, 5% output high
- GaAs FET transistor: 61% open, 26% shorted, 13% parameter change
- Radio frequency (RF) transistor: 50% parameter change, 40% shorted, 10% open

7.10.2 Integrated Circuit Failure Modes

Most IC failures, as for semiconductors, are related to manufacturing defects (Fig. 7.159 is the inside view of a typical acceptable IC). A breakdown of typical IC failure mechanisms is 40.7% wire bond interconnects, 23.4% misapplication/misuse, 4.2% **masking**/etching defect, 3.3% die mechanical damage, 1.4% cracked die, 0.9% die metallization corrosion, 0.9% die contamination, and 24.8% other causes.

These mechanisms result in the following typical failure modes:

- Digital devices: 40% stuck high, 40% stuck low, 20% loss of logic
- Linear devices: 10–20% drift, 10 output high or low, 70–80% no output

Interpretation of failure data in 1991 by the Reliability Analysis Center (RAC) found the following failure mode percentages:

- Digital bipolar: 28% output stuck high, 28% output stuck low, 22% input open, 22% output open
- Digital MOS: 8% output stuck high, 9% output stuck low, 36% input open, 36% output open, 12% supply open

TABLE 7.9 Various Screening Tests Used to Detect Defects (*Continued*)

Test	Process Defect	Failure Mode
<i>Thermal shock:</i> MIL-STD-883; method 1011; JIS C 7022; A-3; IEC PUB 68; Test Nc	Die separation Die bonding	Performance degradation caused by overheating, opens or potential opens, shorts or intermittent shorts
<i>X Ray:</i>	Die bonding; Wire bonding Final seal Lead frame shape irregularities	Performance degradation caused by overheating, intermittents, shorts or opens, intermittent short circuits caused by loose conductive particles in the package.
<i>Acceleration:</i> Constant acceleration; MIL-STD-883 method 2001; JIS C 7022; A-9; IEC PUB 68; Test Ga	Die bonding Final seal	Performance degradation caused by overheating, weak wires will be open or intermittent, intermittent shorts caused by loose conductive particles in the package
<i>Hi-voltage test:</i>	Passivation Final seal	Open or short circuits, increased device leakage, low insulation breakdown
<i>ESD testing:</i> MIL-STD-883; method 3015 Electronic Industries Association of Japan (EIAJ) IC 121:20	Design susceptibility to ESD	Degraded device performance or device failure.
<i>Vibration/PIND test:</i>	Die bonding Wire bonding	Shorts or intermittent shorts caused by loose conductive particles in the package, performance degradation caused by overheating, opens and intermittents
<i>Lead fatigue:</i> Lead integrity; JIS C 7002; A-11; IEC PUB 68; Test U	Final seal	Open circuits, external lead loose
<i>Leak tests:</i> Hermetic seal tests; MIL-STD-883 method 1014; JIS C 7022; A-6; IEC PUB 68; Test Q [Pressure cooker test (PCT) to evaluate moisture resistance in a short period of time; EIAJ IC-121: 18]	Final seal	Performance degradation, shorts or opens caused by chemical corrosion or moisture, intermittents
<i>Precap visual:</i>	Slice preparation Passivation; Masking Etching; Metallizations Die separation Die bonding; Wire bonding	Increased leakage, low insulation breakdown, opens, shorts, intermittents, potential shorts or opens, high internal resistances, intermittent shorts
<i>Visual:</i>	Final seal	Open circuits; package cracks; package seal problems

- Digital programmable array logic (PAL): 80% failed truth table, 20% shorted
- Interface IC: 58% output stuck low, 16% input open, 16% output open, 10% supply open
- Linear IC: 50% degraded/improper output, 41% no output, 3% shorted, 2% open, 2% drift
- Linear-op amps: 69% degraded (unstable, clipped output, drifted etc.), 13% intermittent, 10% shorted, 6% overstressed by transients, 3% no output
- Bipolar memory: 79% slow transfer of data, 21% data bit loss
- MOS memory: 34% data bit loss, 26% short, 23% open, 17% slow transfer of data
- Digital memory: 30% single bit error, 25% column error, 25% row error, 10% row and column error, 10% complete failure

TABLE 7.10 Hybrid Microcircuits—Failure Accelerating Environments

Accelerating Environment	Environments Failure Mechanism	Failure Mode
Mechanical stress (thermal shock, vibration)	Substrate bonding; Cracked/broken substrate; Faulty bonds	Open circuits
High temperature	Damaged resistors	Open or out of tolerance
Thermal cycling	Cracked resistors; Various film defects Excess bonding time Thermal coefficient of expansion mismatch between film and substrate	Open or out of tolerance
High voltage and temperature test	Various film defects; Excess bonding time Thermal coefficient of expansion mismatch between film and substrate	Out of tolerance
Thermal and mechanical stress	Cracked dice; Shorted wires Faulty bonds; Bond separation	Open circuits; Short circuits

- Digital memory RAM: 25% no operation at cold temperatures, 17% parameter change, 16% shorted, 13% open, 13% incorrect data, 7% contaminated (particles inside cavity of hermetic sealed unit)
- Ultraviolet erasable programmable read only memory (UVEPROM): 94% open (unprogrammable) bit locations, 6% would not erase
- Hybrid devices: 51% open circuit (caused by resistor/capacitor opens, internal bond pad corrosion and electromigration), 26% degraded/improper output (distorted or slow response time output), 17% short circuit (**electrostatic discharge (ESD)** overstress, fractures, shorting wire bonds), 6% no output

The analysis data, which can be interpreted by the reader for various applications, is in their report (RAC, 1991). Most vendors have reliability reports on their products that discuss the results of accelerated life tests and provide a device failure rate.

7.10.3 Hybrid Microcircuits and Failures

Hybrid devices are a combination of active components (microcircuits or ICs) and various passive discrete parts mounted on a substrate and interconnected by conductive film traces. Hybrid failure mechanisms, like those of discrete and integrated circuits, are primarily due to manufacturing defects. Failures will occur whether the device is operating or dormant. Various accelerating environments, such as temperature or vibration can reveal the failure mechanisms before parts are shipped (or used in circuits). Table 7.10 lists the accelerating environments and the problems they reveal.

7.10.4 Memory IC Failure Modes

Memory ICs failures result in the inability to read or write data, erroneous data storage, unacceptable output levels, and slow access time. The specific failures that cause these problems are as follows:

- Open and short circuits: can cause various problems from a single bit error to a catastrophic failure of the whole device.
- Open decoder circuits: cause addressing problems to the memory.
- *Multiple writes*: writing one cell actually writes to that cell and other cells (multiple write and address uniqueness problems).
- Pattern sensitivity: the contents of a cell become complemented due to read and write operations in electrically adjacent cells (cell disturbances, adjacent cell disturbances, column disturbances, adjacent column disturbances, row disturbance, adjacent row disturbance).

- *Write recovery*: the access time of the device may be slower than specified when each read cycle is preceded by a write cycle, or a number of write cycles.
- Address decoder switching time: this time can vary depending on the state of the address decoder prior to switching and on the state to which the decoder is switching.
- Sense amplifier sensitivity: memory information may be incorrect after reading a long series of similar data bits followed by a single transition of the opposite data value.
- *Sleeping sickness*: the memory loses information in less than the specified hold time (for DRAMs).
- Refresh problems (may be static or dynamic): the static refresh test checks the data contents after the device has been inactive during a refresh. In dynamic refresh, the device remains active and some cells are refreshed. All cells are then tested to check whether the data in the nonrefreshed cells is still correct.

Special tests are needed for memory devices to insure the integrity of every memory bit location. These functional tests are composed of four basic tests, pattern tests, background tests, timing test, and voltage level tests. A summary of these tests is contained in Table 7.11.

Memory tests cannot be specified to test each part 100% as a RAM can contain any one of 2^N different data patterns and can be addressed in N factorial ($N!$) address sequences without using the same address twice. Test times shown may be extremely long for some high-density memory devices; a GALPAT test for a 4 M DRAM would take 106 days to execute. It is easy to see how impractical it is to overspecify device testing. Any test plan should be developed along with the supplier of the memory devices you are to purchase.

System level tests may use bit-map graphics where the status of the memory cells is displayed on the cathode ray tube (CRT) display of the system (i.e., failing bits show up as a wrong color). Various patterns are read into the memory and the CRT may be configured to show 1 cell equivalent to one pixel (a picture element) or compressed to show 4, 16, or 64 cells per pixel depending on the number of pixels available and the memory size. Zoom features can be used to scale the display for close examination of failing areas of the memory.

Note, in large memory intensive systems, consider using error correction codes to correct hard (permanent failure) and soft errors (i.e., alpha particle upsets, a single upset that does not occur again). One vendor of video RAMs estimates a soft error rate of a 1 Meg part of 3.9 FITs (at a 500-ns cycle time with V_{cc} at 4.5 V, and a 4 Meg DRAM error rate of 41 FITs (at a 90% confidence level, 5 V_{cc} operation with 15.625- μ s cycle (refresh) rate). Soft error rates are dependent on cycle time and operating voltage; the lower the voltage and faster the cycle time, the higher the failure in time rate. One thousand FITs equals 1 PPM (1 failure in 10^6 h), which equals 0.1%/1000 (0.1% failures every 1000 h). When calculating soft error rates, add the refresh mode rate and the active mode rate, which can be determined from acceleration curves provided by the manufacturer.

7.10.5 IC Packages and Failures

Devices can be classified by package style, which can either be **hermetically** sealed (**ceramic** or metal cans) or nonhermetic (epoxy, silicones, phenolics or plastic encapsulated). Materials employed in most microcircuits will change very slowly if stored in a dry environment at a constant low temperature.

Hermetic packages, glass, ceramic, or metal, protect the device from environmental atmospheric effects. Depending on the metal package it can take anywhere from 50 to well over 100 years for the inside of the IC package to reach 50% of the humidity of the outside air. An epoxy package can take anywhere from minutes to a few days. Therefore, equipment designed for harsh environments, such as might be encountered in military applications, use hermetically sealed devices. Plastic packaged devices are low cost, offer mechanical shock and vibration resistance, are free from loose particles inside the device as they do not have a cavity, and are available in smaller package sizes. All plastics, however, contain some moisture and are permeable to moisture to some degree. (Salt environments have also been shown to

TABLE 7.11 Tests for Memory Circuits

Test	Comments
March	An N pattern test that checks for functional cell failures (opens and shorts and address unique faults) and data sensitivity. In this test a background of 0s is written into memory. Then a 1 is written into each sequential cell. Each cell is then tested and changed back to 0 in reverse order until the first address is reached. The same sequence is then repeated by loading in a background of 1s.
Masest	An N pattern test that checks for address uniqueness and address decoder problems (open decode lines). This is an alternating Multiple-Address Selection test that writes a background of 0s to the memory device at the min address, then the max address, then the min +1 address, then the max -1 address, etc. All cells are then read and verified and a complementary pattern of 1s is read into the memory device and the test is repeated.
Refresh	Any one of several patterns designed to test for an acceptable refresh time. Usually an N pattern test
Sliding diagonal	An $N^{3/2}$ pattern that checks for address decoder problems, sense amplifier faults, and sense amplifier recovery. This test is a pattern that generates a diagonal of data in a field of complement data, and slides the diagonal of data in the x direction, creating a barber pole effect.
Surround disturbance	An N pattern test that checks for adjacent cell disturbance. Variations include a row disturbance and column disturbance.
Galloping tests	This is a sequence test where a base cell, containing complement data from the rest of the cells in its set (i.e., the base cell is 1 but the other cells are 0). A set may be a column, row, device or adjacent cells to the base cell.
Walking tests	Walking tests are similar to galloping tests except that the cells in the set with the base cell are read sequentially instead of alternately with the base cell.
Galloping/walking tests:	
GALPAT rows (galloping rows) Rows	An $N^{3/2}$ pattern test that checks adjacent cell walking disturbance and row/column disturbance.
GALPAT columns (galloping columns) Walking columns	An $N^{3/2}$ test that checks for row/column disturbances.
GALPAT (galloping pattern test)	A $4N^2$ pattern test that checks for address decoder problems, adjacent cell disturbances, row/column disturbances and sense amplifier recovery. This is a long execution time test. Into a background of 0s the first cell is complemented (to 1) and then read alternately with every other cell in memory. This sequence is repeated until every memory cell is tested. The test is then repeated with a background of 1s with the cell changed to 0.
GALDIG (galloping diagonal) pattern test	This test finds unsatisfactory address transitions between each cell and the positions in the cell's diagonal. It also finds slow sense amplifier recovery and destruction of stored data due to noise coupling among cells in a column. In this test a diagonal of 1s is written into a background of 0s. All cells are read and verified and the diagonal is then shifted horizontally. This keeps repeating until the diagonal has been shifted throughout the memory. The test is then repeated with complemented data.
GALWREC	A galloping write recovery test, an N^2 pattern test

(continued)

TABLE 7.12 Tests for Memory Circuits (Continued)

Test	Comments
WALKPAT (walking pattern)	An N^2 test that checks for address uniqueness and sense amplifier recovery. This is a long execution time test. In a background of 0s, the first cell is complemented and then all the other cells are read sequentially. The cell is then changed back to zero and the next cell is complemented and all the other cells are then read sequentially again. This repeats for all of the memory cells and then repeats again with a background of 1s with each cell changed to a 0. (A single 1 moves through a field of 0s and a single 0 is moved through a field of 1s.)
Dual walking columns MOVI (moving inversion)	An $N^{3/2}$ pattern test This test checks for address propagation failures. It is similar to a march but in addition uses each address line as the least significant bit in a counting sequence.
Scan test	Each cell is written, or read, sequentially. The addressing sequence can count up from the minimum address (minmax) or down from the maximum address (maxmin). Either the x or y axis can be the fast axis (rowfast or columnfast, respectively).
Address complement	An addressing sequence in which all address lines, except one, are changed in each cycle.
Background tests (may be used with the preceding tests)	
Checkerboard inverted checkerboard	An N pattern test that checks for functional cell failures and data sensitivity (to noise). Each cell is checked to verify that it can be forced to a 1 or a 0. Each cell is surrounded by cells with complementary data (a logical 1 stored in a cell would be surrounded by cells that have logical 0 stored in them). Variations include double checkerboard and complemented double checkerboard which have the same execution time.
Pseudocheckerboard	This checkerboard pattern is generated by exclusive OR-ing data with the least significant row address bit and the least significant column address bit (data XOR X_0 XOR Y_0). This may not generate a true checkerboard background in parts that have folded digit lines, and so a different equation may be necessary for these parts.
Zeros/ones	An N pattern test. A background of either solid 1s or 0s is stored in each cell.
Row stripes	Background data where every row is surrounded by its complement. Therefore a row with logical 1 stored in it would be surrounded by rows with logical 0 in them.
Column stripes	Like row stripes but background data relates to columns instead of rows.
Double variations	The size of the background is doubled, two rows, two columns, or a double checkerboard with two rows by two columns.
Parity	Background data that are generated when the parity of the x and y addresses is even or odd.
Bit map graphics (test that can be used to check memory at system level)	Used to examine patterns of failing cells, characterize the operating regions of memory devices, verify device specifications. This test identifies mask misalignment, diffusion anomalies, contamination defects, design sensitivities and semiconductor defects.

effect silicone encapsulated devices but leave epoxy novalac parts relatively unaffected). The mismatch in thermal coefficients of the plastic vs. the die also reduces the operating temperature of the device from 0 to 70°C vs. hermetic packages, which can operate from -55 to +125°C.

Studies have been done by the Microelectronics and Computer Technology Corporation (Austin, Texas) and Lehigh University on replacing hermetic packages with more effective lightweight protective coatings. Their program, *reliability without hermeticity* (RwoH), was initiated by a research contract awarded to them by the U.S. Air Force Wright Laboratory. The RwoH is an industry working group, initiated in 1988, to address nonhermetic electronic packaging issues, specifically, coating to provide environmental protection for semiconductor devices and multichip modules.

The Joint Electron Device Engineering Council (JEDEC) specification A112 defines six levels of moisture sensitivity with level 1 being the highest rating, or not moisture sensitive. The other levels are reduced levels, such as level 3, which ensures product integrity (i.e., from **popcorning** from entrapped moisture during soldering) when stored at 30°C, 85% Rh for 168 h. Level 4 indicates package integrity is ensured for 84 h, and level 6 only permits 6 h of exposure. Plastic parts shipped in sealed bags with desiccant usually are designed for a 12-mo storage and should only be opened when the parts are to be used. Parts stored for longer than this time, especially plastic quad flatpack (PQFP) packaged devices, should be baked to remove the moisture that has entered the package. Entrapped moisture can vaporize during rapid heating, such as in a solder reflow process, and these stresses can cause package cracking. Subsequent high-temperature and moisture exposures can allow contaminants to enter the IC and cause failure at a later time due to corrosion.

Note Hughes Missile Systems reported in 1995 of conditions where organic-based (such as organic acid (OA)) water-soluble fluxes lead to dendrite growth and short circuits. It was found that component seals of high lead glass **frit** (glass frit is used in cerdip and ceramic flat pack components) and tin and lead on the device **leads** results in the growth of lead dendrites on the surface of the glass seals. The lead comes from the high lead oxide content of the soft glass itself. High temperatures accelerate the dendrite growth, with shorts occurring in as little as 5 min with 140°F warm flux. Prevention of this problem includes using different fluxes and minimizing the application of fluxes to the component side of the PC board. Dendrite growth has also been reported for kovar flatpacks stored in foil-lined cardboard packaging. The chlorine dendrite growth, resulting in a high electrical leakage from pins to case, resulted from the chemical impurities in the cardboard and the device. Fiberboard and paperboard packaging is no longer used for device unit packaging. **Tin whisker** growth also occurs with parts having pure tin plating on the leads.

Specific IC packages have definite failures associated with their use. These include

- *Ball grid array* (BGA) or *Overmolded pad-array carrier* (OMPAC): In manufacture, the primary failure mode for this package is short circuits (98% vs. 2% open circuits).
- *Flip chip*: In manufacture, the primary failure mode for a flip chip on an MCM module is a short circuit.
- PQFP: Packages are susceptible to moisture-induced cracking in applications requiring reflow soldering.
- Quad flatpack (QFP): The most common quad flatpack manufacturing failure mode is a short circuit (82% short circuits, 2% open circuits, and 16% misalignment problems).
- Tape carrier package (TCP): Tape automated bonding (TAB) package has an open circuit (98% vs. 2% misalignment problems) failure mode.

Table 7.9 uses the environmental conditions as screening tests to detect parts that may prematurely fail because of a problem or manufacturing defect. The table shows the various screening tests that can be used to detect the various defects that effect microcircuit reliability. The screens that are rated as good to excellent in identifying component defects, and that are low in cost, are high-temperature storage, temperature cycling, thermal shock, nitrogen bomb test (this tests hermetic package seals), and gross leak test (which also tests hermetic package seals). Screening tests are done prior to putting devices in stock for future use. Proper ESD procedures and controls should be followed, and because of ESD

degradation effects the parts should not be periodically handled or tested; only electrically test devices prior to use.
