The Hebb (1949) learning rule is based on the assumption that if two neighbor neurons must be activated and deactivated at the same time, then the weight connecting these neurons should increase. For neurons operating in the opposite phase, the weight between them should decrease. If there is no signal correlation, the weight should remain unchanged. This assumption can be described by the formula

$$\Delta w_{ij} = cx_i o_j \quad (19.9)$$

where

- w_{ij} = weight from i th to j th neuron
- c = learning constant
- x_i = signal on the i th input
- o_j = output signal

The training process starts usually with values of all weights set to zero. This learning rule can be used for both soft and hard threshold neurons. Since desired responses of neurons is not used in the learning procedure, this is the **unsupervised learning** rule. The absolute values of the weights are usually proportional to the learning time, which is undesired.

Correlation Learning Rule

The correlation learning rule is based on a similar principle as the Hebbian learning rule. It assumes that weights between simultaneously responding neurons should be largely positive, and weights between neurons with opposite reaction should be largely negative.

Contrary to the Hebbian rule, the correlation rule is the **supervised learning**. Instead of actual response o_j , the desired response d_j is used for the weight change calculation

$$\Delta w_{ij} = cx_i d_j \quad (19.10)$$

This training algorithm usually starts with initialization of weights to zero values.

Instar Learning Rule

If input vectors and weights are normalized, or they have only binary bipolar values (-1 or $+1$), then the *net* value will have the largest positive value when the weights and the input signals are the same. Therefore, weights should be changed only if they are different from the signals

$$\Delta w_i = c(x_i - w_i) \quad (19.11)$$

Note, that the information required for the weight is taken only from the input signals. This is a very local and unsupervised learning algorithm.

Winner Takes All (WTA)

The WTA is a modification of the instar algorithm where weights are modified only for the neuron with the highest *net* value. Weights of remaining neurons are left unchanged. Sometimes this algorithm is modified in such a way that a few neurons with the highest net values are modified at the same time. Although this is an unsupervised algorithm because we do not know what are desired outputs, there is a need for “judge” or “supervisor” to find a winner with a largest net value. The WTA algorithm, developed by Kohonen (1982), is often used for automatic clustering and for extracting statistical properties of input data.

Outstar Learning Rule

In the outstar learning rule, it is required that weights connected to a certain node should be equal to the desired outputs for the neurons connected through those weights

$$\Delta w_{ij} = c(d_j - w_{ij}) \quad (19.12)$$

where d_j is the desired neuron output and c is small learning constant, which further decreases during the learning procedure. This is the supervised training procedure because desired outputs must be known. Both instar and outstar learning rules were developed by Grossberg (1969).

Widrow-Hoff LMS Learning Rule

Widrow and Hoff (1960, 1962) developed a supervised training algorithm which allows training a neuron for the desired response. This rule was derived so that the square of the difference between the net and output value is minimized.

$$Error_j = \sum_{p=1}^P (net_{jp} - d_{jp})^2 \quad (19.13)$$

where:

$Error_j$ = error for j th neuron

P = number of applied patterns

d_{jp} = desired output for j th neuron when p th pattern is applied

net = given by Eq. (19.2).

This rule is also known as the least mean square (LMS) rule. By calculating a derivative of Eq. (19.13) with respect to w_{ij} , a formula for the weight change can be found,

$$\Delta w_{ij} = cx_i \sum_{p=1}^P (d_{jp} - net_{jp}) \quad (19.14)$$

Note that weight change Δw_{ij} is a sum of the changes from each of the individual applied patterns. Therefore, it is possible to correct the weight after each individual pattern was applied. This process is known as *incremental updating*; *cumulative updating* is when weights are changed after all patterns have been applied. Incremental updating usually leads to a solution faster, but it is sensitive to the order in which patterns are applied. If the learning constant c is chosen to be small, then both methods give the same result. The LMS rule works well for all types of activation functions. This rule tries to enforce the *net* value to be equal to desired value. Sometimes this is not what the observer is looking for. It is usually not important what the *net* value is, but it is important if the *net* value is positive or negative. For example, a very large *net* value with a proper sign will result in correct output and in large error as defined by Eq. (19.13) and this may be the preferred solution.

Linear Regression

The LMS learning rule requires hundreds or thousands of iterations, using formula (19.14), before it converges to the proper solution. Using the linear regression rule, the same result can be obtained in only one step.

Considering one neuron and using vector notation for a set of the input patterns X applied through weight vector w , the vector of *net* values net is calculated using

$$Xw = net \tag{19.15}$$

where

- X = rectangular array $(n + 1) \times p$
- n = number of inputs
- p = number of patterns

Note that the size of the input patterns is always augmented by one, and this additional weight is responsible for the threshold (see Fig. 19.3(b)). This method, similar to the LMS rule, assumes a linear activation function, and so the *net* values net should be equal to desired output values d

$$Xw = d \tag{19.16}$$

Usually $p > n + 1$, and the preceding equation can be solved only in the least mean square error sense. Using the vector arithmetic, the solution is given by

$$w = (X^T X)^{-1} X^T d \tag{19.17}$$

When traditional method is used the set of p equations with $n + 1$ unknowns Eq. (19.16) has to be converted to the set of $n + 1$ equations with $n + 1$ unknowns

$$Yw = z \tag{19.18}$$

where elements of the Y matrix and the z vector are given by

$$y_{ij} = \sum_{p=1}^P x_{ip}x_{jp} \quad z_i = \sum_{p=1}^P x_{ip}d_p \tag{19.19}$$

Weights are given by Eq. (19.17) or they can be obtained by a solution of Eq. (19.18).

Delta Learning Rule

The LMS method assumes linear activation function $net = o$, and the obtained solution is sometimes far from optimum, as is shown in Fig. 19.20 for a simple two-dimensional case, with four patterns belonging to two categories. In the solution obtained using the LMS algorithm, one pattern is misclassified. If error is defined as

$$Error_j = \sum_{p=1}^P (o_{jp} - d_{jp})^2 \tag{19.20}$$

Then the derivative of the error with respect to the weight w_{ij} is

$$\frac{d Error_j}{dw_{ij}} = 2 \sum_{p=1}^P (o_{jp} - d_{jp}) \frac{df(net_{jp})}{d net_{jp}} x_i \tag{19.21}$$

since $o = f(net)$ and the net is given by Eq. (19.2). Note that this derivative is proportional to the derivative of the activation function $f'(net)$. Thus, this type of approach is possible only for continuous activation

FIGURE 19.20 An example with a comparison of results obtained using LMS and delta training algorithms. Note that LMS is not able to find the proper solution.

functions and this method cannot be used with hard activation functions (19.4) and (19.5). In this respect the LMS method is more general. The derivatives most common continuous activation functions are

$$f' = o(1 - o) \tag{19.22}$$

for the unipolar (Eq. (19.6)) and

$$f' = 0.5(1 - o^2) \tag{19.23}$$

for the bipolar (Eq. (19.7)).

Using the cumulative approach, the neuron weight w_{ij} should be changed with a direction of gradient

$$\Delta w_{ij} = c x_i \sum_{p=1}^P (d_{jp} - o_{jp}) f'_{jp} \tag{19.24}$$

in case of the incremental training for each applied pattern

$$\Delta w_{ij} = c x_i f'_j (d_j - o_j) \tag{19.25}$$

the weight change should be proportional to input signal x_i , to the difference between desired and actual outputs $d_{jp} - o_{jp}$, and to the derivative of the activation function f'_{jp} . Similar to the LMS rule, weights can be updated in both the incremental and the cumulative methods. In comparison to the LMS rule, the delta rule always leads to a solution close to the optimum. As it is illustrated in Fig. 19.20, when the delta rule is used, all four patterns are classified correctly.

Error Backpropagation Learning

The delta learning rule can be generalized for multilayer networks. Using an approach similar to the delta rule, the gradient of the global error can be computed with respect to each weight in the network. Interestingly,

$$\Delta w_{ij} = c x_i f'_j E_j \tag{19.26}$$

where

- c = learning constant
- x_i = signal on the i th neuron input
- f'_j = derivative of activation function

FIGURE 19.21 Illustration of the concept of gain computation in neural networks.

The cumulative error E_j on neuron output is given by

$$E_j = \frac{1}{f'_j} \sum_{k=1}^K (o_k - d_k) A_{jk} \tag{19.27}$$

where K is the number of network outputs A_{jk} is the small signal gain from the input of j th neuron to the k th network output, as Fig. 19.21 shows. The calculation of the backpropagating error starts at the output layer and cumulative errors are calculated layer by layer to the input layer. This approach is not practical from the point of view of hardware realization. Instead, it is simpler to find signal gains from the input of the j th neuron to each of the network outputs (Fig. 19.21). In this case, weights are corrected using

$$\Delta w_{ij} = c x_i \sum_{k=1}^K (o_k - d_k) A_{jk} \tag{19.28}$$

Note that this formula is general, regardless of if neurons are arranged in layers or not. One way to find gains A_{jk} is to introduce an incremental change on the input of the j th neuron and observe the change in the k th network output. This procedure requires only forward signal propagation, and it is easy to implement in a hardware realization. Another possible way is to calculate gains through each layer and then find the total gains as products of layer gains. This procedure is equally or less computationally intensive than a calculation of cumulative errors in the error backpropagation algorithm.

The backpropagation algorithm has a tendency for oscillation. To smooth the process, the weights increment Δw_{ij} can be modified according to Rumelhart, Hinton, and Williams (1986)

$$w_{ij}(n + 1) = w_{ij}(n) + \Delta w_{ij}(n) + \alpha \Delta w_{ij}(n - 1) \tag{19.29}$$

or according to Sejnowski and Rosenberg (1987)

$$w_{ij}(n + 1) = w_{ij}(n) + (1 - \alpha) \Delta w_{ij}(n) + \alpha \Delta w_{ij}(n - 1) \tag{19.30}$$

where α is the momentum term.

The backpropagation algorithm can be significantly sped up, when, after finding components of the gradient, weights are modified along the gradient direction until a minimum is reached. This process can be carried on without the necessity of a computationally intensive gradient calculation at each step. The new gradient components are calculated once a minimum is obtained in the direction of the previous gradient.

FIGURE 19.22 Illustration of the modified derivative calculation for faster convergence of the error backpropagation algorithm.

This process is only possible for cumulative weight adjustment. One method of finding a minimum along the gradient direction is the *tree step process* of finding error for three points along gradient direction and then, using a parabola approximation, jump directly to the minimum. The fast learning algorithm using the described approach was proposed by Fahlman (1988) and is known as the *quickprop*.

The backpropagation algorithm has many disadvantages, which lead to very slow convergence. One of the most painful is that in the backpropagation algorithm, the learning process almost perishes for neurons responding with the maximally wrong answer. For example, if the value on the neuron output is close to +1 and desired output should be close to -1, then the neuron gain $f'(net) \approx 0$ and the error signal cannot backpropagate, and so the learning procedure is not effective. To overcome this difficulty, a modified method for derivative calculation was introduced by Wilamowski and Torvik (1993). The derivative is calculated as the slope of a line connecting the point of the output value with the point of the desired value, as shown in Fig. 19.22.

$$f_{\text{modif}} = \frac{o_{\text{desired}} - o_{\text{actual}}}{net_{\text{desired}} - net_{\text{actual}}} \quad (19.31)$$

Note that for small errors, Eq. (19.31) converges to the derivative of activation function at the point of the output value. With an increase of system dimensionality, the chances for local minima decrease. It is believed that the described phenomenon, rather than a trapping in local minima, is responsible for convergence problems in the error backpropagation algorithm.

19.3.5 Special Feedforward Networks

The multilayer backpropagation network, as shown in Fig. 19.17, is a commonly used feedforward network. This network consists of neurons with the sigmoid type continuous activation function presented in Fig. 19.16(c) and Fig. 19.16(d). In most cases, only one hidden layer is required, and the number of neurons in the hidden layer are chosen to be proportional to the problem complexity. The number of neurons in the hidden layer is usually found by a trial-and-error process. The training process starts with all weights randomized to small values, and the error backpropagation algorithm is used to find a solution. When the learning process does not converge, the training is repeated with a new set of randomly chosen weights. Nguyen and Widrow (1990) proposed an experimental approach for the two-layer network weight initialization. In the second layer, weights are randomly chosen in the range from -0.5 to +0.5. In the first layer, initial weights are calculated from

$$w_{ij} = \frac{\beta z_{ij}}{\|z_j\|}; \quad w_{(n+1)j} = \text{random}(-\beta, +\beta) \quad (19.32)$$

where z_{ij} is the random number from -0.5 to $+0.5$ and the scaling factor β is given by

$$\beta = 0.7P^{\frac{1}{N}} \tag{19.33}$$

where n is the number of inputs and N is the number of hidden neurons in the first layer. This type of weight initialization usually leads to faster solutions.

For adequate solutions with backpropagation networks, typically many tries are required with different network structures and different initial random weights. It is important that the trained network gains a generalization property. This means that the trained network also should be able to handle correctly patterns that were not used for training. Therefore, in the training procedure, often some data are removed from the training patterns and then these patterns are used for verification. The results with backpropagation networks often depend on luck. This encouraged researchers to develop feedforward networks, which can be more reliable. Some of those networks are described in the following sections.

Functional Link Network

One-layer neural networks are relatively easy to train, but these networks can solve only linearly separated problems. One possible solution for nonlinear problems presented by Nilsson (1965) and elaborated by Pao (1989) using the functional link network is shown in Fig. 19.23. Using nonlinear terms with initially determined functions, the actual number of inputs supplied to the one-layer neural network is increased. In the simplest case, nonlinear elements are higher order terms of input patterns. Note that the functional link network can be treated as a one-layer network, where additional input data are generated off line using nonlinear transformations. The learning procedure for one-layer is easy and fast. Figure 19.24 shows an XOR problem solved using functional link networks. Note that when the functional link approach is used, this difficult problem becomes a trivial one. The problem with the functional link network is that proper selection of nonlinear elements is not an easy task. In many practical cases, however, it is not difficult to predict what kind of transformation of input data may linearize the problem, and so the functional link approach can be used.

FIGURE 19.23 The functional link network.

FIGURE 19.25 The counterpropagation network.

Feedforward Version of the Counterpropagation Network

The *counterpropagation network* was originally proposed by Hecht-Nilsen (1987). In this section a modified feedforward version as described by Zurada (1992) is discussed. This network, which is shown in Fig. 19.25, requires numbers of hidden neurons equal to the number of input patterns, or more exactly, to the number of input clusters. The first layer is known as the Kohonen layer with unipolar neurons. In this layer only one neuron, the winner, can be active. The second is the Grossberg outstar layer. The Kohonen layer can be trained in the unsupervised mode, but that need not be the case. When binary input patterns are considered, then the input weights must be exactly equal to the input patterns. In this case,

$$net = \mathbf{x}^t \mathbf{w} = [n - 2HD(\mathbf{x}, \mathbf{w})] \quad (19.34)$$

where

n = number of inputs

\mathbf{w} = weights

\mathbf{x} = input vector

$HD(\mathbf{w}, \mathbf{x})$ = Hamming distance between input pattern and weights

For a neuron in the input layer to be reacting just for the stored pattern, the threshold value for this neuron should be

$$w_{(n+1)} = -(n - 1) \quad (19.35)$$

If it is required that the neuron must also react for similar patterns, then the threshold should be set to $w_{n+1} = -[n - (1 + HD)]$, where HD is the Hamming distance defining the range of similarity. Since for a given input pattern only one neuron in the first layer may have the value of 1 and remaining neurons have 0 values, the weights in the output layer are equal to the required output pattern.

The network, with unipolar activation functions in the first layer, works as a lookup table. When the linear activation function (or no activation function at all) is used in the second layer, then the network also can be considered as an analog memory. For the address applied to the input as a binary vector, the stored set of analog values, as weights in the second layer, can be accurately recovered. The feedforward counterpropagation network may also use analog inputs, but in this case all input data should

be normalized.

$$w_i = \hat{x}_i = \frac{x_i}{\|x_i\|} \tag{19.36}$$

The counterpropagation network is very easy to design. The number of neurons in the hidden layer is equal to the number of patterns (clusters). The weights in the input layer are equal to the input patterns, and the weights in the output layer are equal to the output patterns. This simple network can be used for rapid prototyping. The counterpropagation network usually has more hidden neurons than required. However, such an excessive number of hidden neurons are also used in more sophisticated feedforward networks such as the *probabilistic neural network* (PNN) Specht (1990) or the *general regression neural networks* (GRNN) Specht (1992).

WTA Architecture

The winner takes all network was proposed by Kohonen (1988). This is basically a one-layer network used in the unsupervised training algorithm to extract a statistical property of the input data (Fig. 19.26(a)). At the first step, all input data are normalized so that the length of each input vector is the same and, usually, equal to unity (Eq. (19.36)). The activation functions of neurons are unipolar and continuous. The learning process starts with a weight initialization to small random values. During the learning process the weights are changed only for the neuron with the highest value on the output—the winner.

$$\Delta w_w = c(x - w_w) \tag{19.37}$$

where

- w_w = weights of the winning neuron
- x = input vector
- c = learning constant

Usually, this single-layer network is arranged into a two-dimensional layer shape, as shown in Fig. 19.26(b). The hexagonal shape is usually chosen to secure strong interaction between neurons. Also, the algorithm is modified in such a way that not only the winning neuron but also neighboring neurons are allowed for the weight change. At the same time, the learning constant c in Eq. (19.37) decreases with the distance from the winning neuron. After such a unsupervised training procedure, the Kohonen layer is able to organize data into clusters. Output of the Kohonen layer is then connected to the one- or two-layer feedforward network with the error backpropagation algorithm. This initial data organization in the WTA layer usually leads to rapid training of the following layer or layers.

Cascade Correlation Architecture

The cascade correlation architecture was proposed by Fahlman and Lebiere (1990). The process of network building starts with a one-layer neural network and hidden neurons are added as needed. The network architecture is shown in Fig. 19.27. In each training step, a new hidden neuron is added and its weights are adjusted to maximize the magnitude

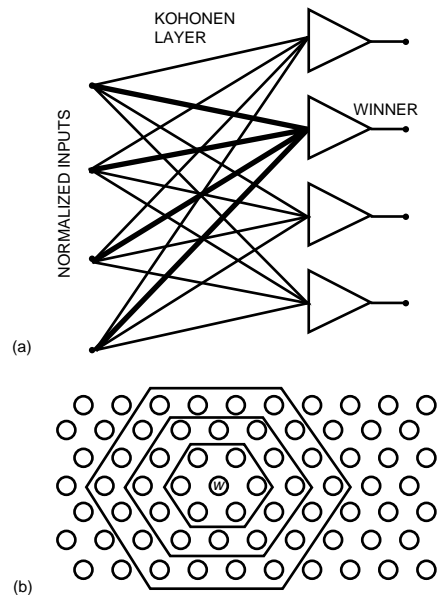

FIGURE 19.26 A winner takes all architecture for cluster extracting in the unsupervised training mode: (a) Network connections, (b) single-layer network arranged into a hexagonal shape.

FIGURE 19.27 The cascade correlation architecture.

of the correlation between the new hidden neuron output and the residual error signal on the network output to be eliminated. The correlation parameter S must be maximized.

$$S = \sum_{o=1}^O \left| \sum_{p=1}^P (V_p - \bar{V})(E_{po} - \bar{E}_o) \right| \tag{19.38}$$

where

- O = number of network outputs
- P = number of training patterns
- V_p = output on the new hidden neuron
- E_{po} = error on the network output

\bar{V} and \bar{E}_o are average values of V_p and E_{po} , respectively. By finding the gradient, $\delta S / \delta w_i$, the weight adjustment for the new neuron can be found as

$$\Delta w_i = \sum_{o=1}^O \sum_{p=1}^P \sigma_o (E_{po} - \bar{E}_o) f'_p x_{ip} \tag{19.39}$$

where

- σ_o = sign of the correlation between the new neuron output value and network output
- f'_p = derivative of activation function for pattern p
- x_{ip} = input signal

The output neurons are trained using the delta or quickprop algorithms. Each hidden neuron is trained just once and then its weights are frozen. The network learning and building process is completed when satisfactory results are obtained.

Radial Basis Function Networks

The structure of the radial basis network is shown in Fig. 19.28. This type of network usually has only one hidden layer with special neurons. Each of these neurons responds only to the inputs signals close to the stored pattern. The output signal h_i of the i th hidden neuron is computed using formula

$$h_i = \exp\left(-\frac{\|\mathbf{x} - \mathbf{s}_i\|^2}{2\sigma^2}\right) \tag{19.40}$$

where

x = input vector

s_i = stored pattern representing the center of the i cluster

σ_i = radius of the cluster

Note that the behavior of this “neuron” significantly differs from the biological neuron. In this “neuron,” excitation is not a function of the weighted sum of the input signals. Instead, the distance between the input and stored pattern is computed. If this distance is zero then the neuron responds with a maximum output magnitude equal to one. This neuron is capable of recognizing certain patterns and generating output signals that are functions of a similarity. Features of this neuron are much more powerful than a neuron used in the backpropagation networks. As a consequence, a network made of such neurons is also more powerful.

If the input signal is the same as a pattern stored in a neuron, then this neuron responds with 1 and remaining neurons have 0 on the output, as is illustrated in Fig. 19.28. Thus, output signals are exactly equal to the weights coming out from the active neuron. This way, if the number of neurons in the hidden layer is large, then any input/output mapping can be obtained. Unfortunately, it may also happen that for some patterns several neurons in the first layer will respond with a nonzero signal. For a proper approximation, the sum of all signals from the hidden layer should be equal to one. To meet this requirement, output signals are often normalized as shown in Fig. 19.28.

The radial-based networks can be designed or trained. Training is usually carried out in two steps. In the first step, the hidden layer is usually trained in the unsupervised mode by choosing the best patterns for cluster representation. An approach, similar to that used in the WTA architecture can be used. Also in this step, radii σ_i must be found for a proper overlapping of clusters.

The second step of training is the error backpropagation algorithm carried on only for the output layer. Since this is a supervised algorithm for one layer only, the training is very rapid, 100–1000 times faster than in the backpropagation multilayer network. This makes the radial basis-function network very attractive. Also, this network can be easily modeled using computers, however, its hardware implementation would be difficult.

FIGURE 19.28 A typical structure of the radial basis function network.

19.3.6 Recurrent Neural Networks

In contrast to feedforward neural networks, with **recurrent networks** neuron outputs can be connected with their inputs. Thus, signals in the network can continuously circulate. Until recently, only a limited number of recurrent neural networks were described.

Hopfield Network

The single-layer recurrent network was analyzed by Hopfield (1982). This network, shown in Fig. 19.29, has unipolar hard threshold neurons with outputs equal to 0 or 1. Weights are given by a symmetrical square matrix \mathbf{W} with zero elements ($w_{ij} = 0$ for $i = j$) on the main diagonal. The stability of the system is usually analyzed by means of the *energy function*

$$E = -\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N W_{ij} v_i v_j \quad (19.41)$$

It has been proved that during signal circulation the energy E of the network decreases and the system converges to the stable points. This is especially true when the values of system outputs are updated in the asynchronous mode. This means that at a given cycle, only one random output can be changed to the required values. Hopfield also proved that those stable points which the system converges can be programmed by adjusting the weights using a modified Hebbian rule,

$$\Delta w_{ij} = \Delta w_{ji} = (2v_i - 1)(2v_j - 1)c \quad (19.42)$$

Such memory has limited storage capacity. Based on experiments, Hopfield estimated that the maximum number of stored patterns is $0.15N$, where N is the number of neurons.

Later the concept of energy function was extended by Hopfield (1984) to one-layer recurrent networks having neurons with continuous activation functions. These types of networks were used to solve many optimization and linear programming problems.

Autoassociative Memory

Hopfield (1984) extended the concept of his network to autoassociative memories. In the same network structure as shown in Fig. 19.29, the bipolar hard-threshold neurons were used with outputs equal to -1

FIGURE 19.29 A Hopfield network or autoassociative memory.

or +1. In this network, pattern s_m are stored into the weight matrix W using the autocorrelation algorithm

$$W = \sum_{m=1}^M s_m s_m^T - MI \tag{19.43}$$

where M is the number of stored pattern and I is the unity matrix. Note that W is the square symmetrical matrix with elements on the main diagonal equal to zero (w_{ji} for $i = j$). Using a modified formula (19.42), new patterns can be added or subtracted from memory. When such memory is exposed to a binary bipolar pattern by enforcing the initial network states, after signal circulation the network will converge to the closest (most similar) stored pattern or to its complement. This stable point will be at the closest minimum of the energy

$$E(v) = -\frac{1}{2} v^T W v \tag{19.44}$$

Like the Hopfield network, the autoassociative memory has limited storage capacity, which is estimated to be about $M_{max} = 0.15N$. When the number of stored patterns is large and close to the memory capacity, the network has a tendency to converge to spurious states, which were not stored. These spurious states are additional minima of the energy function.

Bidirectional Associative Memories (BAM)

The concept of the autoassociative memory was extended to bidirectional associative memories (BAM) by Kosko (1987, 1988). This memory, shown in Fig. 19.30, is able to associate pairs of the patterns a and b . This is the two-layer network with the output of the second layer connected directly to the input of the first layer. The weight matrix of the second layer is W^T and W for the first layer. The rectangular weight matrix W is obtained as a sum of the cross-correlation matrixes

$$W = \sum_{m=1}^M a_m b_m \tag{19.45}$$

where M is the number of stored pairs, and a_m and b_m are the stored vector pairs. If the nodes a or b are initialized with a vector similar to the stored one, then after signal circulations, both stored patterns a_m and b_m should be recovered. The BAM has limited memory capacity and memory corruption problems similar to the autoassociative memory. The BAM concept can be extended for association of three or more vectors.

FIGURE 19.30 An example of the bi-directional autoassociative memory: (a) drawn as a two-layer network with circulating signals, (b) drawn as two-layer network with bi-directional signal flow.

19.3.7 Fuzzy Systems

The main applications of neural networks are related to the nonlinear mapping of n -dimensional input variables into m -dimensional output variables. Such a function is often required in control systems, where for specific measured variables certain control variables must be generated. Another approach for nonlinear mapping of one set of variables into another set of variables is the *fuzzy controller*. The principle of operation of the fuzzy controller significantly differs from neural networks. The block diagram of a fuzzy controller is shown in Fig. 19.31.

FIGURE 19.31 The block diagram of the fuzzy controller.

In the first step, analog inputs are converted into a set of fuzzy variables. In this step, for each analog input, 3–9 fuzzy variables typically are generated. Each fuzzy variable has an analog value between zero and one. In the next step, a fuzzy logic is applied to the input fuzzy variables and a resulting set of output variables is generated. In the last step, known as *defuzzification*, from a set of output fuzzy variables, one or more output analog variables are generated, which are used as control variables.

Fuzzification

The purpose of fuzzification is to convert an analog variable input into a set of fuzzy variables. For higher accuracy, more fuzzy variables will be chosen. To illustrate the fuzzification process, consider that the input variable is the temperature and is coded into five fuzzy variables: cold, cool, normal, warm, and hot. Each fuzzy variable should obtain a value between zero and one, which describes a *degree of association* of the analog input (temperature) within the given fuzzy variable. Sometimes, instead of the term degree of association, the term *degree of membership* is used. The process of fuzzification is illustrated in Fig. 19.32. Using Fig. 19.32 we can find the degree of association of each fuzzy variable with the given temperature. For example, for a temperature of 57°F, the following set of fuzzy variables is obtained: (0, 0.5, 0.2, 0, 0), and for $T = 80^\circ\text{F}$ it is (0, 0, 0.25, 0.7, 0). Usually only one or two fuzzy variables have a value other than zero. In the example, trapezoidal functions are used for calculation of the degree of association. Various different functions such as triangular or Gaussian, can also be used, as long as the computed value is in the range from zero to one. Each membership function is described by only three or four parameters, which have to be stored in memory.

For proper design of the fuzzification stage, certain practical rules should be used:

- Each point of the input analog variable should belong to at least one and no more than two membership functions.
- For overlapping functions, the sum of two membership functions must not be larger than one. This also means that overlaps must not cross the points of maximum values (ones).
- For higher accuracy, more membership functions should be used. However, very dense functions lead to frequent system reaction and sometimes to system instability.

FIGURE 19.32 Fuzzification process: (a) typical membership functions for the fuzzification and the defuzzification processes, (b) example of converting a temperature into fuzzy variables.

Rule Evaluation

Contrary to Boolean logic where variables can have only binary states, in fuzzy logic all variables may have any values between zero and one. The fuzzy logic consists of the same basic \wedge - AND, \vee -OR, and NOT operators

$$\begin{aligned}
 A \wedge B \wedge C &\implies \min\{A, B, C\} \text{—smallest value of } A \text{ or } B \text{ or } C \\
 A \vee B \vee C &\implies \max\{A, B, C\} \text{—largest value of } A \text{ or } B \text{ or } C \\
 \bar{A} &\implies 1 - A \quad \text{—one minus value of } A
 \end{aligned}$$

For example $0.1 \wedge 0.7 \wedge 0.3 = 0.1$, $0.1 \vee 0.7 \vee 0.3 = 0.7$, and $\bar{0.3} = 0.7$. These rules are also known as Zadeh AND, OR, and NOT operators (Zadeh, 1965). Note that these rules are true also for classical binary logic.

Fuzzy rules are specified in the *fuzzy table* as it is shown for a given system. Consider a simple system with two analog input variables x and y , and one output variable z . The goal is to design a fuzzy system generating z as $f(x, y)$. After fuzzification, the analog variable x is represented by five fuzzy variables: x_1, x_2, x_3, x_4, x_5 and an analog variable y is represented by three fuzzy variables: y_1, y_2, y_3 . Assume that an analog output variable is represented by four fuzzy variables: z_1, z_2, z_3, z_4 . The key issue of the design process is to set proper output fuzzy variables z_k for all combinations of input fuzzy variables, as is shown in the table in Fig. 19.33. The designer has to specify many rules such as if inputs are represented by fuzzy variables x_i and y_j , then the output should be represented by fuzzy variable z_k . Once the fuzzy table is specified, the fuzzy logic computation proceeds in two steps. First each field of the fuzzy table is filled with intermediate fuzzy variables t_{ij} , obtained from AND operator $t_{ij} = \min\{x_i, y_j\}$, as shown in Fig. 19.33(b). This step is independent of the required rules for a given system. In the second step, the OR (max) operator is used to compute each output fuzzy variable z_k . In the given example in Fig. 19.33, $z_1 = \max\{t_{11}, t_{12}, t_{21}, t_{41}, t_{51}\}$, $z_2 = \max\{t_{13}, t_{31}, t_{42}, t_{52}\}$, $z_3 = \max\{t_{22}, t_{23}, t_{43}\}$, $z_4 = \max\{t_{32}, t_{34}, t_{53}\}$. Note that the formulas depend on the specifications given in the fuzzy table shown in Fig. 19.33(a).

	y_1	y_2	y_3
x_1	z_1	z_1	z_2
x_2	z_1	z_3	z_3
x_3	z_1	z_3	z_4
x_4	z_2	z_3	z_4
x_5	z_2	z_3	z_4

	y_1	y_2	y_3
x_1	t_{11}	t_{12}	t_{13}
x_2	t_{21}	t_{22}	t_{23}
x_3	t_{31}	t_{32}	t_{33}
x_4	t_{41}	t_{42}	t_{43}
x_5	t_{51}	t_{52}	t_{53}

FIGURE 19.33 Fuzzy tables: (a) table with fuzzy rules, (b) table with the intermediate variables t_{ij} .

Defuzzification

As a result of fuzzy rule evaluation, each analog output variable is represented by several fuzzy variables. The purpose of defuzzification is to obtain analog outputs. This can be done by using a membership function similar to that shown in Fig. 19.32. In the first step, fuzzy variables obtained from rule evaluations are used to modify the membership function employing the formula

$$\mu_k^*(z) = \min\{\mu_k(z), z_k\} \tag{19.46}$$

For example, if the output fuzzy variables are: 0, 0.2, 0.7, 0.0, then the modified membership functions have shapes shown by the thick line in Fig. 19.34. The analog value of the z variable is found as a *center of gravity* of modified membership functions $\mu_k^*(z)$,

$$z_{\text{analog}} = \frac{\left(\sum_{k=1}^n \int_{-\infty}^{+\infty} \mu_k^*(z) z dz \right)}{\left(\sum_{k=1}^n \int_{-\infty}^{+\infty} \mu_k^*(z) dz \right)} \tag{19.47}$$

FIGURE 19.34 Illustration of the defuzzification process.

In the case where shapes of the output membership functions $\mu_k(z)$ are the same, the equation can be simplified to

$$z_{\text{analog}} = \frac{\left(\sum_{k=1}^n z_k z c_k \right)}{\left(\sum_{k=1}^n z_k \right)} \tag{19.48}$$

where

- n = number of membership functions of z_{analog} output variable
- z_k = fuzzy output variables obtained from rule evaluation
- $z c_k$ = analog values corresponding to the center of k th membership function.

Equation (19.47) is usually too complicated to be used in a simple microcontroller based system; therefore, in practical cases, Eq. (19.48) is used more frequently.

19.3.8 Design Example

Consider the design of a simple fuzzy controller for a sprinkler system. The sprinkling time is a function of humidity and temperature. Four membership functions are used for the temperature, three for humidity, and three for the sprinkle time, as shown in Fig. 19.35. Using intuition, the fuzzy table can be developed, as shown in Fig. 19.36(a).

Assume a temperature of 60°F and 70% humidity. Using the membership functions for temperature and humidity the following fuzzy variables can be obtained for the temperature: (0, 0.2, 0.5, 0), and for

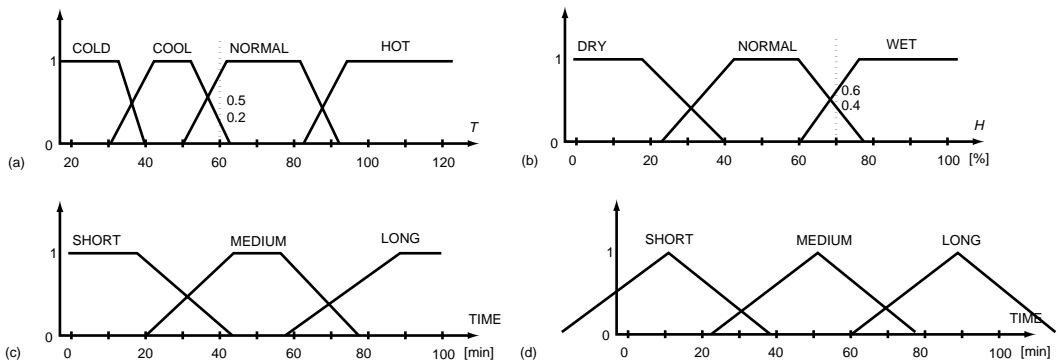

FIGURE 19.35 Membership functions for the presented example: (a) and (b) are membership functions for input variables, (c) and (d) are two possible membership functions for the output variable.

the humidity: (0, 0.4, 0.6). Using the min operator, the fuzzy table can be now filled with temporary fuzzy variables, as shown in Fig. 19.36(b). Note that only four fields have nonzero values. Using fuzzy rules, as shown in Fig. 19.36(a), the max operator can be applied in order to obtain fuzzy output variables: short $\rightarrow o_1 = \max\{0, 0, 0.2, 0.5, 0\} = 0.5$, medium $\rightarrow o_2 = \max\{0, 0, 0.2, 0.4, 0\} = 0.4$, long $\rightarrow o_3 = \max\{0, 0\} = 0$. Using Eq. (19.47) and Fig. 19.35(c) a sprinkle time of 28 min is determined. When the simplified approach is used with Eq. (19.46) and Fig. 19.35(d), then sprinkle time is 27 min.

19.3.9 Genetic Algorithms

The success of the artificial neural networks encouraged researchers to search for other patterns in nature to follow. The power of genetics through evolution was able to create such sophisticated machines as the human being. Genetic algorithms follow the evolution process in nature to find better solutions to some complicated problems. The foundations of genetic algorithms are given by Holland (1975) and Goldberg (1989). After initialization, the steps *selection*, *reproduction with a crossover*, and *mutation* are repeated for each generation. During this procedure, certain strings of symbols, known as chromosomes, evaluate toward a better solution. The genetic algorithm method begins with coding and an initialization. All significant steps of the genetic algorithm will be explained using a simple example of finding a maximum of the function $(\sin^2 x - 0.5x)^2$ (Fig. 19.37) with the range of x from 0 to 1.6. Note that in this range, the function has a global maximum at $x = 1.309$, and a local maximum at $x = 0.262$.

FIGURE 19.37 Function $(\sin^2 x - 0.5x)^2$ for which the minimum must be sought.

TABLE 19.3 Initial Population

String number	String	Decimal value	Variable value	Function value	Fraction of total
1	101101	45	1.125	0.0633	0.2465
2	101000	40	1.000	0.0433	0.1686
3	010100	20	0.500	0.0004	0.0016
4	100101	37	0.925	0.0307	0.1197
5	001010	10	0.250	0.0041	0.0158
6	110001	49	1.225	0.0743	0.2895
7	100111	39	0.975	0.0390	0.1521
8	000100	40	0.100	0.0016	0.0062
Total				0.2568	1.0000

Coding and Initialization

At first, the variable x has to be represented as a string of symbols. With longer strings, the process usually converges faster, so the fewer the symbols for one string field that are used, the better. Although this string may be the sequence of any symbols, the binary symbols 0 and 1 are usually used. In our example, six bit binary numbers are used for coding, having a decimal value of $40x$. The process starts with a random generation of the initial population given in Table 19.3.

Selection and Reproduction

Selection of the best members of the population is an important step in the genetic algorithm. Many different approaches can be used to rank individuals. In this example the ranking function is given. Highest rank has member number 6, and lowest rank has member number 3. Members with higher rank should have higher chances to reproduce. The probability of reproduction for each member can be obtained as a fraction of the sum of all objective function values. This fraction is shown in the last column of Table 19.3. Note that to use this approach, our objective function should always be positive. If it is not, the proper normalization should be introduced at first.

Reproduction

The numbers in the last column of Table 19.3 show the probabilities of reproduction. Therefore, most likely members number 3 and 8 will not be reproduced, and members 1 and 6 may have two or more copies. Using a random reproduction process, the following population, arranged in pairs, could be generated

101101 → 45 110001 → 49 100101 → 37 110001 → 49
 100111 → 39 101101 → 45 110001 → 49 101000 → 40

If the size of the population from one generation to another is the same, two parents should generate two children. By combining two strings, two other strings should be generated. The simplest way to do this is to split in half each of the parent strings and exchange substrings between parents. For example, from parent strings 010100 and 100111, the following child strings will be generated 010111 and 100100. This process is known as the *crossover*. The resultant children are

101111 → 47 110101 → 53 100001 → 33 110000 → 48
 100101 → 37 101001 → 41 110101 → 53 101001 → 41

In general, the string need not be split in half. It is usually enough if only selected bits are exchanged between parents. It is only important that bit positions are not changed.

TABLE 19.4 Population of Second Generation

String number	String	Decimal value	Variable value	Function value	Fraction of total
1	010111	47	1.175	0.0696	0.1587
2	100100	37	0.925	0.0307	0.0701
3	110101	53	1.325	0.0774	0.1766
4	010001	41	1.025	0.0475	0.1084
5	100001	33	0.825	0.0161	0.0368
6	110101	53	1.325	0.0774	0.1766
7	110000	48	1.200	0.0722	0.1646
8	101001	41	1.025	0.0475	0.1084
Total				0.4387	1.0000

Mutation

In the evolutionary process, reproduction is enhanced with mutation. In addition to the properties inherited from parents, offspring acquire some new random properties. This process is known as mutation. In most cases mutation generates low-ranked children, which are eliminated in the reproduction process. Sometimes, however, the mutation may introduce a better individual with a new property. This prevents the process of reproduction from degeneration. In genetic algorithms, mutation usually plays a secondary role. For very high-levels of mutation, the process is similar to random pattern generation, and such a searching algorithm is very inefficient. The mutation rate is usually assumed to be at a level well below 1%. In this example, mutation is equivalent to the random bit change of a given pattern. In this simple case, with short strings and a small population, and with a typical mutation rate of 0.1%, the patterns remain practically unchanged by the mutation process. The second generation for this example is shown in Table 19.4.

Note that two identical highest ranking members of the second generation are very close to the solution $x = 1.309$. The randomly chosen parents for the third generation are

010111 → 47 110101 → 53 110000 → 48 101001 → 41
 110101 → 53 110000 → 48 101001 → 41 110101 → 53

which produces the following children

010101 → 21 110000 → 48 110001 → 49 101101 → 45
 110111 → 55 110101 → 53 101000 → 40 110001 → 49

The best result in the third population is the same as in the second one. By careful inspection of all strings from the second or third generation, it may be concluded that using crossover, where strings are always split in half, the best solution 110100 → 52 will never be reached, regardless of how many generations are created. This is because none of the population in the second generation has a substring ending with 100. For such crossover, a better result can be only obtained due to the mutation process, which may require many generations. Better results in the future generation also can be obtained when strings are split in random places. Another possible solution is that only randomly chosen bits are exchanged between parents.

The genetic algorithm almost always leads to a good solution, but sometimes many generations are required. This solution is usually close to global maximum, but not the best. In the case of a smooth function the gradient methods are converging much faster and to a better solution. GA are much slower, but more robust.

Defining Terms

Backpropagation: Training technique for multilayer neural networks.

Bipolar neuron: Neuron with output signal between -1 and +1.

Feedforward network: Network without feedback.

Perceptron: Network with hard threshold neurons.

Recurrent network: Network with feedback.

Supervised learning: Learning procedure when desired outputs are known.

Unipolar neuron: Neuron with output signal between 0 and +1.

Unsupervised learning: Learning procedure when desired outputs are unknown.

19.4 Machine Vision

David A. Kosiba and Rangachar Kasturi

19.4.1 Introduction

Machine vision, also known as computer vision, is the scientific discipline whereby explicit, meaningful descriptions of physical objects from the world around us are constructed from their images. Machine vision produces measurements or abstractions from geometrical properties and comprises techniques for estimating features in images, relating feature measurements to the geometry of objects in space, and interpreting this geometric information. This overall task is generally termed *image understanding*.

The goal of a machine vision system is to create a model of the real world from images or sequences of images. Since images are two-dimensional projections of the three-dimensional world, the information is not directly available and must be recovered. This recovery requires the inversion of a many-to-one mapping. To reclaim this information, however, knowledge about the objects in the scene and projection geometry is required.

At every stage in a machine vision system decisions must be made requiring knowledge of the application or goal. Emphasis in machine vision systems is on maximizing the automatic operation at each stage, and these systems should use knowledge to accomplish this. The knowledge used by the system includes models of features, image formation, objects, and relationships among objects. Without explicit use of knowledge, machine vision systems can be designed to work only in a very constrained environment for limited applications. To provide more flexibility and robustness, knowledge is represented explicitly and is directly used by the system. Knowledge is also used by the designers of machine vision systems in many implicit as well as explicit forms. In fact, the efficacy and efficiency of a system is usually governed by the quality of the knowledge used by the system. Difficult problems are often solvable only by identifying the proper source of knowledge and appropriate mechanisms to use it in the system.

Relationship to Other Fields

Machine vision is closely related to many other disciplines and incorporates various techniques adopted from many well-established fields, such as physics, mathematics, and psychology. Techniques developed from many areas are used for recovering information from images. In this section, we briefly describe some very closely related fields.

Image processing techniques generally transform images into other images; the task of information recovery is left to a human user. This field includes topics such as image enhancement, image compression, and correcting blurred or out-of-focus images (Gonzalez and Woods, 1982). On the other hand, machine vision algorithms take images as inputs but produce other types of outputs, such as representations for the object contours in an image or the motion of objects in a series of images. Thus, emphasis in machine vision is on recovering information automatically, with minimal interaction with a human. Image processing algorithms are useful in the early stages of a machine vision system. They are usually used to enhance particular information and suppress noise.

Computer graphics generates images from geometric primitives such as lines, circles, and free-form surfaces. Computer graphics techniques play a significant role in visualization and virtual reality (Foley et al., 1990). Machine vision is the inverse problem: estimating the geometric primitives and other features from the image. Thus, computer graphics is the synthesis of images, and machine vision is the analysis of images. However, these two fields are growing closer. Machine vision is using curve and surface representations and several other techniques from computer graphics, and computer graphics is using many techniques from machine vision to enter models into the computer for creating realistic images. Visualization and virtual reality are bringing these two fields closer.

Pattern recognition classifies numerical and symbolic data. Many statistical and syntactical techniques have been developed for classification of patterns. Techniques from pattern recognition play an important role in machine vision for recognizing objects. In fact, many vision applications rely heavily on pattern recognition. Object recognition in machine vision usually requires many other techniques. For a complete discussion of pattern recognition techniques, see Duda and Hart (1973).

Artificial intelligence is concerned with designing systems that are intelligent and with studying computational aspects of intelligence (Winston, 1992; Tanimoto, 1995). Artificial intelligence is used to analyze scenes by computing a symbolic representation of the scene contents after the images have been processed to obtain features. Artificial intelligence may be viewed as having three stages: perception, cognition, and action. Perception translates signals from the world into symbols, cognition manipulates the symbols, and action translates the symbols into signals that effect changes in the world. Many techniques from artificial intelligence play important roles in all aspects of machine vision. In fact, machine vision is often considered a subfield of artificial intelligence. Directly related to artificial intelligence is the study of *neural networks*. The design and analysis of neural networks has become a very active field in the last decade (Kosko, 1992). Neural networks are being increasingly applied to solve some machine vision problems.

Psychophysics, along with cognitive science, has studied human vision for a long time (Marr, 1982). Some techniques in machine vision are related to what is known about human vision. Many researchers in computer vision are more interested in preparing computational models of human vision than in designing machine vision systems. Therefore, some of the techniques used in machine vision have a strong similarity to those in psychophysics.

Fundamentals of Vision

Like other developing disciplines, machine vision is based on certain fundamental principles and techniques. To design and develop successful machine vision systems, one must have a full understanding of all aspects of the system, from initial image formation to final scene interpretation. The following is a list of the primary topics in machine vision:

- Image formation
- Segmentation
- Feature extraction and matching
- Three-dimensional object recognition
- Dynamic vision

In each of these processes, numerous factors influence the choice of algorithms and techniques to be used in developing a specific system. The system designer should be knowledgeable about the design issues of the system and the tradeoffs between the various algorithms and techniques available. In the following, we very briefly introduce these topics. Throughout the following sections, we make no attempt to cite all original work as the list would be nearly endless. The references, however, do give credit appropriately, and we refer you to the Further Information section for a complete discussion on these and many other topics.

19.4.2 Image Formation

An image is formed when a sensor records received radiation as a two-dimensional function. The brightness or intensity values in an image may represent different physical entities. For example, in a typical image obtained by a video camera, the intensity values represent the reflectance of light from various object surfaces in the scene; in a thermal image, they represent the temperature of corresponding regions in the scene; and in range imaging, they represent the distance from the camera to various points in the scene. Multiple images of the same scene are often captured using different types of sensors to facilitate more robust and reliable interpretation of the scene. Selecting an appropriate image formation system plays a key role in the design of practical machine vision systems. The following sections describe the principles of image formation.

Imaging Geometry

A simple camera-centered imaging model is shown in Fig. 19.38. The coordinate system is chosen such that the xy plane is parallel with the image plane and the z axis passes through the lens center at a distance f , the focal length of the camera, from the image plane. The image of a scene point (x, y, z) forms a point (x', y') on the image plane where

$$x' = x \frac{f}{z} \quad \text{and} \quad y' = y \frac{f}{z} \quad (19.49)$$

These are the *perspective projection* equations of the imaging system.

In a typical imaging situation, the camera may have several degrees of freedom, such as translation, pan, and tilt. Also, more than one camera may be imaging the same scene from different points. In this case, it is convenient to adopt a world coordinate system in reference to which the scene coordinates and camera coordinates are defined. In this situation, however, the imaging equations become more cumbersome and we refer you to the references at the end of this chapter for a more complete discussion of imaging geometry including camera calibration.

Image Intensity

Although imaging geometry uniquely determines the relationship between scene coordinates and image coordinates, the brightness or intensity at each point is determined not only by the imaging geometry but also by several other factors, including scene illumination, reflectance properties and surface orientations of objects in the scene, and radiometric properties of the imaging sensor.

The reflectance properties of a surface are characterized by its *bidirectional reflectance distribution function* (BRDF). The BRDF is the ratio of the scene radiance in the direction of the observer to the irradiance due to a light source from a given direction. It captures how bright a surface will appear when viewed from a given direction and illuminated by another. For example, for a flat Lambertian surface illuminated by a distant point light source, the BRDF is constant; hence, the surface appears equally bright from all directions. For a flat specular (mirrorlike) surface, the BRDF is an impulse function as determined by the laws of reflection.

FIGURE 19.38 The camera-centered coordinate system imaging model.

The scene radiance at a point on the surface of an object depends on the reflectance properties of the surface, as well as on the intensity and direction of the illumination sources. For example, for a Lambertian surface illuminated by a point light source, the scene radiance is proportional to the cosine of the angle between the surface normal and the direction of illumination. This relationship between surface orientation and brightness is captured in the *reflectance map*. In the reflectance map for a given surface and illumination, contours of equal brightness are plotted as a function of surface orientation specified by the gradient space coordinates (p, q) , where p and q are the surface gradients in the x and y directions, respectively. A typical reflectance map for a Lambertian surface illuminated by a point source is shown in Fig. 19.39. In this figure, the brightest point corresponds to the surface orientation such that its normal points in the direction of the source. Since image brightness is proportional to scene radiance, a direct relationship exists between the image intensity at an image point and the orientation of the surface of the corresponding scene point. *Shape-from-shading* algorithms exploit this relationship to recover the three-dimensional object shape. *Photometric stereo* exploits the same principles to recover the shape of objects from multiple images obtained by illuminating the scene from different directions.

FIGURE 19.39 The reflectance map for a typical Lambertian surface illuminated by a point source from the direction $(p, q) = (0.2, 0.4)$.

Sampling and Quantization

A continuous function cannot be represented exactly in a computer. The interface between the imaging system and the computer must sample the continuous image function at a finite number of points and represent each sample within a finite number of bits. This is called **sampling** and **quantization**. Each image sample is a *pixel*. Generally images are sampled on a regular grid of squares so that the horizontal and vertical distances between pixels are the same throughout the image. Each pixel is represented in the computer as a small integer and represented as a two-dimensional array. Frequently, a pixel is represented as an unsigned 8-b integer in the range of $(0, 255)$, with 0 corresponding to black, 255 corresponding to white, and shades of gray distributed in between.

Many cameras acquire an analog image, which is then sampled and quantized to convert it to a digital image. The sampling rate determines how many pixels the digital image will have (image resolution), and the quantization determines how many intensity levels will be used to represent the intensity value at each sample point. As shown in Fig. 19.40(a) and Fig. 19.40(b), an image looks very different at different sampling

FIGURE 19.40 Sample image: (a) various spatial resolutions, (b) at differing numbers of quantization levels. Notice the blocky structure in (a) and the appearance of many *false contours* in (b). (Source: Jain, R., Kasturi, R., and Schunk, B.G. 1995. *Machine Vision*. McGraw-Hill, New York. With permission.)

rates and quantization levels. In most machine vision applications, the sampling rate and quantization are predetermined due to the limited choice available of cameras and image acquisition hardware. In many applications, however, it is important to know the effects of sampling and quantization.

Color Vision

The previous sections were only concerned with the intensity of light; however, light consists of a full spectrum of wavelengths. Images can include samples from a number of different wavelengths, leading to a color image. This perception of color depends on (1) the spectral reflectance of scene surfaces, (2) the spectral content of the illuminating light source, and (3) the spectral response of the sensors in the imaging system. In humans, color perception is attributed to differences in the spectral responses of the millions of neurochemical photoreceptors—rods and cones—in the retina. The rods are responsible for monochromatic vision and the cones are responsible for the sensation of color. The human visual system consists of three types of cones, each with a different spectral response. The total response each of the cones is often modeled by the integral

$$R_i(\lambda) = \int f(\lambda)r(\lambda)h_i(\lambda)d\lambda \quad i = 1, 2, 3 \quad (19.50)$$

where λ is the wavelength of light incident on the receptor, $f(\lambda)$ the spectral composition of the illumination, $r(\lambda)$ the spectral reflectance function of the reflecting surface, and $h_i(\lambda)$ the spectral response of the i th type of receptor (cone).

In machine vision, color images are typically represented by the output of three different sensors, each having a different spectral response (e.g., the primary colors red, green, and blue). The choice of these primary colors determines the range of possible colors that can be realized by weighted combinations of the primaries. However, it is not necessary for the response of the sensors to be restricted to visible light. The sensors could just as easily respond to wavelengths in the infrared, ultraviolet, or X-ray portions of the electromagnetic spectrum, for example. In either case, the imaging system creates multiple images, called *channels*, one for each sensor. If the outputs from three sensors are used, this translates into a threefold increase in the processing and memory requirements. However, this increase is often offset by exploiting the extra dimensionality that is now available.

Range Imaging

Although three-dimensional information can be extracted from images with two-dimensional intensity—using image cues such as shading, texture, and motion—the problem is greatly simplified by range imaging. Range imaging is acquiring images for which the value at each pixel is a function of the distance of the corresponding point of the object from the sensor. The resulting images are known as *range images* or *depth maps*. A sample range image of a coffee cup is shown in Fig. 19.41. Here we will briefly discuss two common range imaging techniques, namely *imaging radar* and *triangulation*.

FIGURE 19.41 A range image of a coffee mug.

Imaging Radar

In a time-of-flight pulsed radar system, the distance to the object is computed by observing the time difference between transmitted and received electromagnetic pulses. Range information can also be obtained by detecting the phase difference between the transmitted and received waves of an amplitude-modulated beam or by detecting the beat frequency in a coherently mixed transmitted-and-received signal in a frequency-modulated beam.

FIGURE 19.42 A triangulation-based range imaging system. (Source: Best, P.J. 1988. Active, optical range imaging sensor. *Machine Vision and Applications* 1(2): 127–152.)

Triangulation

In an active triangulation-based range imaging system, a light projector and camera are aligned along the z axis separated by a baseline distance b as shown in Fig. 19.42. The object coordinates (x, y, z) are related to the image coordinates (x', y') and the projection angle θ by the following equation:

$$[x \ y \ z] = \frac{b}{f \cot \theta - x'} [x' \ y' \ f] \quad (19.51)$$

The accuracy with which the angle θ and the horizontal position x' can be measured determines the range resolution of such a triangulation system. This system of active triangulation uses a single point light source that is swept across the scene in a raster scan fashion.

Structured Lighting

Imaging using structured lighting refers to systems in which the scene is illuminated by a known geometric pattern of light. In a simple point projection system—like the triangulation system already described—the scene is illuminated, one point at a time, in a two-dimensional grid pattern. The depth at each point is calculated using the previous equation to obtain the range image. In a typical structured lighting system, either planes or two-dimensional patterns of light are projected onto the scene. A camera, which is displaced spatially from the source of illumination, records the patterns of light projected on the object light surfaces. The distortions contained in the observed images of the patterns are determined by the shape and orientation of surfaces of the objects on which the patterns are projected (see Fig. 19.43).

In situations where the scene is changing dynamically, projecting single light stripes in sequence may not be practical due to the sequential nature of the system. In this situation, a set of multiple light stripes—each uniquely encoded—is projected. For example, using a *binary-coded* scheme, a complete set of data can be acquired by projecting only $\log_2 N$ patterns, where $N - 1$ is the total number of stripes in each pattern. Other structured lighting techniques include *color coding*, *grid coding*, and *Fourier domain processing*. The primary drawback of any structured lighting technique is that data cannot be obtained for object points that are not visible to either the light source or the imaging camera.

Active Vision

Most machine vision systems rely on data captured by hardware with fixed characteristics. These systems include passive sensing systems—such as video cameras—and active sensing systems—such as laser range finders. In an active vision system, the parameters and characteristics of data capture are dynamically controlled by the scene interpretation system. Active vision systems may employ either active or passive sensors. In an active vision system, however, the state parameters of the sensors, such as focus, aperture, vergence, and illumination, are controlled to acquire data that will facilitate scene interpretation.

FIGURE 19.43 A typical structured lighting system. (Source: Jorvis, R.A. 1983. A perspective on range finding techniques for computer vision. *IEEE Transactions on Pattern Analysis and Machine Intelligence* 5(2):122–139. ©1983 IEEE.)

19.4.3 Segmentation

An image must be analyzed and its relevant features extracted before more abstract representations and descriptions can be generated. Careful selection of these so-called low-level operations is critical for the success of higher level scene interpretation algorithms. One of the first operations that a machine vision system must perform is the separation of objects from the background. This operation, commonly called **segmentation**, is approached in one of two ways: (1) an *edge-based* method for locating discontinuities in certain properties or (2) a *region-based* method for the grouping of pixels according to certain similarities.

Edge-Based Segmentation

In an edge-based approach, the boundaries of objects are used to partition an image. Points that lie on the boundaries of an object must be marked. Such points, called *edge points*, can often be detected by analyzing the local neighborhood of a point. By definition, the regions on either side of an edge point (i.e., the object and background) have dissimilar characteristics. Thus, in edge detection, the emphasis is on detecting dissimilarities in the neighborhoods of points.

Gradient

An *edge* in an image is indicated by a significant local change in image intensity, usually associated with a discontinuity in either the image intensity or the first derivative of the image intensity. Therefore, a direct approach to edge detection is to compute the *gradient* at each pixel in an image. The gradient is the two-dimensional equivalent to the first derivative and is defined as the vector

$$\mathbf{G}[f(x, y)] = \begin{bmatrix} G_x \\ G_y \end{bmatrix} = \begin{bmatrix} \frac{df}{dx} \\ \frac{df}{dy} \end{bmatrix} \tag{19.52}$$

where $f(x, y)$ represents the two-dimensional image intensity function. The magnitude and direction of the gradient in terms of the first partial derivatives G_x and G_y are given by

$$G(x, y) = \sqrt{G_x^2 + G_y^2} \quad \text{and} \quad \alpha(x, y) = \tan^{-1} \left(\frac{G_y}{G_x} \right) \tag{19.53}$$

FIGURE 19.44 Operators: (a) the Roberts' operators, (b) Prewitt operators, (c) Sobel operators, and (d) the Laplacian operator. Note that the Laplacian operator is *not* a directional operator.

Only those pixels whose gradient magnitude is larger than a predefined threshold are identified as edge pixels.

Many approximations have been used to compute the partial derivatives in the x and y directions. One of the earlier edge detectors, the *Roberts' cross operator*, computes the partial derivatives by taking the difference in intensities of the diagonal pixels in a 2×2 window. Other approximations, such as the *Prewitt* and *Sobel* operators, use a 3×3 window to calculate the partial derivatives. Occasionally, operators that compute the edge strength in a number of specific directions are used in machine vision. These directional operators are defined over 3×3 or larger neighborhoods. For applications where such simple edge detectors are not adequate, the *Canny* edge detector, which attempts to optimize noise suppression with edge localization, is often used. See Fig. 19.44 for a description of the window operators used in each of the mentioned edge operators.

Laplacian

When using gradient-based edge detectors, multiple responses are often obtained at adjacent pixels depending on the rate of transition of the edge. After **thresholding**, thick edges are usually obtained. However, it is desired to obtain only a single response for a single edge; in other words, only keep the maximum of the gradient and not every response that is above a specified threshold. The maximum of the gradient is found by detecting the zero crossings in the second derivative of the image intensity function. The *Laplacian* is defined in terms of the second partial derivatives as follows

$$\nabla^2 f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} \quad (19.54)$$

The second partial derivatives along the x and y directions are approximated using the difference equations

$$\frac{\partial^2 f}{\partial x^2} = f(x+1, y) - 2f(x, y) + f(x-1, y)$$

and

$$\frac{\partial^2 f}{\partial y^2} = f(x, y+1) - 2f(x, y) + f(x, y-1) \quad (19.55)$$

By combining these two equations, the Laplacian can be implemented in a single window operator (see Fig. 19.44).

The response of the Laplacian operator can be computed in one step by convolving the image with the appropriate window operator. Nevertheless, since the Laplacian is an approximation to the second derivative, it reacts more strongly to lines, line ends, and noise pixels than it does to edges; plus it generates two responses for each edge, one positive and one negative on either side of the edge. Hence, the zero crossing between the two responses is used to localize the edge.

Laplacian of Gaussian

Detecting edge points from the zero crossings of the second derivative of the image intensity is very noisy. Therefore, it is often desirable to filter out the noise before edge detection. To do this, the *Laplacian of Gaussian* (LoG) combines Gaussian filtering with the Laplacian for edge detection. The output of the

LoG operator, $h(x, y)$, is obtained by the convolution operation

$$h(x, y) = \nabla^2(g(x, y) * f(x, y)) \tag{19.56}$$

where

$$g(x, y) = e^{-[\frac{(x^2+y^2)}{2\sigma^2}]} \tag{19.57}$$

is the equation for the Gaussian filter (neglecting the constant factor). Using the derivative rule for convolution, we get the equivalent expression

$$h(x, y) = [\nabla^2g(x, y)] * f(x, y) \tag{19.58}$$

where the term

$$\nabla^2g(x, y) = \left(\frac{x^2 + y^2 - 2\sigma^2}{\sigma^4} \right) e^{-[\frac{(x^2+y^2)}{2\sigma^2}]} \tag{19.59}$$

is commonly called the *Mexican hat* operator because of its appearance when plotted (see Fig. 19.45).

This result shows that the Laplacian of Gaussian can be obtained in either of two ways: (1) Convolve the image with a Gaussian smoothing filter and compute the Laplacian of the result. (2) Convolve the image with a filter that is the Laplacian of the Gaussian filter. The zero crossings still must be detected in order to localize the edges; and like the Laplacian, only those edge points whose corresponding first derivative is above a specified threshold are marked as edge points.

FIGURE 19.45 The *inverted* Laplacian of Gaussian function.

When using the Laplacian of Gaussian approach, edges are detected at a particular resolution (scale) depending on the spread of the Gaussian filter used. The determination of real edges in any image may require the combination of information from operators at several scales using a *scale-space* approach. The presence of edges at a particular resolution are found at the appropriate scale, and the exact locations of the edges are obtained by tracking their locations through lower values of σ .

Surface Fitting

Since a digital image is actually a sampling of a continuous function of two-dimensional spatial variables, another viable approach to edge detection is to approximate and reconstruct the underlying continuous spatial function that the image represents. This process is termed *surface fitting*. The intensity values in the neighborhood of a point can be used to obtain the underlying continuous intensity surface, which then can be used as a best approximation from which properties in the neighborhood of the point can be computed. The continuous intensity function can be described by

$$z = f(x, y) \tag{19.60}$$

If the image represents one surface, the preceding equation will correctly characterize the image. However, an image generally contains several surfaces, in which case this equation would be satisfied only at local surface points. Therefore, this approach uses the intensity values in the neighborhood about each pixel to approximate a local surface about that point. The *facet model* is a result of this idea. In the facet model, the neighborhood of a point is approximated by the cubic surface patch that best fits the area using

$$f(r, c) = k_1 + k_2r + k_3c + k_4r^2 + k_5rc + k_6c^2 + k_7r^3 + k_8r^2c + k_9rc^2 + k_{10}c^3 \tag{19.61}$$

where r and c are local coordinates about the point in the center of the neighborhood being approximated. From this approximation, the second directional derivative can be calculated and the zero crossings can be detected, and the edge points can be found.

Edge Linking

The detection of edge pixels is only part of the segmentation task. The outputs of typical edge detectors must be linked to form complete boundaries of objects. Edge pixels seldom form closed boundaries; missed edge points will result in breaks in the boundaries. Thus, *edge linking* is an extremely important, but difficult, step in image segmentation. Several methods have been suggested to improve the performance of edge detectors ranging from *relaxation-based edge linking*, which uses the magnitude and direction of an edge point to locate other edges in the neighborhood, to *sequential edge detectors*—also called *edge trackers*—which finds a strong edge point and grows the object boundary by considering neighboring edge strengths and directions.

Region-Based Segmentation

In region-based segmentation, all pixels corresponding to a single object are grouped together and are marked to indicate that they belong to the same object. The grouping of the points is based on some criterion that distinguishes pixels belonging to the same object from all other pixels. Points that have similar characteristics are identified and grouped into a set of connected points, called *regions*. Such points usually belong to a single object or part of an object. Several techniques are available for segmenting an image using this region-based approach.

Region Formation

The segmentation process usually begins with a simple region formation step. In this step, intrinsic characteristics of the image are used to form initial regions. Thresholds obtained from a **histogram** of the image intensity are commonly used to perform this initial grouping. In general, an image will have several regions, each of which may have different intrinsic characteristics. In such cases, the intensity histogram of the image will show several peaks; each peak may correspond to one or more regions. Several thresholds are selected using these peaks. After thresholding, a connected-component algorithm can be used to find initial regions.

Thresholding techniques usually produce too many regions. Since they were formed based only on first-order characteristics, the regions obtained are usually simplistic and do not correspond to complete objects. The regions obtained via thresholding may be considered to be only the first step in segmentation. After the initial histogram-based segmentation, more sophisticated techniques are used to refine the segmentation.

Split and Merge

Automatic refinement of an initial intensity-based segmentation is often done using a combination of *split* and *merge* operations. Split and merge operations eliminate false boundaries and spurious regions by either splitting a region that contains pieces from more than one object or merging adjacent regions that actually belong to the same object. If some property of a region is not uniform, the region should be split. Segmentation based on the split approach starts with large regions. In many cases, the whole image may be used as the starting region. Several decisions must be made before a region is split. One is to decide “when” a property is nonuniform over a region; another is “how” to split a region so that the property for each of the resulting components is uniform. These decisions usually are not easy to make. In some applications, the variance of the intensity values is used as a measure of uniformity.

More difficult than determining the property uniformity is deciding “where” to split a region. Splitting regions based on property values is very difficult. One approach used when trying to determine the best boundaries with which to divide a region is to consider edgeness values within a region. The easiest schemes for splitting region are those that divide a region into a fixed number of equal regions; such methods are called *regular decomposition methods*. For example, in the *quad tree* approach, if a region is considered nonuniform, it is split into four equal quadrants in each step.

Many approaches have been proposed to judge the similarity of regions. Broadly, the approaches are based on either the characteristics of regions or the weakness of edges between them. Two common approaches to judging the similarity of adjacent regions based on region characteristics are to (1) compare their mean intensities and (2) assume their intensity values are drawn from a known probability distribution. In the first approach, if their mean intensities do not differ by more than some predetermined value, the regions are considered to be similar and are candidates for merging. A modified form of this approach uses surface fitting to determine if the regions can be approximated by one surface. In the latter approach, the decision of whether or not to merge adjacent regions is based on considering the probability that they will have the same statistical distribution of intensity values. This approach uses hypothesis testing to judge the similarity of adjacent regions.

Another approach to merging is to combine two regions only if the boundary between them is weak. A weak boundary is one for which the intensities on either side differ by less than a given threshold. This approach attempts to remove weak edges between adjacent regions by considering not only the intensity characteristics, but also the length of the common boundary. The common boundary is dissolved if it is weak and the resulting boundary (of the merged region) does not grow too fast.

Split and merge operations may be used together. After a presegmentation based on thresholding, a succession of splits and merges may be applied as dictated by the properties of the regions. Such schemes have been proposed for segmentation of complex scenes. Domain knowledge with which the split and merge operations can be controlled may also be introduced.

Other Segmentation Methods

In the preceding discussion, the primary focus was with intensity images. Segmentation techniques that are based on *color*, *texture*, and *motion* have also been developed. Segmentation based on spectral pattern classification techniques is used extensively in remote-sensing applications.

19.4.4 Feature Extraction and Matching

Segmented images are often represented in a compact form to facilitate further abstraction. Representation schemes are chosen to match methods used for object recognition and description. The task of object recognition requires matching an object description in an image to models of known objects. The models, in turn, use certain descriptive features and their relations. Matching also plays an important role in other aspects of information recovery from images. In the following, schemes for representation and description that are popular in machine vision are discussed along with techniques for feature extraction and matching.

Representation and Description

Representation and description of symbolic information can be approached in many ways. One approach is to represent the object in terms of its bounding curve. Popular among several methods developed for boundary representation are chain codes, **polygonalization**, one-dimensional signatures, and representations using dominant points for representing an object. Another approach is to obtain region-based shape descriptors, such as topological or texture descriptors. Representation and shape description schemes are usually chosen such that the descriptors are invariant to rotation, translation, and scale changes.

Chain Codes

One of the earliest methods for representing a boundary uses directional codes, called *chain codes*. The object boundary is resampled at an appropriate scale, and an ordered list of points along the boundary is represented by a string of directions codes (see Fig. 19.46(a)). Often to retain all of the information in the boundary, the resampling step is bypassed. However, resampling eliminates minor fluctuations that typically are due to noise. Chain codes possess some attractive features; namely, the rotation of an object by multiples of 45° is easily implemented; the derivative of the chain code, the *difference code* obtained by computing the first differences of the chain code, is rotation invariant; and other characteristics of a region, such as area and corners, can be computed directly from the chain code. The limitations of this

FIGURE 19.46 (a) An object and its chain code. (b) A simple geometric object and its one-dimensional (s, θ) signature.

representation method are attributed to the restricted directions used to represent the tangent at a point. Although codes with larger numbers of directions are occasionally used, the eight-directional chain code is the most commonly used.

Polygonalization

Polygonal approximation of boundaries has been studied extensively and numerous methods have been developed. The fit of a polygon is made to reduce a chosen error criterion between the approximation and the original curve. In an *iterative endpoint* scheme, the first step is to connect a straight-line segment between the two farthest points on the boundary. The perpendicular distances from the segment to each point on the curve is measured. If any distance is greater than a chosen threshold, the segment is replaced by two segments; one each from the segment endpoint to the curve point where the distance to the segment is greatest. In another approach, a straight-line fit is constrained to pass within a radius around each data point. The line segment is grown from the first point, and when further extension of the line segment causes it to fall outside the radius point, a new line is started. A *minimax* approach can also be used in which the line segment approximations are chosen to minimize the maximum distance between the data points and the approximating line segment.

Besides polygonal approximation methods, higher order curve- and spline-fitting methods may be used where more precise approximations are required. These are more computationally expensive than most polygonalization methods, and they can be more difficult to apply.

One-Dimensional Signatures

The slope of the tangent to the curve denoted by the angle θ as a function of s , the position along the curve from an arbitrary starting point, is used to represent curves in many applications. Plots of these functions have some interesting and useful characteristics. Horizontal lines in $s-\theta$ plots represent straight lines and straight lines at an angle with the horizontal represent circular arcs whose radii are proportional to the slope of the straight line. An $s-\theta$ curve can also be treated as a periodic function with a period given by the perimeter of the curve; hence, Fourier techniques can be used. Other functions, such as the distance to the curve from an arbitrary point inside the curve plotted as a function of the angle with reference to the horizontal, are also used as shape signatures. Figure 19.46(b) shows a simple geometric object and its one-dimensional signature.

Boundary Descriptors

Descriptors for objects represented by their boundaries may be generated using the representations already described. Simple descriptors, such as perimeter, length, and orientation of the major axis, shape number, and eccentricity, may be readily computed from the boundary data. The ordered set of points on the boundary having two-dimensional coordinates (x_k, y_k) , where $k = 1, \dots, N$ and N is the total number of points on the boundary, can be treated as a one-dimensional complex function $x_k + iy_k$. The coefficients of the discrete Fourier transform applied to this function can also be used as a shape descriptor.

Other descriptors that use the one-dimensional signature functions may also be obtained. A major drawback of many of these descriptors is that complete data for the object boundary are required. Because of either problems in segmentation or occlusions in the image, however, complete data for the object boundary are often not available. In such instances, recognition strategies based on partial information are needed.

Many region-based representation and description methods analogous to those used to represent object boundaries have been developed. Examples of such methods are the *medial-axis transform*, *skeletons*, *convex hulls*, and *deficiencies*. *Morphological operators* have been developed to extract shape features and generate useful descriptions of object shape. Topological descriptors, such as *Euler number*, are also useful to characterize shape. The facet model has even been used to generate a topographic primal sketch of images using a set of seven descriptive labels, including pit, peak, and ridge to name a few. Such descriptions are useful in object matching. Region-based representation and description are particularly useful to describe objects for which properties within the region, for example, texture, are significant for object recognition. For a complete discussion of these topics, refer to the references at the end of this chapter.

Feature Extraction

If the object to be recognized has unique discriminating features, special-purpose algorithms may be employed to extract such features. Important for object matching and recognition are corners, high-curvature regions, inflection points, or other places along curves at which curvature discontinuities exist. In region-based matching methods, identifying groups of pixels that can be easily distinguished and identified is important. Many methods have been proposed to detect both dominant points in curves and interesting points in regions.

Critical Points

The detection of *critical points*, also called *dominant points*, in curves, such as corners and inflection points, is important for subsequent object matching and recognition. Most algorithms for detecting critical points mark local curvature maxima as dominant. One approach is to analyze the deviations of a curve from a chord to detect dominant points along the curve. Points are marked as either being critical or belonging to a smooth or noisy interval. These markings depend on whether the curve makes a single excursion away from the chord, stays close to the chord, or makes two or more excursions away from the chord, respectively. Other approaches use mathematical expressions to directly compute and plot the curvature values along the contour.

Interesting Points

Points used in matching between two images must be ones that are easily identified and matched. These are known as *interesting points*. Obviously, those points in a uniform region and on edges are not good candidates for matching. Interest operators find image areas with high variance. In applications such as stereo and structure from motion, images should have enough such interesting regions to facilitate matching.

One commonly used interest operator, the *Moravec interest operator*, uses directional variances as a measure of how interesting a point is. A point is considered interesting if it has a local maximum of minimal sums of directional variances. The directional variances in the local neighborhood about a point are calculated by

$$\begin{aligned}
 I_1 &= \sum_{(x,y) \in \mathcal{S}} [f(x,y) - f(x,y+1)]^2 \\
 I_2 &= \sum_{(x,y) \in \mathcal{S}} [f(x,y) - f(x+1,y)]^2 \\
 I_3 &= \sum_{(x,y) \in \mathcal{S}} [f(x,y) - f(x+1,y+1)]^2 \\
 I_4 &= \sum_{(x,y) \in \mathcal{S}} [f(x,y) - f(x+1,y-1)]^2
 \end{aligned} \tag{19.62}$$

where s represents the neighborhood about the current point. Typical neighborhoods range from 5×5 to 11×11 pixels. The *interestingness* of the point is then given by

$$I(x, y) = \min(I_1, I_2, I_3, I_4) \quad (19.63)$$

Feature points are chosen where the interestingness is a local maximum. Doing this eliminates the detection of simple edge points since they have no variance in the direction of the edge. Furthermore, a point is considered a good interesting point if its local maximum is above a preset threshold. The Moravec interest operator has found extensive use in stereo matching applications.

Matching

Matching plays a very important role in many phases of machine vision. Object recognition requires matching a description of an object with models of known objects. The goal of matching is to either (1) detect the presence of a known entity, object, or feature or (2) find what an unknown image component is. The difficulty in achieving these matching goals is first encountered with goal-directed matching, wherein the goal is to find a very specific entity in an image. Usually, the location of all instances of such an entity must be found. In stereo and structure-from-motion applications, entities are obtained in one image, and their locations are then determined in a second image. The second problem requires matching an unknown entity with several models to determine which model matches best.

Point Pattern Matching

In matching points in two slightly different images of the same scene (i.e., in a stereo image pair or a motion sequence), interesting points are detected by applying an operator such as the Moravec interest operator. The correspondence process considers the local structure of a selected point in one image in order to assign initial matchable candidate points from the second image. However, this *correspondence problem* is not an easy one to solve, and many constraints are often imposed to ease the process. For example, in stereo-matching applications, the displacements of a point from one image to the other are usually small. Thus, only points within a local neighborhood are considered for matching. To obtain the final correspondence, the set of initial matches is refined by computing the similarity in global structure around each candidate point. In dynamic-scene analysis, one may assume that motions of neighboring points do not differ significantly. To obtain the final matching of points in the two images, relaxation techniques are often employed. An example of the point matching problem is illustrated in Fig. 19.47.

FIGURE 19.47 An illustration of the point pattern matching process.

Template Matching

In some applications, a particular pictorial or iconic structure, called a *template*, is to be detected in an image. Templates are usually represented by small two-dimensional intensity functions (typically less than 64×64 pixels). *Template matching* is the process of moving the template over the entire image and detecting the locations at which the template best fits the image. A common measure of similarity to determine a match is the *normalized cross correlation*. The correlation coefficient is given by

$$M(x, y) = \frac{\sum \sum_{(u,v) \in R} g(u, v) f(x + u, y + v)}{\left\{ \sum \sum_{(u,v) \in R} f^2(x + u, y + v) \right\}^{1/2}} \quad (19.64)$$

where $g(u, v)$ is the template, $f(x, y)$ the image, and R the region spanned by the template. The value M takes maximum value for the point (x, y) at which $g = cf$ (in other words where the pixel values of the template and the image only differ by a constant scaling factor). By thresholding the result of this

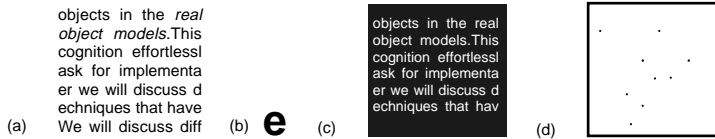

FIGURE 19.48 (a) A test image. (b) a template (enlarged) of the letter *e*. (c) the results of the normalized cross correlation. (d) the thresholded result indicating the match locations ($T = 240$). (Source: Jain, R., Kasturi, R., and Schunck, B.G. 1995. *Machine Vision*. McGraw-Hill, New York. With Permission.)

cross-correlation operation, the locations of a template match can be found. Figure 19.48 shows a test image, a template, and the results of the normalized cross correlation.

A major limitation of the template-matching technique is its sensitivity to the rotation and scaling of objects. To match scaled and rotated objects, separate templates must be constructed. In some approaches, a template is partitioned into several subtemplates, and matching is carried out for these subtemplates. The relationships among the subtemplates are verified in the final matching step.

Hough Transform

Parametric transforms, such as the Hough transform, are useful methods for the recognition of straight lines and curves. For a straight line, the transformation into the parameter space is defined by the parametric representation of a straight line given by

$$\rho = x \cos \theta + y \sin \theta \quad (19.65)$$

where (ρ, θ) are the variables in the parameter space that represent the length and orientation, respectively, of the normal to the line from the origin. Each point (x, y) in the image plane transforms into a sinusoid in the (ρ, θ) domain. However, all sinusoids corresponding to points that are colinear in the image plane will intersect at a single point in the Hough domain. Thus, pixels belonging to straight lines can be easily detected.

The Hough transform can also be defined to recognize other types of curves. For example, points on a circle can be detected by searching through a three-dimensional parameter space of (x_c, y_c, r) where the first two parameters define the location of the center of the circle and r represents the radius. The Hough transform can also be generalized to detect arbitrary shapes. However, one problem with the Hough transform is the large parameter search space required to detect even simple curves. This problem can be alleviated somewhat by the use of additional information that may be available in the spatial domain. For example, in detecting circles by the brute-force method, searching must be done in a three-dimensional parameter space; however, when the direction of the curve gradient is known, the search is restricted to only one dimension.

Pattern Classification

Features extracted from images may be represented in a multidimensional feature space. A classifier—such as a minimum distance classifier, which is used extensively in statistical pattern recognition—may be used to identify objects. This pattern classification method is especially useful in applications wherein the objective is to assign a label, from among many possible labels, to a region in the image. The classifier may be taught in a supervised-learning mode, by using prototypes of known object classes, or in an unsupervised mode, in which the learning is automatic. Proper selection of features is crucial for the success of this approach. Several methods of pattern classification using structural relationships have also been developed. For a complete discussion of pattern classification, see Duda and Hart (1973).

19.4.5 Three-Dimensional Object Recognition

The real world that we see and touch is primarily composed of three-dimensional solid objects. When an object is viewed for the first time, people typically gather information about that object from many different viewpoints. The process of gathering detailed object information and storing that information is

referred to as model formation. Once a person is familiar with many objects, the objects are then identified from an arbitrary viewpoint without further investigation. People are also able to identify, locate, and qualitatively describe the orientation of objects in black-and-white photographs. This basic capability is significant to machine vision because it involves the spatial variation of a single parameter within a framed rectangular region that corresponds to a fixed, single view of the world.

Recognition System Components

Recognition implies awareness of something already known. In modeling real-world objects for recognition purposes, different kinds of schemes have been used. To determine how recognition will take place, a method for matching model data to sensor data must be considered. A straightforward blind-search approach would entail (1) transforming all possible combinations of all possible known object models in all possible distinguishable orientations and locations into a digitized sensor format and (2) matching based on the minimization of a matching-error criterion. Clearly, this approach is impractical. On the other hand, since object models contain more object information than sensor data, we are prohibited from transforming sensor data into complete model data and matching in the model data format. However, this does not prevent us from matching with partial model data. As a result, working with an intermediate domain that is computable from both sensor and model data is advantageous. This domain is referred to as the symbolic scene description domain. A matching procedure is carried out on the quantities in this domain, which are referred to as *features*.

The interactions between the individual components of a recognition system are illustrated in Fig. 19.49. The image formation process creates intensity or range data based purely on physical principles. The description process acts on the sensor data and extracts relevant application-independent features. This process is completely data-driven and includes only the knowledge of the image formation process. The modeling process provides object models for real-world objects. Object reconstruction from sensor data is one method for building models automatically. The understanding, or recognition, process involves an algorithm to perform matching between model and data descriptions. This process might include data- and model-driven subprocesses, where segmented sensor data regions seek explanations in terms of models and hypothesized models seek verification from the data. The rendering process produces synthetic sensor data from object models. Rendering provides an important feedback link by allowing an autonomous system to check on its own understanding of the sensor data by comparing synthetic images to sensed images.

Object Representation Schemes

Numerous schemes have been developed for representing three-dimensional objects. The choice of a particular scheme is governed by its intended application. In computer graphics, schemes such as the wire-frame and constructive solid-geometry representations are popular since their data structures are suitable for image rendering. In machine vision systems, other methods such as generalized cones and characteristic views are used extensively. In the following, we briefly describe some commonly used object representation schemes.

Wire Frame

The wire-frame representation of a three-dimensional object consists of a three-dimensional vertex point list and an edge list of vertex pairs. Although this representation is very simple, it is an ambiguous representation for determining such quantities as surface area and volume of an object. Wire-frame

FIGURE 19.50 Various object representation schemes: (a) wire-frame, (b) constructive solid geometry, (c) spatial occupancy, (d) surface-boundary, (e) generalized-cone, (f) aspect graph.

models can sometimes be interpreted as several different solid objects or as different orientations of the same object. Figure 19.50(a) shows the wire-frame representation of a simple three-dimensional object.

Constructive Solid Geometry

The constructive solid-geometry (CSG) representations of an object is specified in terms of a set of three-dimensional volumetric primitives (blocks, cylinders, cones, spheres, etc.) and a set of boolean operators: union, intersection, and difference. Figure 19.50(b) shows the CSG representation for a simple geometric object. The storage data structure is a binary tree, where the terminal nodes are instances of the geometric primitives and the branching nodes represent the Boolean set operations and positioning information. CSG trees define object surface area unambiguously and can, with very little data, represent complex objects. However, the boundary evaluation algorithms required to obtain usable surface information are very computationally expensive. Also, general sculptured surfaces are not easily represented using CSG models.

Spatial Occupancy

Spatial-occupancy representations use nonoverlapping subregions of three-dimensional space occupied by an object to define that object. This method unambiguously defines an object's volume. Some commonly used single primitive representations of this type are the voxel and octree representations. *Voxels* are small volume elements of discretized three-dimensional space (see Fig. 19.50(c)). They are usually fixed-size cubes. Objects are represented by the lists of voxels occupied by the object. Voxel representations tend to be very memory intensive, but algorithms using them tend to be very simple. An *octree* is a hierarchical representation of spatial occupancy. Volumes are decomposed into cubes of different size, where the cube size depends on the distance from the root node. Each branching node of the tree represents a cube and points to eight other nodes, each of which describes object volume occupancy in the corresponding octant subcubes of the branching node cube. The octree representation offers the advantages of the voxel description but is more compact. Because of this compactness, more complicated algorithms are required for many computations than those needed for voxel representation.

Surface Boundary

The surface-boundary representation defines a solid object by defining the three-dimensional surfaces that bound the object. Figure 19.50(d) shows a surface-boundary representation for a simple geometric object. The simplest boundary representation is the triangle-faced polyhedron, which can be stored as a list of three-dimensional triangles. Arbitrary surfaces are approximated to any desired degree of accuracy by utilizing many triangles. A slightly more compact representation allows the replacement of adjacent, connected, coplanar triangles with arbitrary n -sided planar polygons. Structural relationships between bounding surfaces may also be included as part of the model.

Generalized Cone

In the generalized-cone (generalized-cylinder or sweep) representation, an object is represented by a three-dimensional space curve that acts as a spine or axis of the cone, a two-dimensional cross-sectional figure, and a sweeping rule that defines how the cross section is to be swept (and possibly modified) along the space curve (see Fig. 19.50(e)). Generalized cones are well suited for representing many real-world shapes. However, certain objects, such as the human face or an automobile body, are difficult to represent as generalized cones. Despite its limitations, the generalized-cone representation is popular in machine vision.

Skeleton

Skeleton representations use space-curve skeletons. A skeleton can be considered an abstraction of the generalized cone description that consists of only the spines. Skeleton geometry provides useful abstract information. If a radius function is specified at each point on the skeleton, this representation is capable of general-purpose object description.

Multiple Two-Dimensional Projection

For some applications, a library of two-dimensional silhouette projections that represent three-dimensional objects can be conveniently stored. For the recognition of three-dimensional objects with a small number of stable orientations on a flat table, this representation is ideal—if the object silhouettes are sufficiently different. For example, silhouettes have been used to recognize aircraft in any orientation against a well-lit sky background. However, because many different three-dimensional-object shapes can possess the same silhouette projection, this type of representation is not a general-purpose technique.

Aspect Graphs

In the aspect graph representation, the space of viewpoints is partitioned into maximal regions, where every viewpoint in each region gives the same qualitative view of the object, called the *aspect*. Within each region, **projections** of the object will have the same number and types of features, with identical spatial relationships among them. However, the quantitative properties of these features, such as lengths of edges, vary with the change in viewpoint. Changes in the aspect, called *visual events*, take place at the boundaries between regions. Two aspects are said to be connected by a visual event if their corresponding regions are adjacent in the viewpoint space. An aspect graph is a graph structure whose nodes represent aspects and their associated regions and whose arcs denote the visual events and boundaries between adjacent regions. Figure 19.50(f) shows the aspect graph for a cube.

Characteristic Views

A concept very similar to aspect graphs is that of characteristic views. All of the infinite two-dimensional perspective projection views of an object are grouped into a finite number of topologically equivalent classes. Different views within an equivalence class are related via linear transformations. A representative member of an equivalence class is called the *characteristic view* for that class. In this scheme, objects are assumed to rest on a supporting plane; hence, they are restricted to appear in a number of stable positions. Characteristic views of objects are derived with certain constraints on the camera configuration. It is this use

of camera position and orientation information that differentiates the characteristic view representation scheme from the aspect graph. Because characteristic views specify the three-dimensional structure of an object, they also provide a general-purpose object representation.

19.4.6 Dynamic Vision

Early machine vision systems were concerned primarily with static scenes; however, the world is dynamic. Designing machine vision systems capable of analyzing dynamic scenes is increasingly becoming more popular. For a machine vision system engaged in the performance of nontrivial real-world operations and tasks, the ability to cope with moving and changing objects and viewpoints is vital.

The input to a dynamic-scene analysis system is a sequence of image frames. The camera used to acquire the image sequence may itself be in motion. Each frame represents an image of the scene at a particular instant in time. The changes in a scene may be due to camera motion, object motion, illumination changes, or changes in object structure, size, or shape. Changes in a scene are usually assumed to be due to camera and/or object motion; objects are usually assumed to be either rigid or quasirigid. Other changes are not allowed.

A scene usually contains several objects. An image of the scene at a given time represents a projection of part of the scene; the part of the scene depends on the position of the camera. Four cases represent the possibilities for the dynamic-camera/world setup:

1. Stationary camera, stationary objects (SCSO)
2. Stationary camera, moving objects (SCMO)
3. Moving camera, stationary objects (MCSO)
4. Moving camera, moving objects (MCMO)

The first case is simple static-scene analysis. In many applications, processing a single image to obtain the required information may be feasible. However, many more applications exist that require information to be extracted from a dynamic environment.

Clearly, a sequence of image frames offers much more information to aid in scene understanding, but significantly increases the amount of data to be processed by the system. Applying static-scene analysis techniques to each frame of a sequence requires an enormous amount of computation, while still suffering from all of the problems of static-scene analysis. Fortunately, research in dynamic-scene analysis has shown that information recovery may be easier in dynamic scenes than in static scenes. In some cases, the total computational effort may be significantly less and the performance is better.

SCMO scenes have received the most attention in dynamic-scene analysis. The objectives of such scene analysis usually are to detect motion, to extract masks of moving objects with the aim of recognizing them, and to compute their motion characteristics. MCMO is the most general case and possibly presents the most difficult situation in dynamic-scene analysis. Many techniques that have been developed assuming a stationary camera are not applicable to a moving camera. Likewise, techniques developed for a moving camera generally assume a stationary scene and are usually not applicable if the objects are moving. SCMO and MCSO have found uses in many applications and have been studied by researchers in various contexts under various assumptions.

Change Detection

Any perceptible motion in a scene results in some change in the sequence of frames of the scene. If such changes are detected, motion characteristics can be analyzed. A good quantitative estimate of the motion components of an object can be obtained if the motion is restricted to a plane that is parallel to the image plane; for three-dimensional motion, only qualitative estimates are possible. By analyzing frame-to-frame differences, a global analysis of the sequence can be performed. Changes can be detected at different levels: pixel, edge, or region.

Difference Pictures

The most obvious method of detecting change between two frames is to directly compare the corresponding pixels of the frames to determine whether or not they are the same. In the simplest form, a binary *difference picture* $DP_{jk}(x, y)$ between frames j and k is obtained by

$$DP_{jk}(x, y) = \begin{cases} 1 & \text{if } |F(x, y, j) - F(x, y, k)| > \tau \\ 0 & \text{otherwise} \end{cases} \quad (19.66)$$

where τ is a threshold and $F(x, y, j)$ and $F(x, y, k)$ are the image arrays of the j th and k th frames, respectively.

In the difference picture, pixels that have a value of 1 may be considered to be the result of object motion. Because of noise, however, such a simple test on real scenes usually produces unsatisfactory results. A simple size filter may be used to ignore pixels not forming a connected cluster of minimal size. Then only those pixels in the difference picture with the value of 1 that belong to a four-connected (or eight-connected) component larger than a set number of pixels will be attributed to object motion. This filter is very effective in reducing noise, but unfortunately it also filters some desirable signals, such as those from small or slowly moving objects.

Likelihood Ratio

To make change detection more robust, regions or groups of pixels at the same location in two frames may be considered and their intensity characteristics may be compared more rigorously. One method using this approach is based on comparing the frames using the *likelihood ratio*. Thus, we can compute the difference picture by replacing $|F(x, y, j) - F(x, y, k)|$ with λ where

$$\lambda = \frac{\left[\frac{\sigma_1^2 + \sigma_2^2}{2} + \left(\frac{\mu_1 - \mu_2}{2} \right)^2 \right]^2}{\sigma_1^2 \sigma_2^2} \quad (19.67)$$

and μ and σ denote the mean gray value and the square root of the variance from the frames for the sample area, respectively.

The likelihood ratio can only be applied to regions and not to single pixels. This limitation presents a minor problem, which can be solved by considering corresponding areas of the frames. The likelihood ratio test, combined with a size filter, works well for noise removal in many real-world scenes. The likelihood ratio test can be applied to every point in each frame by considering overlapping areas centered on each pixel of the image, or to a subsampling of points by using nonoverlapping areas, called *superpixels*.

Accumulative Difference Pictures

The problem of missing the detection of small or slowly moving objects can be solved by analyzing change over a series of frames, instead of just between two frames. The *accumulative difference picture* (ADP) is used to detect the motion of small and slowly moving objects. An accumulative difference picture is formed by comparing every frame in an image sequence to a common reference frame. The entry in the accumulative difference picture is increased by one whenever the likelihood ratio for that region exceeds the threshold. Thus, an accumulative difference picture acquired over k frames is given by

$$\begin{aligned} ADP_0(x, y) &= 0 \\ ADP_k(x, y) &= ADP_{k-1}(x, y) + DP_{1k}(x, y) \end{aligned} \quad (19.68)$$

where the first frame of a sequence is usually the reference frame.

Time-Varying Edge Detection

As a result of the importance of edge detection in static scenes, it is reasonable to expect that time-varying edge detection may also be important in dynamic-scene analysis. Moving edges can be detected by combining the spatial and temporal gradients using a logical AND operation, which is implemented

through multiplication. Thus, the time-varying edgeness of a point in a frame is given by

$$E_t(x, y, t) = \frac{dF(x, y, t)}{dS} \frac{dF(x, y, t)}{dt} \quad (19.69)$$

where dF/dS and dF/dt are the magnitudes of the spatial and temporal gradients of the intensity at point (x, y, t) , respectively. Various conventional edge detectors can be used to compute the spatial gradient, and a simple difference can be used to compute the temporal gradient. In most cases, this edge detector works effectively. By applying a threshold to the product—rather than first differencing and then applying an edge detector, or first detecting edges and then computing their temporal gradient—this method overcomes the problem of missing weak or slowly moving edges.

Optical Flow

Optical flow is the distribution of velocity, relative to the observer, over the points of an image. Optical flow carries information that is valuable in dynamic-scene analysis. Optical flow is determined by the velocity vector at each pixel in an image. Several methods have been devised for calculating optical flow based on two or more frames of a sequence. These methods can be classified into two general categories: *feature based* and *gradient based*. If a stationary camera is used, most of the points in an image frame will have zero velocity. This is assuming that a very small subset of the scene is in motion, which is usually true. Thus, most applications for optical flow involve a moving camera.

Feature-Based Methods

Feature-based methods for computing optical flow first select some features in consecutive image frames, match these features between frames, and then calculate the disparities between them. As mentioned earlier, the **correspondence problem** can be solved using relaxation. However, the problem of selecting features and establishing correspondence is not easy. Moreover, this method only produces velocity vectors at sparse points within the image.

Gradient-Based Methods

Gradient-based methods exploit the relationship between the spatial and temporal gradients of image intensity. This relationship can be used to segment images based on the velocity of image points. The relationship between the spatial and temporal gradients and the velocity components is

$$F_x u + F_y v + F_t = 0 \quad (19.70)$$

where $u = dx/dt$ and $v = dy/dt$. In this equation, F_x , F_y , and F_t represent the spatial gradients in the x and y directions and the temporal gradient, respectively, and can be computed directly from the image. Then, at every point in an image, there are two unknowns, u and v , yet there is only one equation. Thus, optical flow cannot be directly determined.

The velocity field, however, can be assumed to vary smoothly over an image. Under this assumption, an iterative approach for computing optical flow using two or more frames can be utilized. The following iterative equations are used for the computation of image flow:

$$u = u_{\text{average}} - F_x \frac{P}{D} \quad v = v_{\text{average}} - F_y \frac{P}{D} \quad (19.71)$$

where

$$P = F_x u_{\text{average}} + F_y v_{\text{average}} + F_t \quad (19.72)$$

$$D = \lambda^2 + F_x^2 + F_y^2 \quad (19.73)$$

where λ is a constant multiplier. When only two frames are used, the computation is iterated over the same frames many times. For more than two frames, each iteration uses a new frame.

Segmentation Using a Moving Camera

If the camera is moving, then every point in the image has nonzero velocity relative to the camera (except the case where object points are moving with the same velocity as the camera). The velocity relative to the camera depends on both the velocity of the point itself and the distance of the point from the camera. Approaches based on differences may be extended for segmenting moving-camera scenes. If the aim is to extract images of moving objects, however, then additional information is required to decide whether the motion at a point is due solely to its depth or is due to a combination of its depth and its motion. Gradient-based approaches will also require additional information.

If the camera's direction of motion is known, the *focus of expansion* (FOE) with respect to the stationary components in the scene can easily be computed. The FOE will have coordinates (x_f, y_f) where

$$x_f = \frac{dx}{dz} \quad y_f = \frac{dy}{dz} \quad (19.74)$$

in the image plane. The velocity vectors of all stationary points in a scene project onto the image plane so that they intersect at the FOE. A transformation with respect to the FOE can be used to simplify the task of segmentation. The *ego-motion polar* (EMP) transformation of an image transforms a frame $F(x, y, t)$ into $E(r, \theta, t)$ using

$$E(r, \theta, t) = F(x, y, t) \quad (19.75)$$

where

$$r = \sqrt{(x - x_f)^2 + (y - y_f)^2} \quad (19.76)$$

and

$$\theta = \tan^{-1} \left[\frac{(y - y_f)}{(x - x_f)} \right] \quad (19.77)$$

In EMP space, stationary points are displaced only along the θ axis between the frames of an image sequence, whereas points on moving objects are displaced along the r axis as well as the θ axis. Thus, the displacement in EMP space can be used to segment a scene into its stationary and nonstationary components. Moreover, when *complex logarithmic mapping* (CLM) is performed about the FOE, interesting points in the EMP space can be obtained.

19.4.7 Applications

Machine vision systems have uses in a wide variety of disciplines, from medicine to robotics, from automatic inspection to autonomous navigation, and from document analysis to multimedia systems. New machine vision systems are constantly emerging and becoming a part of everyday life. In this section, we present a brief description some of the various applications of machine vision.

Optical Character Recognition (OCR) and Document Image Analysis

The objective of document image analysis is to recognize the text and graphics components in images and extract the intended information as a human would. Two categories of document processing can be defined, *textual processing* and *graphics processing*. Textual processing deals with the text components of a document image. Some tasks here are recognizing the text by optical character recognition (OCR); skew detection and correction (any tilt at which the documents may have been scanned); and finding the columns, paragraphs, text lines, and words. Graphics processing deals with the nontextual components of a document image, such as lines and symbols that make up line diagrams, delimiting lines between text sections, and company logos.

Document analysis is currently a very active area of research. Researchers have devised systems ranging from automatic engineering drawing interpretation and recognition of tabular drawings to the recognition of zip codes from postal envelopes and the interpretation of musical scores. However, the real success story

of document analysis is OCR. This is the one area of machine vision in which scientific study has led to numerous low-cost marketed products. Many of the current OCR systems report accuracies well in the upper 90th percentile.

Many document analysis publications can be found in the journals and conference proceedings listed in the Further Information section. In addition, the International Conference on Document Analysis and Recognition (ICDAR) and the International Workshop on Graphics Recognition (IWGR) are biannual meetings held in conjunction with each other dedicated entirely to the field of document analysis.

Medical Image Analysis

Medical imaging analysis deals primarily with images such as X-rays, computerized tomograph (CT) scans, and magnetic resonance imaging (MRI) images. Early work in medical image analysis overlapped with that of image processing; the main task was to enhance medical images for viewing by a physician; no automatic interpretation or high-level reasoning by the system was involved. However, more recent work is being conducted on medical imagery, which more closely fits the definition of machine vision; for example, systems to search images for diseased organs or tissues based on known models (images) and features of the diseased samples and systems to generate three-dimensional models of organs based on CT scan and MRI. Some active areas of research include the use of three-dimensional images in surgery and surgical planning (especially neurosurgery), virtual surgery, and generating time-varying three-dimensional models obtained from sequences of images (e.g., pumping heart). These systems encompass many of the aspects of typical machine vision systems plus incorporate many aspects of computer graphics.

In addition to the listings at the end of this section, the following are excellent sources of information on current research in medical imaging: *IEEE Transactions on Medical Imaging*, *IEEE Transactions on Biomedical Engineering*, *IEEE Transactions on Image Processing*, and *IEEE Engineering in Medicine and Biology Magazine*. There are also a number of conferences dedicated to medical imaging research: SPIE Medical Imaging, IEEE Engineering in Medicine and Biology, Medicine Meets Virtual Reality, select sessions/symposium of IEEE Visualization, and SPIE Visualization in Biomedical Computing.

Photogrammetry and Aerial Image Analysis

Photogrammetry deals with the task of making reliable measurements from images. In the early days of photogrammetry, the images were actual printed photographs often taken from balloons. Today, however, the remote sensing process is multispectral using energy in many other parts of the electromagnetic spectrum, such as ultraviolet and infrared. The images are often transmitted directly from satellites orbiting the globe, such as the Landsat satellites first launched in the early 1970s. Some of the applications of photogrammetry and aerial image analysis include atmospheric exploration; thermal image analysis for energy conservation; monitoring natural resources, crop conditions, land cover, and land use; weather prediction; pollution studies; urban planning; military reconnaissance; plus many others in geology, hydrology, and oceanography.

There are several organizations dedicated to the study of these types of remote sensing tasks. The following are very good sources for information on photogrammetry and aerial image analysis: The American Society of Photogrammetry, The International Remote Sensing Institute (ISRI), and The American Congress on Surveying and Mapping. In addition, there are several conferences and symposia dealing with this topic: SPIE Remote Sensing, International Geosciences and Remote Sensing Symposium, *IEEE Transactions on Geoscience and Remote Sensing*, and the Symposium on Remote Sensing sponsored by the American Geological Institute.

Industrial Inspection and Robotics

Unlike many of the already mentioned machine vision tasks, automatic inspection and robotics perform many tasks in real time that significantly increases the complexity of the system. The general goal of such systems is sensor-guided control. Typical industrial applications include automatic inspection of machined parts, solder joint surfaces (welds), silicon wafers, produce, and even candy. Some of the challenges

faced by industrial vision system designers include determining the optimal configuration of the camera and lighting, determining the most suitable color space representation of the illumination, modeling various surface reflectance mechanisms, dynamic sensor feedback, real-time manipulator control, real-time operating system interfaces, and neural networks.

Structured lighting techniques have been used extensively in industrial vision applications where the illumination of the scene can be easily controlled. In a typical application, objects on a conveyor belt pass through a plane of light, creating a distortion in the image of the light stripe. The profile of the object at the plane of the light beam is then calculated. This process is repeated at regular intervals as the object moves along the conveyor belt to recover the shape of the object. Then appropriate actions are taken depending on the goal of the system.

The following are sources dedicated primarily to industrial vision applications and robotics: *International Journal of Robotics Research*, *IEEE Transactions on Robotics and Automation*, IEEE's International Conference on Robotics and Automation, and *IEEE Transactions on Systems, Man, and Cybernetics*.

Autonomous Navigation

Closely related to robotics is the area of autonomous navigation. Much work is being done to develop systems to enable robots or other mobile vehicles to automatically navigate through a specific environment. Techniques involved include active vision (sensor control), neural networks, high-speed stereo vision, three-dimensional vision (range imaging), high-level reasoning for navigational planning, and signal compression and transmission for accurate remote vehicle control.

Visual Information Management Systems

Probably one of the newest areas of machine vision research is in visual information management systems (VIMS). With the recent advances in low-cost computing power and the ever increasing number of multimedia applications, digital imagery is becoming a larger and larger part of every day life. Research in VIMS is providing methods to handle all of this digital information. Such VIMS applications include interactive television, video teleconferencing, digital libraries, video-on-demand, and large-scale video databases. Image processing and machine vision play a very important role in much of this work ranging anywhere from designing video compression schemes, which allow many processing techniques to be performed directly on the compressed datastream and developing more efficient indexing methods for multidimensional data, to automatic scene cut detection for automatically indexing large stockpiles of video data and developing methods to query image databases by image content as opposed to standard structured grey language (SQL) techniques.

Defining Terms

Correspondence problem: The problem of matching points in one image with their corresponding points in a second image.

Histogram: A plot of the frequency of occurrence of the grey levels in an image.

Quantization: The process of representing the continuous range of image intensities by a limited number of discrete grey values.

Sampling: The process of representing the continuous image intensity function as a discrete two-dimensional array.

Segmentation: The process of separating the objects from the background.

Polygonalization: A method of representing a contour by a set of connected straight line segments; for closed curves, these segments form a polygon.

Projection: The transformation and representation of a high-dimensional space in a lesser number of dimensions (i.e., a three-dimensional scene represented as a two-dimensional image).

Thresholding: A method of separating objects from the background by selecting an interval (usually in pixel intensity) and setting any points within the interval to 1 and points outside the interval to 0.

19.5 A Brief Survey of Speech Enhancement²

Yariv Ephraim, Hanoch Lev-Ari, and William J.J. Roberts

19.5.1 Introduction

Speech enhancement aims at improving the performance of speech communication systems in noisy environments. Speech enhancement may be applied, for example, to a mobile radio communication system, a speech recognition system, a set of low quality recordings, or to improve the performance of aids for the hearing impaired. The interference source may be a wide-band noise in the form of a white or colored noise, a periodic signal such as in hum noise, room reverberations, or it can take the form of fading noise. The first two examples represent additive noise sources, while the other two examples represent convolutional and multiplicative noise sources, respectively. The speech signal may be simultaneously attacked by more than one noise source.

There are two principal perceptual criteria for measuring the performance of a speech enhancement system. The *quality* of the enhanced signal measures its clarity, distorted nature, and the level of residual noise in that signal. The quality is a *subjective* measure that is indicative of the extent to which the listener is comfortable with the enhanced signal. The second criterion measures the *intelligibility* of the enhanced signal. This is an *objective* measure which provides the percentage of words that could be correctly identified by listeners. The words in this test need not be meaningful. The two performance measures are not correlated. A signal may be of good quality and poor intelligibility and vice versa. Most speech enhancement systems improve the quality of the signal at the expense of reducing its intelligibility. Listeners can usually extract more information from the noisy signal than from the enhanced signal by careful listening to that signal. This is obvious from the *data processing theorem* of information theory. Listeners, however, experience fatigue over extended listening sessions, a fact that results in reduced intelligibility of the noisy signal. In such situations, the intelligibility of the enhanced signal may be higher than that of the noisy signal. Less effort would usually be required from the listener to decode portions of the enhanced signal that correspond to high signal to noise ratio segments of the noisy signal.

Both the quality and intelligibility are elaborate and expensive to measure, since they require listening sessions with live subjects. Thus, researchers often resort to less formal listening tests to assess the quality of an enhanced signal, and they use automatic speech recognition tests to assess the intelligibility of that signal. Quality and intelligibility are also hard to quantify and express in a closed form that is amenable to mathematical optimization. Thus, the design of speech enhancement systems is often based on mathematical measures that are somehow believed to be correlated with the quality and intelligibility of the speech signal. A popular example involves estimation of the clean signal by minimizing the mean square error (MSE) between the logarithms of the spectra of the original and estimated signals [5]. This criterion is believed to be more perceptually meaningful than the minimization of the MSE between the original and estimated signal waveforms [13].

Another difficulty in designing efficient speech enhancement systems is the lack of *explicit* statistical models for the speech signal and noise process. In addition, the speech signal, and possibly also the noise process, are not strictly stationary processes. Common parametric models for speech signals, such as an autoregressive process for short-term modeling of the signal, and a hidden Markov process (HMP) for long-term modeling of the signal, have not provided adequate models for speech enhancement applications. A variant of the *expectation-maximization* (EM) algorithm, for maximum likelihood (ML) estimation of the autoregressive parameter from a noisy signal, was developed by Lim and Oppenheim [12] and tested in speech enhancement. Several estimation schemes, which are based on hidden Markov modeling of the clean speech signal and of the noise process, were developed over the years, see, e.g., Ephraim [6]. In each

² This paper is partially based on "Extension of the Signal Subspace Speech Enhancement Approach to Colored Noise" by Hanoch Lev-Ari and Yariv Ephraim which appeared in *IEEE Sig. Proc. Let.*, vol. 10, pp. 104–106, April 2003 ©2003 IEEE.

case, the HMPs for the speech signal and noise process were designed from training sequences from the two processes, respectively. While autoregressive and hidden Markov models have proved extremely useful in coding and recognition of *clean* speech signals, respectively, they were not found to be sufficiently refined models for speech enhancement applications.

In this chapter we review some common approaches to speech enhancement that were developed primarily for additive wide-band noise sources. Although some of these approaches have been applied to reduction of reverberation noise, we believe that the dereverberation problem requires a completely different approach that is beyond the scope of this chapter. Our primary focus is on the spectral subtraction approach [13] and some of its derivatives such as the signal subspace approach [7] [11], and the estimation of the short-term spectral magnitude [16, 4, 5]. This choice is motivated by the fact that some derivatives of the spectral subtraction approach are still the best approaches available to date. These approaches are relatively simple to implement and they usually outperform more elaborate approaches which rely on parametric statistical models and training procedures.

19.5.2 The Signal Subspace Approach

In this section we present the principles of the signal subspace approach and its relations to Wiener filtering and spectral subtraction. Our presentation follows [7] and [11]. This approach assumes that the signal and noise are noncorrelated, and that their second-order statistics are available. It makes no assumptions about the distributions of the two processes.

Let Y and W be k -dimensional random vectors in a Euclidean space \mathcal{R}^k representing the clean signal and noise, respectively. Assume that the expected value of each random variable is zero in an appropriately defined probability space. Let $Z = Y + W$ denote the noisy vector. Let R_y and R_w denote the covariance matrices of the clean signal and noise process, respectively. Assume that R_w is positive definite. Let H denote a $k \times k$ real matrix in the linear space $\mathcal{R}^{k \times k}$, and let $\hat{Y} = HZ$ denote the linear estimator of Y given Z . The residual signal in this estimation is given by

$$Y - \hat{Y} = (I - H)Y - HW \tag{19.78}$$

where I denotes, as usual, the identity matrix. To simplify notation, we shall not explicitly indicate the dimensions of the identity matrix. These dimensions should be clear from the context. In Eq. (19.78), $D = (I - H)Y$ is the signal distortion and $N = HW$ is the residual noise in the linear estimation. Let $(\cdot)'$ denote the transpose of a real matrix or the conjugate transpose of a complex matrix. Let

$$\overline{\epsilon_d^2} = \frac{1}{k} \text{tr} E \{ DD' \} = \frac{1}{k} \text{tr} \{ (I - H)R_y(I - H)' \} \tag{19.79}$$

denote the average signal distortion power where $\text{tr}\{\cdot\}$ denotes the trace of a matrix. Similarly, let

$$\overline{\epsilon_n^2} = \frac{1}{k} \text{tr} E \{ NN' \} = \frac{1}{k} \text{tr} \{ HR_w H' \} \tag{19.80}$$

denote the average residual noise power.

The matrix H is estimated by minimizing the signal distortion $\overline{\epsilon_d^2}$ subject to a threshold on the residual noise power $\overline{\epsilon_n^2}$. It is obtained from

$$\begin{aligned} & \min_H \overline{\epsilon_d^2} \\ & \text{subject to : } \overline{\epsilon_n^2} \leq \alpha \end{aligned} \tag{19.81}$$

for some given α . Let $\mu \geq 0$ denote the Lagrange multiplier of the inequality constraint. The optimal matrix, say $H = H_1$, is given by

$$H_1 = R_y(R_y + \mu R_w)^{-1} \tag{19.82}$$

The matrix H_1 can be implemented as follows. Let $R_w^{1/2}$ denote the symmetric positive definite square root of R_w and let $R_w^{-1/2} = (R_w^{1/2})^{-1}$. Let U denote an orthogonal matrix of eigenvectors of the symmetric matrix $R_w^{-1/2} R_y R_w^{-1/2}$. Let $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_k)$ denote the diagonal matrix of nonnegative eigenvalues of $R_w^{-1/2} R_y R_w^{-1/2}$. Then

$$H_1 = R_w^{1/2} U \Lambda (\Lambda + \mu I)^{-1} U' R_w^{-1/2} \tag{19.83}$$

When H_1 in Eq. (19.83) is applied to Z , it first whitens the input noise by applying $R_w^{-1/2}$ to Z . Then, the orthogonal transformation U' corresponding to the covariance matrix of the whitened clean signal is applied, and the transformed signal is modified by a diagonal Wiener-type gain matrix.

In Eq. (19.83), components of the whitened noisy signal that contain noise only are nulled. The indices of these components are given by $\{j : \lambda_j = 0\}$. When the noise is white, $R_w = \sigma_w^2 I$, and U and Λ are the matrices of eigenvectors and eigenvalues of R_y/σ_w^2 , respectively. The existence of null components $\{j : \lambda_j = 0\}$ for the signal means that the signal lies in a subspace of the Euclidean space \mathcal{R}^k . At the same time, the eigenvalues of the noise are all equal to σ_w^2 and the noise occupies the entire space \mathcal{R}^k . Thus, the signal subspace approach first eliminates the noise components outside the signal subspace and then modifies the signal components inside the signal subspace in accordance with the criterion of Eq. (19.81).

When the signal and noise are *wide-sense stationary*, the matrices R_y and R_w are Toeplitz with associated power spectral densities of $f_y(\theta)$ and $f_w(\theta)$, respectively. The angular frequency θ lies in $[0, 2\pi)$. When the signal and noise are *asymptotically weakly stationary*, the matrices R_y and R_w are asymptotically Toeplitz and have the associated power spectral densities $f_y(\theta)$ and $f_w(\theta)$, respectively [10]. Since the latter represents a somewhat more general situation, we proceed with asymptotically weakly stationary signal and noise. The filter H_1 in Eq. (19.82) is then asymptotically Toeplitz with associated power spectral density

$$h_1(\theta) = \frac{f_y(\theta)}{f_y(\theta) + \mu f_w(\theta)} \tag{19.84}$$

This is the noncausal Wiener filter for the clean signal with an adjustable noise level determined by the constraint α in Eq. (19.81). This filter is commonly implemented using estimates of the two power spectral densities. Let $\hat{f}_y(\theta)$ and $\hat{f}_w(\theta)$ denote the estimates of $f_y(\theta)$ and $f_w(\theta)$, respectively. These estimates could, for example, be obtained from the periodogram or the smoothed periodogram. In that case, the filter is implemented as

$$\hat{h}_1(\theta) = \frac{\hat{f}_y(\theta)}{\hat{f}_y(\theta) + \mu \hat{f}_w(\theta)} \tag{19.85}$$

When $\hat{f}_y(\theta)$ is implemented as

$$\hat{f}_y(\theta) = \begin{cases} \hat{f}_z(\theta) - \hat{f}_w(\theta) & \text{if nonnegative} \\ \varepsilon & \text{otherwise} \end{cases} \tag{19.86}$$

then a *spectral subtraction* estimator for the clean signal results. The constant $\varepsilon \geq 0$ is often referred to as a “spectral floor.” Usually $\mu \geq 2$ is chosen for this estimator.

The enhancement filter H could also be designed by imposing constraints on the spectrum of the residual noise. This approach enables shaping of the spectrum of the residual noise to minimize its perceptual effect. Suppose that a set $\{v_i, i = 1, \dots, m\}$, $m \leq k$, of k -dimensional real or complex orthonormal vectors, and a set $\{\alpha_i, i = 1, \dots, m\}$ of non-negative constants, are chosen. The vectors $\{v_i\}$ are used to transform the residual noise into the spectral domain, and the constants $\{\alpha_i\}$ are used as upper bounds on the variances of these spectral components. The matrix H is obtained from

$$\begin{aligned} & \min_H \overline{\epsilon_d^2} \\ & \text{subject to : } E\{|v_i' N|^2\} \leq \alpha_i, \quad i = 1, \dots, m \end{aligned} \tag{19.87}$$

When the noise is white, the set $\{v_i\}$ could be the set of eigenvectors of R_y and the variances of the residual noise along these coordinate vectors are constrained. Alternatively, the set $\{v_i\}$ could be the set of orthonormal vectors related to the DFT. These vectors are given by $v'_i = k^{-1/2}(1, e^{-j\frac{2\pi}{k}(i-1)}, \dots, e^{-j\frac{2\pi}{k}(i-1)\cdot(k-1)})$. Here we must choose $\alpha_i = \alpha_{k-i+2}, i = 2, \dots, k/2$, assuming k is even, for the residual noise power spectrum to be symmetric. This implies that at most $k/2 + 1$ constraints can be imposed. The DFT-related $\{v_i\}$ enable the use of constraints that are consistent with auditory perception of the residual noise.

To present the optimal filter, let e_l denote a unit vector in \mathcal{R}^k for which the l th component is one and all other components are zero. Extend $\{v_1, \dots, v_m\}$ to a $k \times k$ orthogonal or unitary matrix $V = (v_1, \dots, v_k)$. Set $\mu_i = 0$ for $m < i \leq k$, and let $M = \text{diag}(k\mu_1, \dots, k\mu_k)$ denote the matrix of k times the Lagrange multipliers which are assumed nonnegative. Define $Q = R_w^{-1/2}U$ and $T = Q'V$. The optimal estimation matrix, say $H = H_2$, is given by [11]

$$H_2 = R_w^{1/2}U \tilde{H}_2 U' R_w^{-1/2} \tag{19.88}$$

where the columns of \tilde{H}_2 are given by

$$\tilde{h}_l = T\lambda_l(M + \lambda_l I)^{-1} T^{-1} e_l, \quad l = 1, \dots, k \tag{19.89}$$

provided that $k\mu_i \neq -\lambda_l$ for all i, l . The optimal estimator first whitens the noise, then applies the orthogonal transformation U' obtained from eigendecomposition of the covariance matrix of the whitened signal, and then modifies the resulting components using the matrix \tilde{H}_2 . This is analogous to the operation of the estimator H_1 in Eq. (19.83). The matrix \tilde{H}_2 , however, is not diagonal when the input noise is colored.

When the noise is white with variance σ_w^2 and $V = U$ and $m = k$ are chosen, the optimization problem of Eq. (19.87) becomes trivial since knowledge of input and output noise variances uniquely determines the filter H . This filter is given by $H = UGU'$ where $G = \text{diag}(\sqrt{\alpha_1}, \dots, \sqrt{\alpha_k})$ [7]. For this case, the heuristic choice of

$$\alpha_i = \exp\{-\nu\sigma_w^2/\lambda_i\} \tag{19.90}$$

where $\nu \geq 1$ is an experimental constant and was found useful in practice [7]. This choice is motivated by the observation that for $\nu = 2$, the first order Taylor expansion of $\alpha_i^{-1/2}$ leads to an estimator $H = UGU'$ which coincides with the Wiener estimation matrix in Eq. (19.83) with $\mu = 1$. The estimation matrix using Eq. (19.90) performs significantly better than the Wiener filter in practice.

19.5.3 Short-Term Spectral Estimation

In another earlier approach for speech enhancement, the short-time spectral magnitude of the clean signal is estimated from the noisy signal. The speech signal and noise process are assumed statistically independent, and spectral components of each of these two processes are assumed zero mean statistically independent Gaussian random variables. Let $A_y e^{j\theta_y}$ denote a spectral component of the clean signal Y in a given frame. Let $A_z e^{j\theta_z}$ denote the corresponding spectral component of the noisy signal. Let $\sigma_y^2 = E\{A_y^2\}$ and $\sigma_z^2 = E\{A_z^2\}$ denote, respectively, the variances of the clean and noisy spectral components. If the variance of the corresponding spectral component of the noise process in that frame is denoted by σ_w^2 , then we have $\sigma_z^2 = \sigma_y^2 + \sigma_w^2$. Let

$$\xi = \frac{\sigma_y^2}{\sigma_w^2}; \quad \gamma = \frac{A_z^2}{\sigma_w^2}; \quad \vartheta = \frac{\xi}{\xi + 1} \gamma \tag{19.91}$$

The MMSE estimation of A_y from $A_z e^{j\theta_z}$ is given by [4]

$$\hat{A}_y = \Gamma(1.5) \frac{\sqrt{\vartheta}}{\gamma} \exp\left(-\frac{\vartheta}{2}\right) \left[(1 + \vartheta) I_0\left(\frac{\vartheta}{2}\right) + \vartheta I_1\left(\frac{\vartheta}{2}\right) \right] A_z \tag{19.92}$$

where $\Gamma(1.5) = \frac{\sqrt{\pi}}{2}$, and $I_0(\cdot)$ and $I_1(\cdot)$ denote, respectively, the modified Bessel functions of the zeroth and first order. Similarly to the Wiener filter given in Eq. (19.82), this estimator requires knowledge of second order statistics of each signal and noise spectral components, σ_y^2 and σ_w^2 , respectively.

To form an estimator for the spectral component of the clean signal, the spectral magnitude estimator Eq. (19.92) is combined with an estimator of the complex exponential of that component. Let $\widehat{e^{j\theta_y}}$ be an estimator of $e^{j\theta_y}$. This estimator is a function of the noisy spectral component $A_z e^{j\theta_z}$. MMSE estimation of the complex exponential $e^{j\theta_y}$ is obtained from

$$\begin{aligned} \min_{\widehat{e^{j\theta_y}}} E\{|e^{j\theta_y} - \widehat{e^{j\theta_y}}|^2\} \\ \text{subject to : } |\widehat{e^{j\theta_y}}| = 1 \end{aligned} \quad (19.93)$$

The constraint in Eq. (19.93) ensures that the estimator $\widehat{e^{j\theta_y}}$ does not affect the optimality of the estimator \hat{A}_y when the two are combined. The constrained minimization problem in Eq. (19.93) results in the estimator $\widehat{e^{j\theta_y}} = e^{j\theta_z}$ which is simply the complex exponential of the noisy signal.

Note that the Wiener filter Eq. (19.85) has zero phase and hence it effectively uses the complex exponential of the noisy signal $e^{j\theta_z}$ in estimating the clean signal spectral component. Thus, both the Wiener estimator of Eq. (19.85) and the MMSE spectral magnitude estimator of Eq. (19.92) use the complex exponential of the noisy phase. The spectral magnitude estimate of the clean signal obtained by the Wiener filter, however, is not optimal in the MMSE sense.

Other criteria for estimating A_y could also be used. For example, A_y could be estimated from

$$\min_{\hat{A}_y} E\{(\log A_y - \log \hat{A}_y)^2\} \quad (19.94)$$

This criterion aims at producing an estimate of A_y whose logarithm is as close as possible to the logarithm of A_y in the MMSE sense. This perceptually motivated criterion results in the estimator given by [5]

$$\hat{A}_y = \frac{\sigma_y^2}{\sigma_y^2 + \sigma_w^2} \exp\left(\frac{1}{2} \int_{\vartheta}^{\infty} \frac{e^{-t}}{t} dt\right) A_z \quad (19.95)$$

The integral in Eq. (19.95) is the well known exponential integral of ϑ and it can be numerically evaluated.

In another example, A_y^2 could be estimated from

$$\min_{\hat{A}_y} E\{(A_y^2 - \widehat{A}_y^2)^2\} \quad (19.96)$$

and an estimate of A_y could be obtained from $\sqrt{\widehat{A}_y^2}$. The criterion in Eq. (19.96) aims at estimating the magnitude squared of the spectral component of the clean signal in the MMSE sense. This estimator is particularly useful when subsequent processing of the enhanced signal is performed, for example, in autoregressive analysis for low bit rate signal coding applications [13]. In that case, an estimator of the autocorrelation function of the clean signal can be obtained from the estimator \widehat{A}_y^2 . The optimal estimator in the sense of Eq. (19.96) is well known and is given by (see e.g., [6])

$$\widehat{A}_y^2 = \frac{\sigma_y^2 \sigma_w^2}{\sigma_y^2 + \sigma_w^2} + \left| \frac{\sigma_y^2}{\sigma_y^2 + \sigma_w^2} A_z \right|^2 \quad (19.97)$$

19.5.4 Multiple State Speech Model

All estimators presented in Section 19.5.2 and Section 19.5.3 make the implicit assumption that the speech signal is always present in the noisy signal. In the notation of Section 19.5.2, $Z = Y + W$. Since the length of a frame is relatively short, in the order of 30 – 50 msec, it is more realistic to assume that speech may be present in the noisy signal with some probability, say η , and may be absent from the noisy signal with

one minus that probability. Thus we have two hypotheses, one of speech presence, say H_1 , and the other of speech absence, say H_0 , that occur with probabilities η and $1 - \eta$, respectively. We have

$$Z = \begin{cases} Y + W & \text{under } H_1 \\ W & \text{under } H_0 \end{cases} \tag{19.98}$$

The MMSE estimator of A_y under the uncertainty model can be shown to be

$$\begin{aligned} \tilde{A}_y &= \Pr(H_1|Z) \cdot E\{A_y|Z, H_1\} + \Pr(H_0|Z) \cdot E\{A_y|Z, H_0\} \\ &= \Pr(H_1|Z) \cdot \hat{A}_y \end{aligned} \tag{19.99}$$

since $E\{A_y|Z, H_0\} = 0$ and $E\{A_y|Z, H_1\} = \hat{A}_y$ as given by Eq. (19.92). The more realistic estimator given in Eq. (19.99) was found useful in practice as it improved the performance of the estimator in Eq. (19.92). Other estimators may be derived under this model. Note that the model as in Eq. (19.98) is not applicable to the estimator in Eq. (19.95) since A_y must be positive for the criterion in Eq. (19.94) to be meaningful. Speech enhancement under the speech presence uncertainty model was first proposed and applied by McAulay and Malpass in their pioneering work [16].

An extension of this model leads to the assumption that speech vectors may be in different states at different time instants. The speech presence uncertainty model assumes two states representing speech presence and speech absence. In another model of Drucker [3], five states were proposed representing fricative, stop, vowel, glide, and nasal speech sounds. A speech absence state could be added to that model as a sixth state. This model requires an estimator for each state just as in Eq. (19.99).

A further extension of these ideas, in which multiple states that evolve in time are possible, is obtained when one models the speech signal by a hidden Markov process (HMP) [8]. An HMP is a bivariate random process of states and observations sequences. The state process $\{S_t, t = 1, 2, \dots\}$ is a finite-state homogeneous Markov chain that is not directly observed. The observation process $\{Y_t, t = 1, 2, \dots\}$ is conditionally independent given the state process. Thus, each observation depends statistically only on the state of the Markov chain at the same time and not on any other states or observations. Consider, for example, an HMP observed in an additive white noise process $\{W_t, t = 1, 2, \dots\}$. For each t , let $Z_t = Y_t + W_t$ denote the noisy signal. Let $Z^t = \{Z_1, \dots, Z_t\}$. Let J denote the number of states of the Markov chain. The causal MMSE estimator of Y_t given $\{Z^t\}$ is given by [6]

$$\begin{aligned} \hat{Y}_t &= E\{Y_t|Z^t\} \\ &= \sum_{j=1}^J \Pr(S_t = j|Z^t) E\{Y_t|S_t = j, Z_t\} \end{aligned} \tag{19.100}$$

The estimator as given in Eq. (19.100) reduces to Eq. (19.99) when $J = 2$ and $\Pr(S_t = j|Z^t) = \Pr(S_t = j|Z_t)$, or when the states are statistically independent of each other.

An HMP is a parametric process that depends on the initial distribution and transition matrix of the Markov chain and on the parameter of the conditional distributions of observations given states. The parameter of an HMP can be estimated off-line from training data and then used in constructing the estimator in Eq. (19.100). This approach has a great theoretical appeal since it provides a solid statistical model for speech signals. It also enjoys a great intuitive appeal since speech signals do cluster into sound groups of distinct nature, and dedication of a filter for each group is appropriate. The difficulty in implementing this approach is in achieving low probability of error in mapping vectors of the noisy speech onto states of the HMP. Decoding errors result in wrong association of speech vectors with the set of predesigned estimators $\{E\{Y_t|S_t = j, Z_t\}, j = 1, \dots, J\}$, and thus in poorly filtered speech vectors. In addition, the complexity of the approach grows with the number of states, since each vector of the signal must be processed by all J filters.

The approach outlined above could be applied based on other models for the speech signal. For example, in [20], a harmonic process based on an estimated pitch period was used to model the speech signal.

19.5.5 Second-Order Statistics Estimation

Each of the estimators presented in Section 19.5.2 and Section 19.5.3 depends on some statistics of the clean signal and noise process which are assumed known *a-priori*. The signal subspace estimators as in Eq. (19.82) and Eq. (19.88) require knowledge of the covariance matrices of the signal and noise. The spectral magnitude estimators in Eq. (19.92), Eq. (19.95), and Eq. (19.97) require knowledge of the variance of each spectral component of the speech signal and of the noise process. In the absence of explicit knowledge of the second-order statistics of the clean signal and noise process, these statistics must be estimated either from training sequences or directly from the noisy signal.

We note that when estimates of the second-order statistics of the signal and noise replace the true second-order statistics in a given estimation scheme, the optimality of that scheme can no longer be guaranteed. The quality of the estimates of these second-order statistics is key for the overall performance of the speech enhancement system. Estimation of the second-order statistics can be performed in various ways usually outlined in the theory of spectral estimation [19]. Some of these approaches are reviewed in this section.

Estimation of speech signals second-order statistics from training data has proven successful in coding and recognition of clean speech signals. This is commonly done in coding applications using vector quantization and in recognition applications using hidden Markov modeling. When only noisy signals are available, however, matching of a given speech frame to a codeword of a vector quantizer or to a state of an HMP is susceptible to decoding errors. The significance of these errors is the creation of a mismatch between the true and estimated second order statistics of the signal. This mismatch results in application of wrong filters to frames of the noisy speech signal, and in unacceptable quality of the processed noisy signal.

On-line estimation of the second-order statistics of a speech signal from a sample function of the noisy signal has proven to be a better choice. Since the analysis frame length is usually relatively small, the covariance matrices of the speech signal may be assumed Toeplitz. Thus, the autocorrelation function of the clean signal in each analysis frame must be estimated. The Fourier transform of a windowed autocorrelation function estimate provides estimates of the variances of the clean signal spectral components.

For a wide-sense stationary noise process, the noise autocorrelation function can be estimated from an initial segment of the noisy signal that contains noise only. If the noise process is not wide-sense stationary, frames of the noisy signal must be classified as in Eq. (19.98), and the autocorrelation function of the noise process must be updated whenever a new noise frame is detected.

In the signal subspace approach [7], the power spectral densities of the noise and noisy processes are first estimated using windowed autocorrelation function estimates. Then, the power spectral density of the clean signal is estimated using Eq. (19.86). That estimate is inverse Fourier transformed to produce an estimate of the desired autocorrelation function of the clean signal. In implementing the MMSE spectral estimator as in Eq. (19.92), a recursive estimator for the variance of each spectral component of the clean signal developed in [4] is often used, see, e.g., [1, 2]. Let $\hat{A}_y(t)$ denote an estimator of the magnitude of a spectral component of the clean signal in a frame at time t . This estimator may be the MMSE estimator as in Eq. (19.92). Let $A_z(t)$ denote the magnitude of the corresponding spectral component of the noisy signal. Let $\hat{\sigma}_w^2(t)$ denote the estimated variance of the spectral component of the noise process in that frame. Let $\hat{\sigma}_y^2(t)$ denote the estimated variance of the spectral component of the clean signal in that frame. This estimator is given by

$$\hat{\sigma}_y^2(t) = \beta \hat{A}_y^2(t-1) + (1-\beta) \max\{A_z^2(t) - \hat{\sigma}_w^2(t), 0\} \quad (19.101)$$

where $0 \leq \beta \leq 1$ is an experimental constant. We note that while this estimator was found useful in practice, it is heuristically motivated and its analytical performance is not known.

A parametric approach for estimating the power spectral density of the speech signal from a given sample function of the noisy signal was developed by Musicus and Lim [18]. The clean signal in a given frame is assumed a zero mean Gaussian autoregressive process. The noise is assumed a zero mean white Gaussian process that is independent of the signal. The parameter of the noisy signal comprises the autoregressive coefficients, the gain of the autoregressive process, and the variance of the noise process. This parameter is estimated in the ML sense using the EM algorithm. The EM algorithm and conditions for its convergence

were originally developed for this problem by Musicus [17]. The approach starts with an initial estimate of the parameter. This estimate is used to calculate the conditional mean estimates of the clean signal and of the sample covariance matrix of the clean signal given the noisy signal. These estimates are then used to produce a new parameter, and the process is repeated until a fixed point is reached or a stopping criterion is met.

This EM procedure is summarized as follows: Consider a scalar autoregressive process $\{Y_t, t = 1, 2, \dots\}$ of order r and coefficients $a = (a_1, \dots, a_r)'$. Let $\{V_t\}$ denote an independent identically distributed (iid) sequence of zero mean unit variance Gaussian random variables. Let σ_v denote a gain factor. A sample function of the autoregressive process is given by

$$y_t = - \sum_{i=1}^r a_i y_{t-i} + \sigma_v v_t \tag{19.102}$$

Assume that the initial conditions of Eq. (19.102) are zero, i.e., $y_t = 0$ for $t < 1$. Let $\{W_t, t = 1, 2, \dots\}$ denote the noise process which comprises an iid sequence of zero mean unit variance Gaussian random variables. Consider a k -dimensional vector of the noisy autoregressive process. Let $Y = (Y_1, \dots, Y_k)'$, and define similarly the vectors V and W corresponding to the processes $\{V_t\}$ and $\{W_t\}$, respectively. Let A denote a lower triangular Toeplitz matrix with the first column given by $(1, a_1, \dots, a_r, 0, \dots, 0)'$. Then

$$Z = \sigma_v A^{-1} V + \sigma_w W \tag{19.103}$$

Suppose $\phi_m = (a(m), \sigma_v(m), \sigma_w(m))$ denotes an estimate of the parameter of Z at the end of the m th iteration. Let $A(m)$ denote the matrix A constructed from the vector $a(m)$. Let $R_y(m) = \sigma_v^2(m) A(m)^{-1} (A(m))^{-1}'$ denote the covariance matrix of the autoregressive process of Eq. (19.102) as obtained from ϕ_m . Let $R_z(m) = R_y(m) + \sigma_w^2(m) I$ denote the covariance matrix of the noisy signal as shown in Eq. (19.103) based on ϕ_m . Let \hat{Y} and \hat{R} denote, respectively, the conditional mean estimates of the clean signal Y and of the sample covariance of Y given Z and the current estimate ϕ_m . Under the Gaussian assumptions of this problem, we have

$$\begin{aligned} \hat{Y} &= E\{Y|Z; \phi_m\} \\ &= R_y(m) R_z^{-1}(m) Z \end{aligned} \tag{19.104}$$

$$\begin{aligned} \hat{R} &= E\{YY'|Z; \phi_m\} \\ &= R_y(m) - R_y(m) R_z^{-1}(m) R_y(m) + \hat{Y} \hat{Y}' \end{aligned} \tag{19.105}$$

The estimation of the statistics of the clean signal in Eq. (19.104) and Eq. (19.105) comprise the E -step of the EM algorithm.

Define the $r + 1 \times r + 1$ covariance matrix S with entries

$$S(i, j) = \sum_{l=\max(i,j)}^{k-1} \hat{R}(l - i, l - j), \quad i, j = 0, \dots, r \tag{19.106}$$

Define the $r \times 1$ vector $q = (S(1, 0), \dots, S(r, 0))'$ and the $r \times r$ covariance matrix $Q = \{S(i, j), i, j = 1, \dots, r\}$. The new estimate of parameter ϕ at the end of the $m + 1$ iteration is given by

$$a(m + 1) = -Q^{-1}q \tag{19.107}$$

$$\sigma_v^2(m + 1) = (S(0, 0) + 2a'(m)q + a'(m)Qa(m))/k \tag{19.108}$$

$$\begin{aligned} \sigma_w^2(m + 1) &= \text{tr} \{E\{(Z - Y)(Z - Y)'|Z, \phi_m\}\} / k \\ &= \text{tr} \{ZZ' - 2\hat{Y}Z' + \hat{R}\} / k. \end{aligned} \tag{19.109}$$

The calculation of the parameter of the noisy signal in Eq. (19.107) to Eq. (19.109) comprise the M -step of the EM algorithm.

Note that the enhanced signal can be obtained as a by-product of this algorithm using the estimator as in Eq. (19.104) at the last iteration of the algorithm. Formulation of the above parameter estimation problem in a state space assuming colored noise in the form of another autoregressive process, and implementation of the estimators as given in Eq. (19.104) and Eq. (19.105) using Kalman filtering and smoothing was done in [9].

The EM approach presented above differs from an earlier approach pioneered by Lim and Oppenheim [12]. Assume for this comparison that the noise variance is known. In the EM approach, the goal is to derive the ML estimate of the true parameter of the autoregressive process. This is done by local maximization of the likelihood function of the noisy signal over the parameter set of the process. The EM approach results in alternate estimation of the clean signal Y and its sample correlation matrix YY' , and of the parameter of the autoregressive process (a, σ_v) . The approach taken in [12] aims at estimating the parameter of the autoregressive process that maximizes the joint likelihood function of the clean and noisy signals. Using alternate maximization of the joint likelihood function, the approach resulted in alternate estimation of the clean signal Y and of the parameter of the autoregressive process (a, σ_v) . Thus, the main difference between the two approaches is in the estimated statistics from which the autoregressive parameter is estimated in each iteration. This difference impacts the convergence properties of the algorithm [12] which is known to produce an inconsistent parameter estimate. The algorithm [12] is simpler to implement than the EM approach and it is popular among some authors. To overcome the inconsistency, they developed a set of constraints for the parameter estimate in each iteration.

19.5.6 Concluding Remarks

We have surveyed some aspects of the speech enhancement problem and presented state-of-the-art solutions to this problem. In particular, we have identified the difficulties inherent to speech enhancement, and presented statistical models and distortion measures commonly used in designing estimators for the clean signal. We have mainly focused on speech signals degraded by additive noncorrelated wide-band noise. As we have noted earlier, even for this case, a universally accepted solution is not available and more research is required to refine current approaches or alternatively develop new ones. Other noise sources, such as room reverberation noise, present a more significant challenge as the noise is a non-stationary process that is correlated with the signal and it cannot be easily modeled. The speech enhancement problem is expected to attract significant research effort in the future due to challenges that this problem poses, the numerous potential applications, and future advances in computing devices.

Defining Terms

Speech Enhancement: The action of improving perceptual aspects of a given sample of speech signals.

Quality: A subjective measure of the way a speech signal is perceived.

Intelligibility: An objective measure which indicates the percentage of words from a given text that are expected to be correctly understood by listeners.

Signal estimator: A function of the observed noisy signal which approximates the clean signal.

Expectation-maximization: An iterative approach for parameter estimation using alternate estimation and maximization steps.

Autoregressive process: A random process obtained by passing white noise through an all-pole filter.

Wide-sense stationarity: A property of a random process whose second-order statistics do not change with time.

Asymptotically weakly stationarity: A property of a random process indicating eventual wide-sense stationarity.

Hidden Markov Process: A Markov chain observed through a noisy channel.

19.6 Ad Hoc Networks

*Michel D. Yacoub, Paulo Cardieri, Élvio João Leonardo,
and Álvaro Augusto Machado Medeiros*

19.6.1 Introduction

An ad hoc network is a wireless network that is established without the aid of infrastructure or centralized administration. It is formed by a group of wireless terminals (nodes) such that a communication between any two terminals is carried out by means of a store-and-relay mechanism. A terminal wishing to transmit

accesses the medium and sends its information to a nearby terminal. Upon receiving such information this terminal determines that this is not addressed to it. It then stores the information in order to relay it to another terminal at an appropriate time, and this process continues until the destination is reached. Note that in ad hoc networks there are no fixed routers. Nodes may be mobile and can be connected dynamically in an arbitrary manner. Nodes function as routers, which discover and maintain routes to other nodes in the network. Ad hoc networks find applications in emergency-and-rescue operations, meeting or conventions, data acquisition operations in inhospitable terrain, sensor networks, and home and office networks. Cheaper hardware, smaller transceivers, and faster processors fuel the increased interest in wireless ad hoc networks. This chapter addresses the ad hoc networks from four main aspects: routing, medium access, TCP/IP issues, and capacity. In routing, the main routing algorithms are illustrated. In medium access, the main medium access protocols are described. In TCP/IP issues, the aspects concerning the performance of TCP/IP in an ad hoc network is discussed. In capacity, some formulation concerning the capacity of the network is tackled.

19.6.2 Routing Algorithms

The design of routing algorithms in ad hoc networks is a challenging task. Algorithms must provide for a high degree of sophistication and intelligence so that the limited resources inherent to the wireless systems can be dealt with efficiently. They must be robust in order to cope with the unkind wireless environment. At the same time they must be flexible in order to adapt to the changing network conditions such as network size, traffic distribution, and mobility. Routing algorithms have long been used in wired systems and they are usually classified into two categories: Distant vector (DV) and Link-state (LS). DV algorithms provide each node with a vector containing the hop distance and the next hop to all the destinations. LS algorithms provide each node with an updated view of the network topology by periodical flooding of link information about its neighbors. A direct application of these algorithms in a wireless and mobile environment may be cumbersome. DV protocols suffer from slow route convergence and may create loops. LS protocols require the frequent use of the resources, thence large bandwidth, in order to maintain the nodes updated.

With the increasing interest in wireless networks, a variety of routing algorithms overcoming the limitations of the DV and LS protocols have been proposed. They are usually classified into three categories: proactive or table-driven, reactive or on-demand, and hybrid. The proactive protocols require the nodes to keep tables with routing information. Updates occur on a periodical basis or as soon as changes in the network topology are perceived. The algorithms differ basically in the type of information is kept and in the way updates occur. The reactive protocols create routes on demand. This is accomplished by means of a route discovery process, which is completed once a route has been found or all possible route permutations have been examined. The discovery process occurs by flooding route request packets through the network. After establishing a route, it is maintained by a route maintenance procedure until either the destination becomes inaccessible along every path from the source or until the route is no longer desired. The hybrid protocols are both proactive and reactive. Nodes with close proximity form a backbone within which proactive protocols are applied. Routes to faraway nodes are found through reactive protocols.

Proactive Algorithms

CGSR—Clusterhead-gateway switch routing (Chiang, 1997). In CGSR, the whole network is partitioned into clusters of nodes. Within each cluster a *clusterhead* is elected among the nodes. A node may belong to one cluster only, in which case it is an internal node, or to more than one cluster, in which case it becomes a *gateway*. Packets are transmitted from the node to the clusterhead and from the clusterhead to the node. Routing within such a network occurs as follows. Assume source and destination belonging to different clusters. The source sends its packets to the clusterhead, which relays these packets to a gateway, which relays them to another clusterhead, and this process continues until the destination is reached.

DREAM—Distance routing effect algorithm for mobility (Basagni, 1998). In DREAM, GPS is used so that each node can maintain a location table with records of locations of all the nodes. The nodes broadcast control packets for location updating purposes. A source having packets to send calculates the direction

toward the destination. It then selects a set of one-hop neighbors in the respective direction. (If the set is empty, the data are flooded to the whole network.) The data header encloses the respective set and is sent. Those nodes specified in the header are entitled to receive and process the data. All the nodes of the paths repeat this process until the destination is reached. Upon receiving the packets, the destination issues an ACK, which is transmitted to the source using the same algorithm.

DSDV—Destination-sequential distance-vector routing (Perkins, 1994). In DSDV, each node keeps a routing table containing all of the possible destinations within the network in conjunction with the number of hops to each destination. The entries are marked with a sequence number assigned by the destination node so that mobile nodes can distinguish stable routes from the new ones in order to avoid routing loops. Table consistency is kept by periodical updates transmitted throughout the network.

FSLs—Fuzzy sighted link state (Santivanez, 2001). In FSLs, an optimal link state update algorithm (hazy sighted link state) is used. Updates occur every $2^k T$, in which k is the hop distance, T is the minimum link state update transmission period, and 2^k is the number of nodes to be updated. FSLs operates in a way very similar to FSR, as described below.

FSR—Fisheye state routing (Iwata, 1999; Pei, 2000). In FSR, each node maintains a topology map, and link state information is exchanged with neighbors periodically. The frequency with which it occurs depends on the hop distance to the current node. Nearby destinations are updated more frequently whereas for the faraway ones the updates are less frequent. Therefore, FSR produces accurate distance and path information about immediate neighborhood, and imprecise information about the best path to a distant node. On the other hand, such an imprecision is compensated for as the packet approaches its destination.

GSR—Global state routing (Chen, 1998). In GSR, a link state table based on the update messages from neighboring nodes is kept and periodical exchanges of link state information are carried out. The size of update messages increases with the increase of the size of the network, and a considerable amount of bandwidth is required in this case.

HSR—Hierarchical state routing (Pei, 1999). In HSR, the link state algorithm principle is used in conjunction with a hierarchical addressing and topology map. Clustering algorithms may also be used so as to organize the nodes with close proximity into clusters. Each node has a unique identity, which are typically a MAC address and a hierarchical address. A communication between any two nodes occurs by means of physical and logical links. The physical links support the true communication between nodes whereas the logical links are used for the purposes of the hierarchical structure of the communication. This way, several levels in the hierarchy may be built. The lowest level is always the physical level whereas the higher levels constitute the logical levels. Communications then occur starting from the lowest level up to the higher levels and down again to the lowest level.

MMWN—Multimedia support in mobile wireless networks (Kasera, 1997). In MMWN, a clustering hierarchy is used, each cluster having two types of nodes: switch and endpoint. Endpoints do not communicate with each other but with switches only. Within a cluster, one of the switches is chosen as a location manager, which performs location updating and location finding. This means that routing overhead is drastically reduced as compared to the traditional table-driven algorithms. This way, information in MMWN is stored in a dynamically distributed database.

OLSR—Optimized link state routing (Jacquet, 2001). In OLSR, each node keeps topology information on the network by periodically exchanging link state messages. OLSR uses the multipoint replaying strategy (MPR) in order to minimize the size of the control messages and the number of re-broadcasting nodes. To this end, each node selects a set of neighboring nodes (multipoint relays—MPRs) to retransmit its packets. Those not in the selected set may read and process each packet but not retransmit. The selection of the appropriate set is carried out as follows. Each node periodically broadcasts a list of its one-hop neighbors. From the lists the nodes are able to choose a subset of one-hop neighbors that covers all of its two-hop neighbors. An optimal route to every destination is constructed and stored in a routing table.

STAR—Source-tree adaptive routing (Garci-Luna-Aceves, 1999). In STAR, each node keeps a source tree with the preferred paths to destinations. It uses the least overhead routing approach (LORA) to reduce the amount of routing overhead disseminated into the network. The reduction in the amount of messages is achieved by making update dissemination conditional to the occurrence of certain events.

TBRPF—Topology broadcast based on reverse path forwarding (Bellur, 1999; Ogier, 2002). In TBRPF, two separate modules are implemented: neighbor discovery module and the routing module. The first module performs a differential HELLO messages that reports only the changes (up or lost) of neighbors. The second module operates based on partial topology information. The information is obtained through periodic and differential topology updates. If a node n is to send an update message, then every node in the network selects its next hop (parent) node toward that node. Link state updates are propagated in the reverse direction on the spanning tree formed by the minimum-hop paths from all nodes to the sending node. This means that updates originated at n are only accepted if these updates arrive from the respective parent node. They are then propagated toward the children nodes pertaining to n .

WRP—Wireless routing protocol (Murthy, 1996). In WRP, each node maintains a set of tables as follows: distance table, routing table, link-cost table, message retransmission list (MRL) table. Each entry of the MRL table contains a sequence number of the update message, a retransmission counter, an acknowledgement required flag vector with one entry per neighbor, and a list of updates sent in the update message. It records which updates need to be retransmitted and which neighbors should acknowledge the retransmission. Update messages are sent only between neighboring nodes and they occur after processing updates or detecting a change in the link to the neighbor. Nodes learn of the existence of their neighbors from the receipt of ACK and other messages. In case a node is not sending messages of any kind, then a HELLO message is sent within a specified period of time to ensure connectivity.

Reactive Algorithms

ABR—Associativity-based routing (ABR) (Toh, 1996). In ABR, a query-reply technique is used to determine routes to the required destination. Stable routes are chosen based on an associativity tick that each node maintains with its neighbors, with the links with the higher associativity tick being selected. This may not lead to the shortest paths but rather to paths that last longer. In such a case, fewer route reconstructions are needed thence more bandwidth is available. ABR requires periodical beaconing so as to determine the degree of associativity of the links which requires all nodes to remain active at all time, which result in additional power consumption.

AODV—Ad hoc on demand distance vector (Das, 2002). In AODV, periodic beaconing and sequence numbering procedure are used. The packets convey the destination address rather than the full routing information, this also occurring in the route replies. The advantage of AODV is its adaptability to highly dynamic networks. On the other hand, the nodes may experience large delays in route construction.

ARA—Ant-colony-based routing algorithm (Günes, 2002). In ARA, the food searching behavior of ants is used in order to reduce routing overheads. When searching for food, ants leave a trail behind (pheromone) that is followed by the other ants until it vanishes. In the route discovery procedure, ARA propagates a forwarding ANT (FANT) through the network until it reaches the destination. Then a backward ANT (BANT) is returned, a path is created, and data packet dissemination starts. The route is maintained by means of increasing or decreasing the pheromone value at each node. The pheromone at a given node is increased each time a packet travels through it, and it is decreased overtime until it expires. As can be inferred, the size of FANT and BANT is small; therefore the amount of overhead per control packet is minimized.

CBRP—Cluster-based routing protocol (Jiang, 1999). In CBRP, the nodes are grouped into clusters, a cluster presenting a clusterhead. The advantage of using the hierarchical approach is the decrease in the number of control overhead through the network as compared with the traditional flooding methods. Of course, there are overheads associated with the formation and maintenance of the clusters. The long propagation delay due to the hierarchical structure may render the nodes bearing inconsistent topology information, which may lead to temporary routing loops.

DSR—Dynamic source routing (Johnson, 2002). In DSR, there is no periodic beaconing (HELLO message), an important feature that can be used for battery saving purposes, in which the node may enter the sleep mode. Each packet in DSR conveys the full address of the route, and this is a disadvantage for large or highly dynamic networks. On the other hand, the nodes can store multiple routes in their route cache. The advantage of this is that the node can check its route cache for a valid route before initiating route

discovery. A valid route found avoids the need for route discovery. And this is an advantageous feature for low mobility networks.

FORP—Flow oriented routing protocol (Su, 1999). In FORP, routing failure due to mobility is minimized by means of the following algorithm. A Flow-REQ message is disseminated through the network. A node receiving such a message, and based on GPS information, estimates a link expiration time (LET) with the previous hop and append this into its Flow-REQ packet, which is re-transmitted. Upon arrival at the destination, a route expiration time (RET) is estimated using the minimum of all LETs for each node. A Flow-SETUP message is sent back toward the source. Therefore, the destination is able to predict when a link failure may occur. In such a case, a Flow-HANDOFF message is generated and propagated in a similar manner.

LAR—Location aided routing (Ko, 1998). In LAR, using location information routing overhead is minimized, which is commonly present in the traditional flooding algorithms. Assuming each node provided with a GPS, the packets travel in the direction where the relative distance to the destination becomes smaller as they travel from one hop to another.

LMR—Light-weight mobile routing (Corson, 1995). In LMR, the flooding technique is used in order to determine the required routes. Multiple routes are kept at the nodes, the multiplicity being used for reliability purposes as well as to avoid the re-initiation of a route discovery procedure. In addition, the route information concerns the neighborhood only and not the complete route.

RDMAR—Relative distance micro-discovery ad hoc routing (Aggelou, 1999). In RDMAR, a relative-distance micro-discovery procedure is used in order to minimize routing overheads. This is carried out by means of calculating the distance between source and destination, thence limiting each route request packet to a certain number of hops (i.e., the route discovery procedure becomes confined to localized regions). In fact, this is only feasible if previous communications between source and destination has been established. Otherwise, a flooding procedure is applied.

ROAM—Routing on-demand acyclic multi-path (Raju, 1999). In ROAM, inter-nodal coordination and directed acyclic sub-graphs, derived from the distance of the router to the destination, are used. In case the required destination is no longer reachable multiple flood searches stop. In addition, each time the distance of a router to a destination changes by more than a given threshold, the router broadcasts update messages to its neighboring nodes. This increases the network connectivity at the expense of preventing the nodes entering the sleep mode to save battery.

SSA—Signal stability adaptive (Dube, 1997). In SSA, route selection is carried out based on signal strength and location stability, and not on associativity tick. In addition, route requests sent toward a destination cannot be replied by intermediate nodes, which may cause delays before a route is effectively discovered. This is due to the fact that the destination is responsible for selecting the route for data transfer.

TORA—Temporarily ordered routing algorithm (Park, 1997). In TORA, the key design concept is the localization of control messages to a very small set of nodes near the occurrence of a topological change. The nodes maintain routing information about one-hop nodes. Route creation and route maintenance phases use a height metric to establish a directed acyclic graph rooted at the destination. Then, links are assigned as upstream or downstream based on the relative height metric to neighboring nodes. Route's erasure phase involves flooding a broadcast clear packet throughout the network in order to erase invalid routes.

Hybrid Algorithms

DDR—Distributed dynamic routing (Nikaiein, 2001). In DDR, a tree-based routing protocol is used but a root node is not required. The trees are set up by means of periodic beaconing messages, exchanged by neighboring nodes only. Different trees, composing a forest, are connected via gateway nodes. Each tree constitutes a zone, which is assigned a zone ID. The routes are determined by hybrid ad hoc protocols.

DST—Distributed spanning trees based routing protocol (Radhakrishnan, 1999). In DST, all nodes are grouped into trees, within which a node becomes a routing node or an internal node. The root, which is also a node, controls the structure of the tree. This may become a disadvantage of DST for the root node creates a single point of failure.

SLURP—Scalable location update routing protocol (Woo, 2001). In SLURP, the nodes are organized into nonoverlapping zones and a home region for each node in the network is assigned. The home region for each node is determined by means of a static mapping function known to all nodes whose inputs are the node ID and the number of nodes. Thus, all nodes are able to determine the home region for each node. The current location of the node within its home region is maintained by unicasting a location update packet toward its region. Once it reaches its home region, it is broadcast to all nodes within its home.

ZHLS—Zone-based hierarchical link state (Joa-Ng, 1999). In ZHLS, hierarchical topology is used such that two levels are established: node level and zone level, for which the use of GPS is required. Each node then has a node ID and a zone ID. In case a route to a node within another zone is required, the source node broadcasts a zone-level location request to all of the other zones. This generates lower overhead as compared to the flooding approach in reactive protocols. Mobility within its own zone maintains the topology of the network such that no further location search is required. In ZHLS, all nodes are supposed to have a pre-programmed static zone map for initial operation.

ZRP—Zone routing protocol (Haas, 1999). In ZRP, a routing zone is established that defines a range in hops within which network connectivity is proactively maintained. This way, nodes within such a zone have the routes available immediately. Outside the zone, routes are determined reactively (on demand) and any reactive algorithm may be used.

19.6.3 Medium Access Protocols

Medium access control (MAC) for wireless ad hoc networks is currently a very active research topic. The characteristics of the network, the diverse physical-layer technologies available, and the range of services envisioned render a difficult task the design of an algorithm to discipline the access to the shared medium that results efficient, fair, power consumption sensitive, and delay bound. A number of issues distinguish wireless MAC protocols from those used in wireline networks (Chandra, 2002), as quoted next.

Half-duplex operation. Due to self-interference (i.e., the energy from the transmitter that leaks into the receiver), it is difficult to construct terminals able to receive while transmitting. Therefore collision detection while sending data is not possible and Ethernet-like protocols cannot be used. Since collisions cannot be detected, wireless MAC protocols use collision avoidance mechanisms to minimize the probability of collision.

Time varying channel. In multipath fading channels, the received signal is the sum of time-shifted and attenuated copies of the transmitted signal. With the change of the channel characteristics as well as in the relative position of terminals, the signal envelope varies as a function of time. The signal experiences fading that may be severe. The nodes establishing a wireless link need to sense the channel so as to assess the communication link conditions.

Burst channel errors. Wireless channels experience higher bit error rate than wireline transmissions. Besides, errors occur in bursts as the signal fades, resulting in high probability of packet loss. Therefore, an acknowledgement mechanism must be implemented so that the packet retransmission may be possible in case of packet loss.

Location-dependent carrier sensing. Because the signal strength decays with distance according to a power law, only nodes within a specific range are able to communicate. This gives rise to the hidden and exposed terminals and the capture effect, as described next.

Hidden terminal. Refer to Fig. 19.51 where the relative positions of terminals A, B, and C are shown. B is within range of both A and C but A and C are out of range of each other. If terminal A is transmitting to B and terminal C wishes to transmit to B, it incorrectly senses that the channel is free because it is out of range of A, the current transmitter. If C starts transmitting it interferes with the reception at B. In this case C is termed the hidden terminal to A. The hidden terminal problem can be minimized with the use of the request-to-sent/clear-to-send (RTS/CTS) handshake protocol (to be explained later) before the data transmission starts.

Exposed terminal. An exposed terminal is one that is within range of the transmitter but out of range of the receiver. In Fig. 19.51, if terminal B is transmitting to A and terminal C senses the channel it perceives it as busy. However, since it is out of range of terminal A it cannot interfere with the current conversation.

FIGURE 19.51

Therefore it can utilize the channel to establish a parallel link with another terminal that is out of range of B, for instance, terminal D. In this case C is termed the exposed terminal to B. Exposed terminals may result in under-usage of the channel. As in the hidden terminal problem, this also can be minimized with the use of the RTS/CTS handshake protocol.

Capture. Capture at a given terminal occurs in case among several simultaneous signals arriving at it the signal strength of one of them prevails over all of the others combined. In Fig. 19.51, terminals C and E are both within range of terminal B. If C and E are transmitting the interference may result in a collision at B. However, B may be able to receive successfully if one of the signals is much higher than the other, for instance, the signal from E. Capture can improve throughput because it results in less collisions. However, it favors senders that are closer to the intended destination, which may cause unfair allocation of the channel.

From the above considerations, it is promptly inferred that the design of a MAC protocol for ad hoc networks requires a different set of parameters must be considered as compared with those of the wireline systems.

Protocols Categories

Jurdak et al. (Jurdak, 2004), after conducting a survey and analysis of a number of current MAC protocol proposals, offer a set of key features that may be used in order to classify MAC protocols for ad hoc networks.

Channel separation and access. The way the medium is organized is an important issue in the protocol design. For instance, all stations may share a single channel, which they use for control and data transmissions. On the other hand, the medium may be divided into multiple channels, in general one for control and the others for data. The single channel approach was favored in earlier MAC designs because of its simplicity. However, it is intrinsically subject to collisions and it does not perform well in medium to heavy traffic conditions. Particularly at heavy loads, simulations show that single channel protocols are prone to increased number of collisions of control packets, for example, RTS and CTS, which cause increased back off delays while the medium is idle (Tseng, 2002). The choice for multiple channels brings the issue of how to separate these channels. The most common ways of separating channels make use of FDMA, TDMA, and CDMA technologies. *Frequency division multiple access* (FDMA) uses multiple carriers to divide the medium into several frequency slots. It allows multiple transmissions to occur simultaneously although each sender can use only the bandwidth of its assigned frequency slot. *Time division multiple access* (TDMA) divides the medium into fixed length time slots. A group of slots forms a time frame and defines the slot repetition rate. Because of its periodic nature, TDMA protocols are suitable to delay sensitive traffic. In TDMA, a sender uses the whole available bandwidth for the duration of a slot assigned to it. In addition, to access the medium terminals need to keep track of frames and slots and, as a result, TDMA protocols require synchronization among terminals. *Code division multiple access* (CDMA) allows

senders to use the whole available bandwidth all the time. Each sender is assigned one of several orthogonal codes and simultaneous transmissions are possible for users are identified by their unique code. A general requirement in CDMA is for power control. The reason behind it is that an unwanted signal that is stronger than the desired signal may overwhelm it at the receiver's antenna. This is known as the near-far effect. *space division multiple access* (SDMA), similarly to CDMA, aims at allowing senders to use the whole available bandwidth all the time. However, the terminals use directional antennas and are allowed to start transmission only if the desired transmission's direction does not interfere with an ongoing conversation.

RTS/CTS handshake. Many MAC protocols for ad hoc networks use variants of the RTS/CTS handshake. The original three-way handshake minimizes both the hidden and exposed terminal problems. A terminal wishing to send data first senses the channel. If the channel is idle for the appropriate amount of time, the terminal sends a short request-to-send (RTS) packet. All terminals on hearing the RTS defer their transmissions. The destination responds with a clear-to-send (CTS) packet. All terminals on hearing the CTS also defer their transmissions. The sender, on receiving the CTS assumes the channel is acquired and initiates the data transmission.

Topology. Ad hoc networks have a large degree of flexibility and uncertainty. Terminals may be mobile and have distinct capabilities and resources. The network must take this into account and adapt dynamically while optimizing performance and minimizing power consumption (Jurdak, 2004). A network topology can be centralized, clustered, or flat. *Centralized topologies* have a single terminal or base station that controls and manages the network. The central terminal may be responsible for broadcasting information relevant to the operation of the network. In addition, terminals may only communicate through the central terminal. *Clustered topologies* create a local version of a centralized network where one terminal assumes some or all of the duties expected from the central terminal. *Flat topologies* implement a fully distributed approach where all terminals are at the same level, and central control is not used. Flat topologies are further divided into single-hop and multiple-hop. *Single-hop* assumes that the destination node is within range of the sender. *Multiple-hop* assumes that the destination node may be beyond the sender's reachable neighbors. In this case, intermediate terminals are responsible for relaying the packets until they reach the intended destination. Single-hop protocols are simpler but pose limitations on the size of the network. Multiple-hop adds scalability to the network at the expense of higher complexity.

Power. Power consumption is a relevant issue for all wireless networks. Power conservation is particularly influential for the mobile terminals because of the limited battery power available. An efficient power conservation strategy involves several aspects. The energy used to transmit the signal represents a large share of the power consumption. Ideally the transmit power used should be just enough to reach the intended destination. Another source of wasted energy is the long periods of time terminals need to spend sensing the channel or overhearing irrelevant conversation. If terminals are able to learn in advance about when the medium will be unavailable they may decide to go into a sleep mode for that period of time in order to save energy. The network behavior may be influenced by the terminals' battery power level, for instance, in the selection of a cluster head or in assigning transmission priorities. Terminals aware of their battery level may adjust their behavior accordingly. The exchange of control messages before the data transmission phase also represents power wastage. Reduced control overhead should therefore be pursued for the sake of power efficiency.

Transmission initiation. Intuitively, it is expected that a terminal wishing to start a conversation must initiate the transmission. And, in fact, most of the protocols are organized this way. However, a receiver-initiated protocol may be more suitable to some specialized networks, for instance, a sensor network. In receiver-initiated protocols the receiver polls its neighbors by sending a ready-to-receive (RTR) packet, which indicates its readiness to receive data. If the receiver is able to know or successfully predict when a neighbor wishes to send its data, this class of protocols actually produces better performance. However, for generalized networks and unpredictable traffic, sender-initiated protocols are still a better choice.

Traffic load and scalability. Protocols are usually optimized for the worst expected scenario. Sparse node distribution and light traffic conditions do not pose a challenge for the implementation of ad hoc networks. The protocols are optimized for high traffic load, high node density, and/or real-time traffic, depending on the intended use. Protocols that offer the possibility of channel reservation are those with

best performance on both high load and real-traffic situations. Receiver-initiated approaches also tend to work well in high load conditions because there is a high probability that RTR packets reach terminals wishing to send data. If the network ranks terminals and traffic, then it is able to assign priorities based on the traffic nature. Therefore, it can offer favored handling of real-time traffic. Dense networks tend to suffer from higher interference because of the proximity of transmitting nodes. For this reason the use of power control makes a significant difference in the performance of the network.

Range. Transmission range is the distance from the transmitter’s antenna that the radio signal strength still remains above the minimum usable level. Protocols can be classified (Jurdak, 2004) as very short-range (range up to 10 m), short-range (from 10 up to 100 m), medium-range (from 100 up to 1000 m), and long-range (from 1000 m). There is a trade-off between increasing the transmission range and achieving high spatial capacity that needs to be negotiated during the protocol design.

Industry Standard Protocols

IEEE 802.11

The family of IEEE 802.11 standards (IEEE, 1999a; IEEE, 1999b; IEEE, 1999c) can be viewed as a wireless version of the local area network (LAN) protocol Ethernet. The 802.11a standard operates in the unlicensed 5 GHz band and offers data rates up to 54 Mb/s. The commercially popular 802.11b operates in the industrial, scientific, and medical (ISM) band at 2.4 GHz and offers data rates up to 11 Mb/s. The current activity of the 802.11-working group is toward quality of service (QoS) (802.11e, described later) and security (802.11i). The 802.11 standards focus on the specification of the MAC and physical (PHY) layers. While their PHY layers differ, existing 802.11 standards rely on the same medium access mechanisms. The basic (and mandatory) access mechanism is referred to as distributed coordination function (DCF). The optional point coordination function (PCF) is an access mechanism in which a central node (the access point) polls terminals according to a list. DCF is available for both flat ad hoc and centralized topologies whereas PCF is only available in centralized configurations. MAC offers two types of traffic services. The mandatory asynchronous data service is based on the best effort and is suited to delay insensitive data. The optional time-bound service is implemented using PCF.

DCF uses the listen-before-talk scheme based on carrier sense multiple access (CSMA). A terminal wishing to transmit a data packet first monitors the medium activity. If the channel is detected idle the terminal waits for a DCF interframe space (DIFS) time interval (34 us in 802.11a). If the channel remains idle during the DIFS period, the terminal starts transmitting its packet immediately after DIFS has expired. The transmission is successfully completed when the sender receives an acknowledgement (ACK) packet from the destination. However, if the channel is sensed busy a collision avoidance procedure is used. In this procedure, after sensing the channel idle again for a DIFS period, the terminal wishing to transmit waits an additional random backoff time. The terminal then initiates its transmission if the channel remains idle during this additional time. The backoff time is a multiple of the slot time (9 us in 802.11a) and it is determined individually and independently by each station. A random number between zero and contention window (CW) is selected for any new transmission attempt. The back off time is decremented while the medium is in contention phase and frozen otherwise. Thus the backoff time may be carried over for several busy cycles of the medium before it expires. Refer to Fig. 19.52 for an example of the backoff

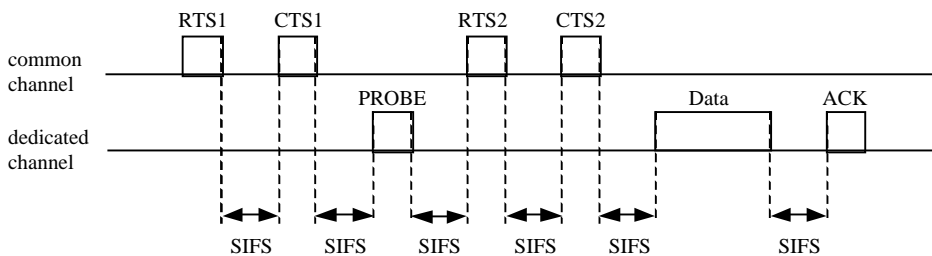

FIGURE 19.52

procedure. The initial value for CW is CWmin (15 for 802.11a) and since all terminals operate with the same CWmin value they all have the same initial medium access priority. After any failed transmission, that is, when the transmitted packet is not acknowledged, the sender doubles its CW up to a maximum defined by CWmax (1023 in 802.11a). A now larger CW decreases the probability of collisions if multiple terminals are trying to access the medium. To reduce the hidden terminal problem, 802.11 optionally uses the RTS/CTS handshake. Both RTS and CTS packets include information on how long the data frame transmission is going to last, including the corresponding ACK. Terminals receiving either the RTS or CTS use this information to start a timer, called network allocation vector (NAV), which informs the period of time the medium is unavailable. Between consecutive frames RTS and CTS, and a data frame and its ACK, the short interframe space (SIFS) (16 us in 802.11) is used. SIFS is shorter than DIFS and therefore gives the terminals sending these frames priority to access the medium.

HIPERLAN 1

High Performance LAN type 1 (HIPERLAN 1) is a wireless LAN standard operating in the 5 GHz band, which offers data rate up to 23.5 Mb/s to mobile users in either clustered ad hoc or centralized topology. HIPERLAN 1 offers asynchronous best effort and time-bound services with hierarchical priorities. There are five priority values defined, from zero (highest) to four (lowest). Each individual MAC protocol data unit (PDU) is assigned a priority that is closely related to its normalized residual lifetime (NRL) value. The NRL is an estimation of the time-to-live the PDU has considering the number of hops it still has to travel. A PDU is discarded if its NRL value reaches zero. In addition, some terminals are designed forwarders and are responsible to relay data to distant nodes in a multi-hop fashion. HIPERLAN 1 allows terminals to go into sleep mode in order to save energy. These terminals, called p-savers, inform support terminals, called p-supporters, of their sleep/wake-up patterns. p-supporters then buffer packets directed to p-savers terminals, as required. Although it has some interesting features, HIPERLAN 1 has not been a commercial success. The channel access mechanism used in HIPERLAN 1 is the elimination-yield non-preemptive priority access (EY-NPMA). It comprises three phases: prioritization (determine the highest priority data packets to be sent); contention (eliminate all contenders except one); and transmission. During the prioritization phase, time is divided in five minislots, numbered sequentially from zero to four. A terminal wishing to transmit has to send a burst during the minislot corresponding to its MAC PDU priority. For example, a terminal with a priority two PDU monitors the medium during minislots zero and one before it can assert its intention by transmitting a burst during minislot two. If the medium becomes busy during either minislot zero or one this terminal defers its transmission. Once a burst is transmitted, the prioritization phase ends and only terminals having PDUs at the same priority level remains in the dispute. The contention phase follows. It starts with the contending terminals transmitting an elimination burst. The individual terminals select the burst length, varying from 0 to 12 minislots, at random and independently. After transmitting the burst the terminals sense the medium. If it is busy they defer their transmissions. Otherwise, the remaining terminals enter the yield listening period. They select at random and independently a value between 0 and 9 and start monitoring the medium. If at the end of this period the medium is still idle the terminal assumes it has won the contention and is allowed to transmit its data. Otherwise, it defers its transmission. It is clear that the mechanism does not allow any lower priority packet to be sent if another with higher priority packet is waiting. At the same time the mechanism does not totally eliminate the possibility of collision but reduces it considerably. Similarly to IEEE 802.11, if the medium has been idle for a time longer than the interframe period a terminal wishing to transmit can bypass the EY-NPMA and transmit immediately.

Bluetooth

Bluetooth (Bluetooth, 1999) is a wireless protocol using the license-free ISM band to connect mobile and desktop devices such as computers and computers peripherals, handheld devices, cell phones, etc. The aim is to produce low-cost, low-power, and very-short range devices able to convey voice and data transmissions at a maximum gross rate of 1 Mb/s. Bluetooth uses frequency hopping spread spectrum (FHSS) with 1600 hops/s. For voice, a 64 kb/s full-duplex link called synchronous connection oriented

(SCO) is used. SCO assigns a periodic single slot to a point-to-point conversation. Data communication uses the best effort asynchronous connectionless (ACL) link in which up to five slots can be assigned. Terminals in Bluetooth are organized in piconets. A piconet contains one terminal identified as the master and up to seven other active slaves. The master determines the hopping pattern and the other terminals need to synchronize to the piconet master. When it joins a piconet, an active terminal is assigned a unique 3-bit long active member address (AMA). It then stays in either transmit state, when it is engaged in a conversation, or connected state. Bluetooth supports three low-power states: park, hold, and sniff. A parked terminal releases its AMA and is assigned one of the 8-bit long parked member address (PMA). Terminals in the hold and sniff states keep their AMA but have limited participation in the piconet. For instance, a terminal in the hold state is unable to communicate using ACL. A terminal not participating in any piconet is in stand-by state. Bluetooth piconets can co-exist in space and time and a terminal may belong to several piconets. A piconet is formed when its future master starts an inquiry process, that is, inquiry messages are broadcast in order to find other terminals in the vicinity. After receiving inquiry responses the master may explicitly page terminals to join the piconet. If a master knows already another terminal's identity it may skip the inquiry phase and page the terminal directly. Bluetooth uses time division duplex (TDD) in which master and slave alternate the opportunity to transmit. A slave can only transmit if the master has just transmitted to it, that is, slaves transmit if polled by the master. Transmissions may last one, three, or five slots although only single-slot transmission is a mandatory feature.

IEEE 802.11e

The IEEE 802.11e is an emerging MAC protocol, which defines a set of QoS features to be added to the 802.11 family of wireless LAN standards. Currently there is a draft version of the specifications (IEEE, 2003). The aim is to better serve delay-sensitive applications, such as voice and multi-media. In 802.11e, the contention-based medium access is referred to as enhanced distributed channel access (EDCA). In order to accommodate different traffic priorities, four access categories (AC) have been introduced. To each AC corresponds a backoff entity. The four distinct parallel backoff entities present in each 802.11e terminal are called (from highest to lowest priority): voice, video, best effort, and background. For the sake of comparison, existing 802.11/a/b standards define only one backoff entity per terminal. Each backoff entity has a distinct set of parameters, such as CW_{min}, CW_{max}, and the arbitration interframe space (AIFS). AIFS is at least equal to DIFS and can be enlarged if desired. Another feature added to 802.11e is referred to as transmission opportunity (TxOP). A TxOP defines a time interval, which a back off entity can use to transmit data. It is specified by its starting time and duration, and the maximum length is AC dependent. The protocol also defines the maximum lifetime of each MAC service data unit (MSDU), which is also AC dependent. Once the maximum lifetime has elapsed, the MSDU is discarded. Finally, the protocol allows for the optional block acknowledgement in which a number of consecutive MSDUs are acknowledged with a single ACK frame.

Other Protocols

PRMA—Packet reservation multiple access (Goodman, 1989). In PRMA, the medium is divided into slots and a group of N slots forms a frame. Slots are either reserved or available. The access to the medium is provided by means of the slotted-ALOHA protocol. Data may be either periodic or sporadic, and this is informed in the header of the packet. Terminals are allowed to reserve a slot when they have periodic data to transmit. Once the central node successfully acknowledges the periodic packet, the terminal assumes the slot is reserved and uses it without contention. When the terminal stops sending periodic information then the reserved slot is released. PRMA assumes the existence of a central node but the mechanism can be adapted to other topologies (Jiang, 2002).

MACA-BI—Multiple access with collision avoidance by invitation (Talucci, 1997). In MACA-BI, the receiver polls a prospective sender by transmitting a ready-to-receive (RTR) packet. (This is an example of a receiver-initiated protocol.) In order to perform the polling in a timely fashion the receiver is required to correctly predict the traffic originated by the sender. Periodic traffic makes this task easier. In case either the data buffer or the delay at the terminal increases above a certain threshold this terminal may trigger a

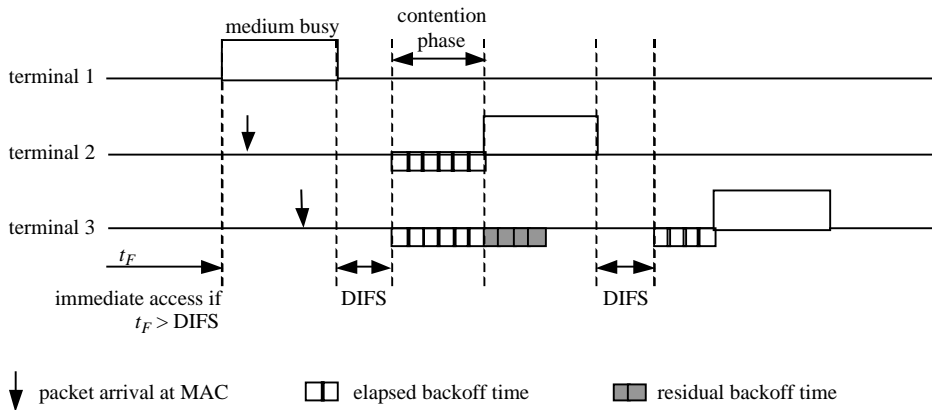

FIGURE 19.53 MAC Handshake Process.

conversation by transmitting an RTS packet. Improvements to MACA-BI are proposed in (Garcia, 1999), in which RIMA-SP—receiver initiated multiple access with simple polling—, and RIMA-DP—Receiver initiated multiple access with dual-purpose polling—are introduced. Both protocols render the RTR-data handshake collision free. RIMA-DP gives an additional purpose to the RTR packet: a request for transmission from the polling terminal. After a reservation phase both terminals can exchange data between them.

DBTMA—Dual busy tone multiple access (Haas, 2002). In DBTMA, the RTS/CTS handshake is replaced by two out-of-band busy tones, namely: BTt (transmit busy tone) and BTr (receive busy tone). When a terminal has data to transmit, it first senses the presence of the BTt and BTr tones. If the medium is free (no busy tone detected), the terminal turns on the BTt, sends an RTS packet, and turns off the BTt. As in other protocols, there is a random backoff time if the medium is busy. The destination terminal, upon receipt of an RTS addressed to it, turns on the BTr and waits for the data. Once the BTr tone is sensed, the sender assumes it has successfully acquired the medium. After waiting a short time (for the BTr to propagate) it transmits the data packet. On successful reception of the data packet the destination terminal turns off the BTr tone, completing the conversation. If no data are received, the BTr tone is turned off after a timer expires at the destination terminal.

Fitzek et al. (Fitzek, 2003) proposes a multi-hop MAC protocol based on the IEEE 802.11. A common channel conveys signaling and dedicated channels carry the data traffic and the ACK packets. Figure 19.53 presents the proposed MAC handshake. The first RTS packet is used to contact the destination and assess its willingness to receive data. The sender includes a list of idle dedicated channels, which is used by the destination terminal to select the dedicated channel. It then transmits this information to the sender in a CTS packet. If no suitable dedicated channel is available the handshake ends. After receiving the CTS packet, the sender transmits a PROBE packet on the dedicated channel. The destination terminal uses this packet to test the channel conditions. It then sends a second CTS packet on the common channel informing about the chosen coding/modulation scheme. The sender to confirm the parameters chosen transmits a second RTS packet. Although at a higher complexity cost, the authors claim that the proposed scheme outperforms the original 802.11.

LA-MAC—Load awareness MAC (Chao, 2003). In LA-MAC, the protocol switches between contention-based and contention-free mechanisms depending on the traffic volume. Contention-based mechanisms are best suited to light traffic conditions in which the probability of collision while attempting to gain the medium is small. For heavy traffic a contention-free mechanism allows higher and more evenly distributed throughput. In (Chao, 2003), the IEEE 802.11 DCF is adopted during contention-based periods while contention-free periods use a token passing protocol. The traffic load is measured by the delay packets are experiencing. Each terminal for the packets it has to transmit computes such delay. During a contention-based period, before a terminal transmits its data packet, it checks the packet's current delay. If the delay

is greater than a pre-defined threshold A the terminal creates a token and transmits it attached to the data packet. This indicates to all terminals the start of a contention-free period. Once the delay has fallen below another pre-defined threshold B, the terminal about to transmit removes the token. This indicates the end of the contention-free period and the start of a contention-based period. Threshold A is chosen to be greater than B to give the switching decision some hysteresis.

PCDC—Power controlled dual channel (Muqattash, 2003). In PCDC, the objective is to maintain network connectivity at the lowest possible transmit power. PCDC is a multi-hop protocol that uses the RTS/CTS handshake found in IEEE 802.11 with some modifications. Each terminal is required to keep a list of neighboring terminals and the transmit power needed to reach them. When a packet is received, the list needs to be visited. If the sender is not known an entry is added. Otherwise, the existing entry is updated. In any case, the receiver needs to re-evaluate its connectivity information and confirm that it knows the cheapest way (in a transmit power sense) to reach all terminals that appears in its neighbor list. For instance, for some terminals it might be cheaper to use an intermediate terminal instead of the direct route. At heavy traffic loads there exist enough packets transiting to keep terminals well informed of their neighborhood. For long idle periods terminals are required to broadcast a "hello" packet periodically for this purpose. PCDC achieves space efficiency and simulations carried by the authors indicate an increase in the network's throughput.

MAC ReSerVation—MAC-RSV (Fang, 2003). In MAC-RSV, a reservation-based multihop MAC scheme is proposed. The TDMA frame consists of data and signaling slots. Data slots are marked as follows: reserved for transmission (RT), reserved for reception (RR), free for transmission (FT), free for reception (FR), or free for transmission and reception (FTR). The signaling slot is divided in minislots with each minislot further divided in three parts: request, reply, and confirm. A terminal wishing to transmit sends an RTS packet. In the RTS, the sender informs its own identity, the intended receiver's identity, and the data slots it wishes to reserve. The intended receiver replies with a CTS if any of the requested slots is among its FR or FTR slots. Otherwise, it remains silent. It is possible that the CTS packet accepts reservation of only a subset of the requested slots. Terminals other than the intended receiver replies with a Not CTS (NCTS) if any of the requested slots is among its RR. Any terminal that detects an RTS collision also replies by sending an NCTS. Otherwise, it remains silent. Finally, if the sender successfully receives a CTS it confirms the reservation by sending a confirm packet (CONF). Otherwise, it remains silent. RTS packets are transmitted in the request part of the minislot; CTS and NCTS use the reply part; and CONF packets use the confirm part. Data slots are divided in three parts: receiver beacon (RB), data, and acknowledgement (ACK). A terminal that has a data slot marked RR transmits an RB with the identity of the active data transmitter. In addition, the receiver acknowledges the correct data reception by transmitting an ACK at the end of the data slot. Simulations carried out by the authors indicate that the proposed protocol outperforms the IEEE 802.11 at moderate to heavy traffic loads.

Comments

In (Jurdak, 2004) a set of guidelines is provided that a suitable general-purpose MAC protocol should follow. In particular, it is mentioned that the use of multiple channels to separate control and data is desirable in order to reduce the probability of collisions. The need of flexible channel bandwidth, multiple channels, and the high bandwidth efficiency suggests that CDMA is the optimal choice for channel partition. Multi-hop support is recommended to ensure scalability with flat or clustered topologies depending on the application. In order to favor power efficient terminals, protocols need to be power aware, must control transmission power, and allow for sleep mode. To complete the set of recommendations, the authors include, for the sake of flexibility, short to medium range networks and a sender-initiated approach.

19.6.4 TCP over Ad Hoc Networks

TCP is the prevalent transport protocol in the Internet today and its use over ad hoc networks is a certainty. This has motivated a great deal of research efforts aiming not only at evaluating TCP performance over ad hoc networks, but also at proposing appropriate TCP schemes for this kind of networks. TCP was originally

designed for wired network, based on the following assumptions, typical of such an environment: packet losses are mainly caused by congestion, links are reliable (very low bit error rate), round-trip times are stable, and bandwidth is constant (Postel, 1981; Huston, 2001). Based on these assumptions, TCP flow control employs a window-based technique, in which the key idea is to probe the network to determine the available resources. The window is adjusted according to an additive-increase/multiplicative-decrease strategy. When packet loss is detected, the TCP sender retransmits the lost packets and the congestion control mechanisms are invoked, which include exponential backoff of the retransmission timers and reduction of the transmission rate by shrinking the window size. Packet losses are therefore interpreted by TCP as a symptom of congestion (Chandran, 2001). Previous studies on the use of TCP over cellular wireless networks have shown that this protocol suffers from poor performance mainly because the principal cause of packet loss in wireless networks is no longer congestion, but the error-prone wireless medium (Xylomenos, 2001; Balakrishnan, 1997). In addition, multiple users in a wireless network may share the same medium, rendering the transmission delay time-variant. Therefore, packet loss due to transmission error or a delayed packet can be interpreted by TCP as being caused by congestion. When TCP is used over ad hoc networks, additional problems arise. Unlike cellular networks, where only the last hop is wireless, in ad hoc networks the entire path between the TCP sender and the TCP destination may be made up of wireless hops (multihop). Therefore, as discussed earlier in this chapter, appropriate routing protocols and medium access control mechanisms (at the link control layer) are required to establish a path connecting the sender and the destination. The interaction between TCP and the protocols at the physical, link, and network layers can cause serious performance degradation, as discussed in the following.

Physical Layer Impact

Interference and propagation channel effects are the main causes of high bit error rate in wireless networks. Channel induced errors can corrupt TCP data packets or acknowledgement packets (ACK), resulting in packet losses. If an ACK is not received within the retransmit timeout (RTO) interval, the lost packets may be mistakenly interpreted as a symptom of congestion, causing the invocation of TCP congestion control mechanisms. As a consequence, the TCP transmission rate is drastically reduced, degrading the overall performance. Therefore, the reaction of TCP to packet losses due to errors is clearly inappropriate. One approach to avoid this TCP behavior is to make the wireless channel more reliable by employing appropriate forward error correction coding (FEC), at the expense of a reduction of the effective bandwidth (due to the addition of redundancy) and an increase in the transmission delay (Shakkottai, 2003). In addition to FEC, link layer automatic repeat request (ARQ) schemes can be used to provide faster retransmission than that provided at upper layers. ARQ schemes may increase the transmission delay, leading TCP to assume a large round-trip time or to trigger its own retransmission procedure at the same time (Huston, 2001).

MAC Layer Impact

It is well known that the hidden and exposed terminal problems strongly degrade the overall performance of ad hoc networks. Several techniques for avoiding such problems have been proposed, including the RTS/CTS control packets exchange employed in the IEEE 802.11 MAC protocol. However, despite the use of such techniques, hidden and exposed terminal problems can still occur, causing anomalous TCP behavior. The inappropriate interaction between TCP and link control layer mechanisms in multihop scenarios may cause the so-called TCP instability (Xu, 2001). TCP adaptively controls its transmission rate by adjusting its contention window size. The window size determines the number of packets in flight in the network (i.e., the number of packets that can be transmitted before an ACK is received by the TCP sender). Large window sizes increase the contention level at the link layer, as more packets will be trying to make their way to the destination terminal. This increased contention level leads to packet collisions and causes the exposed terminal problem, preventing intermediate nodes from reaching their adjacent terminals (Xu, 2001). When a terminal cannot deliver its packets to its neighbor, it reports a route failure to the source terminal, which reacts by invoking the route reestablishment mechanisms at the routing protocol. If the route reestablishment takes longer than RTO, the TCP congestion control mechanisms are triggered, shrinking the window size and retransmitting the lost packets. The invocation of congestion

control mechanisms results in momentary reduction of TCP throughput, causing the mentioned TCP instability. It has been experimentally verified that reducing the TCP contention window size minimizes TCP instability (Xu, 2001). However, reduced window size inhibits spatial channel reuse in multihop scenarios. For the case of IEEE 802.11 MAC, which uses a four-way handshake (RTS-CTS-Data-ACK), it can be shown that, in an H -hop chain configuration, a maximum of $H/4$ terminals can simultaneously transmit (Fu, 2003), assuming ideal scheduling and identical packet sizes. Therefore, a window size smaller than this upper limit degrades the channel utilization efficiency. Another important issue related to the interaction between TCP and the link layer protocols regards the unfairness problem when multiple TCP sessions are active. The unfairness problem (Xu, 2001; Tang, 2001) is also rooted in the hidden (collisions) and exposed terminal problems and can completely shut down one of the TCP sessions. When a terminal is not allowed to send its data packet to its neighbor due to collisions or the exposed terminal problem, its backoff scheme is invoked at the link layer level, increasing (though randomly) its backoff time. If the backoff scheme is repeatedly triggered, the terminal will hardly win a contention, and the winner terminal will eventually capture the medium, shutting down the TCP sessions at the loser terminals.

Mobility Impact

Due to terminal mobility, route failures can frequently occur during the lifetime of a TCP session. As discussed above, when a route failure is detected, the routing protocol invokes its route reestablishment mechanisms, and if the discovery of a new route takes longer than RTO, the TCP sender will interpret the route failure as congestion. Consequently, the TCP congestion control is invoked and the lost packets are retransmitted. However, this reaction of TCP in this situation is clearly inappropriate due to several reasons (Chandran, 2001). Firstly, lost packets should not be retransmitted until the route is reestablished. Secondly, when the route is eventually restored, the TCP slow start strategy will force the throughput to be unnecessarily low immediately after the route reestablishment. In addition, if route failures are frequent, TCP throughput will never reach high rates.

Main TCP Schemes Proposals for Ad Hoc Networks

TCP—Feedback

This TCP scheme is based on explicitly informing the TCP sender of a route failure, such that it does not mistakenly invoke the congestion control (Chandran, 2001). When an intermediate terminal detects a route failure, it sends a route failure notification (RFN) to the TCP sender terminal and records this event. Upon receiving an RFN, the TCP sender transitions to a “snooze” state and (i) stops sending packets, (ii) freezes its flow control window size, as well as all its timers, and (iii) starts a route failure timer, among other actions. When an intermediate terminal that forwarded the RFN finds out a new route, it sends a route reestablishment notification (RRN) to the TCP sender, which in turn leaves the snooze state and resumes its normal operation.

TCP with Explicit Link Failure Notification

Explicit link failure notification (ELFN) technique is based on providing TCP sender with information about link or route failures, preventing TCP from reacting to such failures as if congestions had occurred (Holland, 2002). In this approach, the ELFN message is generated by the routing protocol and a notice to TCP sender about link failure is piggybacked on it. When the TCP sender receives this notice, it disables its retransmission timers and periodically probes the network (by sending packets) to check if the route has been reestablished. When an ACK is received, the TCP sender assumes that a new route has been established and resumes its normal operation.

Ad Hoc TCP

A key feature of this approach is that the standard TCP is not modified, but an intermediate layer, called ad hoc TCP (ATCP), is inserted between IP and TCP (transport) layers. Therefore, ATCP is invisible to TCP and terminals with and without ATCP installed can interoperate. ATCP operates based on the network status information provided by the internet control message protocol (ICMP) and the explicit

congestion notification mechanism (ECN) (Floyd, 1994). The ECN mechanism is used to inform the TCP destination of the congestion situation in the network. An ECN bit is included in the TCP header and is set to zero by the TCP sender. Whenever an intermediate router detects congestion, it sets the ECN bit to one. When the TCP destination receives a packet with ECN bit set to one, it informs the TCP sender about the congestion situation, which in turn reduces its transmission rate. ATCP has four possible states: normal, congested, loss, and disconnected. In the normal state ATCP does nothing and is invisible to TCP. In the congested, loss, and disconnected states, ATCP deals with congested network, lossy channel, and partitioned network, respectively. When ATCP sees three duplicate ACKs (likely caused by channel induced errors), ATCP transitions to the loss state and puts TCP into persist mode, ensuring that TCP does not invoke its congestion control mechanisms. In the loss state, ATCP retransmits the unacknowledged segments. When a new ACK arrives, ATCP returns to the normal state and removes TCP from the persist mode, restoring the TCP normal operation. When network congestion occurs, ATCP sees the ECN bit set to one and transitions to congested state. In this state, ATCP does not interfere with TCP congestion control mechanisms. Finally, when a route failure occurs, a destination unreachable message is issued by ICMP. Upon receiving this message, ATCP puts TCP into persist mode and transitions to the disconnected state. While in the persist mode, TCP periodically sends probe packets. When the route is eventually reestablished, TCP is removed from persist mode and ATCP transitions back to the normal state.

19.6.5 Capacity of Ad Hoc Networks

The classical information theory introduced by Shannon (Shannon, 1948) presents the theoretical results on the channel capacity, that is, how much information can be transmitted over a noisy and limited communication channel. In ad-hoc networks, this problem is led to a higher level of difficulty for the capacity now must be investigated in terms of several transmitters and several receivers. The analysis of the capacity of wireless networks has a similar objective as that of the classical information theory: to estimate the limit of how much information can be transmitted and to determine the optimal operation mode, so that this limit can be achieved. A first attempt to calculate these bounds is made by Gupta and Kumar in (Gupta, 2000). In this work, the authors propose a model for studying the capacity of a static ad hoc network (i.e., nodes do not move), based on the following scenario. Suppose that nodes are located in a region of area 1. Each node can transmit at bits per second over a common wireless channel. Packets are sent from node to node in a multi-hop fashion until their final destination is reached and they can be buffered at intermediate nodes while waiting for transmission. Two types of network configurations are considered: arbitrary networks, where the node locations, traffic destinations, rates, and power level are all arbitrary; and random networks, where the node locations and destinations are random, but they have the same transmit power and data rate. Two models of successful reception over one hop are also proposed:

- Protocol Model—in which a transmission from node i to j , with a distance d_{ij} between them, is successful if $d_{kj} \geq (1 + \Delta) d_{ij}$, that is, if the distance between nodes i and j is smaller than that of nodes k and j with both i and k transmitting to j simultaneously over the same channel. The quantity $\Delta > 0$ models the guard zone specified by the protocol to prevent a neighboring node from simultaneous transmission.
- Physical Model—in which, for a subset T of simultaneous transmitting nodes, the transmission from a node $i \in T$ is successfully received by node j if

$$\frac{P_i/d_{ij}^\alpha}{N + \sum_{\substack{k \in T \\ k \neq i}} P_k/d_{kj}^\alpha} \geq \beta \quad (19.110)$$

with a minimum signal-to-interference ratio (SIR) β for successful receptions, noise power level N , transmission power level P_i for node i , and signal power decay α .

TABLE 19.5 Capacity Upper Bounds for Arbitrary and Random Networks

	Protocol Model	Physical Model
Arbitrary Networks (transport capacity in bit-meters/s)	$\Theta(W\sqrt{n})$	Feasible $cW\sqrt{n}$ Not feasible $c'Wn^{(\frac{\alpha-1}{\alpha})}$ for appropriate values of c and c'
Random Networks (node throughput in bits/s)	$\Theta\left(\frac{W}{\sqrt{n \log n}}\right)$	Feasible $cW/\sqrt{n \log n}$ Not feasible $c'W/\sqrt{n}$ fore appropriate values of c and c'

The transport capacity is so defined as the quantity of bits transported in a certain distance, measured in bit-meter. One bit-meter signifies that one bit has been transported over a distance of one meter toward its destination. With the reception models as described previously, the upper bounds for the transport capacity in arbitrary networks and the throughput per node in random networks were calculated. They are summarized in Table 19.5, where the Knuth's notation has been used, that is, $f(n) = \Theta(g(n))$ denotes that $f(n) = O(g(n))$ as well as $g(n) = O(f(n))$. In Table 19.5, c and c' are constants which are functions of α and β . These results show that, for arbitrary networks, if the transport capacity is divided into equal parts among all nodes, the throughput per node will be $\Theta(W/\sqrt{n})$ bits per second. This shows that, as the number of nodes increases, the throughput capacity for each node diminishes in a square root proportion. The same type of results holds for random networks. These results assume a perfect scheduling algorithm which knows the locations of all nodes and all traffic demands, and which coordinates wireless transmissions temporally and spatially to avoid collisions. Without these assumptions the capacity can be even smaller.

Troumpis and Goldsmith (Troumpis, 2000) extend the analysis of upper limits of (Gupta, 2000) to a three dimensional topology, and incorporated the channel capacity into the link model. In this work, the nodes are assumed as uniformly distributed within a cube of volume $1 m^3$. The capacity $C(n)$ follows the inequality

$$k_1 \frac{n^{1/3}}{\log(n)} \leq C(n) \leq k_2 \log(n)n^{1/2} \tag{19.111}$$

with probability approaching unity as $n \rightarrow \infty$, and k_1, k_2 some positive constants. Equation Eq. (19.111) also suggests that, although the capacity increases with the number of users, the available rate per user decreases.

Case Studies on Capacity of Ad Hoc Networks

IEEE802.11

Li et al (Li, 2001) study the capacity of ad hoc networks through simulations and field tests. Again, the static ad hoc network is the basic scenario, which is justified by the fact that at most mobility scenarios nodes do not move significant distances during packet transmissions. The 802.11 MAC protocol is used to analyze the capacity of different configuration networks.

For the chain of nodes, the ideal capacity is 1/4 of the raw channel bandwidth obtainable from the radio (single-hop throughput). The simulated 802.11-based ad hoc network achieves a capacity of 1/7 of the single-hop throughput, because the 802.11 protocol fails to discover the optimum schedule of transmission and its backoff procedure performs poorly with ad hoc forwarding. The field experiment does not present different results from those obtained in the simulation. The same results are found for the lattice topology. For random networks with random traffic patterns, the 802.11 protocol is less efficient, but the theoretical maximum capacity of $O(1/\sqrt{n})$ per node can be achieved.

It is also shown that the scalability of ad hoc networks is a function of the traffic pattern. In order for the total capacity to scale up with the network size, the average distance between source and destination nodes must remain small as the network grows. Therefore, the key factor deciding whether large networks

are feasible is the traffic pattern. For networks with localized traffic the expansion is feasible whereas for networks in which the traffic must traverse it then the expansion is questionable.

Wireless Mesh Networks

A particular case of ad-hoc network, which is drawing significant attention, is the wireless mesh network (WMN). The main characteristic that differentiates a WMN from others ad-hoc networks is the traffic pattern: practically, all traffic is either to or from a node (gateway) that is connected to other networks (e.g. Internet). Consequently, the gateway plays a decisive role in the WMN: the greater the number of gateways the greater the capacity of this network as well as its reliability. Jun and Sichitiu (Jun, (Oct) 2003) analyze the capacity of WMNs with stationary nodes. Their work shows that the capacity of WMNs is extremely dependent on the following aspects:

- Relayed traffic and fairness—Each node in a WMN must transmit relayed traffic as well as its own. Thus, there is an inevitable contention between its own traffic and relayed traffic. In practice, as the offered load at each node increases, the nodes closest to the gateway tends to consume a larger bandwidth, even for a fair MAC layer protocol. The absolute fairness must be forced according to the offered load.
- Nominal capacity of MAC layer (B)—It is defined as the maximum achievable throughput at the MAC layer in one-hop network. It can be calculated as presented in (Jun (April) 2003).
- Link constraints and collision domains—In essence, all MAC protocols are designed to avoid collisions while ensuring that only one node transmits at a time in a given region. The collision domain is the set of links (including the transmitting one) that must be inactive for one link to transmit successfully.

The chain topology is first analyzed. It is observed that the node closer to the gateway has to forward more traffic than nodes farther away. For a n -node network and a per node generated load G , the link between the gateway and the node closer to it has to be able to forward a traffic equal to nG . The link between this node and the next node has to be able to forward traffic equal to $(n - 1)G$, and so on. The collision domains are identified and the bottleneck collision domain, which has to transfer the most traffic in the network, is determined. The throughput available for each node is bounded by the nominal capacity B divided by the total traffic of the bottleneck collision domain. The chain topology analysis can be extended to a two-dimensional topology (arbitrary network). The values obtained for the throughput per node are validated with simulation results.

These results lead to an asymptotic throughput per node of $O(1/n)$. This is significantly worse than the results showed in Table 19.5, mainly because of the presence of gateways, which are the network bottlenecks. Clearly, the available throughput improves with the increase of the number of gateways in the network.

Increasing the Capacity of Ad Hoc Networks

The expressions presented in Table 19.5 indicate the best performance achievable considering optimal scheduling, routing, and relaying of packets in the static networks. This is a bad result as far as scalability is concerned and encourages researches to pursue techniques that increase the average throughput. One approach to increase capacity is to add relay-only nodes in the network. The major disadvantage of this scheme is that it requires a large number of pure relay nodes. For random networks under the protocol model with m additional relay nodes, the throughput available per node becomes $\Theta(W(n + m)/n\sqrt{(n + m)\log(n + m)})$ (Gupta, 2000). For example, in a network with 100 senders, at least 4476 relay nodes are needed to quintuplicate the capacity (Gupta, 2000). Another strategy is to introduce mobility into the model. Grossglauer and Tse (Grossglauer, 2001) show that it is possible for each sender-receiver pair to obtain a constant fraction of the total available bandwidth, which is independent of the number of pairs, at the expense of an increasing delay in the transmission of packets and the size of the buffers needed at the intermediate relay nodes. The same results are presented by Bansal and Liu (Bansal, 2003), but with low delay constraints and a particular mobility model similar to the random waypoint model (Bettstetter, 2002). However, mobility introduces new problems such as maintaining connectivity within the ad hoc network, distributing routing

information, and establishing access control. (An analysis on the connectivity of ad hoc networks can be found at (Bettstetter, 2002).) The nodes can also be grouped into small clusters, where in each cluster a specific node (clusterhead) is designated to carry all the relaying packets (Lin, 1997). This can increase the capacity and reduce the impact of the transmission overhead due to routing and MAC protocols. On the other hand, the mechanisms to update the information in clusterheads generate additional transmissions, which reduces the effective node throughput.

19.7 Network Communication

James E. Goldman

19.7.1 General Principles of Network Analysis and Design

Use of Top-Down Business Oriented Approach

Network communication is the transport of data, voice, video, image, or facsimile (fax) from one location to another achieved by compatibly combining elements of hardware, software, and media. From a business perspective, network communications is delivering the right information to the right decision maker at the right place and time for the right cost. Because there are so many variables involved in the analysis, design, and implementation of such networks, a structured methodology must be followed in order to assure that the implemented network meets the communications needs of the intended business, organization, or individual.

One such structured methodology is known as the top-down approach. Such an approach can be graphically illustrated in a top-down model as shown in Fig. 19.54. Using a top-down approach as illustrated in the top-down model is relatively straightforward.

One must start with the business level objectives. What is the company (organization, individual) trying to accomplish by installing this network? Without a clear understanding of business level objectives, it is nearly impossible to configure and implement a successful network.

Once business level objectives are understood, one must understand the *applications* which will be running on the computer systems attached to these networks. After all, it is the applications that will be generating the traffic that will travel over the implemented network.

FIGURE 19.54 Top-down design approach: business data communications analysis.

Data Traffic Analysis Type	Data Traffic Analysis Description
Payload type analysis	Most locations will require at least voice and data service. Videoconferencing and multimedia may need to be supported as well. All payload types should be considered and documented prior to circuit and networking hardware selection.
Transaction analysis	Use process flow analysis or document flow analysis to identify each type of transaction. Analyze detailed data requirements for each transaction type.
Time studies	Once all transaction types have been identified, analyze when and how often each transaction type occurs.
Traffic volume analysis	By combining all types of transactions along with the results of the time study, a time-sensitive traffic volume requirements profile can be produced. This will be a starting point for mapping bandwidth requirements to circuit capacity.
Mission-critical analysis	Results of this analysis may dictate the need for special data security procedures such as encryption or special network design considerations such as redundant links.
Protocol stack analysis	Each corporate location's data traffic is analyzed as to protocols which must be transported across the corporate wide area network. Many alternatives for the transport of numerous protocols exist, but first these protocols must be identified.

FIGURE 19.55 Data traffic analysis.

Once applications are understood and have been documented, the *data* which those applications generate must be examined. In this case, the term data is used in a general sense as today's networks are likely to transport a variety of payloads including voice, video, image, and fax in addition to true data. Data traffic analysis must determine not only the amount of data to be transported, but also must determine important characteristics about the nature of that data. A summarization of data traffic analysis is outlined in Fig. 19.55. It is also during this stage of the top-down analysis in which the geographic proximity of the nodes of the network are examined.

Geographic proximity is one differentiating factor among different categories of networking, which will be examined further subsequently.

Once data traffic analysis has been completed, the following should be known:

1. Physical locations of data (Where?)
2. Data characteristics and compatibility issues (What?)
3. Amount of data generated and transported (How much?)

Given these requirements as determined by the upper layers of the top-down model, the next job is to determine the requirements of the *network* that will possess the capability to deliver this data in a timely, cost-effective manner. Details on the determination of these requirements comprise the remainder of this section on network communications. These network performance criteria could be referred to as *what* the implemented network must do in order to meet the business objectives outlined at the outset of this top-down analysis. These requirements are also sometimes referred to as the *logical network design*.

The *technology* layer analysis, in contrast, will determine *how* various hardware and software components will be combined to build a functional network which will meet predetermined business objectives. The delineation of required technology is often referred to as the *physical network design*.

Overall, the relationship between the layers of the top-down model could be described as follows: analysis at upper layers produces requirements that are passed down to lower layers while solutions meeting these requirements are passed back to upper layers. If this relationship among layers holds true throughout the business oriented network analysis, then the implemented technology (bottom layer) should meet the initially outlined business objectives (top layer).

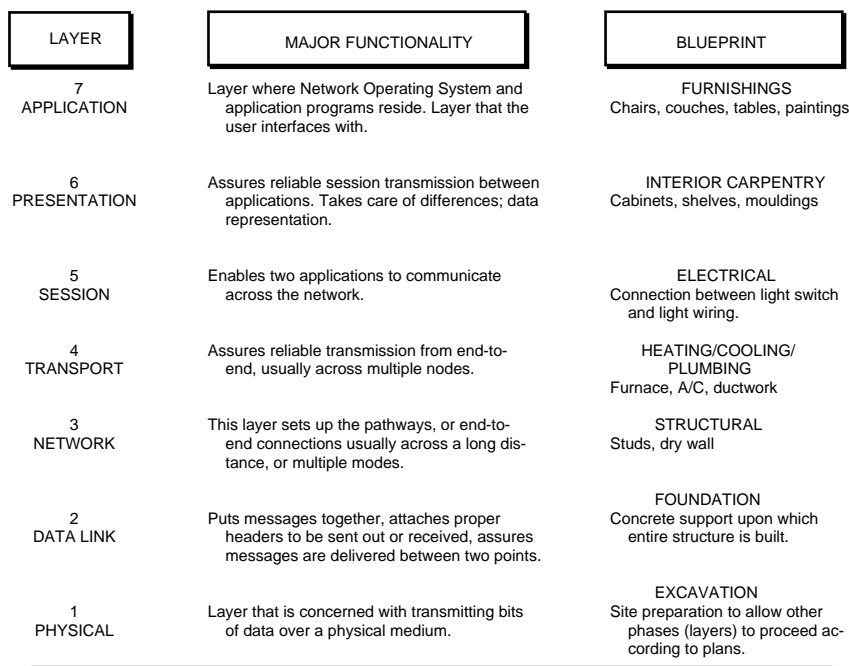

FIGURE 19.56 The OSI reference model.

Use of Open Systems Interconnection (OSI) Model

Determining which technology to employ to meet the requirements determined in the logical network design (network layer) requires a structured methodology of its own. Fortunately, a framework for organizing networking technology solutions has been developed by the International Standards Organization (ISO) and is known as the open systems interconnection (OSI) model. The OSI model is illustrated in Fig. 19.56.

The OSI model divides the communication between any two networked computing devices into seven layers or categories. The OSI model allows data communications technology developers as well as standards developers to talk about the interconnection of two networks or computers in common terms without dealing in proprietary vendor jargon.

These common terms are the result of the layered architecture of the seven-layer OSI model. The architecture breaks the task of two computers communicating to each other into separate but interrelated tasks, each represented by its own layer. As can be seen in Fig. 19.56, the top layer (layer 7) represents the application program running on each computer and is therefore aptly named the *application layer*. The bottom layer (layer 1) is concerned with the actual physical connection of the two computers or networks and is therefore named the *physical layer*. The remaining layers (2–6) may not be as obvious but, nonetheless, represent a sufficiently distinct logical group of functions required to connect two computers, as to justify a separate layer.

To use the OSI model, a network analyst lists the known protocols for each computing device or network node in the proper layer of its own seven-layer OSI model. The collection of these known protocols in their proper layers is known as the *protocol stack* of the network node. For example, the physical media employed, such as unshielded twisted pair, coaxial cable, or fiber optic cable, would be entered as a layer 1 protocol, whereas **ethernet** or **token ring** network architectures might be entered as a layer 2 protocol. Other examples of possible protocols in respective layers will be explored in the remainder of this section.

The OSI model allows network analysts to produce an accurate inventory of the protocols present on any given network node. This protocol profile represents a unique personality of each network node and gives the network analyst some insight into what *protocol conversion*, if any, may be necessary in order to get any two network nodes to communicate successfully. Ultimately, the OSI model provides a structured

methodology for determining what hardware and software technology will be required in the physical network design in order to meet the requirements of the logical network design.

Perhaps the best analogy for the OSI reference model, which illustrates its architectural or framework purpose, is that of a blueprint for a large office building or skyscraper. The various subcontractors on the job may only be concerned with the layer of the plans that outlines their specific job specifications. However, each specific subcontractor needs to be able to depend on the work of the lower layers subcontractors just as the subcontractors of the upper layers depend on these subcontractors performing their function to specification. Similarly, each layer of the OSI model operates independently of all other layers, while depending on neighboring layers to perform according to specification while cooperating in the attainment of the overall task of communication between two computers or networks.

Differentiation Among Major Categories of Networking

As part of the top-down analysis, geographic proximity of computers or network nodes was mentioned as a key piece of analysis information. Although there are no hard and fast rules for network categorization, following are a few of the more common categories of networking:

- **Remote connectivity:** A single remote user wishes to access local network resources. This type of networking is particularly important to mobile professionals such as sales representatives, service technicians, field auditors, etc.
- **Local area networking:** Multiple users' computers are interconnecting for the purpose of sharing applications, data, or networked technology such as printers or CD-ROMs. Local area networks (LANs) may have anywhere from two or three users to several hundred. LANs are often limited to a single department or floor in a building, although technically any single location corporation could be networked via a LAN.
- **Internetworking:** Also known as LAN-to-LAN networking or connectivity, internetworking involves the connection of multiple LANs and is very common in corporations in which users on departmental LANs now need to share data or otherwise communicate. The challenge of internetworking is in getting departmental LANs of different protocol stacks (as determined by use of the OSI model) to talk to each other, while only allowing authorized users access to the internetwork and other LANs. Variations of internetworking also deal with connecting LANs to mainframes or minicomputers rather than to other LANs.
- **Wide area networking:** Also known as *enterprise networking*, involves the connection of computers, network nodes, or LANs over a sufficient distance as to require the purchase of wide area network (WAN) service from the phone company or alternative carrier. In some cases, the wide area portion of the network may be owned and operated by the corporation itself. Nonetheless, the geographic distance between nodes is the determining factor in categorizing a wide area network. A subset of WANs known as metropolitan area networks (MANs) are confined to a campus or metropolitan area of usually not more than a few miles in diameter.

The important thing to remember is that categorization of networking is somewhat arbitrary and that what really matters is that the proper networking technology (hardware and software) is specified in any given networking opportunity in order to meet stated business objectives.

19.7.2 Personal Remote Connectivity

Applications

The overall methodology for analysis and design of remote connectivity networking can be summarized as follows:

1. Needs analysis
2. Logical topology choice
3. Physical topology or architecture choice
4. Technology review and specification

Remote Connectivity Needs Analysis

Remote connectivity needs analysis involves documenting the nature and extent of the use of local LAN resources by the remotely connected user. Choices of logical or physical topology for this remote LAN connectivity may be limited depending on the outcome of the remote connectivity needs analysis. Among the possible information sharing needs of remote users are the following: (1) exchange e-mail, (2) upload and download files, (3) run interactive application programs remotely, and (4) utilize LAN attached resources such as printers. One additional question will have a direct impact on topology choice: (5) How many remote users will require simultaneous access to local LAN attached resources?

Remote connectivity architectures comprise the combination of a chosen remote connectivity logical topology and a chosen remote connectivity physical topology.

Logical Topologies

Remote connectivity logical topologies are differentiated by: (1) location of application program execution (local or remote PC) and (2) nature of the data traffic between the local and remote PC. The two most common remote connectivity logical topologies or operations modes are: (1) remote client mode and (2) remote control mode.

Remote Client Mode

Remote client mode, alternatively known as remote access node, executes and often stores applications on the remote PC, using only shared data and other locally attached LAN resources connected to the local LAN **server**. A single local LAN server or specialized communications server can service multiple remote PC clients. The remote node has the same full capabilities as any local node on the network. The fact that the client PC is remote to the local server is transparent. The data traffic between the remote PC and local LAN server are data packets particular to the network operating system, which both the remote PC and local LAN server have installed.

Remote Control Mode

Remote control mode requires a dedicated local PC to be assigned to each remote PC since applications are stored and executed on the local PC. Shared data and other LAN-attached resources are accessed from the LAN server through the local PC. The remote PC is really nothing more than a simple input/output device. All processing is performed on the local PC. Only keystrokes and screen images are transmitted between the remote PC and the local PC. This setup is really just a remote keyboard and monitor for a local PC. The remote PC *controls* the local PC and all of its LAN attached resources, hence the name, remote control mode.

Figure 19.57 outlines some of the details, features and requirements of these two remote PC modes of operation or logical topologies.

Physical Topologies

Remote connectivity physical topologies refer to the physical arrangement of hardware and media which offers access to the local LAN for the remote user. As Fig. 19.58 illustrates, there are three basic ways in which a remote PC user can gain access to the local LAN resources. (1) a LAN attached PC, (2) communications server, and (3) LAN modem.

It is important to understand that the actual implementation of each of these LAN access arrangements may require additional hardware and/or software. They may also be limited in their ability to utilize all LAN attached resources.

19.7.3 Local Area Networks

LAN Applications

Possible business analysis questions for local area networking solutions are listed in Fig. 19.59. This list of business analysis questions is not meant to be exhaustive or all encompassing. Two important things to

Characteristic	Remote Client Operation Mode	Modem Remote Control Operation Mode
Is redirector hardware and/or software required?	Yes	No
Where do the applications actually execute?	On the remote PC	On the local LAN-attached PC or communications server.
What is the nature of the data traffic over the dial-up line?	All interaction between the LAN server and remote PC travels over the dial-up link.	Only keystrokes from the remote PC keyboard and output for the remote PC monitor travel over the dial-up link.
Network interface	Actually using the remote PC's serial port and modem as a substitute NIC. This option provides a very low speed interface.	Uses installed NIC on local LAN attached PC or communication server to interface to the LAN at a very high speed.
Relative performance	Slower than modem remote control operation mode with substantially more traffic, depending whether application programs are stored remotely or on the LAN.	Faster than remote client mode and generates substantially less traffic. Often not appropriate for Windows-based applications
Also called	Remote LAN node. LAN remote control.	

FIGURE 19.57 Remote LAN connectivity: remote PC operations mode.

remember about any list of business analysis questions are

1. The questions should dig deeper into the required information systems-related business activities.
2. The answers to these questions should provide sufficient insight as to enable the investigation of possible technical solutions.

Next, each of the business analysis questions' categories is explained briefly.

User Issues

User satisfaction is the key to any successful network implementation. To satisfy users, their needs must be first thoroughly understood. Beyond the obvious question of: How many users must the network support? are the more probing questions dealing with specific business activities of individual users. Do users process many short transactions throughout the day? Do users require large file transfers at certain times of day? Are there certain activities which absolutely must be done at certain times of day or within a certain amount of elapsed time? These questions are important in order to establish the amount of network communication required by individual users. Required levels of security should also be addressed. Are payroll files going to be accessed via the network? Who should have access to these files and what security measures will assure authorized access? What is the overall technical ability of the users? Will technical staff need to be hired? Can support be obtained locally from an outside organization?

Local Communication

Remembering that these are business analysis questions and not technical analysis questions, users really cannot be asked how fast their network connections must be. Bits per second or megabits per second have little or no meaning for most users. If users have business activities such as computer aided design/computer aided manufacturing (CAD/CAM) or other three-dimensional modeling or graphics software that will be accessing the network, the network analyst should be aware that these are large consumers of network bandwidth and should document those information system-related business activities which may be large consumers of networking bandwidth.

ACCESS POINT 1: SERIAL PORT OF LAN ATTACHED PC

ACCESS POINT 2: COMMUNICATIONS SERVER

ACCESS POINT 3: LAN MODEMS

FIGURE 19.58 Remote LAN connectivity: three primary access points.

Resource Sharing

It is important to identify which resources and how many are to be shared: printers, modems, faxes, and the preferred locations of these shared resources. The required distance between shared resources and users can have a bearing on acceptable technical options.

	Current	2-3 years	5 years
<i>User issues:</i>			
How many users?			
What are their business activities?			
What is the budgeted cost/user?			
Comprehensive cost of ownership?			
What are the security needs? (password protection levels, supervisor privileges)			
What are the support issues?			
<i>Local communication:</i>			
Required speed?			
<i>Resource sharing:</i>			
How many printers, modems, and faxes are to be shared?			
What is the greatest distance from the server to each service?			
<i>File sharing:</i>			
Is printer/queue management required?			
How many simultaneous users?			
<i>Application sharing:</i>			
What is the number and type of required applications?			
Are e-mail services required?			
<i>Distributed data access:</i>			
Where will shared data files be stored?			
<i>Lan management/administration:</i>			
Will training be required to manage the network?			
How easy is the network to use?			
<i>Extended communication:</i>			
How many mini/mainframe connections are needed (and what type, IBM, DEC, UNIX based)?			
Will this be an inter-LAN network? [LAN to LAN concerns. Which NOS? Must other protocols be considered? Are the connections local or remote (long-distance?)]			

FIGURE 19.59 LAN and LAN look alike: business analysis questions.

File Sharing and Application Sharing

Which programs or software packages are users going to need to perform their jobs? Which programs are they currently using? Which new products must be purchased? In many cases, network versions of software packages may cost less than multiple individual licenses of the same software package for individual PCs. The network analyst is really trying at this point to compile a listing of all applications programs which will be shared by users. Not all PC-based software packages are available in network versions and not all PC-based software packages allow simultaneous access by multiple users. Once a complete list of required shared application programs has been completed, it is important to investigate both the availability and capability of the network versions of these programs in order to assure happy, productive users and the successful attainment of business needs.

Distributed Data Access

Although users cannot be expected to be database analysts, sufficient questions must be asked in order to determine which data is to be shared by whom and where these users are located. The major objective of data distribution analysis is to determine the best location on the network for the storage of various data files. That best location is usually the one closest to the greatest number of the most active users of that data.

Some data files that are typically shared, especially in regionalized or multilocation companies, include customer files, employee files, and inventory files. Distributed data access is even more of a concern when the users sharing the data are beyond the reach of a local area network and must share the data via wide area networking solutions. A good starting point for the network analyst might be to ask the question: Has anyone done a comparison of the forms that are used in the various regional and branch offices to determine which data needs to be sent across the network?

Extended Communications

The ability of certain local area networking solutions to communicate beyond the local area network remains a key differentiating factor among local area networking alternatives. Users should be able to articulate connectivity requirements beyond the LAN. The accomplishment of these requirements is the job of the network analyst. Some possible examples of extended communications might include communications to another LAN. If this is the case, the network analyst must investigate all of the technical specifications of this target LAN in order to determine compatibility with the local LAN. The target LAN may be local (within the same building) or remote (across town or around the world). LAN to LAN connection is known as *internetworking* and will be studied in the next section. Other examples of extended communications may be the necessity for LAN users to gain access to mainframes, either locally or remotely. Again, users are only asked *what* they need connections to, and *where* those connections must occur, it is the network analyst's job to figure out *how* to make those connections function.

LAN Management and Administration

Another key differentiating factor among LAN alternatives is the level of sophistication required to **manage** and administer the **network**. If the LAN requires a full time, highly trained manager, then that manager's salary should be considered as part of the purchase cost as well as the operational cost of the proposed LAN. Secondly, the users may have requirements for certain management or administration features which must be present. Examples might be user-identification creation or management, or control of access to files or user directories.

Budget Reality

The most comprehensive, well documented, and researched networking proposal is of little value if its costs are beyond the means of the funding organization or business. Initial research into possible networking solutions is often followed by feasibility option reports that outline possible network designs of varying price ranges. Senior management then dictates which options deserve further study based on financial availability. In some cases, senior management may have an approximate project budget in mind which could be shared with network analysts. This acceptable financial range, sometimes expressed as budgeted cost per user, serves as a frame of reference for analysts as technical options are explored. In this sense, budgetary constraints are just another overall, high-level business need or perspective that helps to shape eventual networking proposals.

Anticipated Growth is Key

User needs are not always immediate in nature. These needs can vary dramatically over time. To design networking solutions that will not become obsolete in the near future, it is essential to gain a sense of what the anticipated growth in user demands might be. Imagine the chagrin of the network analyst who must explain to management that the network which was installed last year cannot be expanded and must be replaced due to unanticipated growth of network demand. One method of gaining the necessary insight into future networking requirements, illustrated in Fig. 19.59, is to ask users the same set of business analysis questions with projected time horizons of 2–3 years and 5 years. Incredible as it may seem, 5 years is about the maximum projected lifetime for a given network architecture or design. Of course, there are exceptions. End users may not have the information or knowledge necessary to make these projections. Management can be very helpful in the area of projected growth and informational needs, especially if the company has engaged in any sort of formalized strategic planning methodology.

Network Application	Issues
Network printing	Printers shared; printer requests, buffered and spooled; 2nd generation network printers faster/smarter. Queue/device management, multiple print formats.
Network backup	Match hardware and software to your needs and network. Check out restore features. Scheduling unattended backups. Generation of log reports. Hardware dependencies and capacities.
Network security	Virus control. Additional User ID/password protection. Encryption. User authentication. Automatic logout of inactive terminals.
Network management	Network monitors. Diagnostic and analysis tools, which may be separated depending on cable and network type. Administration concerns. Software often in NOS for simple LANs.
Network resource optimization	Hardware and Software inventory database. Reporting and query capabilities. Planning and network configuration tools. Monitoring and network alarm capabilities.
Configuration mgmt. Inventory mgmt.	
Remote access-control software	Included in many fully integrated LANs.
Connectivity/gateway software MAC integration software	
Groupware	Workflow automation. Interactive work document review. Information sharing. Group schedules. Enhanced e-mail.

FIGURE 19.60 LAN and LAN look alike: network applications analysis.

Network Applications: What Can a LAN Do for You ?

Beyond merely being able to share the same application software packages (spreadsheets, word processing, databases), which ran on individual PCs before they were networked together over a LAN, networking PCs together provides some unique opportunities to run additional networked applications, which can significantly increase worker productivity and/or decrease costs.

Figure 19.60 summarizes the attributes and issues of some of the most popular uses of a LAN. It should be noted that the uses, features, and issues described next apply only to the listed applications functioning on a local area network. Many of these same functions become much more complicated when running across multiple LANs (internetworking) or over long distance WANs. A short description of each of these LAN applications follows

Network Printing

Network printing continues to evolve as user demands change and technology changes to meet those demands.

On a typical LAN, a networked PC would send a request for printing out onto the network through a network interface card. The networked request for printing services would be accepted by a device in charge of organizing the print requests for a networked printer. Depending on the LAN implementation configuration, that device may be a PC with attached printer, a specialized print server with attached printers, or a directly networked printer. Some type of software must manage all of this requesting, spooling, buffering, queuing and printing. The required software may be part of an overall network operating system or may be specifically written for only network printer management.

Network Backup

Backing up data and application files on a network is essential to overall network security and the ability to recover from the inevitable data-destroying disaster. Although the process and overall components are relatively simple, the implementation can be anything but simple. Basically there are only two components to a network backup system: (1) the software, which manages the backup, and (2) the hardware device, which captures the backed-up files.

Some network backup software and hardware work with only certain network operating systems. Other network backup software will work with only the hardware device with which it is sold. The interaction between hardware devices and software such as operating systems or network operating systems is often controlled by specialized software programs (drivers). It is essential to make sure that the necessary drivers are supplied by either the tape backup device vendor or software vendor in order to ensure the operability of the tape backup device. Hardware devices may be various types of tape subsystems, or optical drives. Key differences among hardware devices include

1. How much? What is the storage capacity of the backup device?
2. How fast? How quickly can data be transferred from a PC or server to the backup device? This attribute is important if you are backing up large capacity disk drives.
3. How compressed? Can data be stored on the backup device in compressed form? If so, it may save significant room on the backup media.

Remember, backup is not necessarily a one way process. Restoration of backed up files and the ease with which that restoration can be accomplished is a major purchasing consideration. Being able to schedule unattended backups or restorals as well as the ability to spool or print log reports of backup/restoral activity are also important to **network managers**.

Network Management

The overall task of network management is usually broken down into at least three distinct areas of operation. First, networks must be *monitored*. Therefore, one of the foremost jobs of network management software is to monitor the LAN to detect any irregular activity such as malfunctioning network adapter cards, or an unusually high data transmission rate monopolizing the available network bandwidth to be shared among all attached workstations. Sophisticated LAN monitoring programs can display maps of the network on graphics terminals. Operators can zoom in on a particular node or workstation for more information or performance statistics. Some monitoring programs also have the ability to compare current network activity to preset acceptable parameters and to set off alarms on network monitor terminals, perhaps by turning a node symbol bright red on the screen, when activity goes beyond acceptable limits. Monitoring software is also written specifically for monitoring file servers on a LAN. Besides monitoring server performance and setting off alarms, some monitoring packages have the ability to dial and set off pagers belonging to network managers who may be away from the network console.

Once a problem has been monitored and identified, it must be *analyzed* and *diagnosed*. This is the second major task of network management software. Diagnosis is often done by a class of devices known as protocol analyzers or by the more common name, sniffers. These devices are attached to the LAN and watch, measure, and in some cases, record every bit of data that passes their way. By using multiple sniffers at various points on a LAN, otherwise known as distributed sniffers, bottlenecks can be identified and performance degradation factors can be pinpointed. LAN testing devices must be able to test and isolate the three major segments of any LAN: (1) the wire or cable of the network, (2) the network adapter cards, which interface between the cable and the workstation, and (3) the workstation or PC that generates the network activity.

Having diagnosed the cause of the networking problem, corrective action must be taken against that problem. Perhaps a misbehaving network interface card must be disabled or an application on a workstation that is monopolizing network resources must be logged out. The power to do these things is sometimes called network *administration* or management. In this case, the term administration is preferable in order to provide a contrast to the previous more general use of the term network management. Most often, the

required network management software to manage LANs is included in the network operating system itself.

LAN monitoring software and other specialized network management functions are available as an add-on product for most network operating systems. When these add-on products are manufactured by a company other than the original network operating system vendor, they are known as third-party products. These third-party enhancements are often of high quality but should be purchased with caution. Compatibility with associated software or future releases of the network operating system are not necessarily guaranteed.

Network Security

In addition to the typical security features, such as password protection and directory access control supplied with most network operating systems, more sophisticated network security software/hardware is available for LANs. For instance, security software may be added to workstations and or servers which will

1. Require user identification and valid password to be entered before the PC can be booted.
2. Encrypt important data or application files to prevent tampering.
3. Automatically logout inactive terminals to prevent unauthorized access to system resources.
4. Allow certain users to run only certain applications.
5. Require verification of user authenticity by security verifiers.

Another area of network security that is receiving a lot of attention is that of *viruses*. Virus control software is sometimes included in network security packages. Virus control is really a three-step process, implying that effective virus control software should address at least the following three areas:

1. Virus protection: User access to systems is sufficiently controlled as to prevent an unauthorized user from infecting the LAN.
2. Virus detection: Sophisticated software to find viruses regardless of how cleverly they may be disguised.
3. Virus eradication: Sometimes called antibiotic programs, this software eliminates all traces of the virus.

Groupware

Groupware is the name of a category of software that seeks to take advantage of the fact that workers are networked together electronically in order to maximize worker productivity. Groupware is a general term that describes all or some of the following software categories: workflow automation, interactive work, group scheduling, document review, information sharing, electronic whiteboard, and enhanced electronic mail.

Local Area Network Architectures

The choice of a particular network architecture will have a definite bearing on the choice of network adapter cards and less of an impact on the choice of media or network operating system. For instance, an ethernet network architecture requires ethernet adapter cards. As will soon be seen, it is the adapter card which holds the key, or media access control (MAC) layer protocol, which determines whether a network is ethernet, token ring, **fiber distributed data interface (FDDI)** or any other network architecture. Ethernet runs over thick or thin coaxial cable, shielded or unshielded twisted pair, fiber or wireless—clearly a wide choice of media options.

Ethernet

Ethernet, adhering to the IEEE 802.3 standard, is a **carrier sense multiple access with collision detection- (CSMA/CD-)** based network architecture traditionally installed in a bus configuration, but most often installed in a hub-based star physical topology. Every device, most often network adapter cards, attached to an ethernet network has a unique hardware address assigned to it at time of manufacture. As new devices

are added to an ethernet network, their addresses become new possible destinations for all other attached ethernet devices.

The media access layer protocol elements of ethernet form data packets for transmission over the shared media according to a standardized format. This ethernet packet format is nearly equivalent to the IEEE 802.3 standard, and the two terms are often used interchangeably.

The potential for collisions and retransmission exists on an ethernet network thanks to its CSMA/CD access methodology. In some cases, ethernet networks with between 100 and 200 users barely use the capacity of the network. However, the nature of the data transmitted is the key to determining potential network capacity problems. Character-based transmissions, such as typical data entry, in which a few characters at a time are typed and sent over the network are much less likely to cause network capacity problems than the transfer of graphical user interface (GUI) screen oriented transmission such as Windows-based applications. CAD/CAM images are even more bandwidth intensive. Simultaneous requests for full screen Windows-based transfers by 30 or more workstations can cause collision and network capacity problems on an ethernet network. As with any data communication problem, there are always solutions or workarounds to these problems. The point in relaying these examples is to provide some assurance that although ethernet is not unlimited in its network capacity, in most cases, it provides more than enough bandwidth.

Token Ring

IBM's token ring network architecture, adhering to the IEEE 802.5 standard, utilizes a star physical topology, sequential message delivery, and a token passing access methodology scheme. Since the sequential logical topology is equivalent to passing messages from neighbor to neighbor around a ring, the token ring network architecture is sometimes referred to as: *logical ring, physical star*. The token ring's use of the token passing access methodology furnishes one of the key positive attributes of this network architecture. The guarantee of no data collisions with assured data delivery afforded by the token passing access methodology is a key selling point in some environments where immediate, guaranteed delivery is essential.

FDDI

As far as trends in network architecture go, as more and more users are attached to LANS, the demand for overall network bandwidth increases. LANs are increasing both in size and overall complexity. Internetworking of LANs of various protocols via bridges and routers means more overall LAN traffic. Network applications are driving the demand for increased bandwidth as well. The concepts of distributed computing, data distribution, and client/server computing all rely on a network architecture foundation of high bandwidth and high reliability. Imaging, multimedia, and data/voice integration all require high amounts of bandwidth in order to transport and display these various data formats in real time. In other words, if full-motion video is to be transported across the LAN as part of a multimedia program, there should be sufficient bandwidth available on that LAN for the video to run at full speed and not in slow motion. Likewise, digitized voice transmission should sound normal when transported across a LAN of sufficient bandwidth.

FDDI supplies not only a great deal of bandwidth, but also a high degree of reliability and security while adhering to standards-based protocols. FDDI's reliability comes not only from the fiber itself which, as we know, is immune to both electromagnetic interference (EMI) and radio frequency interference (RFI). An additional degree of reliability is achieved through the design of the physical topology of FDDI.

FDDI's physical topology comprises not one, but two, separate rings around which data moves simultaneously in opposite directions. One ring is the primary data ring while the other is a secondary or backup data ring to be used only in the case of the failure of the primary ring. Whereas both rings are attached to a single hub or concentrator, a single point of failure remains in the hub while achieving redundancy in the network media. In addition to speed and reliability, distance is another key feature of an FDDI LAN.

Another positive attribute of FDDI is its ability to interoperate easily with ethernet networks. In this way, a business does not have to scrap its entire existing network in order to upgrade a piece of it to FDDI. An FDDI to ethernet bridge is the specific technology employed in such a setup.

The uses of the FDDI network architecture typically fall into three categories:

1. **Campus backbone:** Not necessarily implying a college campus, this implementation is used for connecting LANs located throughout a series of closely situated buildings.
2. **High bandwidth workgroups:** The second application category is when the FDDI LAN is used as a truly local area network, connecting a few PCs or workstations which require high bandwidth communication with each other. Multimedia workstations, engineering workstations, or CAD/CAM workstations are all good examples of high bandwidth workstations.
3. **High bandwidth subworkgroup connections:** In some cases, only two or three devices, perhaps three servers, have high bandwidth requirements. As distributing computing and data distribution increase, an increasing demand for high-speed server to server data transfer has been seen.

Wireless LANs

Many of the previously mentioned network architectures function over more than one type of media. Another media option is wireless transmission (which is really the absence of any media) for local area networks. There are currently three popular wireless transmission technologies in the local area network technology area. They are microwave transmission, spread spectrum transmission, and infrared transmission.

These are all just radio transmissions at varying frequencies.

Wireless LAN Applications

A primary application of **wireless LANs** optimizes the ease of access of the wireless technology. Portable or notebook PCs equipped with their own wireless LAN adapters can create an instant LAN connection merely by getting within range of a server-based wireless LAN adapter or wireless hub. In this way, a student or employee can sit down anywhere and log into a LAN as long as the user is within range of the wireless hub and has the proper wireless adapter installed in the portable PC.

Meeting rooms can be equipped with wireless hubs to allow spontaneous workgroups to log into network resources without running cables all over the meeting room. Similarly, by quickly installing wireless hubs and portable PCs with wireless adapters, temporary expansion needs or emergency/disaster recovery situations can be handled quickly and with relative ease. No rerunning of wires or finding the proper cross-connects in the wiring closet are necessary.

Finally, wireless LAN technology allows entire LANs to be preconfigured at a central site and shipped ready to run to remote sites. The nontechnical users at the remote site literally just have to plug the power cords into the electrical outlets and they have an instant LAN. For companies with a great number of remote sites and limited technical staff, such a technology is ideal. No preinstallation site visits are necessary. Also avoided are costs and supervision of building wiring jobs and troubleshooting building wiring problems during and after installation.

Local Area Network Hardware

Servers

A server's job is to manage the sharing of networked resources among client PCs. Depending on the number of client PCs and the extent of the shared resources, it may be necessary to have multiple servers and/or to specialize some servers as to the type of resources that they manage. If servers are to be specialized, then shared resources should be grouped in some logical fashion so as to optimize the server performance for managing the sharing of a particular type of resource. A list of potentially shared network resources would probably include: files, application programs, databases, printers, access to other LANs (local), access to other LANs (remote), access to information services, and access to the LAN from remote PCs.

Hubs/Multistation Access Units (MAUs)

The heart of the star physical topology, employed by both ethernet and token ring, is the wiring center, alternatively known as a hub, a concentrator, a repeater or a multistation access unit (MAU).

Repeaters

A repeater, as its name would imply, merely repeats each bit of digital data that it receives. This repeating action actually cleans up the digital signals by retiming and regenerating them before passing this repeated data from one attached device or LAN segment to the next.

Hubs

The terms hub and *concentrator* or *intelligent concentrator* are often used interchangeably. Distinctions can be made, however, between these two broad classes of wiring centers, although there is nothing to stop manufacturers from using the terms as they wish. A hub is often the term reserved for describing a stand-alone device with a fixed number of ports, which offers features beyond that of a simple repeater. The type of media connections and network architecture offered by the hub is determined at the time of manufacture as well. For example, a 10BaseT ethernet hub will offer a fixed number of RJ-45 twisted pair connections for an ethernet network. Additional types of media or network architectures are not usually supported.

MAUs

A MAU is IBM's name for a token ring hub. A MAU would be manufactured with a fixed number of ports and connections for unshielded or shielded twisted pair. IBM uses special connectors for token ring over shielded twisted pair (STP) connections to a MAU. MAUs offer varying degrees of management capability.

Concentrators

The term concentrator or intelligent concentrator (or smart hub) is often reserved for a device characterized by its flexibility and expandability. A concentrator starts with a fairly empty, boxlike device often called a chassis. This chassis contains one or more power supplies and a builtin network backbone. This backbone might be ethernet, token ring, FDDI, or some combination of these. Into this backplane, individual cards or modules are inserted.

For instance, an 8- or 16-port twisted pair ethernet module could be purchased and slid into place in the concentrator chassis. A network management module supporting the SNMP (simple network management protocol) network management protocol could then be purchased and slid into the chassis next to the previously installed 10BaseT Port module. In this mix and match scenario, additional cards could be added for connection of PCs with token ring adapters, PCs, or workstations with FDDI adapters, or dumb asynchronous terminals.

This network in a box is now ready for workstations to be hooked up to it through twisted pair connections to the media interfaces on the network interface cards of the PCs or workstations. Remember that ethernet can run over UTP (unshielded twisted pair), STP, thick and thin coaxial as well as fiber.

Additional modules available for some, but not all, concentrators may allow data traffic from this network in box to travel to other local LANs via bridge or router add-on modules. (Bridges and routers will be discussed in the next section on internetworking.) These combination concentrators are sometimes called *internetworking hubs*. Communication to remote LANs or workstations may be available through the addition of other specialized cards, or modules, designed to provide access to wide area network services purchased from common carriers.

Switching Hubs

The network in a box or backbone in a box offered by concentrators and hubs shrinks the length of the network backbone but does not change the architectural characteristics of a particular network backbone. For instance, in an ethernet concentrator, multiple workstations may access the built in ethernet backbone via a variety of media, but the basic rules of ethernet, such as CSMA/CD access methodology still control performance on this ethernet in a box. Only one workstation at a time can broadcast its message onto the shared backbone.

A *switching hub* seeks to overcome this one at a time broadcast scheme, which can potentially lead to data collisions, retransmissions, and reduced throughput between high-bandwidth demanding devices such as engineering workstations or server-to-server communications.

The ethernet switch is actually able to create connections, or switch, between any two attached ethernet devices on a packet by packet basis. The one-at-time broadcast limitation previously associated with ethernet is overcome with an ethernet switch.

Wiring Centers Technology Analysis

Some of the major technical features to be used for comparative analysis are listed in Fig. 19.61. Before purchasing a hub of any type, consider the implications of these various possible features. To summarize, the following major criteria should be thoroughly considered before a hub or concentrator purchase:

Characteristic/Feature	Options/Implications
Expandability	Options: ports, LANs, slots. Remember, most stand-alone hubs are not expandable, although they may be cascaded. Concentrators may vary in their overall expandability (number of open slots,) or in their ability to add additional ports. Several concentrators allow only one LAN backbone module. Have you anticipated growth in 2- and 5-year horizons?
Network Architecture	Options: ethernet, token ring, FDDI. Some concentrators allow only one type of LAN module, with ethernet being the most widely supported type of LAN module. Before purchasing concentrator, make sure all of the necessary LAN types are supported.
Media	Options: Unshielded twisted pair, shielded twisted pair, thin coax, thick coax, fiber. Remember that each of these different media will connect to the hub with a different type of interface. Make sure that the port modules offer the correct interfaces for attachment of your media; also, remember that a NIC is on the other end of the attached media. Is this concentrator/hub compatible with your network adapter cards?
Extended Communications:	
Internetworking	Options: Internetworking to: ethernet, token ring, FDDI. Internetworking solutions are unique, dependent on the two LANs to be connected. In other words, unless a concentrator offers a module which specifically internetworks ethernet module traffic to token ring LAN, this communication can not take place within the concentrator.
Wide Area Networking	Options: Interfaces to different carrier services.
Management	Options: What level of management is offered? 1. Can individual ports be managed? 2. Is monitoring software included? 3. Can wide area as well as local area link performance be analyzed/monitored through the concentrator? 4. What level of security in general or regarding management functions specifically is offered? 5. Can ports be remotely enabled/disabled? 6. Can the hub/concentrator be controlled from any attached workstation? Via modem? 7. Can management/monitoring functions be included through a graphical user interface? 8. How are alarm thresholds set? 9. How are faults managed? 10. Can port access be limited by day and/or time? 11. What operating systems can the management software run on? 12. Can a map of the network be displayed?
Reliability	Options: 1. Is integrated UPS included? 2. Are there multiple, redundant power supplies? 3. Can individual modules be swapped out "hot", without powering down the entire hub

FIGURE 19.61 Wiring center technology analysis grid.

(1) expandability (2) supported network architectures (3) supported media types (4) extended communications capabilities, that is, terminal support, internetworking options, and wide area networking options, (5) hub/concentrator management capabilities and (6) reliability features.

Network Interface Cards

Network adapter cards, also known as network interface cards are the physical link between a client or server PC and the shared media of the network. Providing this interface between the network and the PC or workstation requires that the network adapter card have the ability to adhere to the access methodology (CSMA/CD or token passing) of the network architecture to which it is attached. These software rules, implemented by the network adapter card which control the access to the shared network media, are known as *media access control* (MAC) protocols and are represented on the MAC sublayer of the data link layer (layer 2) of the OSI 7-layer reference model.

Since these are MAC layer interface cards and are, therefore, the keepers of the MAC layer interface protocol, it is fair to say that it is the adapter cards themselves that determine network architecture and its constituent protocols more than any other component. Take an ethernet adapter card out of the expansion slot of a PC and replace it with a token ring adapter card and you have a token ring workstation. In this same scenario, the media may not even need to be changed since ethernet, token ring, and FDDI/CDDI often work over the same media.

Role of Adapter Card Drivers

Assuring that the purchased adapter card interfaces successfully to the bus of the CPU as well as the chosen media of the network architecture will assure hardware connectivity. Full interoperability, however, depends on the chosen network adapter card being able to communicate successfully with the network operating system and operating system of the PC into which it is installed.

19.7.4 Internetworking

Applications: What Can Internetworking Do for You?

It is nearly inevitable that sooner or later nearly any organization will need to share information across multiple information platforms or architectures. This sharing may be between LANs that may differ in network architecture or network operating systems. Information systems that combine multiple computing platforms or a variety of network architectures and network operating systems are often referred to as *enterprise computing* environments. Underlying this enterprise computing environment is an *enterprise network* or *internetwork*. The key to successful *internetworking* is that to the end user sitting at a LAN-attached workstation, the connectivity to enterprise computing resources should be completely transparent.

In other words, an end user should not need to know the physical location of a database server or disk drive to which they need access. All the user needs to know is a node name or drive indicator letter and the fact that when these node name or drive letters are entered, data is properly accessed from wherever it may be physically located. That physical location may be across the room or across the country.

As information has become increasingly recognized as a corporate asset to be leveraged to competitive advantage, the delivery of that information in the right form, to the right person at the right place and time has become the goal of information systems and the role of internetworking. Mergers, acquisitions, and enterprise partnerships have accelerated the need to share information seamlessly across geographic or physical LAN boundaries. Intelligent inter-LAN devices perform the task of keeping track of what network attached resources are located and where and how to get a packet of data from one LAN to another. This task is further complicated by the fact that LANS can differ in any of the following categories: (1) network architecture, (2) media, (3) network operating system, and (4) operating system.

This collection of differences is defined by rules or *protocols* that define how certain clearly defined aspects of network communications are to take place. When LANs that need to share information operate according to different protocols, an inter-LAN device that has *protocol conversion* capabilities must be employed. In cases such as this, the inter-LAN device would be transmitting data across logical, as opposed to physical or geographic, boundaries. Among the inter-LAN devices which will be explored in this section

FIGURE 19.62 Relationship between the OSI model and internetworking devices.

are repeaters, bridges, routers, and gateways. Although the differences in functionality of these devices will be distinguished from a technical standpoint, there is no guarantee that manufacturers will follow this differentiation. Functional analysis of data communications devices is the best way to assure that inter-LAN devices will meet internetworking connectivity needs. Internetworking analysis and design is a highly complex and confusing area of study. The purpose of this section is to familiarize the reader with internetworking technology and applications and to provide a list of resources for further study.

The OSI Model and Internetworking Devices

The OSI model was first introduced in Sec. 19.7.1 as a common framework or reference model within which protocols and networking systems could be developed with some assurance of interoperability. In this section, the OSI model provides a most effective framework in which to distinguish between the operational characteristics of the previously mentioned internetworking devices. Figure 19.62 depicts the relationship between each type of internetworking device and its related OSI layer. Each device as well as the related OSI model layer will be explained in detail.

Internetworking Technology

Repeaters: Layer 1—The Physical Layer

Remember that all data traffic on a LAN is in a digital format of discrete voltages of discrete duration traveling over one type of physical media or another. Given this, a repeater’s job is fairly simple to understand:

1. Repeat the digital signal by regenerating and retiming the incoming signal.
2. Pass all signals between all attached segments.
3. Do not read destination addresses of data packets.
4. Allow for the connection of different types of media.
5. Effectively extend overall LAN distance by repeating signals between LAN segments.

A repeater is a nondiscriminatory internetworking device. It does not discriminate between data packets. Every signal which comes into one side of a repeater gets regenerated and sent out the other side of the repeater. Repeaters are available for both ethernet and token ring network architectures for a wide variety of media types. A repeater is a physical layer device concerned with physical layer signaling protocols relating to signal voltage levels and timing. It cannot distinguish between upper layer protocols such as between ethernet vs. token ring frames (layer 2, data link protocols). Therefore, repeaters must be specifically manufactured for either ethernet or token ring network architectures. The primary reasons for employing a repeater are (1) increase the overall length of the network media by repeating signals across multiple LAN segments, (2) isolate key network resources onto different LAN segments, and (3) some repeaters also allow network segments of the same network architecture but different media (layer 1—physical) types to be interconnected.

Bridges: Layer 2—The Data Link Layer

Bridge Functionality

The primary reasons for employing bridges are (1) network traffic on a LAN segment has increased to the point where performance is suffering, and (2) access from the departmental LAN to the corporate LAN backbone needs to be controlled so that local LAN data is not unnecessarily causing congestion problems on the corporate backbone network.

By dividing users across multiple LAN segments connected by a bridge, a substantial reduction in LAN traffic on each segment can be achieved provided the division of users is done in a logical manner. Users should be divided according to job function, need to communicate with each other, and need to access data stored on particular servers. The rule of thumb for segmenting users is that 80% of LAN traffic should remain within the LAN segment and only about 20% should cross the bridge to adjacent LAN segments.

Controlling access to the corporate backbone via a bridge can ensure the viability of enterprise communications by only allowing essential network communication onto the corporate backbone. Servers and other internetworking devices can be connected directly to the corporate backbone while all user's workstations are connected to LAN segments isolated from the corporate backbone by bridges.

When users on one LAN need occasional access to data or resources from another LAN, an internetworking device, which is more sophisticated and discriminating than a repeater, is required. From a comparative standpoint on the functionality of bridges vs repeaters, one could say that bridges are more discriminating. Rather than merely transferring *all* data between LANs or LAN segments like a repeater, a bridge reads the *destination address* of each data frame on a LAN, decides whether the destination is local or remote (on the other side of the bridge), and only allows those data frames with nonlocal destination addresses to cross the bridge to the remote LAN.

How does the bridge know whether a destination is local or not? Data-link protocols such as ethernet contain *source addresses* as well as destination addresses within the predefined ethernet frame layout. A bridge also checks the source address of each frame it receives and adds that source address to a table of known local nodes. After each destination address is read, it is compared with the contents of the known local nodes table in order to determine whether the frame should be allowed to cross the bridge or not (whether the destination is local or not). Bridges are sometimes known as a forward-if-not-local device.

This reading, processing, and discriminating indicates a higher level of sophistication of the bridge, afforded by installed software.

Bridge Categorization

Bridges come in many varieties. Physically, bridges may be cards that can be plugged into an expansion slot of a PC, or they may be standalone devices. Although it is known that the bridge will do the internetwork processing between two LANs, the exact nature of that processing, as well as the bridge's input and output interfaces, will be determined by the characteristics of the two LANs that the bridge is internetworking. In determining the attributes of the input and output bridge one must consider the following issues: MAC sublayer protocol, speed of LANs, local or remote, and wide area network services and media.

1. MAC Sub-Layer Protocol: Depending on the MAC sublayer or network architecture of the LANs to be bridged, any of the following types of bridges may be required: transparent bridges, translating

Bridge Type	LAN Segment Linked
Transparent	<ul style="list-style-type: none"> • Ethernet to ethernet • Nonsource routing token ring to nonsource routing token ring
Translating	<ul style="list-style-type: none"> • Ethernet to token ring and vice versa
Encapsulating	<ul style="list-style-type: none"> • Ethernet to FDDI and vice versa
Source routing	<ul style="list-style-type: none"> • Source routing token ring to source routing token ring
Source routing transparent	<ul style="list-style-type: none"> • Source routing token ring to ethernet and vice versa
Adaptive source routing transparent	<ul style="list-style-type: none"> • Ethernet to ethernet • Source routing token ring to source routing token ring • Source routing token ring to ethernet and vice versa

FIGURE 19.63 Bridges link LAN segments.

bridges, encapsulating bridges, source routing bridges, source routing transparent bridges, and adaptive source routing transparent bridges. First and foremost, are the two LANs which are to be bridged ethernet or token ring? Bridges that connect LANs of similar data link format are known as *transparent bridges*. A special type of bridge that includes a *format converter* can bridge between ethernet and token ring. These special bridges may also be called *multiprotocol bridges* or *translating bridges*. A third type of bridge, somewhat like a translating bridge, is used to bridge between ethernet and FDDI networks. Unlike the translating bridge, which must actually manipulate the data-link layer message before repackaging it, the *encapsulating bridge* merely takes the entire ethernet data link layer message and stuffs it in an envelope (data frame) that conforms to the FDDI data-link layer protocol. *Source routing bridges* are specifically designed for connecting token ring LANs. Bridges that can support links between source routing token ring LANs and nonsource routing LANs, such as ethernet, are known as *source routing transparent bridges*. Finally, bridges that can link transparent bridged ethernet LAN segments to each other, source routing token ring LAN segments to each other, or any combination of the two are known as *adaptive source routing transparent bridges*. Figure 19.63 outlines these various bridge possibilities.

2. Speed of LANs: The speeds of the input and output LANs must be known in order to determine what speed conversion, if any, must be performed by our bridge.
3. Local or Remote: Having determined the MAC layer protocol and speed of the LANs, their geographic proximity to one another must be taken into consideration. If the two LANs are not in close enough proximity to link via traditional LAN media such as UTP, coax, or fiber, the bridge must be equipped with an interface appropriate for linking to wide area carrier services.

Bridge Performance

Bridge performance is generally measured by two criteria:

1. *Filtering rate*: Measured in packets per second or frames per second. When a bridge reads the destination address on an ethernet frame or token ring packet and decides whether or not that packet should be allowed access to the internetwork through the bridge, that process is known as *filtering*.
2. *Forwarding rate*: Also measured in packets per second or frames per second. Having decided whether or not to grant a packet access to the internetwork in the filtering process, the bridge now must perform a separate operation of forwarding the packet onto the internetwork media whether local or remote.

Bridges, Protocols, and the OSI Model

Bridges read the destination addresses within data frames of a predefined structure or protocol. In other words, ethernet and token ring network architectures define a bit-by-bit protocol for formation of data frames. The bridge can rely on this protocol and, therefore, knows just where to look within the ethernet data frames to find the bits, which represent the destination addresses. In terms of the OSI model, ethernet and token ring are considered MAC sublayer protocols. The MAC sublayer is one of two sublayers of OSI model layer 2—the data link layer. The other data link sublayer is known as the *logical link control* sublayer. Because the protocols that a bridge reads and processes are located on the MAC sublayer, bridges are sometimes referred to as MAC layer bridges.

Embedded within the data field of the ethernet frame are all of the higher OSI layer protocols. These higher layer protocols can vary independently of the data-link layer ethernet protocol. In other words, the data-link layer protocols such as ethernet and token ring are *network architectures*, whereas the network layer protocols could be from any one of a number of different *network operating systems*. Bridges only pay attention to network architecture (MAC sublayer) protocols or formats. They completely ignore upper level protocols.

Most network operating systems actually consist of stacks of protocols. In some cases, this *protocol stack* may consist of a separate protocol for each of layers 3–7. Each protocol of a network operating system performs a different networking related function corresponding to the generalized functional definition for the corresponding layer of the OSI model. As an example, the network layer protocol for TCP/IP suite of protocols is known as *internet protocol* (IP).

Routers: The Network Layer Processors

The delivery of data packets to destination addresses across multiple LANs, and perhaps over wide area network links, is the responsibility of a class of internetworking devices known as *routers*. Routers are primarily employed for the following reasons:

1. To build large hierarchical networks. Routers are used to create the backbone network itself.
2. To take part in or gain access to a larger hierarchical network such as the Internet.

Router Functionality

Although they both examine and forward data packets, routers and bridges differ significantly in two key functional areas. First, although a bridge reads the destination address of every data packet on the LAN to which it is attached, a router only examines those data packets that are specifically addressed to it. Second, rather than just merely allowing the data packet access to the internetwork in a manner similar to a bridge, a router is more cautious as well as more helpful. Before indiscriminately forwarding a data packet, a router first confirms the existence of the destination address as well as the latest information on available network paths to reach that destination. Next, based on the latest traffic conditions, the router chooses the best path for the data packet to reach its destination and sends the data packet on its way. The word best is a relative term, controlled by a number of different protocols, which will be examined shortly.

The router itself is a destination address, available to receive, examine, and forward data packets from anywhere on any network to which it is either directly or indirectly internetworked. The destination address on an ethernet or token ring packet must be the address of the router that will handle further internetwork forwarding. Thus, a router is addressed in the data-link layer destination address field. The router then discards this MAC sublayer envelope, which contained its address, and proceeds to read the contents of the data field of the ethernet or token ring frame.

Just as in the case of the data-link layer protocols, network layer protocols dictate a bit-by-bit data frame structure that the router understands. What looked like just data and was ignored by the data-link layer internetworking device (the bridge) is unwrapped by the router and examined thoroughly in order to determine further processing. After reading the network layer destination address and the protocol of the network layer data, the router consults its *routing tables* in order to determine the best path on which to forward this data packet. Having found the best path, the router has the ability to repackage the data packet as required for the delivery route (best path) it has chosen.

As an example, if a packet switched data network was chosen as the wide area link for delivery, then the local router would encapsulate the data packet in compliant envelope. On the other hand, if the best path was over a local ethernet connection, the local router would put the data packet back into a fresh ethernet envelope and send it on its way.

Unlike the bridge, which merely allows access to the internetwork (forward-if-not-local logic), the router specifically addresses the data packet to a distant router. Before a router actually releases a data packet onto the internetwork, however, it confirms the existence of the destination address to which this data packet is bound. Only once the router is satisfied with both the viability of the destination address, as well as with the quality of the intended path, will it release the carefully packaged data packet. This meticulous processing activity on the part of the router is known as *forward-if-proven-remote* logic.

Determination of Best Path

The best path can take into account variables such as

1. Number of intermediate hops. That is, how many other routers will the packet have to be processed by before it reaches its final destination? Every router takes time to process the data packet. Therefore, the fewer the routers, the faster the overall delivery.
2. The speed or condition of the communications circuits. Routers can dynamically maintain their routing tables keeping up to the minute information on network traffic conditions.
3. The protocol of the network operating system, for instance, remembering that multiple protocols can be sealed within ethernet envelopes. We may ask the router to open the ethernet envelopes and forward all NetWare (IPX) traffic to one network and all TCP/IP (IP) to another. In some cases, a certain protocol may require priority handling.

Multiprotocol Routers

Routers are made to read specific network layer protocols in order to maximize filtering and forwarding rates. If a router only has to route one type of network protocol, then it knows exactly where to look for destination addresses every time and can process packets much faster. However, realizing that different network layer protocols will have different packet structures with the destination addresses of various lengths and positions, some more sophisticated routers known as *multiprotocol routers* have the capability to interpret, process, and forward data packets of multiple protocols.

Some common network layer protocols and their associated network operating systems or upper layer protocols as well as other protocols which are actually data-link control protocols processed by some routers are listed in Table 19.6. Remembering that bridges are used to process data-link layer protocols, those routers that can also perform the functionality of a bridge are called bridging routers or *brouters*.

TABLE 19.6 Network and Data-Link Protocols

Network Layer Protocol	Network Operating System or Protocol Stack Name
IPX	NetWare
IP	TCP/IP
VIP	Vines
AFP	Appletalk
XNS	3Com
OSI	Open Systems
<i>Other Protocols</i>	
LAT	Digital DecNet
SNA/SDLC	IBM SNA
Netbios	DOS-based LANs

Router Configuration

Like bridges, routers generally take one of the two physical forms: (1) stand-alone variety, self-contained; and (2) modularized for installation in a slotted chassis. Routers may be installed to link LAN segments either locally or remotely. *Boundary routing* recognizes the need for simple, affordable wide area network devices at remote offices while providing full routing capabilities throughout the wide area network. Boundary routing's physical topology is sometimes referred to as a *hub and spoke topology* due to the fact that each remote branch is connected to a hub office via a single WAN link. If redundant links are a business requirement of a particular node, then it must be a full-function router and not a boundary router in this topology.

Full-function routers are placed at each hub or central node, while less sophisticated boundary routers, or branch-office routers, are placed at each remote or spoke node. Since there are only connected to a single WAN link, these boundary routers make only one decision when examining each piece of data, "If these data are not addressed to a local destination, then it should be forwarded." This forward-if-not-local logic should suggest that, in fact, these boundary routers are acting as bridges.

Gateways

Recalling that in terms of the OSI model, repeaters are considered a physical layer (layer 1) device, bridges are considered a data-link layer (layer 2) device, and routers are considered a network layer (layer 3) device, it could be said that *gateways* provide for interoperability on the session, presentation, and application layers (layers 5–7). Whereas repeaters, bridges and routers provide increasingly more sophisticated connection between two LANs, gateways provide transparent connection between two totally different computing environments. Specialized gateways also translate between different database management systems and are called *database gateways*, or between different e-mail systems and are called e-mail gateways.

The gateway is usually a computer with physical connections to both computing environments to be linked. In addition, the gateway also executes specially written software, which can translate messages between the two computing environments. Unlike other internetworking devices described, gateways are more concerned with translation than with processing destination addresses and delivering messages as efficiently as possible.

19.7.5 Wide Area Networks

Applications

Wide Area Network Architecture

To better understand all of the current and emerging wide area networking technologies and services, a simple model defining the major segments and interrelationships of an overall wide area network architecture is shown in Fig. 19.64. *User demands* are the driving force behind the current and emerging

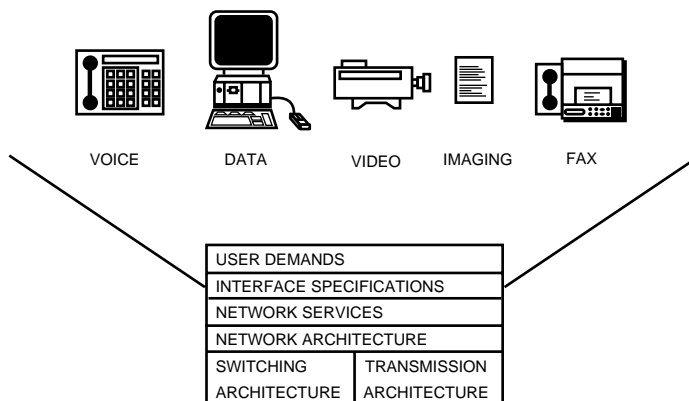

FIGURE 19.64 Major components of a wide area network architecture.

wide area *network services* which are offered to business and residential customers. Companies offering these services are in business to generate profits by implementing the underlying architectures that will enable them to offer the wide area networking services that users are demanding at the lowest possible cost.

Users are demanding simple, transparent access to variable amounts of bandwidth as required. In addition, this wide area network access must offer support for transmission of data, video, imaging, and fax as well as voice. One of the primary driving forces of increased capacity and sophistication for wide area network services is *LAN interconnection*.

Circuit Switching vs. Packet Switching

Switching of some type or another is necessary in a wide area network because the alternative is unthinkable. To explain, without some type of switching mechanism or architecture, every possible source of data in the world would have to be directly connected to every possible destination of data in the world, not a very likely prospect.

Circuit Switching

Switching allows temporary connections to be established, maintained, and terminated between message sources and message destinations, sometime called sinks in data communications. In the case of the voice-based phone network with which most people are familiar, a call is routed through a central office piece of equipment known as a switch, which creates a temporary circuit between the source phone and the phone of the party to whom one wishes to talk. This connection or circuit only lasts for the duration of the call. This switching technique is known as *circuit switching* and is one of two primary switching techniques employed to deliver messages from here to there. In a circuit switched network, a switched dedicated circuit is created to connect the two or more parties, eliminating the need for source and destination address information such as that provided by packetizing techniques.

The *switched dedicated circuit* established on circuit switched networks makes it appear to the user of the circuit as if a wire has been run directly between the phones of the calling parties. The physical resources required to create this temporary connection are dedicated to that particular circuit for the duration of the connection. If system usage should increase to the point where insufficient resources are available to create additional connections, users would not get a dial tone.

Packet Switching

The other primary switching technique employed to deliver messages from here to there is known as *packet switching*. Packet switching differs from circuit switching in several key areas. First, packets travel one at a time from the message source through a *packet switched network*, otherwise known as a *public data network*, to the message destination. A packet switched network is represented in network diagrams by a symbol which resembles a cloud. Figure 19.65 illustrates such a symbol, as well as the difference between circuit switching and packet switching. The cloud is an appropriate symbol for a packet switched network since all that is known is that the packet of data goes in one side of the public data network (PDN) and comes out the other. The physical path which any packet takes may be different than other packets and in any case, is unknown to the end users. What is beneath the cloud in a packet switched network is a large number of *packet switches*, which pass packets among themselves as the packets are routed from source to destination.

Remember that packets are specially structured groups of data, which include control and address information in addition to the data itself. These packets must be assembled (control and address information added to data) somewhere before entry into the packet switched network and must be subsequently disassembled before delivery of the data to the message destination. This packet assembly and disassembly is done by a device known as a *packet assembler/disassembler (PAD)*. PADs may be stand-alone devices or may be integrated into modems or multiplexers.

These PADs may be located at an end-user location, or may be located at the entry point to the packet switched data network. Figure 19.65 illustrates the latter scenario in which the end users employ regular modems to dial up the value added network (VAN) or on-line information service, which provides the PADs to properly assemble the packets prior to transmission over the packet switched network.

FIGURE 19.65 Circuit-switching vs. packet switching.

Packet Switched Networks

The packet switches illustrated inside the PDN cloud in Fig. 19.65 are generically known as *data switching exchanges (DSEs)*, or *packet switching exchanges (PSEs)*. DSE is the packet switching equivalent of the DCE (data communications equipment) and DTE (data terminal equipment) categorization for modems and dial-up transmission.

Another way in which packet switching differs from circuit switching is that as demand for transmission of data increases on a packet switched network, additional users are not denied access to the packet switched network. Overall performance of the network may suffer, errors and retransmission may occur, or packets of data may be lost, but all users experience the same degradation of service. This is because, in the case of a packet switched network, data travel through the network one packet at a time, traveling over any available path within the network rather than waiting for a switched dedicated path as in the case of the circuit switched network.

For any packet switch to process any packet of data bound for anywhere, it is essential that packet address information be included on each packet. Each packet switch then reads and processes each packet by making routing and forwarding decisions based on the packet's destination address and current network conditions. The full destination address uniquely identifying the ultimate destination of each packet is known as the *global address*.

Because an overall data message is broken up into numerous pieces by the packet assembler, these message pieces may actually arrive out of order at the message destination due to the speed and condition

of the alternate paths within the packet switched network over which these message pieces (packets) traveled. The data message must be pieced back together in proper order by the destination PAD before final transmission to the destination address. These self-sufficient packets containing full source and destination address information plus a message segment are known as *datagrams*.

A Business Perspective on Circuit-Switching vs Packet Switching

If the top-down model were applied to an analysis of possible switching methodologies, circuit switching and packet switching could be properly placed on either the network or technology layers. In either case, in order to make the proper switching methodology decision, the top-down model layer directly above the network layer, namely, the data layer must be thoroughly examined. The key data layer question becomes: What is the nature of the data to be transmitted and which switching methodology best supports those data characteristics? The first data-related criteria to examine is the *data source*. What is the nature of the application program (application layer) which will produce this data? Is it a transaction oriented program or more of a batch update or file oriented program?

A transaction oriented program, producing what is sometimes called *interactive data*, is characterized by short *bursts* of data followed by variable length pauses due to users reading screen prompts or pauses between transactions. This *bursty transaction-oriented traffic*, best categorized by banking transactions at an automatic teller machine, must be delivered as quickly and reliably as the network can possibly perform. In addition to data burstiness, time pressures, and reliability constraints are other important data characteristics that will assist in switching methodology decision making.

Applications programs more oriented to large file transfers or batch updates have different data characteristics than transaction oriented programs. Overnight updates from regional offices to corporate headquarters or from local stores to regional offices are typical examples. Rather than occurring in bursts, the data in these types of applications are usually large and flowing steadily. These transfers are important, but often not urgent. If file transfers fail, error detection and correction protocols can retransmit bad data or even restart file transfers at the point of failure.

Defining Terms

Carrier sense multiple access with collision detection (CSMA/CD): A scheme for network communication flow.

Client: The end-users of a network and its resources, typically workstations or personal computers.

Ethernet: A network architecture adhering to IEEE 802.3; a CSMA/CD-based architecture traditionally installed in a bus configuration, but more recently typically in a hub-based star physical topology.

Fiber distributed data interface (FDDI): A networking scheme using separate rings around which data move simultaneously in opposite directions to achieve high speed and operational redundancy.

Gateway: A network device designed to provide a transparent connection between two totally different computing environments.

Hub: The heart of a star physical topology, alternatively known as a concentrator, repeater, or multistation access unit (MAU).

Network interface card (NIC): The physical device or circuit used to interface the network with a local workstation or device.

Network management: The overall task of monitoring and analyzing network traffic and correcting network-related problems.

Open systems interconnection (OSI) model: A framework for organizing networking technology developed by the International Standards Organization.

Router: A device that reads specific network layer protocols in order to maximize filtering and forwarding rates on a network.

Server: The element of a network designed to facilitate and manage the sharing of resources among client devices and workstations.

Token ring: A network architecture adhering to IEEE 802.5, utilizing a star physical topology, sequential message delivery, and a token passing access methodology.

Wireless LAN: An emerging networking system utilizing radio or infrared media as the interconnection method between workstations.

19.8 Printing Technologies and Systems

John D. Meyer

19.8.1 Introduction

The basic parameters of print quality are **resolution**, **addressability**, **gray scale**, and dot microstructure. A real device also has intrinsic variability in the printing process, producing visual artifacts, which come under the general heading of *noise*. Some of the more common manifestations of this are background scatter, dot placement errors, voids (due to nozzle malfunction in ink jet, for example), and banding in images. The significance of any of these aspects of print quality can only be determined by examining them with respect to the properties of the human visual system. The design choices of the basic print quality parameters are, therefore, guided by the properties of the human visual system to determine where improvement needs to be made or where little is to be gained by increasing any one of the specifications.

Resolution and Addressability

Resolution, the most widely used specification to rate print quality, is sometimes confused with the related term addressability. Fundamentally, resolution refers to the ability of the device to render fine detail. This simple definition is complicated by the fact that detail can be regarded as the fineness of the width of a line, the transition between white paper and printed intensity, and/or the smoothness of the edge of a curved line or a line printed at any arbitrary angle. In the simplest case, the resolution of a printer is defined as the spacing of the dots such that full coverage is obtained, that is, no white paper can be seen. For circular dots placed on a square grid, this number would be calculated by dividing the diameter by the square root of two and taking its inverse. For example, an ideal 300 dots per inch (dpi) printer would produce 120- μm -diam dots at an 85 μm spacing. In practice, the dot would be made somewhat larger to allow for dot placement errors. This definition is best understood in terms of the finest line that can be printed by the device. At 300 dpi the line would exhibit a perceptible edge waviness, especially when printed at certain sensitive angles. This would also be true of curved lines. In addition, the range of lines of increasing thickness would have discontinuities since they would consist of an integral number of the basic line, each spaced at 85 μm . These issues have an important bearing on text print quality, which depends on the ability to render both curved and straight lines at variable widths.

The preceding definition is related to the specification of resolution with respect to the human visual system. In this case resolution is determined by the closeness of spacing between alternate black and white lines of equal width and defined contrast. These are known as *line pairs* and for a 300-dpi printer it would result in a value of 150 line pairs per inch. This is not strictly correct since the black lines would be wider than the white spaces due to the roundness of the dot. Since the human visual system has a response that approaches zero near 300 line pairs per inch, gains made in text print quality by increasing resolution

alone can be expected to diminish above this value. At this point, issues such as print noise and grayscale enter if further improvement in print quality is desired.

To focus only on the resolution as defined in the previous paragraphs ignores the specific needs of the components of the printed material, that is, text and lines vs. images and area fill. Gains in text print quality may be had if the device can space the dots closer than the fundamental resolution. This can result in substantial dot overlap but allows the line width to be varied more continuously. In addition, at the edge of a curved line, the subpixel adjustments of individual dots increase the perception of smoothness commonly known as getting rid of the *jaggies*. This ultimate dot spacing of the device is called addressability. For example, printers employing this technique are specified as 300×600 dpi indicating a native resolution of 300 dpi in the horizontal direction and a vertical addressability of 600 dpi.

Grayscale

The ability of a printing technology to modulate the printed intensity on the page is referred to as its grayscale capability. There are three ways in which this may be accomplished: variation of the dot size, variation of the intensity of the printed dot, and digital **halftoning** techniques. The first two depend on the intrinsic properties of the technology, whereas digital halftoning can be employed by any printer. A printer that can continuously vary its intensity from white paper through to maximum colorant density is described as having *continuous tone capability*. Other technologies produce a modest number of intensity levels and make use of digital halftoning techniques to create a continuous tone effect. The manner in which gray scale is achieved is of obvious importance in image printing, particularly in the case of color. In recent years considerable effort has gone into the development of sophisticated digital halftoning algorithms to enable binary (single dot size and no intensity modulation) printers to render images. The resulting image quality depends more strongly on resolution than addressability. But the impact of even a few intrinsic gray levels on the print quality achieved by these algorithms can be dramatic.

An important parameter in grayscale considerations is that of the dynamic range, which is simply called range in the graphic arts. This is measured in terms of optical density, the negative logarithm of the reflectance. An optical density of 1.0 represents 10% of reflected light per instant flux, an optical density of 2.0 corresponds to 1% reflectance, and so on. For printed material the smoothness of the printed surface limits the maximum optical density obtainable. If the surface is smooth and mirrorlike, then the print appears glossy and can have optical densities approaching 2.4. The smooth surface reflects light in a specular manner and, therefore, scatters little stray light from the surface into the eye, and the color intensity is not desaturated. It is most noticeable in the case of photographic paper that has a high gloss finish. If the optical density range of the print is high, it is said to have high dynamic range and a very pleasing image will result. Not all papers, however, are designed to have a glossy finish. Papers used in the office are also used in copiers and have a surface which produces diffuse reflection at the interface between the air and the paper. For most uncoated, nonglossy papers this will be between 3–4% and limits the maximum optical density to around 1.4. Image quality on these stocks will depend on the fixing of the colorant to the substrate to produce a smooth surface. The potential image quality for a printer is therefore a complex tradeoff involving the design choices of resolution, addressability, grayscale method, **digital halftoning** algorithm, paper stock, colorant, and fixing technology. Conclusion: for images, resolution alone is not a predictor of print quality.

Dot Microstructure

The microscopic nature of the dot produced by a given technology also has a bearing on final print quality. The most important parameter here relates to the edge gradient of the dot. Known as the *normal-edge profile*, it characterizes the transition between white paper and maximum colorant intensity, that is, the gradient of optical density that occurs at the edge of the dot and measures the steepness of the transition from white paper to full optical density. Some technologies, such as electrophotography, can vary this profile by adjusting various parameters in the imaging and developing process. For ink jet, various paper types will produce different normal-edge profiles. If the profile is very steep, that is, the transition occurs in a very small distance such as $5 \mu\text{m}$, then the dot is described as being a hard dot or having a very

sharp edge. This is desirable when printing lines and text that benefit from very sharp transitions between black and white. If this transition is gradual, the dot is described as being soft and produces a blurring of the edge, which can degrade the text quality. In the case of images, where smooth tones and tonal changes are desired, a soft dot can be very beneficial.

Hybrid Methods

From what has been said it should not be inferred that the needs of texts and images are in opposition. In recent years the intrinsic grayscale capability has been used to advantage in improving text print quality. The removal of jaggies can be greatly assisted by the combination of increased addressability and a few gray levels. By the use of gray levels in the region of the jagged staircase, the transition can be made to take place over several pixels. This is, in essence, blurring the transition to make it less visible to the eye. In the case of certain fonts, there is fine detail requiring resolutions greater than the native resolution of the printer. This fine detail can be rendered through a combination of gray levels and regular pixels. The implementation of these methods requires a complex set of rules to be applied to the data bit stream before it is sent to the marking level of the printer. These rules draw heavily on image processing techniques and a knowledge of the human visual system and are proprietary. Skillfully applied they can have a dramatic effect on the text and line quality. There are a variety of trademarked names for these technologies designed to convey the sense of enhancement of the print quality.

The application of image processing techniques to manipulate the intrinsic properties of electronic printing technologies have made resolution an insufficient measure of print quality. A more comprehensive measure is needed to simplify the identification of the printing technology to serve the design goals for final output quality. Until such a metric is devised, the tradeoff analysis just described, implemented by means of industry standard test charts that separately probe the printer properties, will provide a predictive measure of print quality. Such test charts must also contain test images, which will be subject to the proprietary subjective image enhancement algorithms offered by the manufacturer.

19.8.2 Printing Technologies

The four basic elements of any printing technology are: addressing, marking substance and its storage and delivery, transfer of the marking substance, and fixing. Addressing refers to the communication of electronic data to the marking unit, typically via electronic or optical means. The marking substance contains the colorant, vehicle/carrier material for transport, binders to secure the colorants to the paper, stabilizing agents to resist fading, and technology specific additives such as biocides for liquid inks. The transfer process is the fundamental physical mechanism whereby a specific amount of the marking substance is removed from the bulk and transferred to the paper. Fixing embodies the processes of adhesion, drying, or solidification of the material onto the paper to form a durable image. These fundamental subsystems interact with each other to give each printing technology its own unique characteristics. The common classification of printing technologies today begins with the broad separation into two classes: Impact and nonimpact printing technologies. Impact methods achieve transfer via the direct mechanical application of force or pressure via a marking element, which can be either a fine wire or fully formed character onto a colorant carrying ribbon in contact with the paper; the simplest form of this is a typewriter. Nonimpact methods cover a wide range of technologies that achieve transfer through a variety of means that may be either contact or noncontact in nature.

19.8.3 Nonimpact Printing Technologies

Ink Jet

The transfer process of ink jet printing is one of removing a drop of liquid ink from the bulk and giving it a velocity of sufficient precision and magnitude to place it on a substrate in close proximity to but not touching the printhead. There are three broad techniques: *continuous*, *electrostatic*, and *drop on demand*. Continuous ink jet printing, because of its intrinsic high drop rate, has tended to find more applications

FIGURE 19.66 Character printing with continuous ink jet. The deflection plate applies an analog voltage to steer the drop to the desired location; unwanted droplets are undeflected and captured by the return gutter. (Source: Durbeck, R.C. and Sherr, S. 1988. *Hardcopy Output Devices*. Academic Press, San Diego, CA. With permission.)

in commercial systems; electrostatic methods have yet to find widespread application, but have been used for facsimile recording; drop on demand, because of its simplicity and ease of implementation of color, has been widely accepted in the office and home market.

Continuous Ink Jet

The basic principle of continuous ink jet is to take advantage of the natural breakup process due to an instability in the jet that is formed when fluid is forced under pressure through a small orifice. This results from the interplay of surface tension and viscosity and takes place in a quasirandom manner unless external stimulation is applied. This breakup process was first studied by Rayleigh who characterized it via a growth rate for the instability, which depended on the jet diameter D , its velocity V , and the frequency F of any external stimulation. Rayleigh showed that the frequency for maximum growth rate of the instability was $F = V/4.5D$. By stimulating the jet at this frequency it is possible to obtain a uniform stream of droplets. The typical method of providing this stimulation today is via a piezoelectric transducer as an integral part of the printhead.

To make use of these droplets for printing it is necessary to charge them at *breakoff*. This is accomplished by placing electrodes in proximity to the breakup region of the jet. Deflection voltages are then applied farther downstream to direct the droplet to the substrate or into a collector for recirculation and reuse. The earliest techniques involved charging the droplet and applying a variable deflection field to direct it to a specific spot on the paper, enabling full height characters to be printed in one pass (see Fig. 19.66). Later methods focused on producing a stream of charged droplets and using the printing (high-voltage) electrode to deflect unwanted drops for recirculation and reuse (Fig. 19.67). This technique, known as *binary charged continuous ink jet*, lends itself to the construction of multiple nozzle arrays, and there are a number of page-wide implementations in use.

Binary charged continuous ink jet with its high droplet rate makes a simple gray scaling technique

FIGURE 19.67 Binary charged continuous ink jet. Droplets, charged at breakoff, are directed to the paper on a rotating drum. Droplets not selected for printing are diverted by the high-voltage electrode to be collected by a return gutter. (Source: Durbeck, R.C. and Sherr, S. 1988. *Hardcopy Output Devices*. Academic Press, San Diego, CA. With permission.)

possible. The dot on the paper is modulated in size by printing from one up to N droplets at the same location, where N is the number of different dot sizes desired. By operating at high frequencies and small drop volumes it is possible to produce sufficient gray levels such that full grayscale printing is achieved at reasonable print speeds. The most recent implementation of this method offers 512 gray levels at addressabilities between 200–300 pixels/in. To achieve the small fundamental droplet size, typical implementations employ glass capillaries with diameters of the order of $10\ \mu\text{m}$ and are pressurized from 500–700 lb/in². A color printhead will contain four capillaries, one for each color ink plus black.

Drop On Demand (DOD) Ink Jet

For office and home applications the complexities of continuous ink jet technology, such as startup and shutdown procedures, ink recirculation, and the limited nozzle count, have led to the development of drop on demand ink jet technology. These devices employ unpressurized ink delivery systems and, as implied by their name, supply a drop only when requested. The basic technique employed is to produce a volume change in either the ink supply channel or an ink chamber adjacent to the nozzle such that the resulting pressure wave causes drop ejection. Refill is achieved by capillary forces and most DOD systems operate with a slight negative pressure at the ink reservoir. The mechanism for generating the pressure wave dominates the design of these devices, and there are two techniques extant in common DOD printers. One employs the pressure pulse derived from the vaporization of superheated fluid, and the other makes use of piezoelectric materials, which can be deformed by the application of electric potentials.

Devices employing the vaporization of superheated fluid are known concurrently as thermal ink jet or bubble jet printers, the choice of name depending on the manufacturer. Since drop on demand ink jets rely on capillary refill, their operational frequencies are much lower than for continuous ink jet devices. This stresses the importance of the compactness of the actuating system so as to achieve reasonable printing speeds via multiple nozzle printheads. The nozzles must also be precisely registered with respect to each other if systematic print artifacts are to be avoided.

Thermal Ink Jet/Bubble Jet DOD Printers

When fluids are heated at extreme rates (e.g., $500 \times 10^6\ \text{W/m}^2$), they enter a short-lived metastable state where temperatures can far exceed the boiling point at atmospheric pressure. The difference between the elevated temperature and the boiling point is known as the *degree of superheat*. This process does not continue indefinitely, and all fluids have what is known as a *superheat limit*. At this point nucleation and vaporization will occur in the bulk of the fluid. These devices employ an electrically driven planar heater (typically, $50\text{--}60\ \mu\text{m}^2$) in contact with the fluid. Under these conditions vaporization commences at the surface of the heater due to the presence of nucleation sites such as microscopic roughness. With correctly chosen heating rates this can be made very reliable. These heating rates lead to electrical pulse widths of $3\text{--}5\ \mu\text{s}$. In this time frame only a submicron portion of the fluid will be superheated. The net result is a vaporization pulse well in excess of atmospheric pressure and of approximately $3/4\text{--}\mu\text{s}$ duration. By locating a nozzle directly over or alongside the resistor this pressure pulse will eject a droplet (Fig. 19.68).

Within limits of the drop volume desired, it is found that the linear dimensions of the nozzle diameter and planar resistor are comparable. The actuator is therefore optimally compact, and this enables high-nozzle count printheads. The fabrication of the resistors is accomplished by photolithographic techniques common to the IC industry and the resistor substrates are silicon with a thin layer of insulating silicon dioxide. Precise registration from nozzle to nozzle is guaranteed under these circumstances, and electrical drive circuits may be integrated into the head to provide multiplexing capability. This is a valuable attribute for scanning printheads, which employ a flexible printed circuit for interconnect. These features have produced printheads currently numbering 300 or more nozzles for a single color. An additional benefit of the compactness of this technology is that the ink supply can be fully integrated with the printhead. This provides the user with virtually maintenance free operation as the printhead is replaced when the ink supply is consumed. Since the majority of problems arise from paper dust particles finding their way into a nozzle and occasionally becoming lodged there, printhead replacement provides for user service at reasonable cost. Some implementations feature a semipermanent printhead, which is supplied by ink from

FIGURE 19.68 Drop ejection sequence for thermal ink jet. Nominal time frames and values for various parameters are given to indicate the scale of the three processes of nucleation, bubble growth, and jet formation followed by drop ejection and refill.

replaceable cartridges. The design choice is then a tradeoff involving many factors: frequency of maintenance, cost of operation, how often the printer is to be used, type of material printed, etc. The important subject of ink and paper for these printers will be taken up at the end of the section on DOD technologies.

Piezoelectric DOD Printers

Crystalline structures, which develop a spontaneous dipole moment when mechanically strained, thereby distorting their crystal structures, are called *piezoelectric*. These materials may conversely be caused to be distorted via electrical potentials applied to the appropriate planes of the crystal. Piezoceramics have a polarization direction established during the manufacturing process, and the applied fields then interact with this internal polarization to produce mechanical displacement. Depending on the direction of the applied fields, the material can compress or extend longitudinally or transversely. These materials have found widespread use as transducers for DOD printers. An early form was that of a sleeve over a glass capillary, which terminated in a nozzle (Fig. 19.69). Depending on the location of the electrodes either a radial or longitudinal compression could be applied leading to a pressure wave in the enclosed ink sufficient to eject a droplet. Using the diameter of the nozzle as a unit of linear dimension, this approach placed the transducer well upstream from the nozzle (Fig. 19.70). Implementation of this design in a multinozzle printhead required careful matching of transducers and fluid impedance of the individual channels feeding each nozzle. This was a challenging task, and most designs bond a planar transducer to an ink chamber adjacent to a nozzle, as shown in Fig. 19.71.

FIGURE 19.70 Drop ejection sequence for piezoelectric printhead. Schematic of drop ejection via deflection of piezocrystal bonded to an ink capillary. In practice the piezodrivers were located well upstream of the nozzle due their size. (Source: Advanced Technology Resources Corporation.)

The method of directly coupling the piezoelectric transducer through an ink chamber to an exit nozzle has seen many enhancements and developments since its invention. A feature of some designs is that of air flow channeled at the orifice in such a way as to entrain the droplet as it exits the nozzle and to improve its directional stability, as well as to accelerate the droplet. This enables the device to be operated at lower transducer deflections and, therefore, at higher droplet rate since the settling time of the device has been reduced. Piezodevices can operate at elevated temperatures and are used to eject inks that are solid at room temperature. For solid inks the material is melted to a design temperature for appropriate viscosity and surface tension and then supplied to the piezoelectric-driven ink chamber. The ink then solidifies instantly on contact with the substrate.

FIGURE 19.71 Design of Stemme Larson electric-driven DOD ink jet. Note the direct coupling of the pressure pulse to the ink chamber at the nozzle. (Source: Advanced Technology Resources Corporation.)

FIGURE 19.72 Schematic of ink chamber and actuator.

A more recent innovation employs piezoelectric transducers operated in the longitudinal mode. The transducers are formed from a single block of piezoceramic material in the form of an array of rods. Suitably placed potentials excite the rods to extend in the longitudinal direction. By bonding one end of the rod in contact with a thin membrane forming the base of an ink chamber, a pressure pulse is generated similar to that of the previous design (Fig. 19.72). To achieve sufficient pressure amplitude a diaphragm is used that is substantially larger than the orifice exit diameter. The consequence of this is that high nozzle density printheads will require multiple rows of nozzles (Fig. 19.73). This design has been implemented to date with liquid inks only.

Grayscale Methods for DOD Ink Jet Printers

The drop rates for DOD devices are typically an order of magnitude less than those of continuous, pressurized systems. This dictates different strategies for the achievement of grayscale. Techniques are based on the generation of a few gray levels that, when incorporated into digital halftoning algorithms, such as error diffusion, clustered, dispersed dot, or blue-noise dither, produce a satisfactory grayscale. The number of levels necessary, their position relative to the maximum modulation achievable (i.e., maximum

FIGURE 19.73 Exploded view of a multi chamber pen.

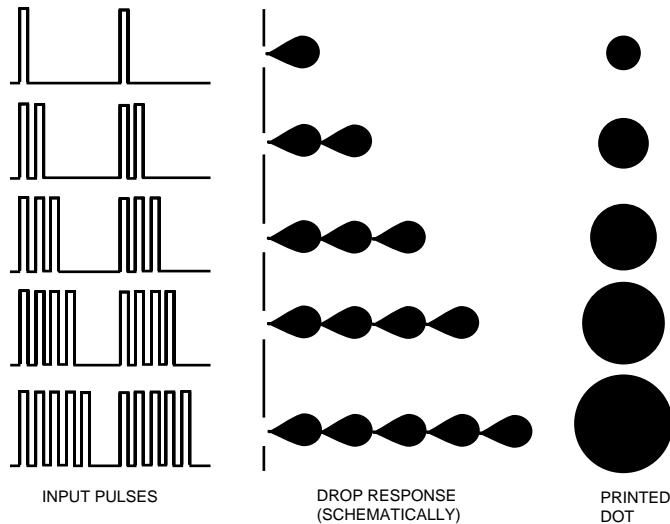

FIGURE 19.74 Stylized representation of multidrop process. Each input pulse consists of a group of drive pulses chosen for the final dot size desired. (Source: Durbeck, R.C. and Sherr, S. 1988. *Hardcopy Output Devices*. Academic Press, San Diego, CA. With permission.)

dot size or maximum intensity), and the specialized techniques employed in digital halftoning are an area of active research. There are many patents in the literature governing these techniques, and manufacturers seek to distinguish their devices by the technique offered. When combined with resolution enhancement methods mentioned in the section on print quality, printers with medium resolution, such as 300 dpi and 2 bits of grayscale, can produce remarkable results for both images, text, and graphics.

There are several methods available for DOD devices to modulate either the size or intensity of the dot. For piezodevices, pulse width modulation has been shown to produce droplets of different volumes and, therefore, dot sizes. All DOD ink jet devices have the option of ejecting a droplet repeatedly at the same location by passing over the same swath as many times as desired but this will affect throughput rates. Printheads with sufficient nozzle count can do this and still keep throughput rates within reason. For vapor bubble driven devices, a unique option exists by virtue of the short duration of the actuating bubble. Typical lifetime of bubbles in these devices, from vaporization through to bubble collapse, is of the order of 20 μs . If the resistor is pulsed shortly after bubble collapse, a second droplet can be ejected virtually on the tail of the initial droplet. This technique has been called *multidrop* in the literature. The ink chamber is fired under partial refill conditions, but with proper design several droplets can be ejected by this method at drop rates at around 40 kHz and having substantially the same volume (Fig. 19.74). These merge on the substrate to produce different dot sizes according to the number of droplets ejected for the location. This is not an option for most piezodevices due to the slower settling time of the actuator. Dye dilution methods have also been demonstrated as a way of modulating the intensity of the dot. If no halftone algorithm is employed, this will require many sets of nozzles to accommodate the different dye dilutions.

Ink and Paper for Ink Jet Devices

When liquid inks are employed the paper properties have a major impact on the print quality. The ink droplets will be absorbed by a substrate whose internal structure and surface energy will determine the size, shape, and overall microstructure of the drop. Paper, being a interlocking mesh of cellulose fibers with sizing and binding chemistry, is quite variable in nature. Figure 19.75 is a schematic indication of the response of paper to different volumes of ink. Note that it can be very nonlinear at low drop volumes and either flat or high gain at large volumes. The implication is that by simply changing the paper the print quality is altered. To control this variability some papers are given a thin coat of claylike material

containing whiteners, which are often fluorescent. This coating presents a microporous structure that is more uniform than the cellulose fibers.

Dot formation on coated papers is therefore circular and more stable than on uncoated stock. Uncoated papers allow the ink to wick down the fibers producing an effect known as *feathering* of the dot. In this case, microscopic tendrils of dye appear at the edge of the dot giving it and the overall print quality a blurred effect. This is particularly serious in the case of text printing, which benefits most from sharp dot edges. Feathering is common for papers used in xerographic copiers. Bond paper, which is a popular office stock, is a partially coated paper and exhibits little feathering.

Depending on the manufacturer, several techniques are employed to minimize the impact of paper variability on print quality. One method, the use of a heater, takes advantage of the fact that absorption into the paper does not commence immediately upon contact. There is a period known as the *wetting time*, which can be as long as 80 μ s during which no absorption takes place. The application of heat immediately in the vicinity of the printhead swath can effectively “freeze the dot” by vaporizing carrier. This makes the printer insensitive to change in paper stock and provides uniformly high print quality regardless of substrate. Other methods make use of altering the fluid chemistry by means of surfactants, which increase penetration rate, and high vapor pressure additives to increase removal of fluid into the atmosphere. If the ink penetrates quickly then it is less likely to spread sideways and, thereby, dot size variation is lessened. When choosing a drop on demand ink jet printer, it is advisable to test the performance over the range of paper stocks to be used. In some cases it will be found that high-quality printing can only be obtained when a paper specified by the manufacturer is chosen.

With reference to the section on print quality, it should be kept in mind that the choice of paper will affect the overall dynamic range of print. Text printing, to be pleasing, needs to have an optical density of at least 1.3–1.4. For images, the more dynamic range the better, and special coated stock will always excel over copy paper if image quality is important. Many of the coated papers available still have a matte surface that diffusely reflects the light and limits the dynamic range for reasons previously discussed. Some manufacturers now offer a high-gloss substrate specifically intended for images. These substrates have a plastic base with special coatings to absorb the ink through to the substrate leaving a high gloss finish. This greatly improves the dynamic range to the point of approximating that of photographic paper. These substrates provide ink jet printers with the capability to produce highly saturated brilliant colors with exceptional chromatic and dynamic range and should be used if image printing is the primary objective.

Besides excellent print quality there are other demands placed on the ink. It must provide reliable operation of the device and a durable image. By this it is meant that the image does not fade rapidly, that it is mechanically sound, that it cannot be easily removed from the paper, and that it is impervious to liquids. For liquid ink, this is a challenge since solvent-based color highlighter pens are commonly used to mark up printed documents. These solvents can cause the ink to smear depending on the choice of ink chemistry and the manner in which the colorants are fixed to the substrate. These issues focus on colorant chemistry, and much research is applied to this problem. There are fade-proof dyes, but many are either incompatible with the ink vehicle, typically water, or are toxic or mutagenic.

19.8.4 Thermal Printing Technologies

Printing technologies that employ the controlled application of thermal energy via a contacting printhead to activate either physical or chemical image formation processes come under this general classification.

FIGURE 19.75 Paper response curves. The lower curve is typical of coated stock, which minimizes dot spread. (Source: Durbeck, R.C. and Sherr, S. 1988. *Hardcopy Output Devices*. Academic Press, San Diego, CA. With permission.)

There are four thermal technologies in current use: direct thermal, direct thermal transfer, dye diffusion thermal transfer, and resistive ribbon thermal transfer.

Direct Thermal

This is the oldest and most prolifically applied thermal technology. The imaging process relies on the application of heat to a thermochromic layer of approximately $10\ \mu\text{m}$ in thickness coated onto a paper substrate. The thermally active layer contains a leuco dye dispersed along with an acid substance in a binder. Upon heating fusion melting occurs resulting in a chemical reaction and conversion of the leuco dye into a visible deeply colored mark. Key to this process is the design of the printhead, which can be either a page-wide array or a vertical array or a scanning printhead. Two technologies are in use, thick film and thin film. Thick-film printheads have resistor material between 10 and $70\ \mu\text{m}$. The resistive material is covered with a glass layer approximately $10\ \mu\text{m}$ thick for wear resistance. The thin-film printheads bear a strong resemblance to those found in thermal ink jet printheads. They employ resistive material, such as tantalum nitride, at $\frac{1}{10}\ \mu\text{m}$ thickness and a $7\text{-}\mu\text{m}$ -thick silicon dioxide wear layer. Thin-film heads are manufactured in resolutions up to 400 dpi. In each case the resistors are cycled via electrical heating pulses through temperature ranges from ambient (25°C) up to 400°C . Overall, the thin-film printheads excel in energy efficiency conversion, print quality, response time, and resolution. For these reasons the thin-film printheads are used when high resolution is required, whereas the thick-film printhead excels in commercial applications such as bar coding, airline tickets, fax, etc.

Direct Thermal Transfer

These printers transfer melted wax directly to the paper (Fig. 19.76(a) and Fig. 19.76(b)). The wax that contains the colorant is typically coated at $4\ \mu\text{m}$ thickness onto a polyester film, which, in common implementations, is approximately $6\ \mu\text{m}$ thick. A thermal printhead of the kind described previously presses this ribbon, wax side down, onto the paper. As the individual heating elements are pulsed, the wax melts and transfers by adhesion to the paper. The process is binary in nature; but, by the use of shaped resistors, which produce current crowding via an hourglass shape, for example, the area of wax transferred can be modulated. Common implementations employ page width arrays at 300 dpi with some providing vertical addressability of 600 dpi. The thermal ribbons are also packaged in cassettes for scanning printhead designs in desktop and portable printers. Power consumption is an issue for all thermal printers, and efforts to reduce this for direct thermal transfer have focused on reducing the thickness of the ribbon.

Dye Diffusion Thermal Transfer

This technology involves the transfer of dye from a coated donor ribbon to a receiver sheet via sublimation and diffusion, separately or in combination. The amount of dye transferred is proportional to the

FIGURE 19.76 Schematic of wax transfer process: (a) Intimate contact between printhead, ribbon, and paper is required for successful transfer, (b) design elements of thin-film thermal printhead. Thermal barrier insulates heater for the duration of the heat pulse but allows relation of heater temperature between pulses.

amount of heat energy supplied; therefore, this is a continuous tone technology. It has found application as an alternative to silver halide photography, graphics, and prepress proofing. As with all thermal printers the energy is transferred via a transient heating process. This is governed by a diffusion equation and depending on the length of the heating pulse will produce either large temperature gradients over very short distances or lesser gradients extending well outside the perimeter of the resistor. Much of the design, therefore, focuses on the thicknesses of the various layers through which the heat is to be conducted. In the case of thermal dye sublimation transfer a soft-edged dot results, which is suitable for images but not for text. Shorter heating pulses will lead to sharper dots.

Resistive Ribbon Thermal Transfer

This technology is similar to direct thermal transfer in that a thermoplastic ink is imaged via thermal energy onto the substrate. The ribbon is composed of three layers: An electrically conductive substrate of polycarbonate and carbon black ($16\ \mu\text{m}$ thick), an aluminum layer $1000\text{--}2000\ \text{\AA}$, and an ink layer which is typically $5\ \mu\text{m}$. The aluminum layer serves as a ground return plane. Heat is generated by passing current from an electrode in the printhead in contact with the ribbon substrate through the polycarbonate/carbon layer to the aluminum layer. The high pressure applied through the printhead ensures intimate contact with the paper, which does not have to be especially smooth for successful transfer. Printed characters can be removed by turning on all electrodes at a reduced energy level and heating the ink to the point that it bonds to the character to be corrected but not to the paper. The unwanted character is removed as the printhead passes over it. This technology does not adapt to color printing in a straightforward way.

19.8.5 Electrophotographic Printing Technology

Electrophotography is a well established and versatile printing technology. Its first application was in 1960 when it was embodied in an office copier. The process itself bears a strong resemblance to offset lithography. The role of the printing plate is played by a cylindrical drum or belt coated with a photoconductor (PC) on which is formed a printing image consisting of charged and uncharged areas. Depending on the implementation of the technology either the charged or uncharged areas will be inked with a charged, pigmented powder known as toner. The image is offset to the paper either by direct contact or indirectly via a silicone-based transfer drum or belt (similar to the blanket cylinder in offset lithography). Early copiers imaged the material to be copied onto the photoconductor by means of geometrical optics. Replacing this optical system with a scanning laser beam, or a linear array of LEDs, which could be electronically modulated, formed the basis of today's laser printers. As a technology it spans the range from desktop office printers (4–10 ppm) to high-speed commercial printers (exceeding 100 ppm). Although capable of E-size printing its broadest application has been in the range of $8\frac{1}{2}$ in to 17 in wide, in color and in black and white.

Printing Process Steps

Electrophotographic printing involves a sequence of interacting processes which must be optimized collectively if quality printing is to be achieved. With respect to Fig. 19.77 they are as follows.

1. Charging of the photoconductor to achieve a uniform electrostatic surface charge can be done by means of a corona in the form of a thin, partially shielded wire maintained at several kilovolts with respect to ground (corotron). For positive voltages, a positive surface charge results from ionization in the vicinity of the wire. For negative voltages, negative surface charge is produced but by a more complex process involving secondary emission, ion impact, etc., that makes for a less uniform discharge. The precise design of the grounded shield for the corona can have a significant effect on the charge uniformity produced. To limit ozone production, many office printers (<20 ppm) employ a charge roller in contact with the photoconductor. A localized, smaller discharge occurs in the gap between the roller and photoconductor, reducing ozone production between two and three orders of magnitude.

2. The charged photoconductor is exposed as described previously to form an image that will be at a significant voltage difference with respect to the background. The particular properties of the

FIGURE 19.77 Schematic of the electrophotographic process. Dual component development is shown with hot roll fusing and coronas for charging and cleaning. (Source: Durbeck, R.C. and Sherr, S. 1988. *Hardcopy Output Devices*. Academic Press, San Diego, CA. With permission.)

photoconductor in this step relate to electron hole generation by means of the light and the transport of either electron or hole to the surface to form the image. This process is photographic in nature and has a transfer curve reminiscent of the **H and D** curves for silver halide. The discharge must be swift and as complete as possible to produce a significant difference in voltage between charged and uncharged areas if optimum print quality is to be achieved. Dark decay must be held to a minimum and the PC must be able to sustain repeated voltage cycling without fatigue. In addition to having adequate sensitivity to the dominant wavelength to the exposing light, the PC must also have a wear-resistant surface, be insensitive to fluctuations in temperature and humidity, and release the toner completely to the paper at transfer. It is possible for either the discharged or the charged region to serve as the image to be printed. Widespread practice today, particularly in laser printers, makes use of the discharged area.

Early PCs were sensitive to visible wavelengths and relied on sulfur, selenium, and tellurium alloys. With the use of diode laser scanners, the need for sensitivity in the near infrared has given rise to organic photoconductors (OPC), which in their implementation consist of multiple layers, including a submicron-thick charge generation layer and a charge transport layer in the range of 30 μm thick. This enables the optimization of both processes and is in wide-spread use today. A passivation or *wear layer* is used for OPCs, which are too soft to resist abrasion at the transfer stage. In many desktop devices the photoconductive drum is embodied in a replaceable cartridge containing enough toner for the life of the photoconductor. This provides a level of user servicing similar to that for thermal ink jet printers having replaceable printheads.

3. Image formation is achieved by bringing the exposed photoconductor surface in contact with toner particles, which are themselves charged. Electrostatic attraction attaches these particles to form the image. Once again, uniformity is vital, as well as a ready supply of toner particles to keep pace with the development process. Two methods are in widespread use today: dual component, popular for high-speed printing and monocomponent toners commonly found in desktop printers. Dual component methods employ magnetic toner particles in the 10- μm range and magnetizable carrier beads whose characteristic dimension is around 100 μm . Mechanical agitation of the mixture triboelectrically charges the toner particles, and the combination is made to form threadlike chains by means of imbedded magnets in the development roller. This dense array of threads extending from the development roller is called a magnet brush and is rotated in contact with the charged photoconductor (Fig. 19.75). The toner is then attracted to regions of opposite charge and a sensor-controlled replenishment system is used to maintain the appropriate ratio of toner to carrier beads.

Monocomponent development simplifies this process by not requiring carrier beads, replenishment system, and attendant sensors. A much more compact development system results, and there are two implementations: magnetic and nonmagnetic. Magnetic methods still form a magnetic brush but it consists of toner particles only. A technique of widespread application is to apply an oscillating voltage to a metal sleeve on the development roller. The toner brush is not held in contact with the photoconductor but, rather, a cloud of toner particles is induced by the oscillating voltage as particles detach and reattach depending on the direction of the electric field. Nonmagnetic monocomponent development is equally popular in currently available printers. There are challenges in supplying these toners in charged condition and at rates sufficient to provide uniform development at the required print speed. Their desirability derives from lower cost and inherent greater transparency (for color printing applications) due to the absence of magnetic additives.

One way of circumventing the limitations on particle size and the need for some form of brush technique is to use liquid development. The toner is dispersed in a hydrocarbon-based carrier and is charged by means of the electrical double layer that is produced when the toner is taken into solution. Typically, the liquid toner is brought into contact with the photoconductor via a roller. Upon contact, particle transport mechanisms, such as *electrophoresis*, supply toner to the image regions. Fluid carryout is a major challenge for these printers. To date this has meant commercial use where complex fluid containment systems can be employed. The technique is capable of competing with offset lithography and has also been used for color proofing.

4. The transfer and fuse stage imposes yet more demands on the toner and photoconductor. The toner must be released to the paper cleanly and then fixed to make a durable image (fusing). The majority of fusing techniques employ heat and pressure, although some commercial systems make use of radiant fusing by means of xenon flash tubes. The toner particles must be melted sufficiently to blend together and form a thin film, which will adhere firmly to the substrate. The viscosity of the melted toner, its surface tension, and particle size influence this process. The design challenge for this process step is to avoid excessive use of heat and to limit the pressure so as to avoid smoothing, that is, calendering and/or curling of the paper. Hot-roll fusing passes the toned paper through a nip formed by a heated elastomer-coated roller in contact with an unheated opposing roller that may or may not have an elastomer composition. Some designs also apply a thin film of silicone oil to the heated roller to aid in release of the melted toner from its surface. There is inevitably some fluid carryout under these conditions, as well as a tendency for the silicone oil to permeate the elastomer and degrade its physical properties. Once again materials innovation plays a major role in electrophotography.

5. The final phase involves removal of any remaining toner from the photoconductor prior to charging and imaging for the next impression. Common techniques involve fiber brushes, magnetic brushes, and scraper blades. Coronas to neutralize any residual charge on the PC or background toner are also typical components of the cleaning process. The toner removed in this step is placed in a waste toner hopper to be discarded. The surface hardness of the PC plays a key role in the efficiency of this step. Successful cleaning is especially important for color laser printers since color contrast can make background scatter particularly visible, for example, magenta toner background in a uniform yellow area.

Dot Microstructure

With respect to image microstructure, the design of the toner material, the development technique, and the properties of the photoconductor play key roles. It is desirable to have toner particles as small as possible and in a tightly grouped distribution about their nominal diameter. Composition of toner is the subject of a vast array of publications and patents. Fundamental goals for toner are a high and consistent charge-to-mass ratio, transparency in the case of color, a tightly grouped distribution, and a minimum, preferably no, wrong-sign particles. The latter are primarily responsible for the undesirable background scatter that degrades the print. Recent developments in toner manufacture seek to control this by means of charge control additives which aid in obtaining the appropriate magnitude of charging and its sign. Grayscale in laser printers is achieved by modulating the pulse width of the diode laser. The shape and steepness of the transfer curve, which relates exposure to developed density, is a function of photoconductor

properties, development process, and toner properties. It is possible to produce transfer curves of low or high gradient. For text, a steep gradient curve is desirable, but for images a flatter gradient curve provides more control. Since the stability of the development process is subject to ambient temperature and humidity, the production of a stable grayscale color laser printer without print artifacts is most challenging.

19.8.6 Magnetographic and Ionographic Technologies

These two technologies are toner based but utilize different addressing and writing media. The photoconductor is replaced by a thin magnetizable medium or hard dielectric layer, such as anodized aluminum, which is used in ionographic printers. Magnetographic printers employ a printhead that produces magnetic flux transitions in the magnetizable media by changing the field direction in the gap between the poles of the printhead. These magnetic transitions are sources of strong field gradient and field strength. Development is accomplished by means of magnetic toner applied via a magnetic brush. The toner particles are magnetized and attracted to the medium by virtue of the strong field gradient. Transfer and fusing proceed in a similar manner to that of electrophotography. Ionographic printers write onto a dielectric coated drum by means of a printhead containing individual electron sources. The electrons are generated in a miniature cavity by means of air breakdown under the influence of an RF field. The electron beam is focused by a screen electrode, and the cavity functions in a manner similar to that of vacuum tube valves. The role of the plate is played by the dielectric coated metal drum held at ground potential. The charge image is typically developed by monocomponent toner followed by a *transfix*, that is, transfer and fuse operation, often without the influence of heat. Both systems require a cleaning process: mechanical scraping for ionography and magnetic scavenging for magnetography.

19.8.7 System Issues

Processing and communicating data to control today's printers raises significant system issues in view of the material to be printed. Hardcopy output may contain typography, computer-generated graphics, and natural or synthetic images in both color and black and white. The complexity of this information can require a large amount of processing, either in the host computer or in the printer itself. Applications software programs can communicate with the printer in two ways: via a page description language (PDL), or through a printer command set. The choice is driven by the scope of the printed material. If full page layout with text, graphics, and images is the goal, then PDL communication will be needed. For computer generated graphics a graphical language interface will often suffice. However, many graphics programs also provide PDL output capability. Many options exist and a careful analysis of the intended printed material is necessary to determine if a PDL interface is required.

When processing is done in the host computer, it is the function of the printer driver to convert the outline fonts, graphical objects, and images into a stream of bits to be sent to the printer. Functions that the driver may have to perform include digital halftoning, rescaling, color data transformations, and color appearance adjustments among other image processing operations, all designed to enable the printer to deliver its best print quality. Data compression in the host and decompression in the printer may be used to prevent the print speed being limited by the data rate. Printers that do their own internal data processing contain a hardware formatter board whose properties are often quoted as part of the overall specification for the printer. This is typical for printers with a PDL-based interface. Some of the advantages for this approach include speed of communication with the printer and relieving of the host computer of the processing burden, which can be significant for complex documents.

The increase in complexity of printed documents has emphasized several practical system aspects that relate to user needs: visibility and control of the printed process, font management, quick return to the software application, and printer configuration. The degree of visibility and control in the printing process depends on the choice of application and/or operating environment. Fonts, either outline or bit map, may reside on disk, on computer, or printer read-only memory (ROM). To increase speed, outline fonts in use are rasterized and stored in formatter random-access memory (RAM) or computer RAM. Worst cases exist

when outline fonts are retrieved at printing and rasterization occurs on a demand basis. This can result in unacceptably slow printing. If quickness of return to the application is important, printers containing their own formatter are an obvious choice. It is necessary, therefore, to take a system view and evaluate the entire configuration (computer hardware; operating system; application program; interconnect; printer formatter, and its CPU, memory, and font storage) to determine if the user needs will be met.

The need to print color images and complex color shaded graphics has brought issues such as color matching, color appearance, and color print quality to the fore. Color printer configuration now includes choices as to halftoning algorithm, color matching method, and, in some cases, smart processing. The latter refers to customized color processing based on whether the object is a text character, image, or graphic. A further complication arises when input devices and software applications also provide some of these services, and it is possible to have color objects suffer redundant processing before being printed. This can severely degrade the print quality and emphasizes the importance of examining the entire image processing chain and turning off the redundant color processing. Color printer configuration choices focus on a tradeoff between print speed and print quality. Halftoning algorithms that minimize visible texture and high print quality modes that require overprinting consume more processing time. For color images and graphics, the relationship between the CRT image and hard copy is a matter of choice and taste. For color graphics, it is common practice to sacrifice accuracy of the hue in the interests of colorfulness or **saturation** of the print. In the case of natural images, hue accuracy, particularly for flesh tones, is more important, and a different tradeoff is made. Some software and hardware vendors provide a default configuration that seeks to make the best processing choice based on a knowledge of the content to be printed. If more precise control is desired, some understanding of the color reproduction issues represented by the combination of color input and output devices linked by a PC having a color monitor is required. This is the domain of color management.

Color Management

The fundamental issue to be addressed by color management is that of enabling the three broad classes of color devices (input, display, output) to communicate with each other in a system configuration. The technical issue in this is one of data representation. Each device has an internal representation of color information that is directly related to the nature in which it either represents or records that information. For printers it is typically amounts of cyan, magenta, yellow, and often black (CMY, K) ink; for displays, digital counts of red, green, and blue (RGB); and for many input devices, digitized values of RGB. These internal spaces are called *device spaces* and map out the volume in three-dimensional color space that can be accessed by the device. To communicate between the devices these internal spaces are converted either by analytical models or three-dimensional lookup tables (LUTs) into a device-independent space. Current practice is to use **Commision Internationale d'Eclairage (CIE)** colorimetric spaces, based on the **CIE 1931 standard observer** for this purpose. This enables the device space to be related to coordinates that are derived from measurements on human color perception. These conversions are known as device profiles, and the common device independent color space is referred to as the *profile connection space* (PCS). When this is done it is found that each device accesses a different volume in human color space. For example, a CRT cannot display yellows at the level of saturation available on most color printers. This problem, in addition to issues relating to viewing conditions and the user state of adaptation, makes it necessary to perform a significant amount of color processing if satisfactory results are to be obtained. Solutions to this problem are known as *color management methods* (CMM) (Fig. 19.78). It is the goal of color management systems to coordinate and perform these operations.

The purpose of a color management system is, therefore, to provide the best possible color preference matching, color editing, and color file transfer capabilities with minimal performance and ease of use penalties. Three levels of color-management solutions are common available, point solutions, application solutions, and operating system solutions. Point solutions perform all processing operations in the device driver and fit transparently into the system. If color matching to the CRT is desired, either information as to the make of CRT or visual calibration tools are provided to calibrate the CRT to the driver. Application solutions contain libraries of device profiles and associated CMMs. This approach is intended

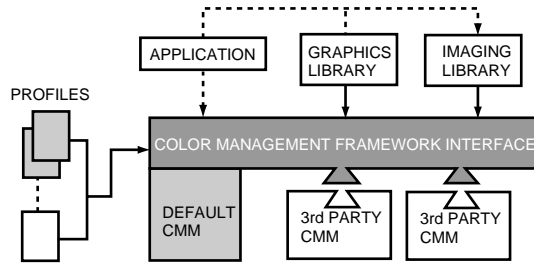

FIGURE 19.78 Proposed ICC color management using ICC profiles. Note fundamental parts: CM framework interface, CMM, third party CMMs, and profiles (which may be resident or embedded in the document).

to be transparent to the peripheral and application vendor. Operating system solutions embed the same functionality within the operating system. These systems provide a default color matching method but also allow vendor-specific CMMs to be used.

Although the creation of a device profile involves straightforward measurement processes, there is much to be done if successful color rendition is to be achieved. It is the property of CIE colorimetry that two colors will match when evaluated under the same viewing conditions. It is rarely the case that viewing conditions are identical and it is necessary to perform a number of adaptations commonly called *color appearance transformations* to allow for this. A simple example is to note that the illuminant in a color scanner will have a different color chromaticity than the white point of the CRT, which will also differ from the white point of the ambient viewing illuminant. In addition, as has been mentioned, different devices access different regions of color space; that is, they have different color gamuts. Colors outside the gamut of a destination device such as a printer must therefore be moved to lie within the printer gamut. This will also apply if the dynamic ranges are mismatched between source and destination. Techniques for performing all of the processes are sophisticated and proprietary and reside in vendor specific CMMs.

Defining Terms

Addressability: The spacing of the dots on the page, specified in dots per unit length. This may be different in horizontal and vertical axes and does not imply a given dot diameter.

CIE 1931 standard observer: Set of curves obtained by averaging the results of color matching experiments performed in 1931 for noncolor defective observers. The relative luminances of the colors of the spectrum were matched by mixtures of three spectral stimuli. The curves are often called *color matching curves*.

Commision Internationale d'Eclairage (CIE): International standards body for lighting and color measurement. Central Bureau of the CIE, a-1033 Vienna, P.O. Box 169, Austria.

Digital halftone: Halftone technique based on patterns of same size dots designed to simulate a shade of gray between white paper and full colorant coverage.

Grayscale: Intrinsic modulation property of the marking technology that enables either dots of different size or intensity to be printed.

Halftone: Technique of simulating continuous tones by varying the amount of area covered by the colorant. Typically accomplished by varying the size of the printed dots in relation to the desired intensity.

H and D curve: Characteristic response curve for a photosensitive material that relates exposure to produced/developed optical density.

Resolution: Spacing of the printer dots such that full ink coverage is just obtained. Calculated from the dot size and represents the fundamental ability of the printer to render fine detail.

Saturation: When applied to color it describes the colorfulness with respect to the achromatic axis. A color is saturated to the degree that it has no achromatic component.

20.1 Audio Frequency Distortion Mechanisms and Analysis

Jerry C. Whitaker

20.1.1 Introduction

Most measurements in the audio field involve characterizing fundamental parameters.¹ These include signal level, phase, and frequency. Most other tests consist of measuring these fundamental parameters and displaying the results in combination by using some convenient format. For example, signal-to-noise ratio (SNR) consists of a pair of level measurements made under different conditions expressed as a logarithmic, or decibel, ratio. When characterizing a device, it is common to view it as a box with input terminals and output terminals. In normal use a signal is applied to the input and the signal, modified in some way, appears at the output. Instruments are necessary to quantify these unintentional changes to the signal. Some measurements are *one-port* tests, such as impedance or noise level, and are not concerned with input/output signals, only with one or the other.

Purpose of Audio Measurements

Measurements are made on audio circuits and equipment to check performance under specified conditions and to assess suitability for use in a particular application. The measurements may be used to verify specified system performance or as a way of comparing several pieces of equipment for use in a system. Measurements may also be used to identify components in need of adjustment or repair. Whatever the application, audio measurements are a key part of audio engineering.

Many parameters are important in audio devices and merit attention in the measurement process. Some common audio measurements are frequency response, gain or loss, harmonic distortion, intermodulation distortion, noise level, phase response, and transient response.

Measurement of level is fundamental to most audio specifications. Level can be measured either in absolute terms or in relative terms. Power output is an example of an absolute level measurement; it does not require any reference. SNR and gain or loss are examples of relative measurements; the result is expressed as a ratio of two measurements. Although it may not appear so at first, frequency response is also a relative measurement. It expresses the gain of the device under test as a function of frequency, with the midband gain, typically, as a reference.

Distortion measurements are a way of quantifying the amount of unwanted components added to a signal by a piece of equipment. The most common technique is total harmonic distortion (THD), but others are often used. Distortion measurements express the amount of unwanted signal components relative to the desired signal, usually as a percentage or decibel value. This is another example of multiple level measurements that are combined to give a new measurement figure.

20.1.2 Level Measurements

The simplest definition of a level measurement is the alternating current (AC) amplitude at a particular place in the audio system. In contrast to direct current measurements, however, there are many ways of specifying AC voltage. The most common methods are average, root-mean-square (RMS), and peak response. Strictly speaking, the term *level* refers to a logarithmic, or decibel, measurement. However, common parlance employs the term for an AC amplitude measurement, and that convention will be followed in this chapter.

¹Portions of this chapter were adapted from: Benson, K.B. and Whitaker, J.C. 1990. *Television and Audio Handbook for Technicians and Engineers*. McGraw-Hill, New York. Used with permission.

FIGURE 20.1 Root-mean-square (RMS) voltage measurements: (a) the relationship of RMS and average values, (b) RMS measurement circuit.

Root-Mean-Square Measurements

The RMS technique measures the effective power of the AC signal. It specifies the value of the DC equivalent that would dissipate the same power if either were applied to a load resistor. This process is illustrated in Fig. 20.1 for voltage measurements. The input signal is squared, and the average value is found. This is equivalent to finding the average power. The square root of this value is taken to translate the signal from a power value back to a voltage. For the case of a sine wave the RMS value is 0.707 of its maximum value.

Consider the case when the signal is not a sine wave, but rather a sine wave and several of its harmonics. If the RMS amplitude of each harmonic is measured individually and added, the resulting value will be the same as an RMS measurement on the signals together. Because RMS voltages cannot be added directly, it is necessary to perform an RMS addition, as follows:

$$V_{\text{rms}} = \sqrt{V_{\text{rms}1}^2 + V_{\text{rms}2}^2 + V_{\text{rms}3}^2 + V_{\text{rms}n}^2}$$

Note that the result is not dependent on the phase relationship of the signal and its harmonics. The RMS value is determined completely by the amplitude of the components. This mathematical predictability is powerful in practical applications of level measurement, enabling measurements made at different places in a system to be correlated. It is also important in correlating measurements with theoretical calculations.

Average-Response Measurements

Average-responding voltmeters were common in audio work some years ago principally because of their low cost. Such devices measure AC voltage by rectifying and filtering the resulting waveform to its average value, which can then be read on a standard DC voltmeter. The average value of a sine wave is 0.637 of its maximum amplitude. Average-responding meters are usually calibrated to read the same as an RMS meter for the case of a single-sine-wave signal. This results in the measurement being scaled by a constant K of 0.707/0.637, or 1.11. Meters of this type are called average-responding, RMS calibrated. For signals other than sine waves, the response will be different and difficult to predict. If multiple sine waves are applied, the reading will depend on the phase shift between the components and will no longer match the RMS measurement. A comparison of RMS and average-response measurements is made in Fig. 20.2 for various waveforms. If the average readings are adjusted as described previously to make the average and RMS values equal for a sine wave, all of the numbers in the *average* column should be increased by 11.1%, whereas the *RMS-average* numbers should be reduced by 11.1%.

Peak-Response Measurements

Peak-responding meters measure the maximum value that the AC signal reaches as a function of time. (See Fig. 20.3.) The signal is full-wave rectified to find its absolute value and then passed through a diode to a storage capacitor. When the absolute value of the voltage rises above the value stored on the capacitor, the diode conducts and increases the stored voltage. When the voltage decreases, the capacitor maintains the old value. Some means for discharging the capacitor is required to allow measuring a new

FIGURE 20.2 Comparison of RMS and average voltage characteristics.

FIGURE 20.3 Peak voltage measurements: (a) illustration of peak detection, (b) peak measurement circuit.

peak value. In a true peak detector, this is accomplished by a switch. Common peak detectors usually include a large resistor to discharge the capacitor gradually after the user has had a chance to read the meter.

The ratio of the true peak to the RMS value is called the **crest factor**. For any signal but an ideal square wave the crest factor will be greater than 1, as illustrated in Fig. 20.4. As the measured signal becomes more peaked, the crest factor increases.

FIGURE 20.4 Illustration of the crest factor in voltage measurements.

By introducing a controlled charge and discharge time, a *quasipeak* detector is achieved. The charge and discharge times may be selected, for example, to simulate the ear's sensitivity to impulsive peaks. International standards define these response times and set requirements for reading accuracy on pulses and sine wave bursts of various durations. The gain of a quasipeak detector is normally calibrated so that it reads the same as an RMS detector for sine waves.

Another method of specifying signal amplitude is the **peak-equivalent sine**, which is the RMS level of a sine wave having the same peak-to-peak amplitude as the signal under consideration. This is the peak value of the waveform scaled by the correction factor 1.414, corresponding to the peak-to-RMS ratio of a sine wave. This is useful when specifying test levels of waveforms in distortion measurements.

Decibel Measurements

Measurements in audio work are usually expressed in decibels. Audio signals span a wide range of level. The sound pressure of a live concert band performance may be one million times that of rustling leaves. This range is too wide to be accommodated on a linear scale. The logarithmic scale of the decibel compresses this

wide range down to a more easily handled range. Order-of-magnitude changes result in equal increments on a decibel scale. Furthermore, the human ear perceives changes in amplitude on a logarithmic basis, making measurements with the decibel scale reflect audibility more accurately.

A decibel may be defined as the logarithmic ratio of two power measurements or as the logarithmic ratio of two voltages:

$$\text{dB} = 20 \log \frac{E_1}{E_2} \text{ for voltage measurements}$$

$$\text{dB} = 10 \log \frac{P_1}{P_2} \text{ for power measurements}$$

There is no difference between decibel values from power measurements and decibel values from voltage measurements if the impedances are equal. In both equations the denominator variable is usually a stated reference. A doubling of voltage will yield a value of 6.02 dB, whereas a doubling of power will yield 3.01 dB. This is true because doubling voltage results in a factor-of-four increase in power.

Audio engineers often express the decibel value of a signal relative to some standard reference instead of another signal. The reference for decibel measurements may be predefined as a power level, as in decibels referenced to 1 mW (dBm), or it may be a voltage reference, as in decibels referenced to 1 V (dBV). When measuring dBm or any power-based decibel value, the reference impedance must be specified or understood. Often it is desirable to specify levels in terms of a reference transmission level somewhere in the system under test. These measurements are designated dB_r, where the reference point or level must be separately conveyed.

20.1.3 Noise Measurement

Noise measurements are simply specialized level measurements. It has long been recognized that the ear's sensitivity varies with frequency, especially at low levels. This effect was studied in detail by Fletcher and Munson and later by Robinson and Dadson. The Fletcher–Munson hearing-sensitivity curve for the threshold of hearing and above is given in Fig. 20.5. The ear is most sensitive in the region of 2–4 kHz, with rolloffs above and below these frequencies. To predict how loud something will sound it is necessary to use a filter that duplicates this nonflat behavior electrically. The filter *weights* the signal level on the basis of frequency, thus earning the name *weighting filter*. Various efforts have been made to do this, resulting in several standards for noise measurement. Some of the common weighting filters are shown overlaid on the hearing threshold curve in Fig. 20.6.

The most common filter used in the U.S. for weighted noise measurements is the A-weighting curve. An average-responding meter is often used for A-weighted noise measurements, although RMS meters are also used for this application.

European audio equipment is usually specified with a CCIR filter and a quasipeak detector. The CCIR curve is significantly more peaked than the A curve and has a sharper rolloff at high frequencies. The CCIR quasipeak standard was developed to quantify the noise in telephone systems. The quasipeak detector more accurately represents the ear's sensitivity to impulsive sounds. When used with the CCIR filter curve,

FIGURE 20.5 The Fletcher–Munson curves of hearing sensitivity vs. frequency.

FIGURE 20.6 Response characteristics of several common weighting filters for audio measurements.

it is supposed to correlate better with the subjective level of the noise than A-weighted average-response measurements do.

Some audio equipment manufacturers specify noise with a 20 Hz–20 kHz bandwidth filter and an RMS-responding meter. This is done to specify noise over the audio band without regard to the ear's differing sensitivity with frequency.

20.1.4 Phase Measurement

Phase in an audio system is typically measured and recorded as a function of frequency over the audio range. For most audio devices phase and amplitude responses are closely coupled. Any change in amplitude that varies with frequency produces a corresponding phase shift. A fixed time delay will introduce a phase shift that is a linear function of frequency. This time delay can introduce large values of phase shift at high frequencies that are of no significance in practical applications. The time delay will not distort the waveshape of complex signals and will not be audible. There can be problems, however, with time delay when the delayed signal is used in conjunction with an undelayed signal.

When dealing with complex signals, the meaning of phase can become unclear. Viewing the signal as the sum of its components according to Fourier theory, we find a different value of phase shift at each frequency. With a different phase value on each component, the question is raised as to which one should be used as the reference. If the signal is periodic and the waveshape is unchanged passing through the device under test, then a phase value may still be defined. This may be done by using the shift of the zero crossings as a fraction of the waveform period. If there is differential phase shift with frequency, however, the waveshape will be changed. It is then not possible to define any phase-shift value, and phase must be expressed as a function of frequency.

Group delay is another useful expression of the phase characteristics of an audio device. Group delay is the slope of the phase response. It expresses the relative delay of the spectral components of a complex waveform. If the group delay is flat, all components will arrive together. A peak or rise in the group delay indicates that those components will arrive later by the amount of the peak or rise. Group delay ϕ is computed by taking the derivative of the phase response vs. frequency:

$$\phi = \frac{-(\alpha_{f_2} - \alpha_{f_1})}{f_2 - f_1}$$

where α_{f_1} is the phase at f_1 and α_{f_2} phase at f_2 . This requires that phase be measured over a range of frequencies to yield a curve that can be differentiated. It also requires that the phase measurements be performed at frequencies close enough together to provide a smooth and accurate derivative.

20.1.5 Nonlinear Distortion Mechanisms

Distortion is a measure of signal impurity. It is usually expressed as a percentage or decibel ratio of the undesired components to the desired components of a signal. There are several methods of measuring distortion, the most common being harmonic distortion and several types of intermodulation distortion.

Harmonic Distortion

The transfer characteristic of a typical amplifier is shown in Fig. 20.7. The transfer characteristic represents the output voltage at any point in the signal waveform for a given input voltage; ideally this is a straight line. The output waveform is the projection of the input sine wave on the device transfer characteristic. A change in the input produces a proportional change in the output. Because the actual transfer characteristic is nonlinear, a distorted version of the input waveshape appears at the output.

Harmonic distortion measurements excite the device under test with a sine wave and measure the spectrum of the output. Because of the nonlinearity of the transfer characteristic, the output is not sinusoidal. By using Fourier series, it can be shown that the output waveform consists of the original input sine wave plus sine waves at integer multiples (harmonics) of the input frequency. The spectrum of the

FIGURE 20.7 Illustration of total harmonic distortion (THD) measurement of an amplifier transfer characteristic.

distorted signal is shown in Fig. 20.8 for a 1-kHz input, and output signals consisting of 1, 2, 3 kHz, etc. The harmonic amplitudes are proportional to the amount of distortion in the device under test. The percentage harmonic distortion is the RMS sum of the harmonic amplitudes divided by the RMS amplitude of the fundamental.

FIGURE 20.8 Example of reading THD from a spectrum analyzer.

Harmonic distortion may also be measured with a spectrum analyzer. As shown in Fig. 20.8, the fundamental amplitude is adjusted to the 0-dB mark on the display. The amplitudes of the harmonics are then read and converted to linear scale. The RMS sum of these values is taken, which represents the THD.

Notch Filter Analyzer

A simpler approach to the measurement of harmonic distortion can be found in the notch-filter distortion analyzer. This device, commonly referred to as simply a distortion analyzer, removes the fundamental of the signal to be investigated and measures the remainder. A block diagram of such a unit is shown in Fig. 20.9. The fundamental is removed with a notch filter, and the output is measured with an AC voltmeter. Because distortion is normally presented as a percentage of the fundamental signal, this level must be measured or set equal to a predetermined reference value. Additional circuitry (not shown) is required to set the level to the reference value for calibrated measurements. Some analyzers use a series of step attenuators

FIGURE 20.9 Simplified block diagram of a harmonic distortion analyzer.

FIGURE 20.10 Example of interference sources in distortion and noise measurements.

and a variable control for setting the input level to the reference value. More sophisticated units eliminate the variable control by using an electronic gain control. Others employ a second AC-to-DC converter to measure the input level and compute the percentage. Automatic units also provide autoranging logic to set the attenuators and ranges, and tabular or graphic display of the results.

The correct method of representing percentage distortion is to express the level of the harmonics as a fraction of the fundamental level. However, most commercial distortion analyzers use the total signal level as the reference voltage. For small amounts of distortion these two quantities are equivalent. At large values of distortion the total signal level will be greater than the fundamental level. This makes distortion measurements on these units lower than the actual value. The errors are not significant until about 20% measured distortion.

Because of the notch-filter response, any signal other than the fundamental will influence the results, not just harmonics. Some of these interfering signals are illustrated in Fig. 20.10. Any practical signal contains some noise, and the distortion analyzer will include these in the reading. Because of these added components, the correct term for this measurement is *total harmonic distortion and noise* (THD + N). Although this fact does limit the reading of very low-THD levels, it is not necessarily bad. Indeed, it can be argued that the ear hears all components present in the signal, not just the harmonics.

Additional filters are included on most distortion analyzers to reduce unwanted hum and noise. These usually consist of one or more high-pass filters (400 Hz) and several low-pass filters. Common low-pass filter frequencies are 22.4, 30, and 80 kHz. A selection of filters eases the tradeoff between limiting bandwidth to reduce noise and the reduction in reading accuracy that results from removing desired components of the signal. When used in conjunction with a good differential input stage on the analyzer, these filters can solve most noise problems.

Intermodulation Distortion

Many methods have been devised to measure the intermodulation (IM) of two or more signals passing through a device simultaneously. The most common of these is **SMPTE IM**, named after the Society of Motion Picture and Television Engineers, which first standardized its use. IM measurements according to the SMPTE method have been in use since the 1930s. The test signal is a low-frequency tone (usually 60 Hz) and a high-frequency tone (usually 7 kHz) mixed in a 4:1 amplitude ratio. Other amplitude ratios and frequencies are used occasionally. The signal is applied to the device under test, and the output signal is examined for modulation of the upper frequency by the low-frequency tone. The amount by which the low-frequency tone modulates the high-frequency tone indicates the degree of nonlinearity. As with harmonic distortion measurement, this test may be done with a spectrum analyzer or with a dedicated distortion analyzer.

The modulation components of the upper signal appear as sidebands spaced at multiples of the lower-frequency tone. The RMS amplitudes of the sidebands are summed and expressed as a percentage of the upper-frequency level.

The most direct way to measure SMPTE IM distortion is to measure each component with a spectrum analyzer and add their RMS values. The spectrum analyzer approach has a drawback in that it is sensitive to frequency modulation of the carrier as well as amplitude modulation. A distortion analyzer for SMPTE testing is quite straightforward. The signal to be analyzed is passed through a high-pass filter to remove

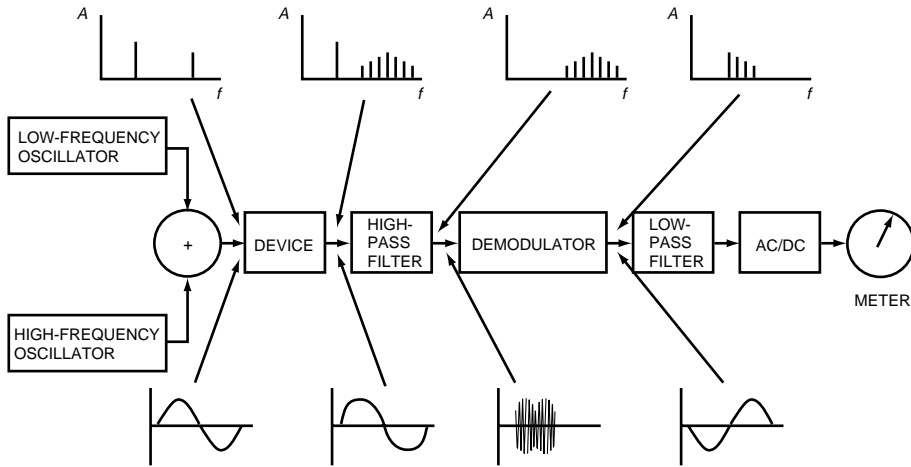

FIGURE 20.11 Simplified block diagram of a SMPTE intermodulation analyzer.

the low-frequency tone, as shown in Fig. 20.11. The high-frequency tone is then demodulated as if it were an amplitude modulated signal to obtain the sidebands. The sidebands pass through a low-pass filter to remove any remaining high-frequency energy. The resulting demodulated low-frequency signal will follow the envelope of the high-frequency tone. This low-frequency fluctuation is the distortion component and is displayed as a percentage of the amplitude of the high-frequency tone. Because low-pass filtering sets the measurement bandwidth, noise has little effect on SMPTE IM measurements.

CCITT IM

Twin-tone intermodulation or CCITT difference frequency distortion is another method of measuring distortion by using two sine waves. The test signal consists of two closely spaced high-frequency tones as shown in Fig. 20.12. When the tones are passed through a nonlinear device, IM products are generated at frequencies related to the difference in frequency between the original tones. For the typical case of signals at 14 and 15 kHz the IM components will be at 1, 2, 3 kHz, etc., and 13, 16, 12, 17 kHz, etc. Even-order, or asymmetrical distortions produce low-frequency difference-frequency components. Odd-order, or symmetrical nonlinearities produce components near the input signal frequencies. The most common application of this test measures only the even-order components because they may be measured with a multipole low-pass filter. Measurement of the odd-order components requires a spectrum analyzer or signal analyzer.

FIGURE 20.12 CCITT intermodulation test of transfer characteristic.

The distortion products in the CCITT IM test are usually far removed from the input signal. This positions them outside the range of the auditory system’s masking effects. If a test that measures what the ear might hear is desired, the CCITT test is the most likely candidate.

Addition and Cancellation of Distortion Components

A common consideration for system-wide distortion measurements is that of distortion addition and cancellation in the devices under test. Consider the example given in Fig. 20.13. Assume that one

FIGURE 20.13 Illustration of the addition of distortion components: (a) addition of transfer-function nonlinearities, (b) addition of distortion components.

device under test has a transfer characteristic similar to that diagrammed at the top of Fig. 20.13(a) and another has the characteristic diagrammed at the bottom. If the devices are cascaded, the resulting transfer-characteristic nonlinearity will be magnified as shown. The effect on sine waves in the time domain is illustrated in Fig. 20.13(b). The distortion component generated by each nonlinearity is in phase and will sum to a component of twice the original magnitude. If the second device under test has a complementary transfer characteristic, however, quite a different result is obtained. When the devices are cascaded, the effects of the two curves cancel, yielding a straight line for the transfer characteristic. The corresponding distortion products are out of phase with each other, resulting in no measured distortion components in the final output.

20.1.6 Multitone Audio Testing

Multitone testing operates on the premise that audio equipment can be stimulated to the same extent by a simultaneous combination of sine waves as it can be by a series of discrete tones occurring one at a time.² The advantage of multitone analysis is clear: it provides complete system evaluation in one step, eliminating the time-consuming process of applying a series of individual tones, allowing a settling time after each, making adjustments after each, and then repeating the process to check for interactions.

Multitone test techniques use carefully designed mixtures of tones applied simultaneously to the device under test (DUT). The individual tone elements have well-defined frequency, phase, and amplitude relationships. The frequencies of multitone components are selected to avoid mathematically predictable harmonic and intermodulation products that would fall on or near any of the fundamentals. The phase of each tone is fixed, but randomly selected relative to each of the other tones. Amplitude relationships may vary, depending on the device under test.

Multitone signals may be created with an inverse FFT for highly accurate and stable signal parameters. Figure 20.14 shows a spectral display of a multitone signal designed for testing wide-band audio recording equipment. Because the frequency, phase, and amplitude relationships of the elements of a multitone signal are well defined, digital signal processor techniques allow easy detection of changes in these relationships. Thus, frequencies not present in the original multitone are the result of distortion and noise. Similarly, changes in phase relationships of the multitone elements can be used to derive phase response information. It follows that deviation from the known amplitude relationships will provide frequency response information.

²This section was adapted from Thompson, B. 1992. *Multitone Audio Testing*. Tektronix Application Note 21 W-7182, Tektronix, Beaverton, OR.

FIGURE 20.14 An audio spectrum display showing the spectral distribution of the numerous fundamental frequencies in a multitone signal. (Source: Tektronix, Beaverton, OR.)

Although implementations of multitone analysis vary from one vendor to the next, plots of level vs. frequency, level difference between channels, phase difference between channels vs. frequency, and noise and/or distortion vs. frequency are among those typically provided. Figures 20.15 and 20.16 show two of these multitone displays, levels vs. frequency (frequency response) and level/phase differences between channels plotted against frequency. An audio spectrum display, such as the one shown in Fig. 20.14, is also a valuable tool when combined with the multitone signal.

FIGURE 20.15 Level vs. frequency plots resulting from audio system measurement with a multitone signal analyzer. (Source: Tektronix, Beaverton, OR.)

FIGURE 20.16 Level and phase difference measurements taken with a multitone signal analyzer. (Source: Tektronix, Beaverton, OR.)

Multitone Versus Discrete Tones

Multitone testing differs from traditional singletone testing in several ways. As previously mentioned, multitone analysis reduces testing and calibration times. This speed advantage stems from several properties:

- All tones are applied at once.
- The entire spectrum is measured/adjusted at once.
- Only one settling time is needed for the generator, DUT, and measurement device because a single signal acquisition is made.
- Level, phase, and noise and distortion calculations are made from one FFT record.

Not only does multitone eliminate the step-and-repeat process, but it can also provide immediate feedback for equipment adjustments. Watching the entire audio spectrum respond to interactive adjustments with little or no time lag further simplifies audio equipment calibration.

When compared to a single sine wave tone, looking at a multitone signal in the time domain (Fig. 20.17) illustrates how closely a multitone waveform resembles program audio. Two factors contribute to this resemblance. First, multitones fill more of the spectrum than single sine wave tones. Second, the crest factor of multitone is similar to that of music or voice signals.

With multitone's similarity to program material, it can be argued that the adjustments performed and measurement results obtained through multitone give more realistic noise and distortion values than discrete tone testing. (In this case, more realistic means a value better representing the noise and distortion present with program material.) In the past, noise measurements were made on audio equipment while no input signal was present. Therefore, the quantization noise and other level-related anomalies were not a part of the noise measurement result. Furthermore, signal processors often operate at different gain ranges depending on the input signal level. So, a no-input noise measurement would be even less representative of actual operating conditions.

The different type of stimulation provided by multitone can, however, lead to measurement results that do not exactly match results obtained with conventional tones or tone sequences. With this in mind, multitone testing should not be used interchangeably with tests made using single-tone input signals. The strengths of multitone testing are speed and convenience, and so it excels in the roles of calibration, production line testing, and equipment performance tracking.

Standardized tone sequence tests require settling, acquisition, and measurement times for each tone in the sequence. All of the advantages of multitone previously mentioned apply here as well. To fully mimic standard tone sequences, a multitone sequence of two or three different levels of multitone can be performed in one-tenth the time of conventional sequences.

FIGURE 20.17 Time-domain display of a multitone signal. The multitone bears a much stronger resemblance to program material than a single sine wave tone. (Source: Tektronix, Beaverton, OR.)

FFT Analysis

A closer look at multitone shows the need for caution when processing the signal. Figures 20.18 and 20.19 illustrate how different processing techniques produce drastically different results, only some of which are meaningful. Both figures are based on a simulated 8192-point (8 K) FFT with a 48-kHz sampling frequency and a 588.87-Hz tone. FFT bin numbers (e.g., bin 100 out of 4096 bins) label the horizontal axes of each graph. The fundamental frequency of 588.87 Hz falls halfway between bin numbers 100 (585.94 Hz) and 101 (591.80 Hz).

Transforming time-domain information into the frequency domain with an FFT requires that the period of the time-domain signal be an integer multiple of the period of the FFT. When such a periodic relationship occurs, a fundamental frequency will fall into a single FFT bin. But this requires that the same sampling clock be used for both signal generation and subsequent resampling of the signal, and further, that no shift in the tone's pitch occurs while passing through the DUT. Because shifts in pitch can occur and because some testing applications require that the generator and analyzer be at separate locations, it is not safe to assume perfect tone-to-bin correspondence.

The result of this imperfect tone-to-bin correspondence is *leakage*, which simply means energy that should fall into a single bin is spread out over a wide frequency range. To reduce the effect of leakage, the time-domain data are multiplied with a window function.

FIGURE 20.18 Computer simulation of FFT without windowing. The 588.87-Hz fundamental frequency in this model does not correspond exactly to an FFT bin. The result is leakage that provides a misleading noise floor display. (Source: Tektronix, Beaverton, OR.)

The graph in Fig. 20.18 clearly shows the effects of leakage. If the fundamental was at 585.94 Hz, a single line at bin 100 with no energy in adjacent bins would result. A rectangular window, which is equivalent to no window, was used in Fig. 20.18. The graph in Fig. 20.19 shows the effect of applying a Blackman–Harris window to the same data. After only four bins either side of the fundamental the leakage is down more than 90 dB. In actual application, an algorithm can determine the exact frequency and amplitude of the fundamental. To compensate for significant shifts in pitch, the spectra surrounding each expected multitone fundamental may be searched $\pm 5\%$ of the frequency of each fundamental.

Extraneous signals introduced into the signal path will also have a serious impact on a nonwindowed analysis. Interfering carriers, hum, and sync buzz are a few types of noncoherent signals that fit into this category. These noncoherent signals do not fall within the periodicity requirements for a nonwindowed FFT and will affect the noise floor of a graphical display in the same manner as will a shift in pitch of the multitone fundamentals. With windowing, 60-Hz hum will cause a noise spike at 60 Hz. Without windowing, the same hum energy will be spread across the audio spectrum, raising the entire noise floor.

For noise and distortion measurements, the eight bins surrounding each fundamental in a multitone are set to zero. The remaining bins are plotted to represent the noise (and distortion) floor of the device under test.

FIGURE 20.19 Computer simulation of FFT with Blackman–Harris windowing. The application of windowing prior to the FFT drastically reduces the effects of leakage. Within 23.44 Hz on either side of the fundamental, leakage is more than 90 dB down. (Source: Tektronix, Beaverton, OR.)

Defining Terms

Clipping: A distortion mechanism in an audio system in which the input level to one or more devices or circuits is sufficiently high in amplitude that the maximum input level of the device or circuit is exceeded, resulting in significant distortion of the output waveform.

Crest factor: In an audio system, the ratio of the true peak to the RMS value. For any signal but an ideal square wave the crest factor will be greater than one.

Group delay: The relative delay of the spectral components of a complex waveform. If the group delay is flat, all components arrive together.

Multitone testing: A measurement technique whereby an audio system is characterized by the simultaneous application of a combination of sine waves to a device under test.

Peak-equivalent sine: A method of specifying signal amplitude in an audio system, equal to the RMS level of a sine wave having the same peak-to-peak amplitude as the signal under consideration.

SMPTE IM: A method of measuring intermodulation distortion in an audio system standardized by the Society of Motion Picture and Television Engineers.

Weighting filter: A standardized filter used to impart predetermined characteristics to noise measurements in an audio system.

Further Information

The Audio Engineering Society (AES) conducts trade shows and highly respected technical seminars annually in the U.S. and abroad. The society also publishes a monthly journal (*Journal of the Audio Engineering Society*) and numerous specialized books on the topic of audio technology in general, and digital audio in particular.

20.2 Analog Video Measurements

Carl Bentz and Jerry C. Whitaker

20.2.1 Introduction

Although there are a number of computer-based television signal monitors capable of measuring video, sync, chroma, and burst levels (as well as pulse widths and other timing factors), sometimes the best way to see what a signal is doing is to monitor it visually. The waveform monitor and vectorscope are oscilloscopes specially adapted for the video environment. The waveform monitor, like a traditional oscilloscope, operates in a voltage-vs.-time mode. While an oscilloscope timebase can be set over a wide range of intervals, the waveform monitor timebase triggers automatically on sync pulses in the conventional TV signal, producing line- and field-rate sweeps, as well as multiple lines, multiple fields, and shorter time intervals. Filters, clamps, and other circuits process the video signal for specific monitoring needs.

The vectorscope operates in an $X - Y$ voltage-vs.-voltage mode to display chrominance information. It decodes the signal in much the same way as a television receiver or a video monitor to extract color information and to display phase relationships. These two instruments serve separate, distinct purposes. Some models combine the functions of both types of monitors in one chassis with a single CRT display. Others include a communications link between two separate instruments.

Beyond basic signal monitoring, the waveform monitor and vectorscope provide a means to identify and analyze signal aberrations. If the signal is distorted, these instruments allow a technician to learn the extent of the problem and to locate the offending equipment.

Although designed for analog video measurement and quality control, the waveform monitor and vectorscope still serve valuable roles in the digital video facility, and will continue to do so for some time.

20.2.2 Color Bar Test Patterns

Color bars are the most common pattern for testing encoders, decoders, and other video devices. The test pattern typically contains several bars filled with primary and complementary colors. There are many variants, which differ in color sequence, orientation, saturation, and intensity.

The standard color bar sequence is white, yellow, cyan, green, magenta, red, blue, and black. This sequence can be produced in an RGB format by a simple 3-bit counter. The typical specification of color bar levels (ITU-R Rec. BT.471-1, "Nomenclature and Description of Color Bar Signals") is a set of four numbers separated by slashes or dots and giving RGB levels as a percentage of reference white in the following sequence:

white bar/black bar/max colored bars/min colored bars

For example, 100/0/100/25 means 100% R, G, and B on the white bar; 0% R, G, and B on the black bar; 100% maximum of R, G, and B on colored bars; and 25% minimum of R, G, and B on colored bars. (See [Figure 20.20a.](#))

Some color bar patterns merit special names. For example, 100/0/75/0 bars are often called "EBU bars" or "75% bars", and 100/0/100/25 bars are known as "BBC bars." Nevertheless, the ITU four number nomenclature remains the only reliable specification system to designate the exact levels for color bar test patterns.

The SMPTE variation is a matrix test pattern according to SMPTE engineering guideline EG 1, "Alignment Color Bar Test Signal for Television Picture Monitors." The guideline specifies that 67% of the field shall contain seven (without black) 75% color bars, plus 8% of the field with the "new chroma set" bars (blue/black/magenta/black/cyan/black/gray), and the remaining 25% shall contain a combination of $-I$, white, Q , black, and the black set signal (a version of PLUGE). This arrangement is illustrated in [Fig. 20.20b.](#)

Chroma gain and chroma phase for picture monitors are usually adjusted by observing the standard encoded color bar signal with the red and green CRT guns switched off. The four visible blue bars are set for equal brightness. The use of the chroma set feature greatly increases the accuracy of this adjustment because it provides a signal with the blue bars to be matched vertically adjacent to each other. Because the bars are adjacent, the eye can easily perceive differences in brightness. This also eliminates effects resulting from shading or purity from one part of the screen to another.

The EIA color bar signal is a matrix test pattern according to RS-189-A, which consists of 75% of the field containing seven (without black) 75% color bars (same as SMPTE) and the remaining 25% containing a combination of $-I$, white, Q , and black. (See [Figure 20.20c.](#))

HD/SD Video Test Signal

The SMPTE, in recognition of the need for convenient measurement of both high-definition (HD) and standard-definition (SD) video signals within a given plant, developed a recommended practice designed to serve both domains [1]. SMPTE RP-219 specifies a color bar pattern compatible with both HD and SD environments. The multi-format color bar signal is originated as an HD signal with an aspect ratio of 16:9 and may be down converted to an SD color bar signal with an aspect ratio of either 4:3 or 16:9.

FIGURE 20.20 Examples of color test bars: (a) ITU nomenclature, (b) SMPTE EG 1 color bar test signal, (c) EIA RS-189-A test signal, (d, next page) multi-format color bar test signal. [Drawing (b) after SMPTE EG 1, (c) after EIA RS-189-A, (d) after SMPTE RP 219.]

The color bar signal is generated with unconventionally slow rise and fall time value, and is therefore only intended to facilitate video level control and monitor color adjustments of HD and SD equipment. It can be applied to HD video productions, especially in a multi-format environment where HD video sources are frequently converted and used as SD video content either in 525- or 625-line environment with same frame frequencies as in the original HDTV signal.

The multi-format color bar signal is composed of four specific patterns, shown in Fig. 20.20d. The first part of the color bar signal represents a signal for the 4:3 aspect ratio; a second part of the total signal

FIGURE 20.20 (Continued)

adds side panels for the 16:9 aspect ratio. A third part adds black and white ramps and additional color information, and the last part completes the total signal by adding white and black bars, in addition to a set of near-black-level steps for monitor black level adjustment.

20.2.3 Basic Waveform Measurements

Waveform monitors are used to evaluate the amplitude and timing of video signals and to show timing relationships between two or more signals [2]. The familiar color-bar pattern is the only signal required for these basic tests. Figure 20.21 shows a typical waveform display of color bars. It is important to realize that all color bars are not created equal. Some generators offer a choice of 75% or 100% amplitude bars. Sync, burst, and setup amplitudes remain the same in the two color-bar signals, but the peak-to-peak

FIGURE 20.21 Waveform monitor display of a color-bar signal at the two-line rate. (Courtesy of Tektronix.)

amplitudes of high-frequency chrominance information and low-frequency luminance levels change. The saturation of color, a function of chrominance and luminance amplitudes, remains constant at 100% in both modes. The 75% bar signal has 75% amplitude with 100% saturation. In 100% bars, amplitude and saturation are both 100%.

Chrominance amplitudes in 100% bars exceed the maximum amplitude that should be transmitted via NTSC. Therefore, 75% amplitude color bars, with no chrominance information exceeding 100 IRE, are the standard amplitude bars for conventional television. In the 75% mode, a choice of 100 IRE or 75 IRE white reference level may be offered. Figure 20.22 shows 75% amplitude bars with a 100 IRE white level. Either white level can be used to set levels, but operators must be aware of which signal has been selected. SMPTE bars have a white level of 75 IRE as well as a 100 IRE white flag.

The vertical response of a waveform monitor depends upon filters that process the signal in order to display certain components. The *flat response* mode displays all components of the signal. A *chroma response* filter removes luminance and displays only chrominance. The low-pass filter removes chrominance, leaving only low-frequency luminance levels in the display. Some monitors include an IRE filter, designed to average-out high-level, fine-detail peaks on a monochrome video signal. The IRE filter aids the operator in setting brightness levels. The IRE response removes most, but not all, of the chrominance.

If the waveform monitor has a dual filter mode, the operator can observe luminance levels and overall amplitudes at the same time. The instrument switches between the flat and low-pass filters. The line select mode is another useful feature for monitoring live signals.

Sync Pulses

The duration and frequency of the sync pulses must be monitored closely for conventional video. Most waveform monitors include $0.5 \mu\text{s}$ or $1 \mu\text{s}$ per division magnification (MAG) modes, which can be used to verify H-sync width between 4.4 and $5.1 \mu\text{s}$. The width is measured at the -4 IRE point. On waveform monitors with good MAG registration, sync appearing in the middle of the screen in the 2-line mode remains centered when the sweep is magnified. Check the rise and fall times of sync, and the widths of the front porch and entire blanking interval. Examine burst and verify there are between 8 and 11 cycles of subcarrier.

FIGURE 20.22 EIA RS-189-A color-bar displays: (a) color displays of gray and color bars, (b) waveform display of reference gray and primary/complementary colors, plus sync and burst.

Check the vertical intervals for correct format, and measure the timing of the equalizing pulses and vertical sync pulses. The acceptable limits for these parameters are shown in Fig. 22.23.

20.2.4 Basic Vectorscope Measurements

The vectorscope displays chrominance amplitudes, aids hue adjustments, and simplifies the matching of burst phases of multiple signals. These functions require only the color-bar test signal as an input stimulus. To evaluate and adjust chrominance in the TV signal, observe color bars on the vectorscope. The instrument should be in its calibrated gain position. Adjust the vectorscope phase control to place the burst vector at the 9 O'clock position. Note the vector dot positions with respect to the six boxes marked on the graticule. If everything is correctly adjusted, each dot will fall on the crosshairs of its corresponding box, as shown in Fig. 20.24.

The chrominance amplitude of a video signal determines the intensity or brightness of color. If the amplitudes are correct, the color dots fall on the crosshairs in the corresponding graticule boxes. If vectors overshoot the boxes, chrominance amplitude is too high; if they undershoot, it is too low. The boxes at each color location can be used to quantify the error. In the radial direction, the small boxes indicate a ± 2.5 IRE error from the standard amplitude. The large boxes indicate a $\pm 20\%$ error.

Other test signals, including a modulated staircase or multiburst, are used for more advanced tests. It is important to closely observe how these signals appear at the output of the waveform generator. Knowing what the undistorted signal looks like simplifies the subsequent identification of distortions.

20.2.5 Line Select Features

Some waveform monitors and vectorscopes have line select capability. They can display one or two lines out of the entire video frame of 525 lines. (In the normal display, all of the lines are overlaid on top of one another.) The principal use of the single line feature is to monitor VITS (*vertical interval test signals*). VITS

FIGURE 20.23 Sync pulse widths for NTSC.

allows in-service testing of the transmission system. A typical VITS waveform is shown in Fig. 20.25. A full-field line selector drives a picture monitor output with an intensifying pulse. The pulse causes a single horizontal line on a picture monitor to be highlighted. This indicates where the line selector is within the frame to correlate the waveform monitor display with the picture.

FIGURE 20.24 Vectorscope display of a color-bar signal. (Courtesy of Tektronix.)

FIGURE 20.25 Composite vertical-interval test signal (VITS) inserted in field 1, line 18. The video level in IRE units is shown on the left; the radiated carrier signal is shown on the right.

20.2.6 Distortion Mechanisms

The video system should respond uniformly to signal components of different frequencies. In an analog system, this parameter is generally evaluated with a waveform monitor. Different signals are required to check the various parts of the frequency spectrum. If the signals are all faithfully reproduced on the waveform monitor screen after passing through the video system, it is safe to assume that there are no serious frequency response problems.

At very low frequencies, look for externally introduced distortions, such as power-line hum or power supply ripple, and distortions resulting from inadequacies in the video processing equipment. Low-frequency distortions usually appear on the video image as flickering or slowly varying brightness. Low-frequency interference can be seen on a waveform monitor when the DC restorer is set to the slow mode and a 2-field sweep is selected. *Sine wave distortion from AC power-line hum may be observed in Fig. 20.26. A bouncing*

FIGURE 20.26 Waveform monitor display showing additive 60 Hz degradation. (Courtesy of Tektronix.)

FIGURE 20.27 Waveform monitor display of a multiburst signal showing poor high-frequency response. (Courtesy of Tektronix.)

APL signal can be used to detect distortion in the video chain. Vertical shifts in the blanking and sync levels indicate the possibility of low-frequency distortion of the signal.

Field-rate distortions appear as a difference in shading from the top to the bottom of the picture. A field-rate 60 Hz square wave is best suited for measuring field-rate distortion. Distortion of this type is observed as a tilt in the waveform in the 2-field mode with the DC restorer off.

Line-rate distortions appear as streaking, shading, or poor picture stability. To detect such errors, look for tilt in the bar portion of a pulse-and-bar signal. The waveform monitor should be in the 1 or 2H mode with the fast DC restorer selected for the measurement.

The *multiburst* signal is used to test the high-frequency response of a system. The multiburst includes packets of discrete frequencies within the television passband, with the higher frequencies toward the right of each line. The highest frequency packet is at about 4.2 MHz, the upper frequency limit of the NTSC system. The next packet to the left is near the color subcarrier frequency (3.58 MHz, approximately) for checking the chrominance transfer characteristics. Other packets are included at intervals down to 500 kHz. The most common distortion is high-frequency rolloff, seen on the waveform monitor as reduced amplitude packets at higher frequencies. This type of problem is shown in Fig. 20.27. The television picture exhibits loss of fine detail and color intensity when such impairments are present. High frequency peaking, appearing on the waveform as higher amplitude packets at the higher frequencies, causes ghosting on the picture.

Differential Phase

Differential phase ($d\phi$) distortion occurs if a change in luminance level produces a change in the chrominance phase. If the distortion is severe, the hue of an object will change as its brightness changes. A modulated staircase or ramp is used to quantify the problem. Either signal places chrominance of uniform amplitude and phase at different luminance levels. Figure 20.28 shows a 100 IRE modulated ramp. Because $d\phi$ can change with changes in APL, measurements at the center and at the two extremes of the APL range are necessary.

To measure $d\phi$ with a vectorscope, increase the gain control until the vector dot is on the edge of the graticule circle. Use the phase shifter to set the vector to the 9 O'clock position. Phase error appears as circumferential elongation of the dot. The vectorscope graticule has a scale marked with degrees of $d\phi$ error. Figure 20.29 shows a $d\phi$ error of 5° .

More information can be obtained from a swept R-Y display, which is a common feature of waveform monitor and vectorscope instruments. If one or two lines of demodulated video from the vectorscope are

FIGURE 20.28 Waveform monitor display of a modulated ramp signal. (Courtesy of Tektronix.)

displayed on a waveform monitor, differential phase appears as tilt across the line. In this mode, the phase control can be adjusted to place the demodulated video on the baseline, which is equivalent in phase to the 9 O'clock position of the vectorscope. Figure 20.30 shows a $d\phi$ error of approximately 6° with the amount of tilt measured against a vertical scale. This mode is useful in troubleshooting applications. By noting where along the line the tilt begins, it is possible to determine at what DC level the problem starts to occur. In addition, field-rate sweeps enable the operator to look at $d\phi$ over the field.

A variation of the swept R-Y display may be available in some instruments for precise measurement of differential phase. Highly accurate measurements can be made with a vectorscope that includes a precision phase shifter and a double-trace mode. This method involves nulling the lowest part of the waveform with the phase shifter, and then using a separate calibrated phase control to null the highest end of the waveform. A readout in tenths of a degree is possible.

FIGURE 20.29 Vectorscope display showing 5° differential phase error. (Courtesy of Tektronix.)

FIGURE 20.30 Vectorscope monitor display showing a differential phase error of 5.95° as a tilt on the vertical scale. (Courtesy of Tektronix.)

Differential Gain

Differential gain (dG) distortion refers to a change in chrominance amplitude with changes in luminance level. The vividness of a colored object changes with variations in scene brightness. The modulated ramp or staircase is used to evaluate this impairment with the measurement taken on signals at different APL points.

To measure differential gain with a vectorscope, set the vector to the 9 o'clock position and use the variable gain control to bring it to the edge of the graticule circle. Differential gain error appears as a lengthening of the vector dot in the radial direction. The dG scale at the left side of the graticule can be used to quantify the error. Figure 20.31 shows a dG error of 10%.

Differential gain can be evaluated on a waveform monitor by using the chroma filter and examining the amplitude of the chrominance from a modulated staircase or ramp. With the waveform monitor in 1H sweep, use the variable gain to set the amplitude of the chrominance to 100 IRE. If the chrominance amplitude is not uniform across the line, there is dG error. With the gain normalized to 100 IRE, the error can be expressed as a percentage. Finally, dG can be precisely evaluated with a swept display of

FIGURE 20.31 Vectorscope display of a 10% differential gain error. (Courtesy of Tektronix.)

FIGURE 20.32 Waveform monitor display using the ICPM graticule of a five-level staircase signal with no distortion. (Courtesy of Tektronix.)

demodulated video. This is similar to the single trace R–Y methods for differential phase. The B–Y signal is examined for tilt when the phase is set so that the B–Y signal is at its maximum amplitude. The tilt can be quantified against a vertical scale.

ICPM

Television receivers typically use a method known as *intercarrier sound* to reproduce audio information. Sound is recovered by beating the audio carrier against the video carrier, producing a 4.5 MHz IF signal, which is demodulated to produce the sound portion of the transmission. From the interaction between audio and video portions of the signal, certain distortions in the video at the transmitter can produce audio buzz at the receiver. Distortions of this type are referred to as *incidental carrier phase modulation* or ICPM. The widespread use of stereo audio for television increased the importance of measuring this parameter at the transmitter, because the buzz is more objectionable in stereo broadcasts. It is generally suggested that less than 3° of ICPM be present in the radiated signal.

ICPM is measured using a high-quality demodulator with a synchronous detector mode and an oscilloscope operated in a high-gain X – Y mode. Some waveform and vector monitors have such a mode as well. Video from the demodulator is fed to the Y input of the scope and the quadrature output is fed to the X input terminal. Low-pass filters make the display easier to resolve.

An unmodulated 5-step staircase signal produces a polar display, shown in Figure 20.32, on a graticule developed for this purpose. Notice that the bumps all rest in a straight vertical line, if there is no ICPM in the system. Tilt indicates an error, as shown in Figure 20.33. The graticule is calibrated in degrees per radial division for differential gain settings. Adjustment, but not measurement, can be performed without a graticule.

Tilt and Rounding

Good picture quality requires that the characteristics of the visual transmitter be as linear as possible. The transmitted channel bandwidth of conventional television (6 MHz for NTSC and greater for PAL and SECAM) introduces various obstacles for achieving a high degree of linearity. The wideband amplifiers of television transmission systems must have a flat response over the entire frequency range of interest. The design process considers solutions for the problems of spurious harmonics resulting from stray component parameters, and distortions to signals from all sources. Frequency distortion in television systems, ranging from 15 kHz to several hundred kilohertz, is more visible on test equipment if a line-frequency square-wave

FIGURE 20.33 Waveform monitor display using the ICPM graticule of a five-level staircase signal with 5° distortion. (Courtesy of Tektronix.)

signal (with a rise time of approximately 200 ns) modulates the visual transmitter. Distortion characteristics of this range generally fall into the category of *rounding* and *tilt*.

It is possible to run tests on a transmission system using a number of specific frequencies, monitoring the response to each at various points in the system. However, a more efficient method involves using square-wave test signals with rise times selected to avoid overshoots in transmission. During monitoring of the signals at various test points, tilt and rounding of the square-wave corners may be observed as impaired frequency response. Two square-wave frequencies prove to be useful for this work. The lower frequency of 60 Hz (50 Hz in PAL) aids in detecting response errors in the frequency range below approximately 15 kHz. A 15 kHz square wave serves to determine response to several hundred kilohertz. These two test signals identify low frequency response problems when observed on an oscilloscope as a tilt of the flat part of the square wave (top or bottom) and a rounding of the corners. Ideal response would produce flat tops and bottoms without any rounding at the corners.

Tilt can be determined for both test signal ranges. The measurement is made on a portion of the square wave derived from a demodulator. Particular start and end points of the measurement are suggested to avoid ringing as a result of pulse rise times. To ensure the best measurements, the sweep range and vertical sensitivity of the oscilloscope are set as wide as possible to accommodate the entire length of trace segment of interest. Tops and bottoms of the square waves should be measured separately (see Fig. 20.34.)

FIGURE 20.34 Measurement of tilt on a visual signal with 50 Hz and 15 kHz signals. (After [3].)

FIGURE 20.35 Measurement of rounding of a 15 kHz square-wave test signal to identify high-frequency-response problems in a television transmitter. (After [3].)

Rounding is determined from the 15 kHz signal. It is realistic to delay the start point and to define a duration along the scope trace for the measurement. Separate observations should be made on rising and falling sides of the square wave, as shown in Fig. 20.35.

The effects of tilt and rounding on a video signal in the transmission system sometimes can be seen in the demodulated image. Unless it is excessive, tilt is least obvious. It appears partly as a flickering in the picture and partly as a variation in luminance level from top-to-bottom and/or side-to-side of the image. Rounding, in this case, manifests itself as a reduction of detail in medium-frequency parts of the image. In cases of excessive tilt or rounding error, it may be difficult for some TV receivers to lock on to the degraded signal.

Group Delay

The transients of higher-frequency components (15 to 250 kHz), produce overshoot on the leading edge of transitions and, possibly, ringing at the top and bottom of the waveform area. The shorter duration of

FIGURE 20.36 Tolerance graticule mask for measuring transient response of a visual transmitter. A complete oscillation is first displayed on the screen. The timebase then is expanded, and the signal X-Y position controls are adjusted to shift the trace into the tolerance mask. (After [4].)

the “flat” top and bottom lowers concern about tilt and rounding. A square wave contains a fundamental frequency and numerous odd harmonics. The number of the harmonics determines the rise or fall times of the pulses. Square waves with rise times of 100 ns (T) and 200 ns ($2T$) are particularly useful for television measurements. In the $2T$ pulse, significant harmonics approach 5 MHz; a T pulse includes components approaching 10 MHz. Because the TV system should carry as much information as possible, and its response should be as flat as possible, the T pulse is a common test signal for determination of group delay.

Group delay is the effect of time- and frequency-sensitive circuitry on a range of frequencies. Time, frequency, phase shift, and signal delay all are related and can be determined from circuit component values. Excessive group delay in a video signal appears as a loss of image definition. Group delay is a fact of life that cannot be avoided, but its effect can be reduced through *predistortion* of the video signal. Group delay adjustments can be made before the modulator stage of the transmitter, while monitoring of the signal from a feedline test port and adjusting for best performance.

Group delay can be monitored using a special purpose scope or waveform graticule. The goal in making adjustments is to fit all excursions of the signal between the smallest tolerance markings of the graticule, as illustrated in Fig. 20.36. Because quadrature phase errors are caused by the vestigial sideband transmission system, synchronous detection is needed to develop the display.

20.2.7 Automated Video Signal Measurement

Video test instruments based on computer systems provide the maintenance engineer with the ability to rapidly measure a number of parameters with exceptional accuracy. Automated instruments offer a number of benefits, including reduced setup time, test repeatability, waveform storage and transmission capability, and remote control of instrument/measurement functions. Typical features of this class of instrument include the following:

- Waveform monitor functions
- Vectorscope monitor functions
- Picture display capability
- Automatic analysis of an input signals
- RS-232 and/or GPIB I/O ports

Figure 20.37 shows a block diagram of a representative automated video test instrument. Sample output waveforms are shown in Figure 20.38.

FIGURE 20.40 Example error log for a monitored signal. (Courtesy of Tektronix.)

Automated test instruments offer the end-user the ability to observe signal parameters and to make detailed measurements on them. The instrument depicted in Figure 20.37 offers a “Measure Mode,” in which a captured waveform can be expanded and individual elements of the waveform examined. The instrument provides interactive control of measurement parameters, as well as graphical displays and digital readouts of the measurement results. Figure 20.39 illustrates measurement of sync parameters on an NTSC waveform.

Another feature of many automated video measurement instruments is the ability to set operational limits and parameters that—if exceeded—are brought to the attention of an operator. In this way, operator involvement is required only if the monitored signal varies from certain preset limits. Figure 20.40 shows an example error log.

20.3 Radio Frequency Distortion Mechanisms and Analysis

Samuel O. Agbo

20.3.1 Introduction

Radio frequency (RF) communication is usually understood to mean radio and television broadcasting, cellular radio communication, point-to-point radio communication, microwave radio, and other wireless radio communication. For such wireless radio communication, the communication channel is the atmosphere or free space. It is in this sense that RF distortion is treated in this section, although RF signals are also transmitted through other media such as coaxial cables.

Distortion refers to the corruption encountered by a signal during transmission or processing that modifies the signal waveform. A simple model of the atmospheric radio channel, as shown in Fig. 20.41, will help to illustrate the sources of radio frequency distortion. The channel is modeled as a linear time-variant system with additive noise and additive interference. In the figure, $s(t)$ is the RF signal to be transmitted through the channel, $h(t, \tau)$ is the channel impulse response, $n(t)$ is the additive noise, $i(t)$ is the interference, and $r(t)$ is the received signal. Sources of signal corruption, such as signal attenuation, amplitude distortion, phase distortion, multipath effects and time-varying channel characteristics, constitute the linear time-variant channel

FIGURE 20.41 Model of the atmospheric radio channel as a linear time-variant system with additive noise and additive interference.

impulse response. Noise and interference are additive sources of signal corruption. Corruption by noise may result in a roughness of the output waveform, but the original signal waveform is usually discernible. This is one sense in which noise differs from the distortion mechanisms discussed in this section.

The impulse response $h(t, \tau)$ is the response of the channel at time t due to an impulse $\delta(t - \tau)$ applied at time $t - \tau$. Let $\alpha_k(t)$ represent the time-dependent attenuation factors for the m multipath components of an atmospheric radio channel. Then a simple representation of the impulse response is

$$h(t, \tau) = \sum_{k=1}^m \alpha_k(t) \delta(t - \tau_k) \quad (20.1)$$

The received signal, which is the convolution of this impulse response with the signal $s(t)$, plus the additive noise and interference acquired in the channel, is given by

$$r(t) = \sum_{k=1}^m \alpha_k s(t - \tau_k) + i(t) + n(t) \quad (20.2)$$

Radio frequency signals are processed in the transmitter, prior to transmission, and in the receiver, prior to demodulation, by electronic circuits. Such processing can be regarded in a generalized way as filtering. Distortion introduced by nonideal filters and the atmospheric radio channel will be discussed. Following this, the effects on demodulation outputs of frequency and phase distortion and interference on radio frequency signals will be discussed.

20.3.2 Types of Distortion

Linear Distortion

The processing of radio frequency signals in transmitter or receiver by electronic circuits can be viewed as forms of filtering. Such processing will introduce distortion unless the filter is ideal or distortionless within a band of frequencies equal to or exceeding the bandwidth of the input signal. A filter is distortionless if its input and output signals have identical waveforms, save for a constant amplitude gain or attenuation and a constant time delay for all of the frequency components. Thus, if $g(t)$ with a bandwidth W is the input signal into an ideal filter of bandwidth B , which is greater than W , the output signal $y(t)$ is given by

$$y(t) = \alpha g(t - \tau) \quad (20.3)$$

In Eq. (20.3) α is the constant gain or attenuation and τ is the time delay in passing through the system. With this definition, $H(f)$, the Fourier transforms of the ideal filter impulse response and $Y(f)$, the filter output are given by, respectively,

$$H(f) = \alpha e^{-j2\pi f\tau} \quad (20.4)$$

$$\begin{aligned} Y(f) &= G(f)H(f) \\ &= \alpha G(f)e^{-j2\pi f\tau} \end{aligned} \quad (20.5)$$

Figure 20.42 shows the frequency-domain representation of an ideal and a nonideal filter and the time-domain representation of the input and output signals. Figures 20.42(a), 20.42(b), and 20.42(c) show, respectively, the frequency response of the ideal filter, the input signal waveform, and the output signal waveform, which is a time delayed version of the input waveform. Both the filter response and the input signal are bandlimited to B Hz.

Figure 20.42(d) shows a nonideal filter frequency response with ideal phase but nonideal amplitude response, which is given by

$$|H(f)| = \begin{cases} \alpha \cos 2\pi fT, & |f| < B \\ 0, & |f| > B \end{cases} \quad (20.6)$$

FIGURE 20.42 (a) Ideal filter frequency response, (b) waveform of input signal, (c) waveform of output signal from ideal filter, (d) nonideal filter frequency response with ideal phase but nonideal amplitude response, (e) output waveform of nonideal filter showing its components as time shifted versions of the input signal, (f) output waveform of nonideal filter: a dispersed version of the input signal.

By employing the time-shifting property of the Fourier transform, the time-domain output signal is obtained as

$$y(t) = \frac{\alpha}{2}(g(t - \tau - T) + g(t - \tau + T)) \tag{20.7}$$

From Eq. 20.7, it is clear that the output signal consists of two scaled and time shifted versions of the input signal as shown in Fig. 20.42(e). The sum of these shifted versions shown in Fig. 20.42(f) indicates that linear distortion results in **dispersion** of the output signal. It is easy to see that nonideal phase response, which implies different delays at different frequencies, also leads to dispersion. Thus, linear distortion causes pulse spreading and interference with neighboring pulses. Consequently, linear distortion should be avoided in time-division multiplexing (TDM) systems where it causes **crosstalk** with neighboring channels. In frequency-division multiplexing (FDM), linear distortion corrupts the signal spectrum, but the pulse spreading does not result in crosstalk because the channels are adjacent in frequency, not in time.

The ideal filter of Fig. 20.42 is a low-pass filter. Bandpass and high-pass filters are more relevant for the processing of RF signals in the transmitter, prior to transmission, and in the receiver, prior to demodulation. For bandpass and high-pass filters, the condition for distortionless filtering is the same as previously indicated: the input signal bandwidth should not exceed the filter bandwidth, and the filter should have a constant gain and the same time delay for all frequencies within its bandwidth. Figure 20.43 illustrates the frequency responses for ideal bandpass and ideal high-pass filters.

Nonlinear Distortion

Nonlinearity in system response usually arises in cases involving large signal amplitudes. For a simple case of memoryless, nonlinear system or channel, with a low-pass input signal $g(t)$, of bandwidth W Hz, the output signal $y(t)$ is given by

$$y(t) = a_0 + a_1g(t) + a_2g^2(t) + a_3g^3(t) + \dots + a_kg^k(t) + \dots \tag{20.8}$$

FIGURE 20.43 (a) Ideal bandpass filter, (b) high-pass filters.

Consider the term $a_k g^k(t)$ in the equation. Let $G(f)$ be the Fourier transform of $g(t)$. Then the Fourier transform of $g^k(t)$ is a $k - 1$ fold convolution of $G(f)$. Thus, the bandwidth of $g^k(t)$ is $k - 1$ times the bandwidth of $g(t)$. Suppose m is the last significant term of the power series of the equation, then the bandwidth of the output signal is $(m - 1)W$ Hz. Thus, the bandwidth of the output signal will far exceed the bandwidth of the input signal.

Figure 20.44 illustrates the spectrum of the input and the output signals. If the input signal is a bandpass signal of bandwidth W and carrier frequency f_c , which would be appropriate for a radio frequency signal, the spectrum of the output signal would be much more complex. In this case, the k th term of the power series of the output signal $y(t)$ will, in general, contribute a component of bandwidth $(k - 1)W$ centered at kf_c , in addition to smaller bandwidth components centered at lower harmonics of f_c .

The preceding discussion shows that nonlinear distortion causes spreading in the frequency domain. Such spreading of the spectrum causes interference in FDM systems because it results in frequency-domain overlap of neighboring channels. However, nonlinear distortion does not cause adjacent channel interference in TDM as the channels in that case are not adjacent in frequency, but in time.

Distortion Due to Time-Variant Multipath Channels

Radio waves from a transmitting antenna often reach the receiving antenna through many different paths. Examples include different reflecting layers in the **ionosphere**, numerous scattering points in the **troposphere**, reflections from the Earth's surface, and the direct line-of-sight path. Each of these paths will contribute a different attenuation and time delay. Shown in Fig. 20.45 is a model of the time-variant multipath radio channel. For the sake of simplicity, the effect of noise has been ignored.

This channel is time dispersive because the different time delays entail a spread in time of the composite received signal relative to the transmitted signal. In addition, because of variations with time and locality in weather, temperature and other atmospheric conditions, the time delay and attenuation of these paths vary with time. Because these variations in channel characteristics are generally unpredictable, a statistical characterization of the time-variant multipath channel is appropriate.

To simplify the analysis, consider the transmission of an unmodulated carrier of unit amplitude, $s(t) = \cos 2\pi f_c t$, through an m multipath channel in the absence of noise. Let $\alpha_k(t)$ be the attenuation and $\tau_k(t)$

FIGURE 20.44 Input and output spectrum for a channel with nonlinear distortion: (a) amplitude spectrum of output signal, (b) amplitude spectrum of input signal.

FIGURE 20.45 Model of a noiseless, time-variant, multipath channel.

be time delay contributed by the k th path at the receiver. The received signal is given by

$$\begin{aligned}
 r(t) &= \sum_{k=1}^m \alpha_k(t) \cos[2\pi f_c(t - \tau_k(t))] \\
 &= \operatorname{Re} \left[\sum_{k=1}^m \alpha_k(t) e^{j2\pi f_c t} e^{-j2\pi f_c \tau_k(t)} \right] \\
 &= [\cos 2\pi f_c t] \operatorname{Re} \left[\sum_{k=1}^m \alpha_k e^{-j2\pi f_c \tau_k(t)} \right]
 \end{aligned} \tag{20.9}$$

It is easy to see that the response of the channel to the unmodulated carrier is

$$h(t, \tau) = \operatorname{Re} \left[\sum_{k=1}^m \alpha_k(t) e^{-j2\pi f_c \tau_k(t)} \right] \tag{20.10}$$

Note that although the channel input was an unmodulated carrier, the channel output contains a frequency spread around the carrier, resulting from the time-varying delays of the various paths. The bandwidth of this output signal is a measure of how rapidly the channel characteristics are changing. A large change in channel characteristics is required to produce a significant change in the time-varying attenuation $\alpha_k(t)$. Because f_c is a large number, a change of 2π in the phase of the output signal $-2\pi f_c \tau_k(t)$ corresponds to only a change of $1/f_c$ in the time delay $\tau_k(t)$. Thus, the attenuation changes slowly, while the phase (or frequency deviation) changes rapidly.

Because these changes are random in nature, the channel impulse response can be modeled as a random process. Constructive addition of the phases of the various paths result in a strong signal, whereas destructive addition of the phases results in a weak signal. Thus, the multipath propagation results in signal fading, primarily due to the time-variant phase changes. When m , the number of multiple propagation paths, is large, the central limit theorem applies and the channel response will approximate a Gaussian random process.

20.3.3 The Wireless Radio Channel

In wireless radio communication, electromagnetic waves are radiated into the atmosphere or free space via a transmitting antenna. For efficient radiation, the antenna length should exceed one-tenth of the wavelength of the electromagnetic wave. The wavelength λ is given by

$$\lambda = \frac{c}{f} \tag{20.11}$$

In Eq. (20.11) $c = 3 * 10^8$ m/s, is the free-space velocity of electromagnetic waves and f is the frequency in Hz. Wireless radio communications covers a wide range of frequencies from about 10 kHz in the very low frequency (VLF) band to above 300 GHz in the extra high frequency (EHF) band. Depending on the

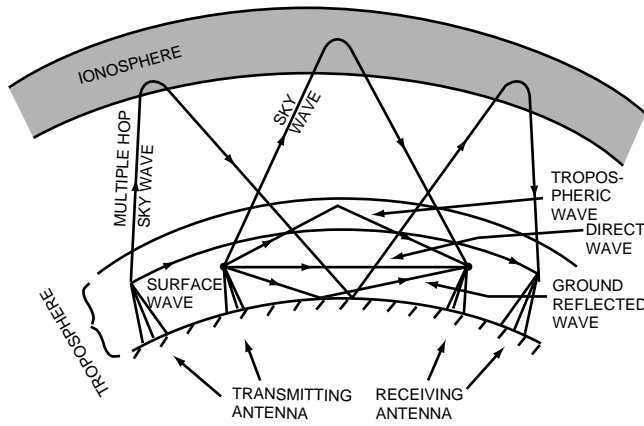

FIGURE 20.46 Wireless radio wave propagation paths.

frequency band and the distance between the transmitter and the receiver, the transmitted wave may reach the receiving antenna by one or a combination of several propagation paths, as shown in Fig. 20.46.

Sky waves are those that reach the receiver after being reflected from the ionosphere, a band of reflecting layers ranging in altitude from 100 to 300 km. Tropospheric waves are those that reach the receiver after being reflected (scattered) by inhomogeneities within the troposphere, the region within 10 km of the Earth’s surface. Other waves reach the receiving antenna via ground waves, which consists of space waves and surface waves. Surface waves (in the LF and VLF ranges) have wavelengths comparable to the altitude of the ionosphere. The ionosphere and the ground surface act as guiding planes, so that surface waves follow the curvature of the Earth, permitting transmission over great distances. Space waves consist of direct (line-of-sight) waves and ground reflected waves, which arrive at the receiver after being reflected from the ground. A classification of radio frequency communication by frequency bands, typical uses, and electromagnetic wave propagation modes is given in Table 20.1.

Ground Waves

In the region adjacent to the Earth’s surface, free-space conditions are modified by the surface topography, physical structures such as buildings, and the atmosphere. One effect of the atmosphere is to cause a refraction of the wave, which carries it beyond the optical horizon. Consequently, the **radio horizon** is

TABLE 20.1 Classification of Wireless Radio Frequency Channels by Frequency Bands, Typical Uses, and Wave Propagation Modes

Frequency Band	Name	Typical Uses	Propagation Mode
3–30 kHz	Very low frequency (VLF)	Navigation, sonar	Ground waves
30–300 kHz	Low frequency (LF)	Navigation, telephony, telegraphy	Ground waves
0.3–3 MHz	Medium frequency (MF)	AM Broadcasting, amateur, and CB radio	Sky waves and ground waves
3–30 MHz	High frequency (HF)	Mobile, amateur, CB, and military radio	Sky waves
30–300 MHz	Very high frequency (VHF)	VHF TV, FM Broadcasting Police, air traffic control	Sky waves, tropospheric waves
0.3–3 GHz	Ultra high frequency (UHF)	UHF TV, radar, satellite communication	Tropospheric waves, space waves
3–30 GHz	Super high frequency (SHF)	Space and satellite, radar microwave relay	Direct waves, ionospheric penetration waves
30–300 GHz	Extra high frequency (EHF)	Experimental, radar radio astronomy	Direct waves, ionospheric penetration waves

longer than the optical horizon. Hills and building structures cause multiple reflections and shieldings, which contribute both attenuation and phase change to the received signal. Ground reflected waves travel a different path length and undergo different attenuation and time delay relative to direct waves and depending on the point of reflection. In addition, at each point of reflection on the Earth's surface, there is a phase change, which depends on the condition of the surface, but is typically a 180° phase change.

Consider the simplified model of ground wave propagation, shown in Fig. 20.47, which involves only two transmission paths: a direct wave and a ground reflected wave. The curved Earth's surface is represented by a flat Earth model after correction has been made for the longer radio horizon. The height of the transmitting antenna and the receiving antenna are h_T and h_r , respectively.

The direct wave travels a path length x from the transmitting antenna to the receiving antenna. The attenuation factor for the atmospheric medium is α . Let the corresponding distance traveled by the ground reflected wave be $x + \Delta x$ and the transmitted signal be $s(t)$. Note that a path length equal to the wavelength λ corresponds to a phase change of 2π . The received direct wave $r_d(t)$, the received ground reflected wave $r_g(t)$, and the composite received wave $r(t)$ are given, respectively, by

$$r_d(t) = e^{-\alpha x} s(t) \cos\left(\frac{2\pi x}{\lambda}\right) \quad (20.12)$$

$$r_g(t) = e^{-\alpha(x+\Delta x)} s(t) \cos\left[\frac{2\pi}{\lambda}(x + \Delta x) - \pi\right] \quad (20.13)$$

$$r(t) = r_d(t) + r_g(t) \quad (20.14)$$

From the preceding equations, it is seen that even for small differences in path lengths, the received signals from the direct and the ground reflected waves tend to have large phase differences. Consequently, the composite received signal has significant attenuation and phase error relative to the transmitted signal.

Tropospheric Waves

Waves propagating through the troposphere are only seriously attenuated by adverse atmospheric conditions at frequencies above 10 GHz. Above 10 GHz, heavy rain causes severe attenuation. However, light rain, clouds, and fog cause serious attenuation only at frequencies above 30 GHz. Attenuation due to snow is negligible at all frequencies. On the other hand, the inhomogeneities in the atmosphere due to the weather and other conditions are favorable for tropospheric scatter propagation of radio waves within the 30 MHz–4 GHz frequency band. Within this range of frequencies, the inhomogeneities within the troposphere form effective point scatterers that deflect the transmitted waves downward toward the receiving antenna. By employing large transmitted power and highly directional antennas, long transmission ranges of up to 400 mi can be obtained.

The range of frequencies favored for tropospheric propagation is essentially the domain of microwave transmission, UHF, and VHF radio. Although atmospheric attenuation is higher for frequencies above 10 GHz, it is still quite significant within the 30 MHz–4 GHz range of frequencies. Hence, microwave repeater stations are spaced about 30 mi apart. This spacing is long compared to the spacing of about 3 mi for repeaters for coaxial cable systems. However, such spacing is relatively close, compared with the more recent development of optical fiber transmission in which repeater spacing of above 300 km is practical.

FIGURE 20.47 Simplified model for ground wave propagation showing the direct wave and the ground reflected wave.

Sky Waves

The ionosphere consists of several layers containing ionized gases at altitudes of 100–300 km. In order of increasing height, these are the C, D, E, F₁, and F₂ layers. The ionization is caused by solar radiation, mainly due to ultraviolet and cosmic rays. Consequently, the electron density in the layers varies with the seasons and with the time of day and night. The gas molecules in the denser, lower layers cause more collisions and hence a higher recombination rate of electrons and ions. At night, the reduced level of radiation and the greater recombination rates cause the lower layers to disappear, so that only the F₂ layer remains.

Electromagnetic wave propagation through the ionosphere is by means of sky waves, mainly in the MF, HF, and VHF bands. The waves are successively refracted at the layers until they are eventually reflected back toward the Earth. At higher frequencies, the waves pass through the ionosphere without being reflected from it. Communication at these higher frequencies depends on a line-of-sight basis. During the daytime, ionospheric propagation is severely attenuated at frequencies below 2 MHz, due to severe absorption in the lower layers, especially the D layer. At night, after the disappearance of these lower layers, powerful AM transmission utilizing the F₂ layer is possible over the range of 100–250 mi. Of course, the maximum transmission range for sky waves depend on the frequency of transmission.

Figure 20.48 shows the geometry relevant to the determination of the range for ionospheric propagation. Because the altitudes involved are much greater than the antenna heights, the latter have been ignored. Rays from the transmitting antenna at angles of elevation greater than the critical angle of elevation for the frequency of transmission result in escape rays, which are not reflected back from the ionosphere. The ray leaving the transmitter at the critical angle, the critical ray, which is reflected from the lowest possible layer, returns to the Earth closest to the transmitter than any other ray, giving the minimum range or the skip zone. The distance between this minimum range and the range of the glancing ray (which is tangential to the Earth at the receiver) is the service range.

The greatest transmission range is obtained when the critical ray is reflected from a layer at so high an altitude that it is also tangential to the Earth’s surface at the receiver. The geometry for this case is shown in Fig. 20.48(b) in which the raypaths have been idealized as straight lines, ignoring the curvature of the paths due to refraction. The height of the virtual reflecting point above the Earth’s surface is h , and R is the radius of the Earth. The angle ϕ and the maximum range d are given, respectively, by

$$\phi = \cos^{-1} \left(\frac{R}{R + h} \right) \tag{20.15}$$

$$d = 2R \cos^{-1} \left(\frac{R}{R + h} \right) \tag{20.16}$$

This computation is for a single-hop reflection. For multiple hops, the transmission range is considerably greater, although the signal strength would be correspondingly reduced. The condition of the ionosphere within a locality greatly affects the critical angle of elevation and the transmission path. Conditions vary

FIGURE 20.48 Geometry of ionospheric single hop: (a) raypaths, skip zone, and service range, (b) geometry for computation of maximum range.

considerably with time and locality within the ionosphere. Such irregularities within the ionosphere can be used for scatter propagation, much like tropospheric scatter propagation, thereby resulting in increased transmission range of up to 1000 mi. However, the undesirable effects of ionospheric inhomogeneities far exceed this favorable effect.

Ionospheric irregularities result from differences in electron densities in the various layers. The irregularities can be quite large in spatial dimensions, ranging from tens of meters to several hundreds of kilometers. Some of these irregularities travel through the ionosphere at speeds in excess of 3000 km/h. These time-varying irregularities are responsible for the time-variant multipath effects and the resultant fading that plagues ionospheric transmission.

20.3.4 Effects of Phase and Frequency Errors in Coherent Demodulation of AM Signals

RF signals acquire phase and amplitude distortion in the wireless radio channel and in processing circuits, through the many mechanisms previously discussed. For coherent (or synchronous) detection, a local carrier, which matches the transmitted signal in phase and frequency, is required at the receiver. In general, such a match is hard to obtain. These mismatch errors are additional to the phase and amplitude errors acquired in the channel.

Double-Sideband Suppressed-Carrier (DSB-SC) Demodulation Errors

The receiver for the synchronous demodulation of double-sideband suppressed-carrier (DSB-SC) waves is shown in Fig. 20.49. In general, it is easy to correct the effect of attenuation or amplitude errors through amplification, filtering, or other processing in the receiver. It is more difficult to correct the effect of phase or frequency errors.

FIGURE 20.49 Receiver for synchronous demodulation of DSB-SC signals.

The received signal at the input to the receiver and the local carrier are given, respectively, by

$$r(t) = m(t) \cos 2\pi f_c t \tag{20.17}$$

$$c(t) = \cos(2\pi (f_c + \Delta f)t + \theta) \tag{20.18}$$

In the last two equations, $m(t)$ is the message signal of bandwidth W , where f_c is the carrier frequency, Δf is the frequency error, and θ is the phase error. The output of the product modulator is $x(t)$. Thus, $x(t)$ and $y(t)$ are given, respectively, by

$$\begin{aligned} x(t) &= m(t) \cos(2\pi f_c t) \cos(2\pi (f_c + \Delta f)t + \theta) \\ &= \frac{1}{2}m(t)\{\cos(2\pi (2f_c + \Delta f)t + \theta) + \cos(2\pi \Delta f t + \theta)\} \end{aligned} \tag{20.19}$$

$$y(t) = \frac{1}{2}m(t) \cos(2\pi \Delta f t + \theta) \tag{20.20}$$

It is easy to see that when both the frequency and the phase errors are zero, the demodulated output is $1/2m(t)$, and the recovery of the message signal is perfect. Consider the case of zero phase error, but finite frequency error. The demodulated signal and its Fourier transform are given, respectively, by

$$y(t) = \frac{1}{2}m(t) \cos 2\pi \Delta f t \tag{20.21}$$

$$Y(f) = \frac{1}{4}(M(f + \Delta f) + M(f - \Delta f)) \tag{20.22}$$

FIGURE 20.50 Frequency spectrum of message signal and demodulated output when there is a Δf frequency error between the local carrier and the carrier in the received DSB-SC signal: (a) message signal spectrum, (b) spectrum of demodulated output signal.

Thus, the demodulated output is a replica of the message signal multiplied by a slowly varying cosine wave of frequency Δf . This is a serious type of distortion, which produces a beating effect. The human ear can tolerate at most about 30 Hz of such frequency drift. Figure 20.50 shows the frequency-domain illustration of this type of distortion. Figure 20.50(a) shows the amplitude spectrum of the original message signal. Figure 20.50(b) shows that the demodulated signal can be viewed as a DSB-SC signal whose carrier is the frequency error Δf . This error is so small that the replicas of the message signal shifted by $+\Delta f$ and $-\Delta f$ overlap in frequency and, therefore, interfere, giving rise to the beating effect.

Next, consider the case in which the frequency error is zero, but the phase error is finite. The demodulated signal is given by

$$y(t) = \frac{1}{2}m(t) \cos \theta \tag{20.23}$$

If θ , the phase error is constant, then it contributes only a constant attenuation, which is easily corrected for through amplification. However, in the extreme case in which $\theta = \pm\pi/2$, the demodulated signal amplitude is reduced to zero. On the other hand, if θ varies randomly with time, as is the case for multipath fading channels, the attenuation induced by the phase error varies randomly and represents a serious problem.

To avoid the undesirable effects of frequency and phase errors between the local and the received carriers, various schemes are employed. One such scheme employs a **pilot carrier** at the transmitter to provide a source of matching carrier at the receiver. Some other schemes employed for providing matching carriers are the *Costas receiver* and signal squaring.

Single-Sideband Suppressed-Carrier (SSB-SC) Demodulation Errors

The receiver for the demodulation of single-sideband suppressed-carrier (SSB-SC) signals is similar to the receiver for DSB-SC signals shown in Fig. 20.49. The local carrier is the same as for the DSB-SC signal, but the received signal is given by

$$r(t) = m(t) \cos 2\pi f_c t \mp m_h(t) \sin 2\pi f_c t \tag{20.24}$$

In Eq. 20.24, the negative (−) sign applies to the upper-sideband (USB) case, whereas the positive sign (+) applies to the lower-sideband (LSB) case. The signal, $m_h(t)$, is the *Hilbert transform* of the message signal $m(t)$. The output of the product modulator is

$$\begin{aligned} x(t) &= (m(t) \cos 2\pi f_c t \mp m_h(t) \sin 2\pi f_c t) \cos(2\pi(f_c + \Delta f)t + \theta) \\ &= \frac{1}{2}m(t)\{\cos(2\pi \Delta f t + \theta) + \cos(2\pi(2f_c + \Delta f)t + \theta)\} \\ &\quad \pm \frac{1}{2}m_h(t)\{\sin(2\pi \Delta f t + \theta) - \sin(2\pi(2f_c + \Delta f)t + \theta)\} \end{aligned} \tag{20.25}$$

FIGURE 20.51 An illustration of the effect of frequency error in synchronous demodulation of SSB-SC signals: (a) amplitude spectrum of message signal, (b) amplitude spectrum of SSB (USB) signal, (c) amplitude spectrum of demodulated USB signal when $\Delta f < 0$, (d) amplitude spectrum of demodulated USB signal when $\Delta f > 0$.

The low-pass filter suppresses the bandpass components of the product modulator output. Hence, the demodulated output $y(t)$ is given by

$$y(t) = \frac{1}{2}m(t) \cos(2\pi \Delta f t + \theta) \pm \frac{1}{2}m_h(t) \sin(2\pi \Delta f t + \theta) \tag{20.26}$$

Note that when both the frequency and the phase errors are set to zero in the equation, the demodulator output signal is $1/2m(t)$, an exact replica of the desired message signal. Consider the case of zero phase error, but nonzero frequency error. In this case, the demodulated output signal $y(t)$ can be expressed as

$$y(t) = \frac{1}{2}m(t) \cos 2\pi \Delta f t \pm \frac{1}{2}m_h(t) \sin 2\pi \Delta f t \tag{20.27}$$

This equation shows that when only frequency error is present between the received and local carriers, the demodulated signal is essentially an SSB-SC signal in which the small frequency error Δf plays the role of the carrier. A comparison of this equation with the expression for the SSB-SC signal shows that if the modulated signal is a USB signal, the demodulated output is and LSB signal, and vice versa.

Figure 20.51 shows the spectra of the message signal, the SSB-SC modulated signal (USB case), and two cases of the demodulated signal when only frequency errors are present. Figure 20.51(c) shows the spectrum of the demodulated output of the USB signal when the frequency error is negative. Figure 20.51(e) shows the spectrum of the demodulated output of the USB signal when the frequency error is positive.

By comparing the demodulated output of an SSB-SC signal with the message signal, it is easy to see that in each case, each frequency component in the demodulated output is shifted by Δf . This does not introduce as serious a distortion as in the DSB-SC carrier case in which each frequency component is shifted by $-\Delta f$ and $+\Delta f$. As shown in Fig. 20.51, $M(f)$, the spectrum of the message signal is zero in the frequency gap from zero to f_g , as should be the case for a well-processed SSB message. By ensuring that f_g exceeds the maximum possible value of Δf , the sidebands for the demodulated output of an SSB-SC wave will never overlap in frequency or interfere with each other as in the DSB-SC case.

For the case of USB modulation in which the frequency error is zero but the phase error is nonzero, the demodulated output is obtained by setting Δf equal to zero in Eq. (20.26). This gives $y(t)$, the demodulated output signal and its frequency domain representation $Y(f)$, respectively, as

$$y(t) = \frac{1}{2}(m(t) \cos \theta + m_h(t) \sin \theta) \tag{20.28}$$

$$Y(f) = \frac{1}{2}(M(f) \cos \theta + M(f) \sin \theta) \tag{20.29}$$

But the frequency domain representation of the Hilbert transform of the message signal, $m_h(f)$, can be expressed as

$$\begin{aligned} M_h(f) &= -j \operatorname{sgn}(f)M(f) \\ &= \begin{cases} -jM(f); & f > 0 \\ jM(f); & f < 0 \end{cases} \end{aligned} \quad (20.30)$$

Thus, $Y(f)$ can be expressed as

$$\begin{aligned} Y(f) &= \begin{cases} \frac{1}{4} \left[M(f)e^{-j\theta} - jM(f) \left(\frac{-e^{-j\theta}}{j} \right) \right]; & f > 0 \\ \frac{1}{4} \left[M(f)e^{j\theta} + jM(f) \left(\frac{e^{j\theta}}{j} \right) \right]; & f < 0 \end{cases} \\ &= \begin{cases} \frac{1}{2}M(f)e^{-j\theta}; & f > 0 \\ \frac{1}{2}M(f)e^{j\theta}; & f < 0 \end{cases} \end{aligned} \quad (20.31)$$

From the preceding equation, it is clear that each positive frequency component in the demodulated output signal undergoes a phase shift of $-\theta$, while each negative frequency component undergoes a phase shift of $+\theta$. Thus, phase errors in SSB-SC signals results in phase distortion in the demodulated outputs. For voice signals, the human ear is relatively insensitive to phase distortion. However, this type of phase distortion, which produces a constant phase shift at all message signal frequencies, is quite objectionable in music signals and intolerable in video signals.

20.3.5 Effects of Linear and Nonlinear Distortion in Demodulation of Angle Modulated Waves

The amplitude of an angle modulated wave is supposed to be constant while the information being transmitted is contained in the phase. Linear distortion can be introduced by the channel, non-ideal filters, and other sub-circuits. In general, linear distortion results in time-variant amplitude and phase errors in the angle modulated wave. In effect, the angle modulated wave now contains both amplitude and phase modulation. Nonlinear distortion usually results from channel or power amplifier nonlinearities. Amplitude nonlinearities result in undesirable (or residual) amplitude modulation (AM), whereas phase nonlinearities result in phase distortion of the angle modulated wave. The effect of undesirable amplitude modulation resulting from linear and nonlinear distortion are discussed under separate subheadings. The effects of the time-variant phase errors resulting from linear distortion and from phase nonlinearities are discussed together under phase distortion in angle modulation.

Amplitude Modulation Effects of Linear Distortion

In an angle modulated waveform, the information resides in the phase of the modulated wave. Such an angle modulated wave can be demodulated by first passing it through a circuit whose amplitude response is proportional to the frequency of the input signal. The resulting intermediate signal has both amplitude modulation and angle modulation, and the information also resides in its amplitude. The demodulation process is then completed by passing this intermediate signal through an envelope detector.

A circuit which can implement this process is shown in Fig. 20.52. The differentiator input signal is the angle modulated wave. The amplitude of its output is proportional to the signal frequency, as shown in Fig. 20.52(b). Thus, the differentiator output is an amplitude as well as a frequency modulated waveform. The envelope detector output contains a replica of the message signal. Consider the case in which the

FIGURE 20.52 FM demodulator employing a differentiator and an envelope detector: (a) FM demodulator, (b) amplitude response of an ideal differentiator.

angle modulation involved is frequency modulation (FM). Suppose the FM signal contains no amplitude or phase errors, its amplitude will be constant. For simplicity, it can be assumed to be of unit amplitude. Let f_c be the carrier frequency, k_f be the frequency sensitivity of the modulator, and $m(t)$ be the message signal. Then the FM signal $s(t)$, the differentiator output $s'(t)$, and the envelope detector output $y(t)$, are given, respectively, by

$$s(t) = \cos \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \quad (20.32)$$

$$s'(t) = -(2\pi f_c + 2\pi k_f m(t)) \cos \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \quad (20.33)$$

$$y(t) = 2\pi f_c + 2\pi k_f m(t) \quad (20.34)$$

It is easy to see that an exact replica of the message signal can be recovered from the envelope detector output.

Consider the case in which the FM signal contains a time variation in its amplitude due to the channel, nonideal filter, or other system effects. Let $a(t)$ represent the time variation in the amplitude relative to the unit carrier amplitude. Then the FM signal and the output of the differentiator are given, respectively, by

$$s(t) = a(t) \cos \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \quad (20.35)$$

$$s'(t) = -a(t)(2\pi f_c + 2\pi k_f m(t)) \sin \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \\ + a'(t) \cos \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \quad (20.36)$$

The output of the envelope detector, $y(t)$, is the envelope of the differentiator output given in the last equation. Thus, the envelope detector output is

$$y(t) = \left\{ a^2(t)(2\pi f_c + 2\pi k_f m(t))^2 + (a'(t))^2 \right\}^{\frac{1}{2}} \quad (20.37)$$

From the last equation it is easy to see that because of the time variation in the amplitude of the FM signal, it is not possible to extract an undistorted replica of the message signal from the envelope detector output. Even if the second term in Eq. (20.36) is ignored, the message signal is still multiplied by the time-variant amplitude. Thus, it is necessary to rid the FM wave of variations in its amplitude prior to demodulation. This is usually accomplished by passing the FM signal through a bandpass limiter, such as is illustrated in Fig. 20.53, prior to demodulation.

The FM wave containing time-variant amplitude errors can be expressed as

$$s(t) = a(t) \cos(\phi(t)) \quad (20.38)$$

FIGURE 20.53 The bandpass limiter and an illustration of the output waveform of the hard limiter: (a) bandpass limiter, (b) output waveform of the hard limiter.

Its phase $\phi(t)$ is given by

$$\phi(t) = 2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \tag{20.39}$$

The hard limiter is a device with a voltage transfer characteristic such that if its input is $s(\phi)$, then its output, $y(\phi)$ is given by

$$y(\phi) = \begin{cases} 1, & \phi > 0 \\ -1, & \phi < 0 \end{cases} \tag{20.40}$$

When the input to the hard limiter is the FM signal, $a(t) \cos(\phi(t))$, the output of the hard limiter is the square waveform shown in Fig. 20.53(b). This periodic square waveform has a Fourier series expression given by

$$y(\phi(t)) = \frac{4}{\pi} \left[\cos(\phi(t)) - \frac{1}{3} \cos(3\phi(t)) + \frac{1}{5} \cos(5\phi(t)) + \dots \right] \tag{20.41}$$

Note that in the last equation, the terms containing $\phi(t), 3\phi(t), 5\phi(t), \dots$, correspond to FM waves with carrier frequencies $f_c, 3f_c, 5f_c, \dots$. Hence, the bandpass filter centered at f_c selects only the desired FM signal with carrier frequency f_c . Note that the output of the bandpass limiter, which is the output of the bandpass filter, has a constant amplitude given by

$$y_0(t) = \frac{4}{\pi} \cos \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \tag{20.42}$$

Effects of Amplitude Nonlinearities on Angle Modulated Waves

Amplitude nonlinearities can arise from nonlinearities in the channel or from nonlinearities in processing circuits such as power amplifiers. Consider a channel or system with amplitude nonlinearities, whose input signal $x(t)$ and output signal $y(t)$ are related as in the following equation:

$$y(t) = a_0 + a_1 x(t) + a_2 x^2(t) + a_3 x^3(t) + \dots \tag{20.43}$$

If the input signal $s(t)$ is the FM wave given by

$$s(t) = \cos(\phi(t)) = \cos \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \tag{20.44}$$

then the output signal $y(t)$ is given by

$$\begin{aligned} y(t) &= a_0 + a_1 \cos(\phi(t)) + a_2 \cos^2(\phi(t)) + a_3 \cos^3(\phi(t)) + \dots \\ &= a_0 + a_1 \cos(\phi(t)) + \frac{1}{2} a_2 (1 + \cos 2\phi(t)) + \frac{1}{2} a_3 \left\{ \cos(\phi(t)) + \frac{1}{2} \cos(\phi(t)) + \frac{1}{2} \cos(3\phi(t)) \right\} + \dots \\ &= \left(a_0 + \frac{1}{2} a_2 \right) + \left(a_1 + \frac{3}{4} a_3 \right) \cos(\phi(t)) + \frac{1}{2} a_2 \cos(2\phi(t)) + \frac{1}{4} a_3 \cos(3\phi(t)) + \dots \end{aligned} \tag{20.45}$$

The phase angles $\phi(t)$, $2\phi(t)$, and $3\phi(t)$, correspond to FM waves with carrier frequencies f_c , $2f_c$, and $3f_c$. Thus if the nonlinear system or channel is followed by a bandpass filter centered at f_c , the filter output is the desired FM wave with a carrier f_c , given by

$$\begin{aligned} y_0(t) &= \left(a_1 + \frac{3}{4}a_3 \right) \cos(\phi(t)) \\ &= \alpha \cos \left[2\pi f_c t + 2\pi k_f \int_{-\infty}^t m(\lambda) d\lambda \right] \end{aligned} \quad (20.46)$$

Let B_{FM} be the transmission bandwidth of the FM signal, W the bandwidth of the message signal and Δf the frequency deviation. The FM bandwidth is given for narrowband FM (NBFM) and for wideband FM (WBFM) by

$$B_{\text{FM}} = \begin{cases} 2(\Delta f + W), & \text{for NBFM} \\ 2(\Delta f + 2W), & \text{for WBFM} \end{cases} \quad (20.47)$$

To ensure that the FM wave with a carrier frequency of $2f_c$ does not interfere with the desired FM signal of carrier frequency f_c , the following condition must be satisfied:

$$f_c + \frac{1}{2}B_{\text{FM}} \leq 2 \left(f_c - \frac{1}{2}B_{\text{FM}} \right) \quad (20.48)$$

This condition is equivalent to ensuring that $f_c \geq 1.5B_{\text{FM}}$. By substituting the expressions for the bandwidths for NBFM and WBFM into the last equation, it is seen that the carrier frequency must satisfy the condition

$$f_c > \begin{cases} 3(\Delta f + W) & \text{for NBFM} \\ 3(\Delta f + 2W) & \text{for WBFM} \end{cases} \quad (20.49)$$

Note that in the case discussed earlier in which the nonlinearities are not time variant, the effect of passing an FM wave through a nonlinear channel or system, followed by a bandpass filter centered at the carrier frequency, is to produce a gain or attenuation in the constant amplitude. If the nonlinearities are time varying, so that the coefficients in the expression relating the channel input to the output are $a_0(t), a_1(t), a_2(t), \dots$, a substitution of these time-varying coefficients into the preceding equation shows that the bandpass filter output will be a time-variant amplitude version of the FM signal at the correct carrier frequency. As before, such amplitude variations can be removed with a bandpass limiter, prior to demodulation. Thus, unlike amplitude modulation, FM is fairly tolerant of channel nonlinearities. Hence, FM is widely used in microwave and satellite communication systems where the nonlinearities of the power amplifiers need to be well tolerated.

Phase Distortion in Angle Modulation

Angle modulation systems are very sensitive to phase nonlinearities because in such systems the information resides in the phase of the modulated signal. Phase distortion of the modulated wave eventually results in distortion of the demodulated output. Phase distortion can result from phase nonlinearities of channel, repeater, filter, or amplifier responses. It can also result from nonideal linear filtering of an angle modulated wave with a time-variant amplitude.

Let the input signal to a nonideal linear filter be an FM signal $s_1(t)$ with envelope $E_1(t)$ and phase $\phi_1(t)$. Let the FM wave have a residual amplitude modulation due to distortion previously acquired in the transmission channel. Let the output $s_2(t)$ of the filter have an envelope $E_2(t)$ and a phase $\phi_2(t)$. Then the input and output signal can be expressed, respectively, as

$$s_1(t) = E_1(t) \cos(\phi_1(t)) \quad (20.50)$$

$$s_2(t) = E_2(t) \cos(\phi_2(t)) \quad (20.51)$$

Note that although $s_2(t)$ is a linear function of $s_1(t)$, both the phase and the envelope of the output signal are nonlinear functions of the output signal $s_2(t)$. Hence, they are both nonlinear functions of the input signal $s_1(t)$. Thus, in general, amplitude modulation at the input to a linear filter results in phase modulation at the output. This is known as AM–PM conversion. On the other hand, phase modulation at the input to a linear filter results in residual amplitude modulation at the filter output. This is known as PM–AM conversion. PM–AM conversion does not present much of a problem in angle modulated systems, since the resulting residual amplitude modulation is easily remedied with the aid of bandpass limiters. However, AM–PM conversion presents a great problem in angle modulated systems because it is usually not possible to separate the resulting phase distortion from the demodulated signal.

In addition to the mechanism just described, phase nonlinearities of amplifiers, filters, repeaters, etc., also cause AM–PM conversion. This type of distortion is common in microwave systems where it results from the dependence of the phase characteristic of the repeaters and amplifiers on the envelope of the input signal. Typically, the phase change $\Delta\phi_2(t)$ in the output signal is proportional to the corresponding change, in decibel, of the envelope of the input signal. Let k°/dB be the constant of proportionality relating the change $\Delta E_1(t)$ in the envelope of the input signal $E_1(t)$ to the phase change in the output signal. Then the phase change is given by

$$\Delta\phi_2(t) = k20 \log \frac{\Delta E_1(t)}{E_1(t)} \quad (20.52)$$

20.3.6 Interference as a Radio Frequency Distortion Mechanism

Interference here refers to the corruption of the received signal in the desired channel by adjacent or nearby channels. Although each channel has an assigned bandwidth, adjacent channel interference often occurs because practical transmission filters do not provide infinite signal suppression outside the desired or assigned bandwidth. Adjacent channel interference from a strong channel can be disastrous for a weak channel. The effect of interference will be discussed for AM, DSB-SC AM, SSB-SC AM, and angle modulation. For each case, f_c will represent the carrier frequency of the desired channel, whereas $f_c + \Delta f$ will represent the carrier frequency of the interfering signal. For simplicity, the interference will be regarded as an unmodulated carrier of amplitude A_i and the phase angle between the interference and the desired modulated wave will be ignored. Thus, the interference $r_i(t)$ at the receiver input is

$$r_i(t) = A_i \cos(2\pi(f_c + \Delta f)t) \quad (20.53)$$

Interference in Amplitude Modulation

In the case of AM, demodulation is performed by passing the received signal through an envelope detector. The received signal, which consists of the desired AM signal with carrier amplitude A_c , and the interference is given by

$$\begin{aligned} r(t) &= (A_c + m(t)) \cos(2\pi f_c t) + A_i \cos 2\pi(f_c + \Delta f)t \\ &= (A_c + m(t) + A_i \cos 2\pi \Delta f t) \cos(2\pi f_c t) - A_i \sin(2\pi \Delta f t) \sin(2\pi f_c t) \\ &= E(t) \cos(2\pi f_c t + \phi(t)) \end{aligned} \quad (20.54)$$

In the last equation, $E(t)$ is the envelope and $\phi(t)$ is the phase of the received signal. The phase is not relevant to the present discussion. The envelope is given by

$$E(t) = \{(A_c + m(t) + A_i \cos(2\pi \Delta f t))^2 + A_i^2 \sin^2(2\pi \Delta f t)\}^{\frac{1}{2}} \quad (20.55)$$

From the expression for the envelope, it is easy to see that if $A_i \ll A_c$, the envelope is approximated by

$$E(t) \approx A_c + m(t) + A_i \cos 2\pi \Delta f t \quad (20.56)$$

FIGURE 20.54 Illustration of interference in AM: (a) amplitude spectrum of AM wave plus interference, (b) amplitude spectrum of demodulated message signal plus interference.

Note that A_c in the last equation can be removed by DC blocking to yield the demodulator output $y(t)$. Let M be the peak amplitude of the message signal. Then it is observed that M/A_i , the ratio of the peak message signal amplitude to the peak interference amplitude, is equal at the input and the output of the receiver. Thus, for the case of small interference, the interference is additive at the demodulator output, and demodulation does not increase or decrease the strength of the interference relative to the message signal. The case for small interference is illustrated in Fig. 20.54. Figure 20.54(a) illustrates the spectrum of the modulated signal and the interference at the receiver input. Figure 20.54(b) illustrates the spectrum of the envelope detector output.

For the case in which the interference amplitude is much larger than the carrier amplitude for the desired channel, the envelope $E(t)$ can be approximated by

$$E(t) \approx (A_c + m(t)) \cos 2\pi \Delta f t + A_i \tag{20.57}$$

In this case, after the constant A_i is blocked with a capacitor, the demodulated output consists of the message signal multiplied by the interference, $\cos 2\pi \Delta f t$ and an additive component of the interference, $A_i \cos 2\pi \Delta f t$. The effect of interference is much worse in this case because the multiplicative interference results in serious distortion.

Interference in DSB-SC AM

Consider the synchronous demodulation of a DSB-SC signal plus the interfering sinusoid previously described. The same receiver of Fig. 20.49 is employed, but in this case, the phase and frequency errors between the received and the local carriers are ignored. The received signal plus interference $r(t)$, the product modulator output $x(t)$, and the demodulated output of the low-pass filter $y(t)$, are given, respectively, by

$$r(t) = m(t) \cos 2\pi f_c t + A_i \cos(2\pi (f_c + \Delta f)t) \tag{20.58}$$

$$x(t) = \frac{1}{2}m(t)(1 + \cos 4\pi f_c t) + \frac{1}{2}A_i(\cos 2\pi \Delta f t + \cos(4\pi f_c t + 2\pi \Delta f t)) \tag{20.59}$$

$$y(t) = \frac{1}{2}m(t) + \frac{1}{2}A_i \cos 2\pi \Delta f t \tag{20.60}$$

The last equation shows that for DSB-SC, the effect of interference is additive to the message signal at the demodulator output. Moreover, the ratio of the peak message output to the interference output M/A_i is equal at both the input and the output of the receiver.

Interference in SSB-SC

The analysis and the results in this case are very similar to those for DSB-SC. The same receiver is employed for both cases. In this case, the received signal plus interference, the product modulator output, and the demodulated output of the low-pass filter are given, respectively, by

$$r(t) = m(t) \cos 2\pi f_c t \mp m_h(t) \sin 2\pi f_c t + A_i \cos 2\pi (f_c + \Delta f)t \tag{20.61}$$

$$x(t) = \frac{1}{2}m(t)(1 + \cos 4\pi f_c t) \mp \frac{1}{2}M_h(t) \sin 4\pi f_c t + \frac{1}{2}A_i(\cos 2\pi \Delta f t + \cos(4\pi f_c t + 2\pi \Delta f t)) \tag{20.62}$$

$$y(t) = \frac{1}{2}m(t) + \frac{1}{2}A_i(t) \cos 2\pi \Delta f t \tag{20.63}$$

The demodulated output in the last equation shows that the effect of interference on SSB-SC is the same as formerly described for DSB-SC. Comparing these results with the AM case, it is easy to see that for small interference, the effect is about the same for AM as for DSB-SC and SSB-SC. However, AM performance is quite inferior to the other two in the case of large interference.

Interference in Angle Modulation

Consider for simplicity, only the unmodulated carrier of an angle modulated wave of carrier frequency f_c given by $A_c \cos 2\pi f_c t$. For the sake of simplicity, the interference is also considered to be the unmodulated sinusoid $A_i \cos 2\pi (f_c + \Delta f)t$. The signal at the input to the receiver is

$$\begin{aligned} r(t) &= A_c \cos 2\pi f_c t + A_i \cos 2\pi (f_c + \Delta f)t \\ &= (A_c + A_i \cos 2\pi \Delta f t) \cos 2\pi f_c t - A_i \sin 2\pi \Delta f t \sin 2\pi f_c t \\ &= E(t) \cos(2\pi f_c t + \phi(t)) \end{aligned} \tag{20.64}$$

In the last equation, $E(t)$ is the envelope of the received signal, whereas $\phi(t)$ is its phase. In angle modulated waves, the phase, but not the envelope, is relevant to the demodulator output. The phase is given by

$$\begin{aligned} \phi(t) &= \tan^{-1} \left(\frac{-A_i \sin 2\pi \Delta f t}{A_c + A_i \cos 2\pi \Delta f t} \right) \\ &\approx -\frac{A_i \sin 2\pi \Delta f t}{A_c} \quad \text{for } A_i \ll A_c \end{aligned} \tag{20.65}$$

For PM, the demodulated signal is given by

$$y(t) = \phi(t) = -\frac{A_i}{A_c} \sin 2\pi \Delta f t \tag{20.66}$$

For FM, the demodulated signal is given by

$$y(t) = \phi'(t) = -\frac{2\pi \Delta f A_i}{A_c} \cos 2\pi \Delta f t \tag{20.67}$$

The last two equations show that for FM, the amplitude of the interference in the demodulated output is proportional to Δf , the difference between the carrier frequencies of the desired channel and the interference. On the other hand, the interference amplitude is constant for all values of Δf in the case of PM. These differences are illustrated in Fig. 20. 55.

The last two equations also show that for both FM and PM, the interference at the demodulator **FIGURE 20.55** Effect of interference in angle modulation.

output is inversely proportional to A_c , the amplitude of the carrier of the desired channel. Thus, the stronger the desired channel and the weaker the interference, the smaller is the effect of the interference. This is superior in performance to amplitude modulated systems in which, at the very best, the interference is independent of the carrier amplitude. In effect, angle modulated systems suppress weak interference. This statement gives a clue to the behavior of angle modulated systems in the presence of large interference. When the interference is large relative to the desired signal, the so-called **capture effect** sets in. The interference now assumes the role of the desired channel and effectively suppresses the weaker desired channel, in the same way that a weak interference would have been suppressed.

Defining Terms

Capture effect: In angle modulation, the demodulated output of the weaker of two interfering signals is inversely proportional to the amplitude of the stronger signal. Consequently, the stronger signal or channel suppresses the weaker channel. If the stronger signal is noise or an undesired channel, it is said to have captured the desired channel.

Crosstalk: Interference between adjacent communication channels in which an interfering adjacent channel is heard or received in the desired channel.

Dispersion: The variation of wave propagation velocity (or time delay) in a medium with the frequency of the wave, which results in the spreading of the output signal over a time duration greater than the duration of the input signal.

Ionosphere: The ionosphere consists of several layers of the upper atmosphere, ranging in altitude from 100 to 300 km, containing ionized particles. The ionization is due to the effect of solar radiation, particularly ultraviolet and cosmic radiations, on gas particles. The ionosphere serves as reflecting layers for radio (sky) waves.

Pilot carrier: A means of providing a carrier at the receiver, which matches the received carrier in phase and frequency. In this method, which is employed in suppressed carrier modulation systems, a carrier of very small amplitude is inserted into the modulated signal prior to transmission, extracted and amplified in the receiver, and then employed as a matching carrier for coherent detection.

Radio horizon: The maximum range, from transmitter to receiver on the Earth's surface, of direct (line-of-sight) radio waves. This is greater than the optical horizon because the radio waves follow a curved path as a result of the continuous refraction it undergoes in the atmosphere.

Troposphere: The region of the atmosphere within about 10 km of the Earth's surface. Within this region, the wireless radio channel is modified relative to free space conditions by weather conditions, pollution, dust particles, etc. These inhomogeneities act as point scatterers which deflect radio waves downward to reach the receiving antennas, thereby providing tropospheric scatter propagation.

20.4 Oscilloscopes

Jerry C. Whitaker

20.4.1 Introduction

The oscilloscope is one of the most general-purpose of all test instruments. A scope can be used to measure voltages, examine waveshapes, check phase relationships, examine clock pulses, and countless other functions. There has been considerable progress in scope technology within the past few years, most noticeably the move to digital systems. Some instruments offer logic tracing functions, and a hard copy printout.

20.4.2 Specifications

A number of parameters are used to characterize the performance of an oscilloscope. Key parameters include bandwidth and risetime.

Bandwidth

Oscilloscope bandwidth is defined as the frequency at which a sinusoidal signal will be attenuated by a factor of 0.707 (or reduced to 70.7% of its maximum value). This is referred to as the -3 dB point. Bandwidth considerations for sine waves are straightforward. For square waves and other complex waveforms, however, bandwidth considerations become substantially more involved.

Square waves are made up of an infinite number of sine waves: the fundamental frequency plus mostly odd harmonics. Fourier analysis shows that a square wave consists of the fundamental sine wave plus sine waves that are odd multiples of the fundamental. Figure 20.56 illustrates the mechanisms involved. The fundamental frequency contributes about 81.7% of the square wave. The third harmonic contributes about 9.02%, and the fifth harmonic about 3.24%. Higher harmonics contribute less to the shape of the square wave. As outlined here, approximately 94% of the square wave is derived from the fundamental and the third and fifth harmonics. Inaccuracies introduced by the instrument are typically 2% or less. The user's ability to read a conventional CRT display may contribute another 4% error. Thus, a total of 6% error may be introduced by the instrument and the operator. A 96% accurate reproduction of a square wave

FIGURE 20.56 The mechanisms involved in square waves: (a) individual waveforms involved, (b) waveshape resulting from combining the fundamental and the first odd harmonic (the third harmonic), (c) waveshape resulting from combining the fundamental and the first, third, and fifth harmonics.

should, therefore, be sufficient for all but the most critical applications. It follows that scope bandwidth is important up to and including the fifth harmonic of the desired signal.

Rise Time

The rise time performance required of an oscilloscope depends on the degree of accuracy needed in measuring the input signals. A 2–3% rise time accuracy can be obtained from an instrument that is specified to have approximately five times the rise time of the signal being measured. Rise time can be determined from the bandwidth of the instrument

$$T_r = \frac{0.35}{BW} \quad (20.68)$$

Where

T_r = instrument rise time

BW = instrument bandwidth

Making Measurements

The oscilloscope is a measurement instrument, displaying voltage waveforms within powered circuits. To conduct certain types of waveform analysis, a separate signal generator is required to inject test signals. With a conventional analog oscilloscope, actual measurement of the waveform must be done visually by the operator. The graticule divisions along the trace are counted and multiplied by the time base setting to determine the time interval. The TIME/DIV control determines the value of each increment on the X-axis of the display. Typical sweep ranges vary from 0.05 to 0.5 μs per division. To determine voltage, the operator must estimate the height of a portion of the trace and multiply it by the voltage range selected on the instrument. The VOLT/DIV control determines the value of each increment on the Y-axis of the display. On a dual channel scope, two controls are provided, one for each source. Typical vertical sensitivity ranges vary from 5 mV to 5 V per division.

The need for interpolation introduces inaccuracies in the measurement process. Determination of exact values is especially difficult in the microsecond ranges, where even small increments can make a big difference in the measurement. It is also difficult with a conventional scope to make a close-up examination of specific portions of a waveform. For this purpose, an oscilloscope with two independently adjustable sweep generators is recommended. A small section of the waveform can be selected for closer examination by adjusting the B channel sweep-time and delay-time controls while observing an intensified portion of the waveform. The intensified section can then be expanded across the screen. This type of close-up examination is useful for measuring pulse rise times and viewing details in complex signals, such as video horizontal sync or color burst.

Advanced Features

Modern oscilloscopes remove the potential inaccuracies of previous instruments by incorporating advanced features, including

- Numeric measurement and display. On-screen readouts provide key measurement parameters for the operator. Readout options include peak waveform voltage, frequency, and sweep and sensitivity settings for the instrument. On-screen readout makes waveform photography or screen capture more valuable because the photograph displays not only the waveform, but instrument settings as well.
- Triggering. A wide selection of trigger modes provides operational flexibility. The trigger mode determines what condition starts the horizontal sweep to display the voltage waveform. The trigger signal can be derived from an external source, or from the input channel(s). The trigger is usually continuously adjustable through both positive and negative slopes of the signal. Selectable trigger coupling includes special settings needed in particular applications. A variable hold-off control can be used to obtain a stable display when measuring periodic or complex signals.
- Control and monitoring. Microprocessors have been integrated into scopes to reduce the number of mechanical switch contacts, which are prone to failure, and to permit front-panel setting recall capabilities. Auxiliary signal outputs are available to feed other instruments, such as a distortion analyzer or frequency counter.

20.4.3 Digital Oscilloscope

The digital storage oscilloscope (DSO) offers a number of significant advantages beyond the capabilities of analog instruments. A DSO can store in memory the signal being observed, permitting in-depth analysis impossible with previous technology. Because the waveform resides in memory, the data associated with the waveform can be transferred to a computer for real-time processing, or for processing at a later time.

Operating Principles

Before the introduction of the DSO, the term *storage oscilloscope* referred to a scope that used a *storage* CRT. This type of instrument stored the display waveform as a trace on the scope face. The digital storage oscilloscope operates on a completely different premise. Figure 20.57 shows a block diagram of a DSO. Instead of being amplified and directly applied to the deflection plates of a CRT, the waveform is first converted into a digital form and stored in memory. To reproduce the waveform on the CRT, the data are sequentially read and converted back into an analog signal for display.

The analog-to-digital (A/D) converter transforms the input analog signal into a sequence of digital bits. The amplitude of the analog signal, which varies continuously in time, is sampled at preset intervals. The analog value of the signal at each sample point is converted into a binary number. This *quantization* process is illustrated in Fig. 20.58. The sample rate of a digital oscilloscope must be greater than two times the highest frequency to be measured. The higher the sampling rate relative to the input signal, the greater the measurement accuracy. A sample rate 10 times the input signal is sufficient for most applications. This rule-of-thumb applies for single-shot signals, or signals that are constantly changing. The sample rate may also be expressed as the *sampling interval*, or the period of time between samples. The sample interval is the inverse of the sampling frequency.

FIGURE 20.57 Simplified block diagram of a digital storage oscilloscope.

FIGURE 20.58 The quantization process.

Although a DSO is specified by its maximum sampling rate, the actual rate used in acquiring a given waveform is usually dependent on the *time-per-division* setting of the oscilloscope. The *record length* (samples recorded over a given period of time) defines a finite number of sample points available for a given acquisition. The DSO must, therefore, adjust its sampling rate to fill a given record over the period set by the sweep control. To determine the sampling rate for a given sweep speed, the number of displayed points per division is divided into the sweep rate per division. Two additional features can modify the actual sampling rate:

- Use of an external clock for pacing the digitizing rate. With the internal digitizing clock disabled, the digitizer will be paced at a rate defined by the operator.
- Use of a *peak detection* (or *glitch capture*) mode. Peak detection allows the digitizer to sample at the full digitizing rate of the DSO, regardless of the time base setting. The minimum and maximum values found between each normal sample interval are retained in memory. These minimum and maximum values are used to reconstruct the waveform display with the help of an algorithm that recreates a smooth trace along with any captured glitches. Peak detection allows the DSO to capture glitches even at its slowest sweep speed. For higher performance, a technique known as *peak-accumulation* (or *envelope mode*) may be used. With this approach, the instrument accumulates and displays the maximum and minimum excursions of a waveform for a given point in time. This builds an envelope of activity that can reveal infrequent noise spikes, long-term amplitude or time drift, and pulse jitter extremes.

A/D Conversion

The A/D conversion process is critical to the overall accuracy of the oscilloscope. Three types of converters are commonly used:

- Flash converter
- Successive approximation converter
- Charge-coupled device (CCD) converter

The CCD is an analog storage array. The DSO can capture high-speed events in real time using a CCD, then route the captured information to be digitized to low cost A/D converters.

Conversion resolution is determined by the number of bits into which the analog signal is transformed. The higher the number of bits available to the A/D converter, the more discrete levels the digital signal is able to describe. For example, an 8-bit digitizer has 256 levels, while a 10-bit digitizer has 1024 levels. Although a higher number of bits allows greater discrimination between voltage values, the overall accuracy of the DSO may be limited by other factors, including the accuracy of the analog amplifier(s) feeding the digitizer(s). The usefulness of a high conversion digitizer may also be limited by the resolution of the display screen.

FIGURE 20.59 Increasing sample density through equivalent-time-sampling.

While most DSOs provide 8-bit digitizing, there may be significant differences between individual 8-bit instruments. First among these is the *useful storage bandwidth*. This specification is further divided into *single-shot bandwidth* and *equivalent-time bandwidth*.

Achieving adequate samples for a high frequency waveform places stringent requirements on the sampling rate. High frequency waveforms require high sampling rates. Equivalent-time sampling is often used to provide high-bandwidth capture. This technique relies on sampling a repetitive waveform at a low rate to build up sample density. This concept is illustrated in Fig. 20.59. When the waveform to be acquired triggers the DSO, several samples are taken over the duration of the waveform. The next repetition of the waveform triggers the instrument again, and more samples are taken at different points on the waveform. Over many repetitions, the number of stored samples can be built up to the equivalent of a high sampling rate.

System operating speed also has an effect on the display update rate. Update performance is critical when measuring waveform or voltage changes. If the display does not track the changes, adjustment of the circuit may be difficult.

DSO System Design

A detailed block diagram of a basic DSO is shown in Fig. 20.60. The features included in this design are typical of a digital scope. The major circuit blocks are

- **Data acquisition**—converts the analog input signal into a digital equivalent for storage. Data control signals are routed to a microprocessor through an I/O port.
- **Data processing**—provides interpolation of the stored data for reproduction of the analog signal on the CRT or other display device. The processed data are transferred to the display memory. Except during transfer periods, the contents of the display memory are constantly being sent to the digital-to-analog (D/A) converter and displayed on the CRT.
- **Vertical deflection**—generates the vertical deflection voltages for the CRT. The input signal is impedance-matched and amplified by the Channel 1 and Channel 2 preamplifiers to a level suitable for driving subsequent stages. Channel selection switches operate under control of the microprocessor.
- **Horizontal deflection**—generates the necessary voltages to deflect the beam spot horizontally across the screen. The stage includes trigger and sweep circuits. The horizontal deflection stage also acts as an X-axis amplifier for X-Y operation. Channel selection switches operate under control of the microprocessor.
- **CRT driver**—provides the high voltages necessary to drive the CRT, and controls the Z-axis of the CRT. The Z-axis circuit sets the intensity and focus of the CRT beam spot. For other types of display devices, such as LCD or plasma units, the appropriate functions are performed in this block.
- **Power supplies**—provides the necessary low voltages for other stages of the instrument.
- **Calibration circuit**—provides a reference signal for calibration of the oscilloscope probe, and for operation of the amplifiers in the noncalibrated mode.

DSO Features

The digital oscilloscope has become a valuable tool in troubleshooting both analog and digital products. Advanced components and construction techniques have led to lower costs for digital scopes and higher performance. Digital scopes can capture and analyze transient signals, such as race conditions, clock jitter, glitches, dropouts, and intermittent faults. Automated features reduce testing and troubleshooting costs through the use of recallable instrument setups, direct parameter readout, and unattended monitoring. Digital oscilloscopes have inherent benefits not available on most analog oscilloscopes. These benefits include

- Increased resolution (determined by the quality of the analog-to-digital converter).
- Memory storage of digitized waveforms.
- Automatic setup for repetitive signal analysis. For complex multichannel configurations that are used often, front-panel storage/recall features can save dozens of manual selections and adjustments. When multiple memory locations are available, multiple front-panel setups can be stored to save even more time.
- Auto-ranging. Many instruments will automatically adjust for optimum sweep, input sensitivity, and triggering. The instrument's microprocessor automatically configures the front panel for optimum display. Such features permit the operator to concentrate on making measurements, not on adjusting the scope.
- Instant hardcopy output from printers and plotters.
- Remote programmability for automated test applications.
- Trigger flexibility. Single-shot digitizing oscilloscopes capture transient signals and allow the user to view the waveform which *preceded* the trigger point.
- Signal analysis. Intelligent scopes can make key measurements and comparisons. Display capabilities include voltage peak, mean voltage, RMS value, rise time, fall time, and frequency.
- Cursor measurement. Advanced oscilloscopes permit the operator to take measurements or perform comparative operations on data appearing on the display. A measurement cursor consists of a pair of lines or dots that can be moved around the screen as needed.
- Trace quality. Eye fatigue is reduced noticeably with a DSO when viewing low-repetition signals. For example, a 60 Hz waveform can be difficult to view for extended periods of time on a conventional scope because the display tends to flicker. A DSO overcomes this problem by writing waveforms to the screen at the same rate regardless of the input signal.

Capturing Transient Waveforms

Single-shot digitizing makes it possible to capture and clearly display transient and intermittent signals. Waveforms such as signal glitches, dropouts, logic race conditions, intermittent faults, clock jitter, and power-up sequences can be examined with the help of a digital oscilloscope. With single-shot digitizing, the waveform is captured the first time it occurs, on the first trigger. It can then be displayed immediately or held in memory for analysis at a later date.

Triggering

Basic triggering modes available on a digital oscilloscope permit the user to select the desired source, its coupling, level, and slope. More advanced digital scopes contain triggering circuitry similar to that found in a logic analyzer. These powerful features let the user trigger on elusive conditions, such as pulse widths less than or greater than expected, intervals less than or greater than expected, and specified logic conditions. The logic triggering can include digital pattern, state qualified, and time/event qualified conditions. Many trigger modes are further enhanced by allowing the user to hold-off the trigger by a selectable time or number of events. Hold-off is especially useful when the input signal contains bursts of data or follows a

repetitive pattern. These features are summarized as follows:

- *Pulse-width triggering* lets the operator quickly check for pulses narrower than expected or wider than expected. The pulse-width trigger circuit checks the time from the trigger source transition of a given slope (typically the rising edge) to the next transition of opposite slope (typically the falling edge). The operator can interactively set the pulse-width threshold for the trigger. For example, a glitch can be considered any signal narrower than 1/2 of a clock period. Conditions preceding the trigger can be displayed to show what events led up to the glitch.
- *Interval triggering* lets the operator quickly check for intervals narrower than expected or wider than expected. Typical applications include monitoring for transmission phase changes in the output of a modem or for signal dropouts, such as missing bits in a transport stream.
- *Pattern triggering* lets the user trigger on the logic state (high, low, or either) of several inputs. The inputs can be external triggers or the input channels themselves. The trigger can be generated either upon entering or exiting the pattern. Applications include triggering on a particular address select or data bus condition. Once the pattern trigger is established, the operator can probe throughout the circuit, taking measurement synchronous with the trigger.
- *State qualified triggering* enables the oscilloscope to trigger on one source, such as the input signal itself, only after the occurrence of a specified logic pattern. The pattern acts as an *enable* or *disable* for the source.

Advanced Features

Some digital oscilloscopes provide enhanced triggering modes that permit the user to select the level and slope for each input. This flexibility makes it easy to look for odd pulse shapes in the pulse-width trigger mode and for subtle dropouts in the interval trigger mode. It also simplifies testing different logic types (TTL, CMOS, and ECL), and testing analog/digital combinational circuits with dual logic triggering. Additional flexibility is available on multiple channel scopes. Once a trigger has been sensed, multiple simultaneously sampled inputs permit the user to monitor conditions at several places in the unit under test, with each channel synchronized to the trigger. Additional useful trigger features for monitoring jitter or drift on a repetitive signal include

- Enveloping
- Extremes
- Waveform delta
- Roof/floor

Each of these functions are related, and in some cases describe the same general operating mode. Various scope manufacturers use different nomenclature to describe proprietary triggering methods. Generally speaking, as the waveshape changes with respect to the trigger, the scope generates upper and lower traces. For every n th sample point with respect to the trigger, the maximum and minimum values are saved. Thus, any jitter or drift is displayed in the envelope.

Advanced triggering features provide the greatest benefit in conjunction with single-shot sampling. Repetitive sampling scopes can only capture and display signals that repeat precisely from cycle to cycle. Several cycles of the waveform are required to create a digitally-reconstructed representation of the input. If the signal varies from cycle to cycle, such scopes can be less effective than a standard analog oscilloscope for accurately viewing a waveform.

20.5 Spectrum Analysis

Jerry C. Whitaker

20.5.1 Introduction

An oscilloscope-type instrument displays voltage levels referenced to time and a spectrum analyzer indicates signal levels referenced to frequency. The frequency components of the signal applied to the input of the analyzer are detected and separated for display against a frequency-related time base. Spectrum analyzers are available in a variety of ranges, with some models designed for use with audio or video frequencies and others intended for use with RF frequencies.

The primary application of a spectrum analyzer is the measurement and identification of RF signals. When connected to a small receiving antenna, the analyzer can measure carrier and sideband power levels. By expanding the sweep width of the display, offset or multiple carriers can be observed. By increasing the vertical sensitivity of the analyzer and adjusting the center frequency and sweep width, it is possible to observe the occupied bandwidth of the RF signal. Convention dictates that the vertical axis displays amplitude and the horizontal axis displays frequency. This frequency-domain presentation allows the user to glean more information about the characteristics of an input signal than is possible from an oscilloscope. Figure 20.61 compares the oscilloscope and spectrum analyzer display formats.

Principles of Operation

A spectrum analyzer intended for use at RF frequencies is shown in block diagram form in Fig. 20.62. The instrument includes a superheterodyne receiver with a swept-tuned local oscillator (LO) that feeds a CRT display. The tuning control determines the center frequency (F_c) of the spectrum analyzer, and the *scan-width* selector determines how much of the frequency spectrum around the center frequency will be covered. Full-feature spectrum analyzers also provide front-panel controls for scan-rate selection and bandpass filter selection. Key specifications for a spectrum analyzer include

- **Resolution:** the frequency separation required between two signals so that they may be resolved into two distinct and separate displays on the screen. Resolution is usually specified for equal-level signals. When two signals differ significantly in amplitude and are close together in frequency, greater resolution is required to separate them on the display.
- **Scan width:** the amount of frequency spectrum that can be scanned and shown on the display. Scan width is usually stated in kilohertz or megahertz per division. The minimum scan width available is usually equal to the resolution of the instrument.

FIGURE 20.61 Comparison of waveform display: (A) oscilloscope, and (B) spectrum analyzer.

- *Dynamic range*: the maximum amplitude difference that two signals can have and still be viewed on the display. Dynamic range is usually stated in decibels.
- *Sensitivity*: the minimum signal level required to produce a usable display on the screen. If low-level signal tracing is planned, as in receiver or off-air monitoring, the sensitivity of the spectrum analyzer is important.

When using the spectrum analyzer, care must be taken not to overload the front-end with a strong input signal. Overloading can cause “false” signals to appear on the display. These false signals are the result of

FIGURE 20.62 Block diagram of a spectrum analyzer.

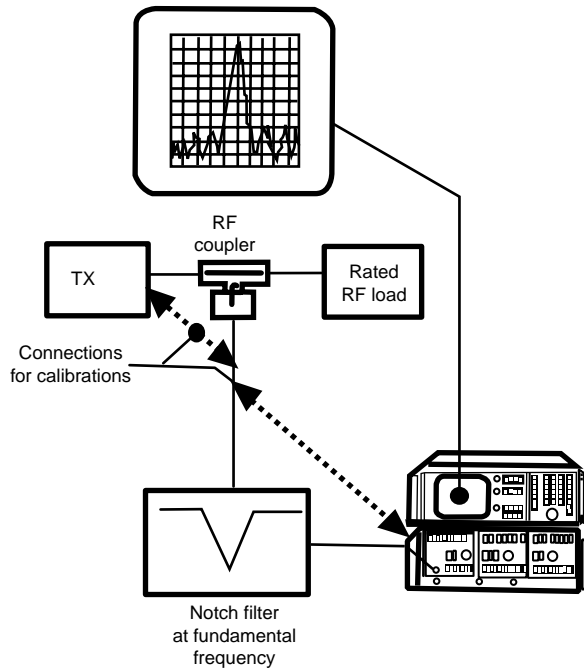

FIGURE 20.63 Typical test setup for measuring the harmonic and spurious output of a transmitter. The notch filter is used to remove the fundamental frequency to prevent overdriving the spectrum analyzer input.

nonlinear mixing in the front end of the instrument. False signals can be identified by changing the RF attenuator setting to a higher level. The amplitude of false signals (caused by overloading) will drop much more than the amount of increased attenuation.

The spectrum analyzer is useful in troubleshooting receivers as well as transmitters. As a tuned signal tracer, it is well adapted to stage-gain measurements and other tests. There is one serious drawback, however. The 50- Ω spectrum analyzer input can load many receiver circuits too heavily, especially high impedance circuits such as FET amplifiers. Isolation probes are available to overcome loading problems. Such probes, however, also attenuate the input signal, and unless the spectrum analyzer has enough reserve gain to overcome the loss caused by the isolation probe, the instrument will fail to provide useful readings. Isolation probes with 20 to 40 dB attenuation are typical. As a rule of thumb, probe impedance should be at least ten times the impedance of the circuit to which it is connected.

Applications

The primary application for a spectrum analyzer centers around measuring the occupied bandwidth of an input signal. Harmonics and spurious signals can be checked and potential causes investigated. Figure 20.63 shows a typical test setup for making transmitter measurements.

The spectrum analyzer is also well-suited for making accurate transmitter FM deviation measurements. This is accomplished using the *Bessel null method*. The Bessel null is a mathematical function that describes the relationship between spectral lines in frequency modulation. The Bessel null technique is highly accurate; it forms the basis for modulation monitor calibration. The concept behind the Bessel null method is to drive the carrier spectral line to zero by changing the modulating frequency. When the carrier amplitude is zero, the modulation index is given by a Bessel function. Deviation can be calculated from

$$\delta f_c = MI \times f$$

FIGURE 20.64 Using a spectrum analyzer to measure the tunnel effect of bandpass filters in a receiver.

where Δf_c is the deviation frequency, MI is the modulation index, and f_m is the modulating frequency. The carrier frequency “disappears” at the Bessel null point, with all power remaining in the FM sidebands.

A *tracking generator* can be used in conjunction with the spectrum analyzer to check the dynamic response of frequency-sensitive devices, such as transmitter isolators, cavities, ring combiners, duplexers, and antenna systems. A tracking generator is a frequency source that is locked in step with the spectrum analyzer horizontal trace rate. The resulting displays shows the relationship of the amplitude-vs.-frequency response of the device under test. The spectrum analyzer can also be used to perform gain-stage measurements. The combination of a spectrum analyzer and a tracking generator makes filter passband measurements possible. As measurements are made along the IF (intermediate frequency) chain of a receiver, the filter passbands become increasingly narrow, as illustrated in Fig. 20.64.

On-Air Measurements

The spectrum analyzer is used for three primary on-air tests:

- *Measuring unknown signal frequencies.* A spectrum analyzer can be coupled to the out-put of a transmitter to determine its exact operating frequency.
- *Intermod and interference signal tracking.* A directional Yagi antenna can be used to identify the source of an interfering signal. If the interference is on-frequency but carries little intelligence, chances are good that it is an intermod being produced by another transmitter. Use the wide dispersion display mode of the analyzer and note signal spikes that appear simultaneously with the interference. A troubleshooter, armed with a spectrum analyzer, a directional antenna, and the

knowledge of how intermod signals are generated, can usually locate a suspected transmitter rapidly. Each suspected unit can then be tested individually by inserting an isolator between the transmitter PA and duplexer (or PA and antenna). When the intermod signal amplitude drops the equivalent of the reverse insert loss of the isolator, the offending transmitter has been located.

- *Field strength measurements.* With an external antenna, a spectrum analyzer can be used for remote field strength measurements. Omnidirectional, broadband antennas are the most versatile because they allow several frequency bands to be checked simultaneously. Obviously, the greater the external antenna height, the greater the testing range.

Spurious Harmonic Distortion

An incorrectly tuned or malfunctioning transmitter can produce spurious harmonics. The spectrum analyzer provides the best way to check for spectral purity. Couple a sample of the transmitter output signal to the analyzer input, either by loop coupling or RF sampling, as illustrated in Fig. 20.65. For low power levels from portable and mobile units, transmit into a dummy load and use a flexible rubber antenna on the analyzer input. For maximum accuracy when measuring larger amounts of power, use an RF sampler to control the input level to the analyzer. Use maximum RF attenuation initially on the analyzer front end to prevent overload damage and internal intermod. False signals on the display can also be observed if covers or shields are not in place on the radio under test. The oscillator, doubler, or tripler levels may radiate sufficient signals to register on the analyzer display.

Energize the transmitter and observe any spurious harmonics on the analyzer display. After centering the main signal of interest and adjusting the input attenuation for maximum display amplitude, calculate the spurious radiation. Spurious signal attenuation is measured in decibels, referenced to the amplitude of the transmitter fundamental. When a radio transmitter has a harmonic distortion problem, the defective stage can usually be isolated by tuning each stage and observing the spurious harmonics on the analyzer display. When the defective stage is tuned, the harmonics either shift frequency or change in amplitude. Signal tracing, with a probe and heavy input attenuation, also helps to determine where the distortion first occurs. Overdriven stages are prime culprits.

Selective-Tuned Filter Alignment

The high input sensitivity and visual frequency-selective display of the spectrum analyzer provide the technician with an efficient analog tuning instrument. Injection circuits can be peaked quickly by loop coupling the analyzer input to the mixer section of a receiver. This is most helpful in tuning older radios when a service manual is not available. Radios without test points, or that require elaborate, specialized test sets, can be tuned in a similar manner. Portable radio transmitters can be tuned directly into their antennas for maximum signal strength. This reveals problems such as improper signal transfer to the antenna or a defective antenna.

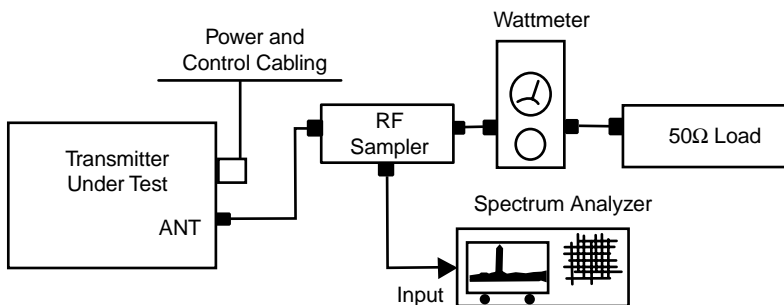

FIGURE 20.65 Common test setup to measure transmitter harmonic distortion with a spectrum analyzer.

FIGURE 20.66 Typical spectrum analyzer display of a single-cavity filter. Bandwidth (BW) = 458 to 465 MHz = 7 MHz. Filter $Q = f_{CT}/BW = 463 \text{ MHz}/7 \text{ MHz} = 66$. The trace shows 1-dB insertion loss.

Cavities, combiners, and duplexers are all selective-tuned filters. They are composed of three types of passive filters:

- Bandpass
- Band-reject
- Combination pass/reject

The spectrum analyzer is well-suited to tuning these types of filters, particularly duplexers. Couple the cavity between the tracking generator and the spectrum analyzer. Calibrate the tuning frequency in the center of the CRT display and adjust the generator output and analyzer input level for an optimal display trace. Then tune the cavity onto frequency. Measure the various filter characteristics and compare them to the manufacturer's specifications. Figure 20.66 shows a typical spectrum analyzer display of a single-cavity device. Important filter characteristics include frequency, bandwidth, insertion loss, and selectivity. Measure the bandwidth at the points 3 dB down from maximum amplitude. Insertion loss is equal to the cavity's attenuation of the center-tune frequency. Calculate filter Q (quality factor), which is directly proportional to selectivity, by dividing the filter center frequency (f_{CT}) by the bandwidth (BW) of the filter.

Duplexer tuning is similar to cavity tuning but is complicated by interaction between the multiple cavities. Using the test setup shown in Fig. 20.67, couple the tracking generator output to the duplexer antenna input. Alternately couple the receive and transmit ports to the spectrum analyzer while tuning the pass or reject performance of each cavity. When adjusting a combination cavity, tune the reject last because it will tend to follow the pass tuning. Alternate tuning between the receive and transmit sides of the duplexer until no further improvement can be gained. To ensure proper alignment, terminate all open ports into a 50- Ω load while tuning.

The duplexer insertion loss of each port can be measured as the difference between a reference amplitude and the pass frequency amplitude. The reference signal is measured by shorting the generator output cable to the analyzer input cable. This reference level nulls any cable losses to prevent them from being included in duplexer insertion loss measurements.

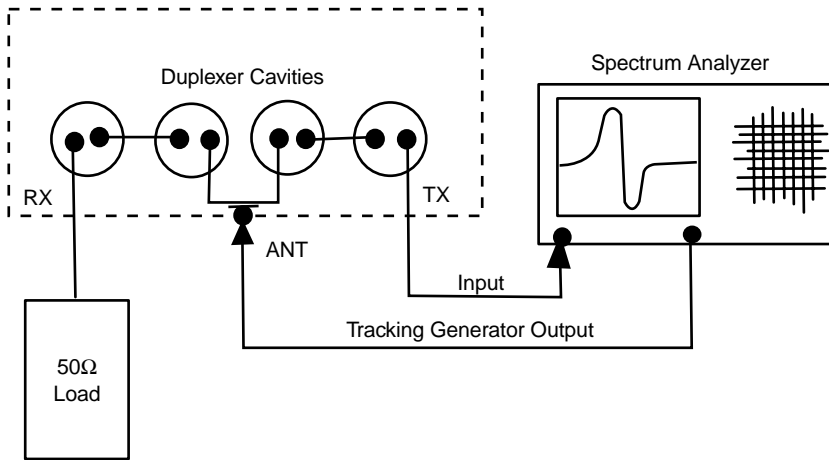

FIGURE 20.67 Test setup for duplexer tuning using a spectrum analyzer.

Small-Signal Troubleshooting

The spectrum analyzer is well-suited for use in small-signal RF troubleshooting. Stage gain, injection level, and signal loss can be easily checked.

Receiver sensitivity loss of less than 6 dB is usually a difficult problem to trace with most test instruments. Such losses are usually associated with the front end of the radio, either as a stage gain or injection amplifier deficiency. Before the spectrum analyzer was commonly available, there was little to aid a technician in tracing such a problem. An RF millivolt meter, with typical usable sensitivity of 1 mV, was of little help in troubleshooting such microvolt-level signals. Oscilloscopes are restricted in the same way, as well as having inadequate bandwidth for the high frequencies used in the front-end circuits of most receivers. A spectrum analyzer, with a typical $1 \mu\text{V}$ sensitivity and broad RF bandwidth, is well-adapted for RF troubleshooting. Microvolt-level signals can be accurately traced, allowing signal losses to be examined at each individual stage.

To conduct measurements, inject a test signal generated by a communications monitor into the antenna input of the radio under test. Use an appropriate probe to trace the signal from stage to stage. Stage gain, mixer output, injection level, and filter loss can be checked from the antenna to the discriminator. Compare measurements taken with those from a correctly functioning unit to isolate the problem. A standard test signal level of $100 \mu\text{V}$ usually works well. It is large enough to allow testing of the RF amplifier without causing overload. If the radio includes an automatic gain control (AGC) circuit, disable it temporarily during testing to permit measurement of the true stage gain.

When tracing a loss of sensitivity, start with the RF mixer. The mixer provides a junction point for narrowing the direction of troubleshooting. If the output of the mixer is correct, the defective stage lies beyond the mixer, probably in the IF amplifier. If the mixer output is low, check the input signal to the mixer. Check the RF amplifier, input cavities, and receive/transmit (RX/TX) switching circuit (if used). If the mixer IF carrier injection is low, check the multipliers and oscillators along that path.

The bandwidth of IF filters can be measured in circuit by varying the receiver input frequency and measuring the bandwidth of the 3-dB roll-off-points. A crystal bandpass filter can be tested for flaws by injecting an over-deviated signal into the receiver. A cracked filter crystal will produce a sharp, deep notch on the analyzer display. The key to comparative troubleshooting is accurate recording of test signal levels of a radio known to be working correctly prior to troubleshooting.

Remember to protect the front end of the analyzer from DC voltages and overload when tracing signals with a probe. When testing unknown signal levels, use maximum input attenuation and external attenuators as needed to avoid analyzer damage. Isolate the analyzer input from DC voltages using a capacitively coupled probe.

Defining Terms³

1 dB compression point: The point approaching saturation at which the output is 1 db less than it should be if the output linearly followed input.

Antenna sweep: A technique for measuring the return loss of an antenna to determine the antenna tuning.

Average detection: A detection scheme wherein the average (mean) amplitude of a signal is measured and displayed.

B-SAVE A (or B, C MINUS A): Waveform subtraction mode wherein a waveform in memory is subtracted from a second, active waveform and the result displayed on screen.

Band switching: Technique for changing the total range of frequencies (band) to which a spectrum analyzer can be tuned.

Baseband: The lowest frequency band in which a signal normally exists (often the frequency range of a receiver's output or a modulator's input); the band from DC to a designated frequency.

Baseline clipper: A means of blanking the bright baseline portion of the analyzer display.

Bessel functions: Solutions to a particular type of differential equation; predicts the amplitudes of FM signal components.

Bessel null method: A technique most often used to calibrate FM deviation meters. A modulating frequency is chosen such that some frequency component of the FM signal nulls at a specified peak deviation.

Calibrator: A signal generator producing a specified output used for calibration purposes.

Carrier-to-noise ratio (C/N): The ratio of carrier signal power to average noise power in a given bandwidth surrounding the carrier; usually expressed in decibels.

Center frequency: The frequency at the center of a given spectrum analyzer display.

Coax bands: The range of frequencies that can be satisfactorily passed via coaxial cable.

Comb generator: A source producing a fundamental frequency component and multiple components at harmonics of the fundamental.

Component: In spectrum analysis, usually denotes one of the constituent sine waves making up electrical signals.

Decibel (dB): Ten times the logarithm of the ratio of one electrical power to another.

Delta F (ΔF): A mode of operation on a spectrum analyzer wherein a difference in frequency may be read out directly.

Distortion: Degradation of a signal, often a result of nonlinear operations, resulting in unwanted signal components. Harmonic and intermodulation distortion are common types.

Dynamic range: The maximum ratio of two simultaneously present signals that can be measured to a specified accuracy.

Emphasis: Deliberate shaping of a signal spectrum or some portion thereof, often used as a means of overcoming system noise. Pre-emphasis is often used before signal transmission and de-emphasis after reception.

Envelope: The limits of an electrical signal or its parameters. For example, the modulation envelope limits the amplitude of an AM carrier.

Equivalent noise bandwidth: The width of a rectangular filter that produces the same noise power at its output as an actual filter when subjected to a spectrally flat input noise signal. Real filters pass different noise power than implied by their nominal bandwidths because their skirts are not infinitely sharp.

External mixers: A mixer, often in a waveguide format, that is used external to a spectrum analyzer.

Filter: A circuit that separates electrical signals or signal components based on their frequencies.

Filter loss: The insertion loss of a filter is the minimum difference, in decibels (dB), between the input signal level and the output level.

³Definitions courtesy of Tektronix, Beaverton, Oregon.

- First mixer input level:** Signal amplitude at the input to the first mixer stage of a spectrum analyzer. An optimum value is usually specified by the manufacturer.
- Flatness:** Unwanted variations in signal amplitude over a specified bandwidth, usually expressed in decibels (dB).
- Fourier analysis:** A mathematical technique for transforming a signal from the time domain to the frequency domain, and vice versa.
- Frequency:** The rate at which a signal oscillates, or changes polarity, expressed as hertz or number of cycles per second.
- Frequency band:** A range of frequencies that can be covered without switching.
- Frequency deviation:** The maximum difference between the instantaneous frequency and the carrier frequency of an FM signal.
- Frequency domain representation:** The portrayal of a signal in the frequency domain; representing a signal by displaying its sine wave components; the signal spectrum.
- Frequency marker:** An intensified or otherwise distinguished spot on a spectrum analyzer display that indicates a specified frequency point.
- Frequency range:** That range of frequencies over which the performance of the instrument is specified.
- Fundamental frequency:** The basic rate at which a signal repeats itself.
- Grass:** Noise or a noise-like signal giving the ragged, hashy appearance of grass seen close-up at eye level.
- Graticule:** The calibrated grid overlaying the display screen of spectrum analyzers, oscilloscopes, and other test instruments.
- Harmonic distortion:** The distortion that results when a signal interacts with a itself, often because of nonlinearities in the equipment, to produce sidebands at multiples, or harmonics, of the frequency components of the original signal.
- Harmonic mixing:** A technique wherein harmonics of the local oscillator signal are deliberately mixed with the input signal to achieve a large total input bandwidth. Enables a spectrum analyzer to function at higher frequencies than would otherwise be possible.
- Harmonics:** Frequency components of a signal occurring at multiples of the signal's fundamental frequency.
- Heterodyne spectrum analyzer:** A type of spectrum analyzer that scans the input signal by sweeping the incoming frequency band past one of a set of fixed RBW filters and measuring the signal level at the output of the filter.
- Intermediate frequency (IF):** In a heterodyne process, the sum of difference frequency at the output of a mixer stage which will be used for further signal processing.
- IF gain:** The gain of an amplifier stage operating at IF.
- Instantaneous frequency:** The rate of change of the phase of a sinusoidal signal at a particular instant.
- Intermodulation distortion:** The distortion that results when two or more signals interact, usually because of nonlinearities in the equipment, to produce new signals.
- Linear scale:** a scale wherein each increment represents a fixed difference between signal levels.
- LO output:** A port on a spectrum analyzer where a signal from the local oscillator (LO) is made available; used for tracking generators and external mixing.
- Local oscillator (LO):** An oscillator that produces the internal signal that is mixed with an incoming signal in a mixer to produce the IF signal.
- Logarithmic scale:** A scale wherein each scale increment represents a fixed ratio between signal levels.
- Magnitude-only measurement:** A measurement that responds only to the magnitude of a signal and is insensitive to its phase.
- MAX HOLD:** A spectrum analyzer feature that captures the maximum signal amplitude at all displayed frequencies over a series of sweeps.
- Max span:** The maximum frequency span that can be swept and displayed by a spectrum analyzer.
- MAX/MIN:** A display mode on some spectrum analyzers that shows the maximum and minimum signal levels at alternate frequency points, its advantage is its resemblance to an analog display.

- Maximum input level:** The maximum input signal amplitude that can be safely handled by a particular instrument.
- MIN HOLD:** A spectrum analyzer feature that captures the minimum signal amplitude at all displayed frequencies over a series of sweeps.
- Mixing:** The process whereby two or more signals are combined to produce sum and difference frequencies of the signals and their harmonics.
- Noise:** Unwanted random disturbances superimposed on a signal that tends to obscure it.
- Noise bandwidth:** The frequency range of a noise-like signal. For white noise, the noise power is directly proportional to the bandwidth of the noise.
- Noise floor:** The self-noise of an instrument or system that represents the minimum limit at which input signals can be observed. The spectrum analyzer noise floor appears as a “grassy” baseline in the display, even when no signal is present.
- Noise sideband:** Undesired response caused by noise internal to the spectrum analyzer appearing on the display immediately around a desired response, often having a pedestal-like appearance.
- Peak/average cursor:** A manually controllable function that enables the user to set the threshold at which the type of signal processing changes prior to display in a digital storage system.
- Peak detection:** A detection scheme wherein the peak amplitude of a signal is measured and displayed. In spectrum analysis, $20 \log(\text{peak})$ is often displayed.
- Peaking:** The process of adjusting a circuit for maximum amplitude of a signal by aligning internal filters. In spectrum analysis, peaking is used to align preselectors.
- Period:** The time interval at which a process recurs; the inverse of the fundamental frequency.
- Phase lock:** The control of an oscillator or signal generator so as to operate at a constant phase angle relative to a stable reference signal source. Used to ensure frequency stability in spectrum analyzers.
- Preselector:** A tracking filter located ahead of the first mixer that allows only a narrow band of frequencies to pass into the mixer.
- Products:** Signal components resulting from mixing or from passing signals through other nonlinear operations such as modulation.
- Pulse stretcher:** Pulse shaper that produces an output pulse whose duration is greater than that of the input pulse and whose amplitude is proportional to that of the peak amplitude of the input pulse.
- Pulse repetition frequency (PRF):** The frequency at which a pulsing signal recurs; equal to the fundamental frequency of the pulse train.
- Reference level:** The signal level required to deflect the CRT display to the top graticule line.
- Reference-level control:** The control used to vary the reference level on a spectrum analyzer.
- Resolution bandwidth (RBW):** The width of the narrowest filter in the IF stages of a spectrum analyzer. The RBW determines how well the analyzer can resolve or separate two or more closely spaced signal components.
- Return loss:** The ration of power sent to a system to that returned by the system. In the case of antennas, the return loss can be used to find the SWR.
- Ring:** A transient response wherein a signal initially performs a damped oscillation about its steady-state value.
- SAVE function:** A feature of spectrum analyzers incorporating display storage that enables them to store displayed spectra.
- Sensitivity:** Measure of a spectrum analyzer’s ability to display minimum level signals at a given IF bandwidth, display mode, and any other influencing factors.
- Shape factor:** In spectrum analysis, the ratio of an RBW filter’s 60-dB bandwidth to its 3-dB or 6-dB width (depending on manufacturer).
- Sideband:** Signal components observable on either or both sides of a carrier as a result of modulation or distortion processes.
- Sideband suppression:** An amplitude modulation technique wherein one of the AM sidebands is deliberately suppressed, usually to conserve bandwidth.

- Single sweep:** Operating mode in which the sweep generator must be reset for each sweep. Especially useful for obtaining single examples of a signal spectrum.
- Span per division, Span/Div:** Frequency difference represented by each major horizontal division of the graticule.
- Spectrum:** The frequency domain representation of a signal wherein it is represented by displaying its frequency distribution.
- Spurious response:** An undesired extraneous signal produced by mixing, amplification, or other signal-processing technique.
- Stability:** The property of retaining defined electrical characteristics for a prescribed time and in specified environments.
- Starting frequency:** The frequency at the left-hand edge of the spectrum analyzer display.
- Sweep speed, sweep rate:** The speed or rate, expressed in time per horizontal divisions, at which the electron beam of the CRT sweeps the screen.
- Time-domain representation:** Representation of signals by displaying the signal amplitude as a function of time. Typical of oscilloscope and waveform monitor displays.
- Time-varying signal:** A signal whose amplitude changes with time.
- Total span:** The total width of the displayed spectrum. The Span/Div times the number of divisions.
- Tracking generator:** A signal generator whose output frequency is synchronized to the frequency being analyzed by the spectrum analyzer.
- Ultimate rejection:** The ratio, in dB, between a filter's passband response and its response beyond the slopes of its skirts.
- Vertical scale factor, vertical display factor:** The number of dB, volts, etc. represented by one vertical division of a spectrum analyzer display screen.
- Waveform memory:** Memory dedicated to storing a digital replica of a spectrum.
- Waveform subtraction:** A process wherein a saved waveform can be subtracted from a second, active waveform.
- Zero hertz peak:** A fictitious signal peak occurring at zero hertz that conveniently marks zero frequency. The peak is present regardless of whether or not there is an input signal.
- Zero span:** A spectrum analyzer mode of operation in which the RBW filter is stationary at the center frequency; the display is essentially a time-domain representation of the signal propagated through the RBW filter.

20.6 Fourier Waveform Analysis

Jerry C. Hamann and John W. Pierre

20.6.1 Introduction

Fourier waveform analysis originated in the early 1800s when Baron Jean Baptiste Joseph Fourier (1768–1830), a French mathematical physicist, developed these methods for investigating the conduction of heat in solid bodies. Fourier contended that rather complex **continuous-time waveforms** could be

decomposed into a summation of simple trigonometric functions, sines and cosines of differing frequencies and magnitudes. When Fourier announced his results at a meeting of the French Academy of Scientists in 1807, his claims drew strong criticism from some of the most prominent mathematicians of the time, most notably Lagrange. Publication of his work in-full was delayed until 1822 when his seminal book, *Theorie Analytique de la Chaleur* (*The Analytical Theory of Heat*), was finally released. Technical doubts regarding Fourier's methods were largely dispelled by the late 19th century through the efforts of Dirichlet, Riemann, and others.

Following this somewhat rocky beginning, the concepts of Fourier analysis have found application in many fields of science, mathematics, and engineering. Indeed, the study of Fourier techniques is now a traditional undertaking within undergraduate electrical engineering programs. With the availability of computers, Fourier techniques have matured dramatically in the analysis of **discrete-time waveforms**. The now ubiquitous **fast Fourier transform (FFT)** is a somewhat general title applied to efficient algorithms for the machine computation of *discrete Fourier transforms* (DFTs).

20.6.2 The Mathematical Preliminaries for Fourier Analysis

The analysis techniques described in the following four sections can be conveniently categorized based on the variety of waveform or function to which they apply. A summary of useful properties of the analysis methods is provided in Table 20.2. We proceed herein to examine the mathematical preliminaries for the Fourier methods.

Most if not all **periodic** and **aperiodic** continuous-time **waveforms** $x(t)$, of practical interest, have Fourier series or Fourier transform counterparts. However, to aid in the existence question, the following sufficient technical constraints on the function $x(t)$, known generally as the *Dirichlet conditions*, guarantee convergence of the Fourier technique:

1. The function must be **single-valued**.
2. The function must have a finite number of discontinuities in the periodic interval, or, if aperiodic, about the entire real line.
3. The function must remain finite and have a finite number of maxima and minima in the periodic interval, or, if aperiodic, about the entire real line.
4. The function must be absolutely integrable, that is, if periodic,

$$\int_{t_0}^{t_0+T} |x(t)| dt$$

must be finite or if aperiodic

$$\int_{-\infty}^{+\infty} |x(t)| dt$$

must be finite.

The techniques of Fourier analysis are perhaps best appreciated initially by an example. Consider the ideal continuous-time square wave of period T s, having a maximum value of A and a minimum value of 0 as shown at the top of Fig. 20.68. Because of the periodic nature of the waveform, the technique of Fourier series (FS) analysis applies, and the resulting decomposition into an infinite sum of simple trigonometric functions is given by

$$x(t) = \frac{A}{2} + \sum_{k=1,3,5,\dots}^{\infty} \frac{2A}{k\pi} (-1)^{(k-1)/2} \cos(k\Omega_0 t) \quad (20.69)$$

In Eq. (20.69), the average value or DC term of the waveform is given by $A/2$, whereas the **fundamental frequency** is described by $\Omega_0 = 2\pi/T$. Because the waveform is an **even function** only cosine terms are present. Because the waveform, less its average value, is characterized by **half-wave symmetry**, only the **odd harmonics** are present. To examine the reconstruction of the function $x(t)$ from the given decomposition, the middle plot of Fig. 20.68 displays the DC term, and the first and third harmonics. The sum of these terms is overlaid with the ideal square wave at the bottom of Fig. 20.68. This progressive reconstruction is continued in Fig. 20.69 with successive odd harmonics added as per Eq. (20.69). The ultimate goal of reconstructing the ideal square wave theoretically demands completion of the infinite sum, an unrealistic task of computation or analog signal summation. By truncating the summation at a large enough value of the harmonic number k , we are assured of having a best approximation of the ideal square wave in a least-square-error sense: that is, the truncated Fourier series is the best fit at any given truncation level $k = k_{\max} < \infty$. The ringing or overshoot, which forms near the discontinuity of the ideal square wave, is described by the **Gibbs phenomenon**, in tribute to an early investigator of the effects of truncating Fourier series summations.

In practice, we are seldom presented with ideal functions such as the square wave of Fig. 20.68. Indeed, an analytical description of the waveform of interest, as is implied by the use of $x(t)$ in formulas of the next two sections, is rarely available.

FIGURE 20.68 Example reconstruction of ideal square wave from Fourier series summation.

FIGURE 20.69 Continued reconstruction of ideal square wave from Fourier series summation.

FIGURE 20.70 Example of aliasing wherein uniformly spaced samples from a high-frequency signal are indistinguishable from samples of a low-frequency signal.

The discrete-time waveform counterparts of the Fourier series and Fourier transform provide viable alternatives for estimating the frequency content of signals if discrete measurements of the desired waveforms are available. This avenue of analysis, which is popular in benchtop instrumentation, is considered in further detail in Sec. 20.6.7.

One critical mathematical preliminary for the processing of discrete-time waveforms, which originate from sampling continuous-time waveforms, is the issue of **sampling rate** and **aliasing**. The *Nyquist sampling theorem* can be summarized as follows:

If $x(t)$ is a **bandlimited** continuous-time waveform having no frequency content greater than or equal to F_N Hz (the **Nyquist frequency**), then $x(t)$ is uniquely determined by a discrete-time waveform $x(n)$, which results from uniform sampling of $x(t)$ at a rate F_S , which is greater than or equal to $2F_N$ (the **Nyquist rate**).

Failure to obey the Nyquist sampling theorem results in aliasing, that is, the effect of frequencies greater than the Nyquist frequency are reflected into the band of frequencies between DC and one-half the sampling rate. This situation is demonstrated in Fig. 20.70, where the samples of the high-frequency sinusoid are indistinguishable from a uniform sampling of the low-frequency sinusoid.

20.6.3 The Fourier Series for Continuous-Time Periodic Functions

Three forms of the FS are commonly encountered for continuous-time waveforms $x(t)$ of period T . The first is the *trigonometric form*,

$$x(t) = \frac{a_0}{2} + \sum_{k=1}^{\infty} \left[a_k \cos\left(\frac{2\pi k}{T}t\right) + b_k \sin\left(\frac{2\pi k}{T}t\right) \right] \quad (20.70)$$

where the coefficients a_k and b_k are calculated via the integrals

$$a_k = \frac{2}{T} \int_{t_0}^{t_0+T} x(t) \cos\left(\frac{2\pi k}{T}t\right) dt \quad (20.71)$$

$$b_k = \frac{2}{T} \int_{t_0}^{t_0+T} x(t) \sin\left(\frac{2\pi k}{T}t\right) dt \quad (20.72)$$

with the representation for a_0 often appearing without the multiplier and divider of two (and therefore directly representing the average value of $x(t)$). Symmetry properties of the particular function $x(t)$ can lead to simplifications of Eq. (20.71) and Eq. (20.72).

A slight adaptation of this leads to the *alternative trigonometric form*,

$$x(t) = \frac{a_0}{2} + \sum_{k=1}^{\infty} A_k \cos\left(\frac{2\pi k}{T}t + \theta_k\right) \quad (20.73)$$

where the magnitude and phase terms are obtained via the respective identities

$$A_k = \sqrt{a_k^2 + b_k^2} \quad (20.74)$$

$$\theta_k = -\arctan\left(\frac{b_k}{a_k}\right) \quad (20.75)$$

Finally, the *complex exponential form* is given by

$$x(t) = \sum_{k=-\infty}^{\infty} C_k e^{j\frac{2\pi k}{T}t} \quad (20.76)$$

where the coefficients C_k are calculated via

$$C_k = \frac{1}{T} \int_{t_0}^{t_0+T} x(t) e^{-j\frac{2\pi k}{T}t} dt \quad (20.77)$$

It should be noted that the C_k are, in general, complex valued. They may be obtained from the trigonometric form data as follows:

$$|C_k| = |C_{-k}| = \frac{A_k}{2} \quad \text{for } k = 0, 1, 2, \dots \quad (20.78)$$

$$\arg C_k = -\arg C_{-k} = \theta_k \quad \text{for } k = 0, 1, 2, \dots \quad (20.79)$$

Common graphical representations of these data include plots of $|C_k|$ (or A_k) and θ_k , which are referred to as the *magnitude* and *phase spectra*, respectively. As is implied by the indexing of the spectral data by the integer k , the Fourier series of a continuous-time waveform is itself discrete in character, that is, it takes on nonzero values at only discrete, isolated points of the frequency axis, namely, the frequencies $\Omega_k = 2\pi k/T$.

The average power in a periodic waveform can be found in one of two ways, with the equality noted below commonly attributed to Parseval:

$$P = \frac{1}{T} \int_{t_0}^{t_0+T} |x(t)|^2 dt = \sum_{k=-\infty}^{\infty} |C_k|^2 \quad (20.80)$$

Because of the right-hand side of Eq. (20.80), a plot of $|C_k|^2$ is commonly referred to as the *power spectral density*.

20.6.4 The Fourier Transform for Continuous-Time Aperiodic Functions

The Fourier transform (FT) for an aperiodic, continuous-time waveform $x(t)$ is given by

$$X(\Omega) = \mathcal{F}\{x(t)\} = \int_{-\infty}^{\infty} x(t) e^{-j\Omega t} dt \quad (20.81)$$

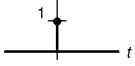

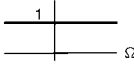

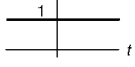

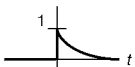

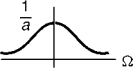

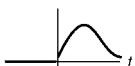

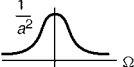

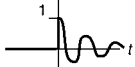

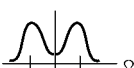

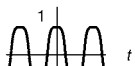

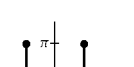

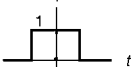

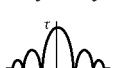

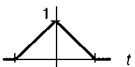

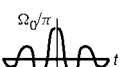

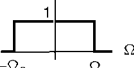

where the implication is that the frequency-domain counterpart $X(\Omega)$ of $x(t)$ is continuous in frequency and can be used to reconstruct $x(t)$ via

$$x(t) = \mathcal{F}^{-1}\{X(\Omega)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(\Omega) e^{j\Omega t} d\Omega \quad (20.82)$$

If the integration described in Eq. (20.82) is carried out in hertz rather than radians per second, the division by the factor 2π is removed.

The transformation given by Eq. (20.81) can also be applied to some familiar periodic functions as well as functions that are not absolutely integrable. Example Fourier transform pairs are shown in Table 20.3.

TABLE 20.3 Example Fourier Transform Pairs

$x(t)$	$x(t)$	$X(\Omega)$	$ X(\Omega) $
	$\delta(t)$	1	
	1	$2\pi\delta(\Omega)$	
	$u(t)$	$\pi\delta(\Omega) + \frac{1}{j\Omega}$	
	$e^{-at}u(t), a > 0$	$\frac{1}{a + j\Omega}$	
	$te^{-at}u(t), a > 0$	$\frac{1}{(a + j\Omega)^2}$	
	$e^{-at}\cos(\Omega_0 t)u(t), a > 0$	$\frac{a + j\Omega}{(a + j\Omega)^2 + \Omega_0^2}$	
	$\cos(\Omega_0 t)$	$\pi[\delta(\Omega - \Omega_0) + \delta(\Omega + \Omega_0)]$	
	$1, t < \tau/2$ $0, t > \tau/2$	$\frac{\sin(\Omega\tau/2)}{\Omega/2}$	
	$1 - t /\tau, t < \tau$ $0, t > \tau$	$\frac{1}{\tau} \frac{\sin^2(\Omega\tau/2)}{(\Omega/2)^2}$	
	$\frac{\sin(\Omega_0 t / 2)}{\pi t}$	$1, \Omega < \Omega_0$ $0, \Omega > \Omega_0$	

The total energy in an aperiodic waveform can be found in one of two ways, with the equality noted commonly attributed to Parseval,

$$E = \int_{-\infty}^{\infty} |x(t)|^2 dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} |X(\Omega)|^2 d\Omega \tag{20.83}$$

Because of the right-hand side of Eq. (20.83), a plot of $|X(\Omega)|^2$ is commonly referred to as the *energy spectral density*. One advantage to the integration vs. frequency is the ability to determine the amount of energy in a signal due to frequency components within a particular range of frequencies.

20.6.5 The Fourier Series for Discrete-Time Periodic Functions

The discrete-time Fourier series (DTFS) for discrete-time waveforms $x(n)$ of period N can also be given in three forms; however, the *complex exponential form* is by far the most common,

$$x(n) = \sum_{k=0}^{N-1} c_k e^{j\frac{2\pi k}{N}n} \tag{20.84}$$

where the coefficients c_k are calculated via the finite summation

$$c_k = \frac{1}{N} \sum_{n=0}^{N-1} x(n) e^{-j \frac{2\pi k}{N} n} \quad (20.85)$$

Because of the periodicity of the exponential in Eq. (20.85), the DTFS coefficients c_k form a discrete, periodic sequence of period N if the index k is extended beyond the fundamental range of 0 to $N - 1$.

The average power in a periodic, discrete-time waveform can be found in one of two ways, with the equality noted commonly attributed to Parseval,

$$P = \frac{1}{N} \sum_{n=0}^{N-1} |x(n)|^2 = \sum_{k=0}^{N-1} |c_k|^2 \quad (20.86)$$

Because of the right-hand side of Eq. (20.86), a plot of $|c_k|^2$ is commonly referred to as the power spectral density.

20.6.6 The Fourier Transform for Discrete-Time Aperiodic Functions

The discrete-time Fourier transform (DTFT) for aperiodic, finite energy discrete-time waveforms $x(n)$ is given by

$$X(\omega) = \sum_{n=-\infty}^{\infty} x(n) e^{-j\omega n} \quad (20.87)$$

where the implication is that the frequency-domain counterpart $X(\omega)$ of $x(n)$ is continuous in the discrete frequency variable ω and can be used to reconstruct $x(n)$ via

$$x(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} X(\omega) e^{j\omega n} d\omega \quad (20.88)$$

If the integration described in Eq. (20.88) is carried out in cycles per sample rather than radian per sample frequency, the division by the factor 2π is removed.

The transformation given by Eq. (20.87) can also be applied to some periodic functions as well as functions that are not absolutely summable. Examples of discrete-time Fourier transform pairs are shown in Table 20.4.

The total energy in an aperiodic, discrete-time waveform can be found in one of two ways, with the equality noted commonly attributed to Parseval,

$$E = \sum_{n=-\infty}^{\infty} |x(n)|^2 = \frac{1}{2\pi} \int_{-\pi}^{\pi} |X(\omega)|^2 d\omega \quad (20.89)$$

Because of the right-hand side of Eq. (20.89), a plot of $|X(\omega)|^2$ is commonly referred to as the energy spectral density.

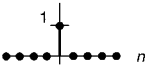

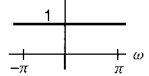

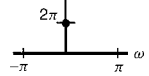

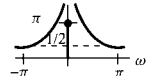

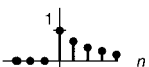

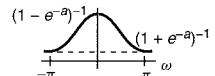

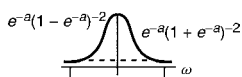

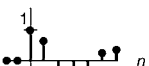

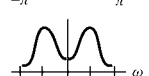

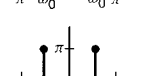

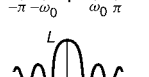

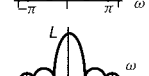

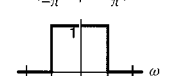

20.6.7 Example Applications of Fourier Waveform Techniques

Using the DFT/FFT in Fourier Analysis

The FFT is arguably the most significant advancement in signal analysis in recent decades. The FFT is actually the name given to many algorithms used to efficiently compute the DFT. The DFT of $x(n)$ is defined as

$$X(k) = DFT\{x(n)\} = \sum_{n=0}^{N-1} x(n) e^{-j \frac{2\pi k}{N} n} \quad \text{for } k = 0, 1, 2, \dots, N - 1 \quad (20.90)$$

TABLE 20.4 Example Discrete-Time Fourier Transform Pairs

$x(n)$	$x(n)$	$X(\omega)$	$ X(\omega) $
	$\delta(n)$	1	
	1	$\sum_{k=-\infty}^{\infty} 2\pi \delta(\omega + 2\pi k)$	
	$u(n)$	$\frac{1}{1 - e^{-j\omega}} + \sum_{k=-\infty}^{\infty} \pi \delta(\omega + 2\pi k)$	
	$e^{-an}u(n), a > 0$	$\frac{1}{1 - e^{-(a+j\omega)}}$	
	$ne^{-an}u(n), a > 0$	$\frac{e^{-(a+j\omega)}}{(1 - e^{-(a+j\omega)})^2}$	
	$e^{-an} \cos(\omega_0 n)u(n), a > 0$	$\frac{1 - \cos(\omega_0)e^{-(a+j\omega)}}{1 - 2 \cos(\omega_0)e^{-(a+j\omega)} + e^{-2(a+j\omega)}}$	
	$\cos(\omega_0 n)$	$\pi \sum_{k=-\infty}^{\infty} [\delta(\omega - \omega_0 + 2\pi k) + \delta(\omega + \omega_0 + 2\pi k)]$	
	$1, n < L/2$ $0, n > (L-1)/2$ L an odd integer	$\frac{\sin(\omega L/2)}{\sin(\omega/2)}$	
	$1 - n /L, n < L$ $0, n \geq L$ L an odd integer	$\frac{1}{L} \frac{\sin^2(\omega L/2)}{\sin^2(\omega/2)}$	
	$\frac{\sin(\omega_0 n)}{\pi n}$	$1, \omega < \omega_0$ $0, \omega_0 < \omega < \pi$	

and the inverse transform is given by

$$x(n) = IDFT\{X(k)\} = \frac{1}{N} \sum_{k=0}^{N-1} X(k)e^{j\frac{2\pi n}{N}k} \quad \text{for } n = 0, 1, 2, \dots, N - 1 \quad (20.91)$$

The DFT/FFT can be used to compute or approximate the four Fourier methods described in Sec. 20.6.3 to Sec. 20.6.6, that is the FS, FT, DTFS, and DTFT. Algorithms for the FFT are discussed extensively in the literature (see the **Further Information** entry for this topic).

The DTFS of a periodic, discrete-time waveform can be directly computed using the DFT. If $x(n)$ is one period of the desired signal, then the DTFS coefficients are given by

$$c_k = \frac{1}{N} DFTx(n) \quad \text{for } k = 0, 1, \dots, N - 1 \quad (20.92)$$

The DTFT of a waveform is a continuous function of the discrete or sample frequency ω . The DFT can be used to compute or approximate the DTFT of an aperiodic waveform at uniformly separated *sample frequencies* $k\omega_0 = k2\pi/N$, where k is any integer between 0 and $N - 1$. If N samples fully describe a finite duration $x(n)$, then

$$X(\omega)|_{\omega=\frac{2\pi}{N}k} = DFTx(n) \quad \text{for } k = 0, 1, \dots, N - 1 \quad (20.93)$$

If the $x(n)$ in Eq. (20.93) is not of finite duration, then the equality should be changed to an approximately equal. In many practical cases of interest, $x(n)$ is not of finite duration. The literature contains many approaches to truncating and **windowing** such $x(n)$ for Fourier analysis purposes.

The continuous-time FS coefficients can also be approximated using the DFT. If a continuous-time waveform $x(t)$ of period T is sampled at a rate of T_s samples per second to obtain $x(n)$, in accordance with the Nyquist sampling theorem, then the FS coefficients are approximated by

$$C_k \approx \frac{T_s}{T} DFT\{x(n)\} \quad \text{for } k = 0, 1, \dots, N - 1 \quad (20.94)$$

where N samples of $x(n)$ should represent precisely one period of the original $x(t)$. Using the DFT in this manner is equivalent to computing the integral in Eq. (20.77) with a simple rectangular or Euler approximate.

In a similar fashion, the continuous-time FT can be approximated using the DFT. If an aperiodic, continuous-time waveform $x(t)$ is sampled at a rate of T_s samples per second to obtain $x(n)$, in accordance with the Nyquist sampling theorem, then uniformly separated samples of the FT are approximated by

$$X(\Omega)|_{\Omega = \frac{2\pi}{NT_s}k} \approx T_s(DFT\{x(n)\}) \quad \text{for } k = 0, 1, \dots, N - 1 \quad (20.95)$$

For $x(t)$ that are not of finite duration, truncating and windowing can be applied to improve the approximation.

Total Harmonic Distortion Measures

The applications of Fourier analysis are extensive in the electronics and instrumentation industry. One typical application, the computation of total harmonic distortion (THD), is described herein. This application provides a measure of the nonlinear distortion, which is introduced to a pure sinusoidal signal when it passes through a system of interest, perhaps an amplifier. The root-mean-square (rms) total harmonic distortion (THD_{rms}) is defined as the ratio of the rms value of the sum of the harmonics, not including the fundamental, to the rms value of the fundamental,

$$THD_{rms} = \frac{\sqrt{\sum_{k=2}^{\infty} A_k^2}}{A_1} \quad (20.96)$$

FIGURE 20.71 A clipped sinusoidal waveform for total harmonic distortion example.

FIGURE 20.72 The magnitude spectrum, through eighth harmonic, for the clipped sinusoid total harmonic distortion example.

As an example, consider the clipped sinusoidal waveform shown in Fig. 20.71. The Fourier series representation of this waveform is given by

$$v(t) = A \left(\frac{1}{2} + \frac{1}{\pi} \right) \cos \left(\frac{2\pi}{T} t \right) + \frac{2\sqrt{2}A}{\pi} \sum_{k=3,5,7,\dots}^{\infty} \frac{\sin \left(\frac{\pi}{4} k \right) - k \cos \left(\frac{\pi}{4} k \right)}{k(1 - k^2)} \cos \left(\frac{2\pi}{T} kt \right) \quad (20.97)$$

The magnitude spectrum for this waveform is shown in Fig. 20.72. Because of symmetry, only the odd harmonics are present. Clearly the fundamental is the dominant component, but due to the clipping, many additional harmonics are present. The THD_{rms} is readily computed from the coefficients in Eq. (20.97), yielding 13.42% for this example. In practice, the coefficients of the Fourier series are typically approximated via the DFT/FFT, as described at the beginning of this section.

Defining Terms

Aliasing: Refers to an often detrimental phenomenon associated with the sampling of continuous-time waveforms at a rate below the Nyquist rate. Frequencies greater than one-half the sampling rate become indistinguishable from frequencies in the fundamental bandwidth, that is, between DC and one-half the sampling rate.

Aperiodic waveform: This phrase is used to describe a waveform that does not repeat itself in a uniform, periodic manner. Compare with periodic waveform.

Bandlimited: A waveform is described as bandlimited if the frequency content of the signal is constrained to lie within a finite band of frequencies. This band is often described by an upper limit, the Nyquist frequency, assuming frequencies from DC up to this upper limit may be present. This concept can be extended to frequency bands that do not include DC.

Continuous-time waveform: A waveform, herein represented by $x(t)$, that takes on values over the continuum of time t , the assumed independent variable. The Fourier series and Fourier transform apply to continuous-time waveforms. Compare with discrete-time waveform.

Discrete-time waveform: A waveform, herein represented by $x(n)$, that takes on values at a countable, discrete set of sample times or sample numbers n , the assumed independent variable. The discrete Fourier transform, the discrete-time Fourier series, and discrete-time Fourier transform apply to discrete-time waveforms. Compare with continuous-time waveform.

Even function: If a function $x(t)$ can be characterized as being a mirror image of itself horizontally about the origin, it is described as an even function. Mathematically, this demands that $x(t) = x(-t)$ for all t . The name arises from the standard example of an even function as a polynomial containing only even powers of the independent variable. A pure cosine is also an even function.

- Fast Fourier transform (FFT):** Title which is now somewhat loosely used to describe any efficient algorithm for the machine computation of the discrete Fourier transform. Perhaps the best known example of these algorithms is the seminal work by Cooley and Tukey in the early 1960s.
- Fourier waveform analysis:** Refers to the concept of decomposing complex waveforms into the sum of simple trigonometric or complex exponential functions.
- Fundamental frequency:** For a periodic waveform, the frequency corresponding to the smallest or fundamental period of repetition of the waveform is described as the fundamental frequency.
- Gibbs phenomenon:** Refers to an oscillatory behavior in the convergence of the Fourier transform or series in the vicinity of a discontinuity, typically observed in the reconstruction of a discontinuous $x(t)$. Formally stated, the Fourier transform does converge uniformly at a discontinuity, but rather, converges to the average value of the waveform in the neighborhood of the discontinuity.
- Half-wave symmetry:** If a periodic function satisfies $x(t) = -x(t - T/2)$, it is said to have half-wave symmetry.
- Harmonic frequency:** Refers to any frequency that is a positive integer multiple of the fundamental frequency of a periodic waveform.
- Nyquist frequency:** For a bandlimited waveform, the width of the band of frequencies contained within the waveform is described by the upper limit known as the Nyquist frequency.
- Nyquist rate:** To obey the Nyquist sampling theorem, a bandlimited waveform should be sampled at a rate which is at least twice the Nyquist frequency. This minimum sampling rate is known as the Nyquist rate. Failure to follow this restriction results in aliasing.
- Odd function:** If a function $x(t)$ can be characterized as being a reverse mirror image of itself horizontally about the origin, it is described as an odd function. Mathematically, this demands that $x(t) = -x(-t)$ for all t . The name arises from the standard example of an odd function as a polynomial containing only odd powers of the independent variable. A pure sine is also an odd function.
- Periodic waveform:** This phrase is used to describe a waveform that repeats itself in a uniform, periodic manner. Mathematically, for the case of a continuous-time waveform, this characteristic is often expressed as $x(t) = x(t \pm kT)$, which implies that the waveform described by the function $x(t)$ takes on the same value for any increment of time kT , where k is any integer and the characteristic value T , a real number greater than zero, describes the fundamental period of $x(t)$. For the case of a discrete-time waveform, we write $x(n) = x(n \pm kN)$, which implies that the waveform $x(n)$ takes on the same value for any increment of sample number kN , where k is any integer and the characteristic value N , an integer greater than zero, describes the fundamental period of $x(n)$.
- Quarter-wave symmetry:** If a periodic function displays half-wave symmetry and is *even* symmetric about the $\frac{1}{4}$ and $\frac{3}{4}$ period points (the negative and positive lobes of the function), then it is said to have quarter-wave symmetry.
- Sampling rate:** Refers to the frequency at which a continuous-time waveform is sampled to obtain a corresponding discrete-time waveform. Values are typically given in hertz.
- Single-valued:** For a function of a single variable, such as $x(t)$, single-valued refers to the quality of having one and only one value $y_0 = x(t_0)$ for any t_0 . The square root is an example of a function which is not single-valued.
- Windowing:** A term used to describe various techniques for preconditioning a discrete-time waveform before processing by algorithms such as the discrete Fourier transform. Typical applications include extracting a finite duration approximation of an infinite duration waveform.

20.7 Digital Test Instruments

Jerry C. Whitaker

20.7.1 Introduction

As the equipment used by consumers and industry becomes more complex, the requirements for highly-skilled maintenance technicians also increases. Maintenance personnel today require advanced test equipment and must think in a “systems mode” to troubleshoot much of the hardware now in the field. New technologies and changing economic conditions have reshaped the way maintenance professionals view their jobs. As technology drives equipment design forward, maintenance difficulties will continue to increase. Such problems can be met only through improved test equipment and increased technician training.

Servicing computer-based professional equipment typically involves isolating the problem to the board level and then replacing the defective PWB. Taken on a case-by-case basis, this approach seems efficient. The inefficiency in the approach, however (which is readily apparent), is the investment required to keep a stock of spare boards on hand. Furthermore, because of the complex interrelation of circuits today, a PWB that appeared to be faulty may actually turn out to be perfect. The ideal solution is to troubleshoot down to the component level and replace the faulty device instead of swapping boards. In many cases, this approach requires sophisticated and expensive test equipment. In other cases, however, simple test instruments will do the job.

Although the cost of most professional equipment has been going up in recent years, maintenance technicians have seen a buyer's market in test instruments. The semiconductor revolution has done more than given consumers low-cost computers and disposable devices. It has also helped to spawn a broad variety of inexpensive test instruments with impressive measurement capabilities.

20.7.2 Digital Multimeters

Beyond the basic voltage-resistance-current measurements, sophisticated digital multimeters (DMMs) provide a number of unique functions. Large-scale integration has made it possible to pack more features into the limited space inside a DMM, and to do so without significantly increasing the cost of the instrument. In addition, because of competition among manufacturers, the functionality of DMMs is continually improving. The result: increasingly sophisticated products.

Digital multimeters can be divided into two basic classifications:

- **Portable.** Hand-held instruments intended for field applications offer extensive capabilities in a portable, rugged package. Some hand-held meters include true-RMS measurements, 1 msec response times, capacitance and frequency modes, and recording capabilities.
- **Benchtop.** Instruments intended for fixed applications usually offer a wide range of features and interface to other instruments. Options include display devices with multiple readouts, and built-in communications capabilities. A communications interface permits the meter to be controlled over standard computer ports for data storage, analysis, and remote operation.

Evolutionary developments in DMM design have provided a number of helpful features to maintenance technicians, including

- Audible continuity check. The instrument emits a beep when the measured resistance value is less than $5\ \Omega$ or so. This permits point-to-point continuity tests to be performed without actually looking at the DMM.
- Audible high voltage warning. The instrument emits a characteristic beep when the measured voltage is dangerously high (100 V or more). This safety feature alerts the technician to use extra care when making measurements.
- Sample-and-hold. The instrument measures and stores the sampled value after it has stabilized. Completion of the sample function is signaled by an audible beep. This feature permits the technician to concentrate on probe placement, not on trying to read the instrument.
- Continuously variable tone. The instrument produces a tone that varies in frequency with the measured parameter. This feature permits a circuit to be adjusted for a peak or null value without actually viewing the DMM. It also may be used to check for intermittent continuity.
- Ruggedized case. Durable cases for portable instruments permit normal physical abuse to be tolerated. Many DMMs in use today may be dropped or exposed to water without failure.
- Input overload hardening. Protection devices are placed at the input circuitry to prevent damage in the event of an accidental overvoltage. Fuses and semiconductor-based protection components are used.
- Logic probe functions. Signal high/low and pulse detection circuitry built into a DMM probe permits the instrument to function as both a conventional multimeter and a logic probe. This eliminates the necessity to change instruments in the middle of a troubleshooting sequence.
- Automatic shutoff. A built-in timer removes power to the DMM after a preset period of non-operation. This feature extends the life of the internal batteries.

DMM functions are further expanded by the wide variety of probes and accessories available for many instruments. Specialized probes include

- High-voltage—used for measuring voltages above 500 V. Many probes permit voltages of 50 kV or more to be measured.
- Clamp-type current—permits current in a conductor to be measured without breaking the circuit. Probes are commonly available in current ranges of 1–2 A and up.
- Demodulator— converts a radio frequency signal into a DC voltage for display on the DMM.

FIGURE 20.73 Functional block diagram of a basic DMM. LSI chip technology has reduced such systems to a single device.

- Temperature—permits the DMM to be used for display of temperature of a probe device. Probes are available for surface measurement of solids and for immersion into liquid or gas.

Advances in DMM technology have resulted in increased reliability. DMMs are engineered to include a minimum of moving parts. Auto-ranging eliminates much of the mechanical switch contacts and movement common with older technology instruments. This approach reduces the number of potential sources of failure, such as corrosion and intermittent switch contacts. Gold plating of the remaining contacts in the DMM further reduces the chance of failure.

Voltage Conversion

Figure 20.73 shows a generalized block diagram of a DMM. Conversion of an input voltage to a digital equivalent can be accomplished in one of several ways. The *dual-slope conversion* method (also known as *double-integration*) is one of the more popular techniques (Figure 20.74). V_{in} represents the input voltage (the voltage to be measured). V_{REF} is a reference voltage with a polarity opposite that of the measured voltage, supplied by the digital conversion circuit. Capacitor C1 and operational amplifier U1 constitute an integrator. S1 is an electronic switch that is initially in the position shown. When the meter probes are first connected to the circuit, the sample voltage is applied to the input of the integrator for a specified period of time, called the *integration period*. The integration period is usually related to the 60 Hz line frequency; integration periods of 1/60th of a second and 1/10th of a second are common. The output signal of the integrator is a voltage determined by the RC time constant of R1 and C1. Because of the nature of the integrator, the maximum voltage (the voltage at the end of the integration period) is proportional to the voltage being measured. At the end of the integration period, switch S1 is moved to the other position (V_{REF}) and a voltage of opposite polarity to the measured voltage is applied. The capacitor is then discharged to zero. As shown in the figure, the discharge interval is directly proportional to the maximum voltage, which in turn is proportional to the applied voltage.

At the same time that the integration interval ends and the discharge interval begins, a counter in the meter begins counting pulses generated by a clock circuit. When the voltage reaches zero, the counter stops. The number of pulses counted is, therefore, proportional to the discharge period. This count is converted to a digital number and displayed as the measured voltage. Although this method works well, it is somewhat slow, so many microcomputer-based meters use a variation called *multislope integration*.

When a DMM is used in the resistance testing mode, it places a low voltage with a constant-current characteristic across the test leads. After the leads are connected, the voltage across the measurement points is determined, which provides the resistance value (voltage divided by the known constant

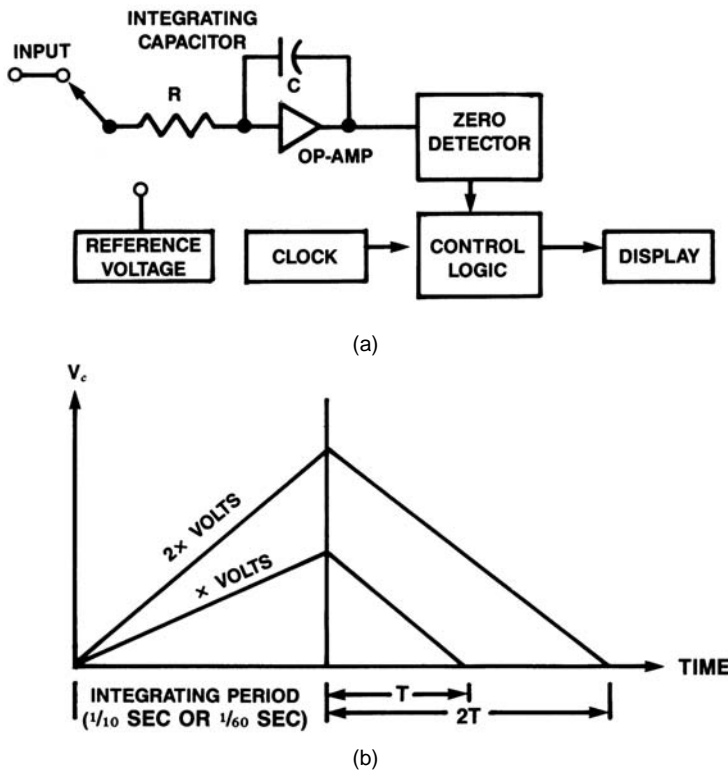

FIGURE 20.74 DMM analog-to-digital conversion process: (a) functional block diagram, (b) graph of V_c vs. time.

current = resistance). The meter converts the voltage reading into an equivalent resistance for display. The voltage placed across the circuit under test is kept low to protect semiconductor devices that might be in the loop. The voltage at the ohmmeter probe is about 0.1 V or less, too low to turn on silicon junctions.

The ultimate performance of a DMM in the field is determined by its inherent accuracy. Key specifications include

- **Accuracy**—how closely the meter indicates the actual value of a measured signal, specified in percent of error. Zero percent indicates a perfect meter.
- **Frequency response**—the range of frequencies that can be measured by the meter without exceeding a specified amount of error.
- **Input impedance**—the combined AC and DC resistance at the input terminals of the multimeter. The impedance, if too low, can load critical circuits and result in measurement errors. An input impedance of 10 M Ω or greater will prevent loading.
- **Precision**—the degree to which a measurement is carried out. As a general rule, the more digits a DMM can display, the more precise the measurement will be.

20.7.3 Conventional Test Instruments

Troubleshooting a digital system requires a wide range of test instruments, from simple to complex. Some of the more common conventional test instruments include frequency counters and logic instruments of various types.

Frequency Counter

A frequency counter provides an accurate measure of signal cycles or pulses over a standard period of time. It is used to totalize or to measure frequency, period, frequency ratio, and time intervals. Key specifications for a counter include

- Frequency range—the maximum frequency that the counter can resolve.
- Resolution—the smallest increment of change that can be displayed. The degree of resolution is selectable on many counters. Higher resolution usually requires a longer acquisition time.
- Sensitivity—the lowest amplitude signal that the instrument will count (measured in fractions of a volt).
- Timebase accuracy—a measure of the stability of the timebase. Stability is measured in parts per million (ppm) while the instrument is subjected to temperature and operating voltage variations.

Multi-Function Hand-held Instrument

Although specialized instruments such as a separate frequency counter or capacitance meter may be the best choice for a specific range of tasks, combinations of instruments are available for the convenience of maintenance personnel. Separate analyzers usually offer a broader range of measurement capabilities, but a combined instrument often makes field servicing easier.

Logic Instruments

The simplest of all logic instruments is the logic probe. A basic logic probe tells the technician whether the logic state of the point being checked is high, low, or pulsed. Most probes include a pulse stretcher that will show the presence of a 1-shot pulse. The indicators are usually LEDs. In some cases, a single LED is used to indicate any of the conditions (high, low, or pulsing); generally, individual LEDs are used to indicate each state. Probes usually include a switch to match the level sense circuitry of the unit to the type of logic being checked (TTL, CMOS, ECL, etc.). The probe receives its power from the circuit under test. Connecting the probe in this manner sets the approximate value of signal voltage that constitutes a logic low or high. For example, if the power supply voltage for a CMOS logic circuit is 18 V, a logic low would be about 30 % of 18 V (5.4 V), and a logic high would be about 70% of 18 V (12.6 V).

The logic pulser is the active counterpart to the logic probe. The logic pulser generates a single pulse, or train of pulses into a circuit to check the response.

Logic Current Tracer

The close spacing of pins and conductors on a crowded PWB invites short circuits. On a large board, locating a short can be a difficult and time-consuming task. The logic current tracer can be a valuable tool in troubleshooting such failures.

Even in an extremely thin printed circuit conductor, a change in current induces a magnetic field. The probe of a logic current tracer is designed to sense changes in the minute magnetic field of a PWB trace. An LED indicates the presence of the field. To locate a short circuit, the current tracer is used in conjunction with the logic pulser. As illustrated in Fig. 20.75, pulses are injected at an identifiable failure point. The tracer is then moved slowly along the circuit trace until the LED goes off, indicating that the point of the fault has been passed.

Logic Test Clip

A logic test clip is a device that clips directly over an IC package to display the logic status of all pins on the chip. Each probe of the clip contacts one pin of the IC. The probes are connected to LEDs that indicate whether that point in the circuit is at a logic high or low, or pulsed.

The IC comparator is an extension of the logic test clip. The comparator allows the operation of an in-circuit IC to be compared against a known-good IC of the same type placed in the comparator's "reference" socket. While the circuit containing the IC under test is operating, the comparator matches the responses of the reference IC to the test device.

FIGURE 20.75 Use of a logic pulser and current tracer to locate a short-circuit on a PWB.

20.7.4 Logic Analyzer

The logic analyzer is really two instruments in one: a *timing analyzer* and a *state analyzer*. The timing analyzer is analogous to an oscilloscope. It displays information in the same general form as a scope, with the horizontal axis representing time and the vertical axis representing voltage amplitude. The timing analyzer samples the input waveform to determine whether it is high or low. The instrument cares about only one voltage threshold. If the signal is above the threshold when it is sampled, it will be displayed as a 1 (or high); any signal below the threshold is displayed as a 0 (or low). From these sample points, a list of ones and zeros is generated to represent a picture of the input waveform. These data are stored in memory and used to reconstruct the input waveform, as shown in Fig. 20.76. A block diagram of a typical timing analyzer is shown in Fig. 20.77.

Sample points for the timing analyzer are developed by an internal clock. The period of the sample can be selected by the user. Because the analyzer samples asynchronously to the unit-under-test under the direction of the internal clock, a long sample period results in a more accurate picture of the data bus. A sample period should be selected that permits an accurate view of data activity, while not filling up the instrument's memory with unnecessary data.

Accurate sampling of data lines requires a trigger source to begin data acquisition. A fixed delay may be inserted between the trigger point and the *trace point* to allow for bus settling. This concept is illustrated in Fig. 20.78. A variety of trigger modes are commonly available on a timing analyzer, including:

- *Level triggering*—data acquisition and/or display begins when a logic high or low is detected.
- *Edge triggering*—data acquisition/display begins on the rising or falling edge of a selected signal. Although many logic devices are level-dependent, clock and control signals are often edge-sensitive.
- *Bus state triggering*—data acquisition/display is triggered when a specific code is detected (specified in binary or hexadecimal).

The timing analyzer is constantly taking data from the monitored bus. Triggering, and subsequent generation of the trace point, controls the *data window* displayed to the technician. It is possible, therefore, to configure the analyzer to display data that precedes the trace point. (See Fig. 20.79) This feature can be a powerful troubleshooting and developmental tool.

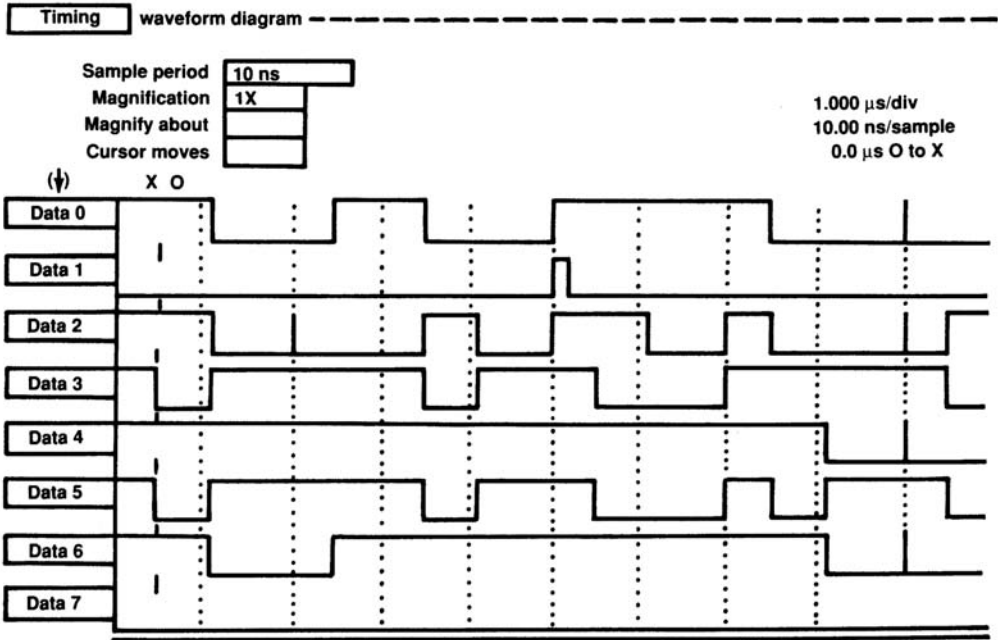

FIGURE 20.76 Typical display of a timing analyzer.

FIGURE 20.77 Block diagram of a timing analyzer.

FIGURE 20.78 Use of a delay period between the trigger point and the trace point of a timing analyzer.

FIGURE 20.79 Data-capturing options available from a timing analyzer.

The timing analyzer is probably the best method of detecting glitches in computer-based equipment. (A *glitch* being defined as any transition that crosses a logic threshold more than once between clock periods. See Fig. 20.80) The triggering input of the analyzer is set to the bus line that is experiencing random glitches. When the analyzer detects a glitch, it displays the bus state preceding, during, or after occurrence of the disturbance.

The state analyzer is the second half of a logic analyzer. It is used most often to trace the execution of instructions through a microprocessor system. Data, address, and status codes are captured and displayed as they occur on the microprocessor bus. A *state* is a sample of the bus when the data are valid. A state is usually displayed in a tabular format of hexadecimal, binary, octal, or assembly language. Because some microprocessors multiplex data and addresses on the same lines, the analyzer must be able to clock-in information at different clock rates. The analyzer, in essence, acts as a demultiplexer to capture an address at the proper time, and then to capture data present on the same bus at a different point in time. A state analyzer also gives the operator the ability to *qualify* the data stored. Operation of the instrument may be triggered by a specific logic pattern on the bus. State analyzers usually offer a *sequence term* feature that aids in triggering. A sequence term allows the operator to qualify data storage more accurately than would be possible with a single trigger point. A sequence term usually takes the following form:

- find xxxx
- then find yyyy
- start on zzzz

A sequence term is useful for probing a subroutine from a specific point in a program. It also makes possible selective storage of data, as shown in Fig. 20.81.

To make the acquired data easier to understand, most state analyzers include software packages that interpret the information. Such *disassemblers* (also known as *inverse assemblers*) translate hex, binary, or octal codes into assembly code (or some other format) to make them easier to read.

FIGURE 20.80 Use of a timing analyzer for detecting glitches on a monitored line.

FIGURE 20.81 Illustration of the selective storage capability of a state analyzer.

The logic analyzer is used routinely by design engineers to gain an in-depth look at signals within digital circuits. A logic analyzer can operate at high speeds, making the instrument ideal for detecting glitches resulting from timing problems. Such faults are usually associated with design flaws, not with manufacturing defects or failures in the field.

While the logic analyzer has benefits for the service technician, its use is limited. Designers require the ability to verify hardware and software implementations with test equipment; service technicians simply need to quickly isolate a fault. It is difficult and costly to automate test procedures for a given PWB using a logic analyzer. The technician must examine a long data stream and decide if the data are good or bad. Writing programs to validate state analysis data is possible, but again is time-consuming.

Signature Analyzer

Signature analysis is a common troubleshooting tool based on the old analog method of signal tracing. In analog troubleshooting, the technician followed an annotated schematic that depicted waveforms and voltages that should be observed with an oscilloscope and voltmeter. The signature analyzer captures a complex data stream from a test point on the PWB and converts it into a hexadecimal signature. These hexadecimal signatures are easy to annotate on schematics, permitting their use as references for comparison against signatures obtained from a unit under test. The signature by itself means nothing; the value of the signature analyzer comes from comparing a known-good signature with the UUT.

A block diagram of a simplified signature analyzer is shown in Fig. 20.82. As shown, a digital bit stream, accepted through a data probe during a specified measurement window, is marched through a 16-bit linear feedback shift register. Whatever data are left over in the register after the specified measurement

FIGURE 20.82 Simplified block diagram of a signature analyzer.

window has closed are converted into a 4-bit hexadecimal readout. The feedback portion of the shift register allows just one faulty bit in a digital bit stream to create an entirely different signature than would be expected in a properly operating system. This tool allows the maintenance technician to identify a single bit error in a digital bit stream with 99.998% certainty, even when picking up errors that are timing-related.

To function properly, the signature analyzer requires start and stop signals, a clock input, and the data input. The start and stop inputs are derived from the circuit being tested and are used to bracket the beginning and end of the measurement window. During this gate period, data are input through the data probe. The clock input controls the sample rate of data entering the analyzer. The clock is most often taken from the clock input pin of the microprocessor. The start, stop, and clock inputs may be configured by the technician to trigger on the rising or falling edges of the input signals.

Manual Probe Diagnosis

Manual probe diagnosis integrates the logic probe, logic analyzer, and signature analyzer to troubleshoot computer-based hardware. The manual probe technique employs a database consisting of nodal-level signature measurements. Each node of a known-good unit-under-test is probed and the signature information saved. These known-good data are then compared to the data from a faulty UUT. Efficient use of the manual probe technique requires a skilled operator to determine the proper order for probing circuit nodes.

Emulative Tester

Guided diagnostics can be used on certain types of hardware to facilitate semi-automated circuit testing. The test connector typically taps into one of the system board input/output ports and, armed with the proper software, the instrument goes through a step-by-step test routine that exercises the computer circuits. When the system encounters a fault condition, it outputs an appropriate message.

Emulative testers are a variation on the general guided diagnostics theme. Such an instrument plugs into the microprocessor socket of the computer and runs a series of diagnostic tests to identify the cause of a fault condition. An emulative tester emulates the board's microprocessor while verifying circuit operation. Testing the board "inside-out" allows easy access to all parts of the circuit; synchronization with the various data and address cycles of the PWB is automatic. Test procedures, such as read/write cycles from the microprocessor are generic, so that high quality functional tests can be quickly created for any board. Signature analysis is used to verify that circuits are operating correctly. Even with long streams of data, there is no maximum memory depth.

Several different types of emulative testers are available. Some are designed to check only one brand of computer, or only computers based on one type of microprocessor. Other instruments can check a variety of microcomputer systems using so-called *personality* modules that adapt the instrument to the system being serviced.

Guided-fault isolation (GFI) is practical with an emulative tester because the instrument maintains control over the entire system. Automated tests can isolate faults to the node level. All board information and test procedures are resident within the emulative test instrument, including prompts to the operator on what to do next. Using the microprocessor test connection combined with movable probes or clips allows a closed loop test of virtually any part of a circuit. Input/output capabilities of emulative testers range from single point probes to well over a hundred I/O lines. These lines can provide stimulus as well as measurement capabilities.

The principal benefit of the guided probe over the manual probe is derived from the creation of a *topology database* for the UUT. The database describes devices on the UUT, their internal fault-propagating characteristics, and their inter-device connections. In this way, the tester can guide the operator down the proper logic path to isolate the fault. A guided probe accomplishes the same analysis as a conventional fault tree, but differs in that troubleshooting is based on a generic algorithm that uses the circuit model as its

input. First, the system compares measurements taken from the failed UUT against the expected results. Next, it searches for a database representation of the UUT to determine the next logical place to take a measurement. The guided probe system automatically determines which nodes impact other nodes. The algorithm tracks its way through the logic system of the board to the source of the fault. Programming of a guided probe system requires the following steps:

- Development of a stimulus routine to exercise and verify the operating condition of the UUT (go/no-go status).
- Acquisition and storage of measurements for each node affected by the stimulus routine. The programmer divides the system or board into measurement sets (MSETs) of nodes having a common timebase. In this way, the user can take maximum advantage of the time domain feature of the algorithm.
- Programming a representation of the UUT that depicts the interconnection between devices, and the manner in which signals can propagate through the system. Common *connectivity* libraries are developed and reused from one application to another.
- Programming a measurement set cross reference database. This allows the guided probe instrument to cross MSET boundaries automatically without operator intervention.
- Implementation of a test program control routine that executes the stimulus routines. When a failure is detected, the guided probe database is invoked to determine the next step in the troubleshooting process.

Protocol Analyzer

Testing a local area network (LAN)—whether copper, fiber optic, or wireless—presents special challenges to the design engineers or maintenance technician. The protocol analyzer is commonly used to service LANs and other communications systems. The protocol analyzer performs data monitoring, terminal simulation, and bit error rate tests (BERTs). Sophisticated analyzers provide *high-level decide* capability. This ability refers to the open system interconnection (OSI) network seven layer model. These functions enable the engineer to observe activity of a communications link and to exercise the facility to verify proper operation. Simulation capability is usually available to emulate almost any data terminal or data communications equipment.

LAN test equipment functions include monitoring of protocols and emulation of a network node, bridge, or terminal. Statistical information is provided to isolate problems to particular devices, or to high periods of activity. Statistical data include use, packet rates, error rates, and collision rates.

20.7.5 Automated Test Instruments

Computers can function as powerful troubleshooting tools. Advanced technology systems, coupled with add-on interface cards and applications software, provide a wide range of testing capabilities. Computers can also be connected to many different instruments to provide for automated testing. There are two basic types of stand-alone automated test instruments (ATEs): *functional* and *in-circuit*.

Functional testing exercises the unit under test to identify faults. Individual PWBs or subassemblies may be checked using this approach. Functional testing provides a fast go/no-go qualification check. Dynamic faults are best discovered through this approach. Functional test instruments are well suited to high volume testing of PWB subassemblies, however, programming is a major undertaking. An intimate knowledge of the subassembly is needed to generate the required test patterns. An in-circuit emulator is one type of functional tester.

In-circuit testing is primarily a diagnostic tool. It verifies the functionality of the individual components of a subassembly. Each device is checked and failing parts are identified. In-circuit testing, while valuable for detailed component checking, does not operate at the clock rate of the subassembly. Propagation delays,

race conditions, and other abnormalities may go undetected. Access to key points on the PWB may be accomplished in one of two ways:

- *Bed of nails.* The subassembly is placed on a dedicated test fixture and held in place by a vacuum or mechanical means. Probes access key electrical traces on the subassembly to check individual devices. Through a technique known as *backdriving*, the inputs of each device are isolated from the associated circuitry and the component is tested for functionality. This type of testing is expensive and is only practical for high-volume subassembly qualification testing and rework.
- PWB clips. Intended for lower volume applications than a bed of nails instrument, PWB clips replace the dedicated test fixture. The operator places the clips on the board as directed by the instrument. As access to all components simultaneously is not required, the tester is less hardware-intensive and programming is simplified. Many systems include a library of software routines designed to test various classes of devices. Test instruments using PWB clips tend to be slow. Test times for an average PWB may range from 8–20 min vs. 1 min or less for a bed of nails.

Software Considerations

Most automated test instrument packages include software that permits the user to customize test procedures to meet the required task. The software, in effect, writes software. The user enters the codes needed by each automatic instrument, selects the measurements to be performed, and tells the computer where to store the test data. The program then puts the final software together after the user answers key configuration questions. The software then looks up the operational codes for each instrument and compiles the software to perform the required tests. Automatic generation of programming greatly reduces the need to have experienced programmers on staff. Once installed in the computer, programming becomes as simple as fitting graphic symbols together on the screen.

Applications

The most common applications for computer-controlled testing are data gathering, product go/ no-go qualification, and troubleshooting. All depend on software to control the instruments. Acquiring data can often be accomplished with a computer and a single instrument. The computer collects dozens or hundreds of readings until the occurrence of some event. The event may be a preset elapsed time or the occurrence of some condition at a test point, such as exceeding a preset voltage or dropping below a preset voltage. Readings from a variety of test points are then stored in the computer. Under computer direction, test instruments can also run checks that might be difficult or time-consuming to perform manually. The computer may control several test instruments such as power supplies, signal generators, and frequency counters. The data are stored for later analysis.

21.1 Probability and Statistics

Allan White and Hagbae Kim

21.1.1 Survey of Probability and Statistics

General Introduction to Probability and Statistics

The approach to probability and statistics used in this chapter is the pragmatic one that probability and statistics are methods of operating in the presence of incomplete knowledge.

The most common example is tossing a coin. It will land heads or tails, but the relative frequency is unknown. The two events are often assumed equally likely, but a skilled coin tosser may be able to get heads almost all of the time. The statistical problem in this case is to determine the relative frequency. Given the relative frequency, probability techniques answer such questions as how long can we expect to wait until three heads appear in a row.

Another example is light bulbs. The outcome is known: any bulb will eventually fail. If we had complete knowledge of the local universe, it is conceivable that we might compute the lifetime of any bulb. In reality, the manufacturing variations and future operating conditions for a lightbulb are unknown to us. It may be possible, however, to describe the failure history for the general population. In the absence of any data, we can propose a failure process that is due to the accumulated effect of small events (corrosion, metal evaporation, and cracks) where each of these small events is a random process. It is shown in the statistics section that a failure process that is the sum of many events is closely approximated by a distribution known as the normal (or Gaussian) distribution. This type of curve is displayed in Fig. 21.1(a).

FIGURE 21.1 Two Gaussian distributions having different means and variances.

A manufacturer can try to improve a product by using better materials and requiring closer tolerances in the assembly. If the light bulbs last longer and there are fewer differences between the bulbs, then the failure curve should move to the right and have less dispersion, as shown in Fig. 21.1(b).

There are three types of statistical problems in the light bulb example. One is identifying the shape of the failure distributions. Are they really the normal distribution as conjectured? Another is to estimate such parameters as the average and the deviation from the average for the populations. Still another is to compare the old manufacturing process with the new. Is there a real difference and is the difference significant?

Suppose the failure curve (for light bulbs) and its parameters have been obtained. This information can then be used in probability models. As an example, suppose a city wishes to maintain sufficient illumination for its streets by constructing a certain number of lamp posts and by having a maintenance crew replace failed lights. Since there will be a time lag between light failure and the arrival of the repair crew, the city may construct more than the minimum number of lamp posts needed in order to maintain sufficient illumination. Determining the number of lamp posts depends on the failure curve for the bulbs and the time lag for repair. Furthermore, the city may consider having the repair crew replace all bulbs, whether failed or not, as the crew makes its circuit. This increases the cost for bulbs but decreases the cost for the repair crew. What is the optimum strategy for the number of lamp posts, the repair crew circuit, and the replacement policy? The objective is to maximize the probability of sufficient illumination while minimizing the cost.

Incomplete Knowledge vs. Complete Lack of Knowledge

People unfamiliar with probability sometimes think that random means completely arbitrary, and there is no way to predict what will happen. Physical reasoning, however, can supply a fair amount

of knowledge:

- It is reasonable to assume the coin will land heads or tails and the probability of heads remains constant. This gives a unique probability distribution with two possible outcomes.
- It is reasonable to assume that light bulb failure is the accumulation of small effects. This implies that the failure distribution for the light bulb population is approximately the normal distribution.
- It will be shown that the probability distribution for time to failure of a device is uniquely determined by the assumption that the device does not wear out.

Of course, it is possible (for random as for deterministic events) that our assumptions are incorrect. It is conceivable that the coin will land on its edge or disintegrate in the air. Power surges that burn out large numbers of bulbs are not incremental phenomena, and their presence will change the distribution for times to failure. In other words, using a probability distribution implies certain assumptions are being made. It is always good to check for a match between the assumptions underlying the probability model and the phenomenon being modeled.

Probability

This section presents enough technical material to support all our discussions on probability. It covers the (1) definition of a **probability space**, (2) Venn (set) diagrams, and (3) density functions.

Probability Space

The definition of a probability space is based on the intuitive ideas presented in the previous section. We begin with the set of all possible events, call this set X .

- If we are tossing a coin three times, X consists of all sequences of heads (H) and tails (T) of length three.
- If we are testing light bulbs until time to failure, X consists of the positive real numbers.

The next step in the definition of a probability space is to ensure that we can consider simple combinations of events. We want to consider the AND and OR combinations as intersections and unions. We also want to include complements.

In the coin-tossing space, getting at least two heads is the union of the four events, that is

$$\{HHT, HTH, THH, HHH\}$$

In the light-bulb-failure space, a bulb lasting more than 10 h but less than 20 h is the intersection of the two events: (1) bulb lasts more than 10 h and (2) bulb lasts less than 20 h. In the coin-tossing space, getting less than two heads is the complement of the first set, that is

$$\{HTT, THT, TTH, TTT\}$$

When it comes to assigning probabilities to events, the procedure arises from the idea of assigning areas to sets. This idea can be conveyed by pictures called Venn diagrams. For example, consider the disjoint sets of events A and B in the Venn diagram of Fig. 21.2.

We want the probability of being in either A or B to be the sum of their probabilities. Finally, when considering physical events it is sufficient to consider only finite or countably infinite combinations

FIGURE 21.2 Venn diagram of two disjoint sets of events.

of simpler events. (It is also true that uncountably infinite combinations can produce mathematical pathologies.)

Example

It is necessary to include countably infinite combinations, not just finite combinations. The simplest example is tossing a coin until a head appears. There is no bound for the number of tosses. The sample space consists of all sequences of heads and tails. The combinatorial process in operation for this example is AND; the first toss is T , and the second toss is T , \dots and the n -th toss is H .

Hence, with this in mind, a probability space is defined as follows:

1. It is a collection of subsets, called events, of a universal space X . This collection of subsets (events) has the following properties:
 - X is in the collection
 - If A is in the collection, its set complement A' is in the collection
 - If $\{A_i\}$ is a finite or countably infinite collection of events, then both $\bigcup A_i$ and $\bigcap A_i$ are in the collection
2. To every event A there is a real number, $Pr[A]$, between 0 and 1 assigned to A such that
 - $Pr[X] = 1$
 - If $\{A_i\}$ is a finite or countably infinite collection of disjoint events, then $Pr[\bigcup A_i] = \sum Pr[A_i]$

As the last axiom suggests, numerous properties about probability are derived by decomposing complex events into unions of disjoint events.

Example

$$Pr[A \cup B] = Pr[A] + Pr[B] - Pr[A \cap B].$$

Let $A \setminus B$ be the elements in A that are not in B . Express the sets as the disjoint decompositions

$$\begin{aligned} A &= (A \setminus B) \cup (A \cap B) \\ B &= (B \setminus A) \cup (A \cap B) \\ A \cup B &= (A \setminus B) \cup (B \setminus A) \cup (A \cap B) \end{aligned}$$

which gives

$$\begin{aligned} Pr[A] &= Pr[A \setminus B] + Pr[A \cap B] \\ Pr[B] &= Pr[B \setminus A] + Pr[A \cap B] \\ Pr[A \cup B] &= Pr[A \setminus B] + Pr[B \setminus A] + Pr[A \cap B] \end{aligned}$$

and the result follows.

Probability from Density Functions and Integrals

The interpretation of probability as an area, when suitably generalized, gives a universal framework. The formulation given here, in terms of Riemann integrals, is sufficient for many applications. Consider a nonnegative function $f(x)$ defined on the real line with the property that its integral over the entire line is equal to one (Fig. 21.3.)

The probability that the values lie on the interval $[a, b]$ is defined to be

$$Pr[a \leq x \leq b] = \int_a^b f(x) dx$$

FIGURE 21.3 A nonnegative function $f(x)$ defined on the real line.

The function $f(x)$ is called the *density function*. The probability that the values are less than or equal to t is given by

$$F(t) = Pr[x \leq t] = \int_{-\infty}^t f(x)dx$$

This function $F(t)$ is called the *distribution function*.

In this formulation by density functions and (Riemann) integrals, the basic events are the intervals $[a, b]$ and countable unions of these disjoint intervals. It is easy to see that this approach satisfies all of the axioms for a probability space listed earlier. This formulation lets us apply all of the techniques of calculus and analysis to probability. This feature is demonstrated repeatedly in the sections to follow.

One last comment should be made. Riemann integration and continuous (or piecewise continuous) density functions are sufficient for a considerable amount of applied probability, but they cannot handle all of the topics in probability because of the highly discontinuous nature of some probability distributions. A generalization of Riemann integration (measure theory and general integration), however, does handle all aspects of probability.

Independence

Conditional probability, and the related topic of independence, give probability a unique character. As already mentioned, mathematical probability can be presented as a topic in measure theory and general integration. The idea of conditional probability distinguishes it from the rest of mathematical analysis. Logically, independence is a consequence of conditional probability, but the exposition to follow attempts an intuitive explanation of independence before introducing conditional events.

Informal Discussion of Independence

In probability, two events are said to be independent if information about one gives no information about the other. Independence is often assumed and used without any explicit discussion, but it is a stringent condition. Furthermore, the probabilistic meaning is different from the usual physical meaning of two events having nothing in common.

Figure 21.4 gives three diagrams illustrating various degrees of correlation and independence. In the first diagram, event A is contained in event B . Hence, if A has occurred then B has occurred, and the events are not independent (since knowledge of A yields some knowledge of B). In the second diagram event A

FIGURE 21.4 Various degrees of correlation and independence.

FIGURE 21.5 Pictorial example of conditional probability.

lies half in and half out of event B . Event B has the same relationship to event A . Hence, the two events in the third diagram are independent—knowledge of the occurrence of one gives no information about the occurrence of the other. This mutual relationship is essential. The third diagram illustrates disjoint events. If one event occurs, then the other cannot. Hence, the occurrence of one event yields information about the occurrence of the other event, which means the two events are not independent.

Conditional Probability and the Multiplicative Property

Conditional probability expresses the amount of information that the occurrence of one event gives about the occurrence of another event. The notation is $Pr[A | B]$ for the probability of A given B . To motivate the mathematical definition consider the events A and B in Fig. 21.5.

By relative area, $Pr[A] = 12/36$, $Pr[B] = 6/36$, and $Pr[A | B] = 2/6$. The mathematical expression for conditional probability is

$$Pr[A | B] = Pr[A \text{ and } B] / Pr[B]$$

From this expression it is easy to derive the multiplication rule for independent events. Suppose A is independent of B . Then information about B gives no information about A . That is, the conditional probability of A given B is the same as the probability of A or (by formula)

$$Pr[A] = Pr[A | B] = Pr[A \text{ and } B] / Pr[B]$$

A little algebra gives

$$Pr[A \text{ and } B] = Pr[A]Pr[B]$$

This multiplicative property means that independence is symmetrical. If A is independent of B , then B is independent of A . In its abstract formulation conditional probability is straightforward, but in applications it can be tricky.

Example (The Monte Hall Problem)

A contestant on a quiz show can choose one of three doors, and there is a prize behind one of them. After the contestant has chosen, the host opens one of the doors not chosen and shows that there is no prize behind the door he has just opened. The contestant is offered the opportunity to change doors. Should the contestant do so? There is a one-third chance that the contestant has chosen the correct door. There is a two-thirds chance that the prize is behind one of the other doors, and it would be nice if the contestant could choose both of the other doors. By opening the other door that does not contain the prize, the host is offering the contestant an opportunity to choose both of the other doors by choosing the other door that has not been opened. Changing doors increases the chance of winning to two-thirds. There are several reasons why this result appears counterintuitive. One is that the information offered is negative

information (no prize behind this door), and it is hard to interpret negative information. Another is the timing. If the host shows that there is no prize behind a door before the contestant chooses, then the chance of a correct choice is one-half. The timing imposes an additional condition on the host.

The (sometimes) subtle nature of conditional probability is important when conducting an experiment. It is almost trite to say that an event A can be measured only if A or its effect can be observed. It is not quite as trite to say that observability is a special property. Experiments involve the conditional probability:

$$Pr[A \text{ has some value} | A \text{ or its effect can be observed}]$$

A primary goal in experimental sampling is to make the observed value of A independent of its observability. One method that accomplishes this is to arrange the experiment so that all events are potentially observable. If X is the set of all events then the equations for this case are

$$Pr[A | X] = Pr[A \text{ and } X] / Pr[X] = Pr[A] / 1 = Pr[A]$$

For this approach to work it is only necessary that all events are potentially observable, not that all events are actually observed. The last section on statistics will show that a small fraction of the population can give a good estimate, provided it is possible to sample the entire population.

An experiment where part of the population cannot be observed can produce misleading results. Imagine a telephone survey where only half of the population has a telephone. The population with the geographic location and wealth to own a telephone may have opinions that differ from the rest of the population.

These comments apply immediately to fault injection experiments for reconfigurable systems. These experiments attempt to study the diagnostic and recovery properties of a system when a fault arrives. If it is not possible to inject faults into the entire system, then the results can be biased, because the unreachable part of the system may have different diagnostic and recovery characteristics than the reachable part.

FIGURE 21.6 A set represented by two density functions $f(x)$ and $g(y)$.

Independence and Density Functions

The product formula for the probability of independent events translates into a product formula for the density of independent events. If x and y are random variables with densities $f(x)$ and $g(y)$, then the probability that (x, y) lies in the set A , displayed in Fig. 21.6, is given by

$$\int \int_A f(x)g(y)dy dx$$

This property extends to any finite number of random variables. It is used extensively in the statistics section to follow because items in a **sample** are **independent events**.

The Probability Distribution for Memoryless Events

As an example of deriving the density function from the properties of the event, this section will show that memoryless events must have an exponential density function. The derivation uses the result from real analysis that the only continuous function $h(x)$ with the property, $h(a + b) = h(a)h(b)$ is the exponential function $h(t) = e^{\alpha t}$ for some α .

An event is memoryless if the probability of its occurrence in the next time increment does not depend on the amount of time that has already elapsed. That is,

$$Pr[\text{occurrence by time } (s + t) \text{ given has not occurred at time } s] = Pr[\text{occurrence by time } t]$$

Changing to distribution functions and using the formula for conditional probability gives

$$\frac{F(s + t) - F(s)}{1 - F(s)} = F(t)$$

A little algebra yields

$$1 - F(s + t) = [1 - F(s)][1 - F(t)]$$

Let $g(x) = 1 - F(x)$, then $g(s + t) = g(s)g(t)$, which means $g(x) = e^{\alpha t}$. Hence, the density function is

$$f(x) = F'(x) = -\alpha e^{\alpha t}$$

Since the density function must be nonnegative, $\alpha < 0$.

This derivation illustrates a of key activity in probability. If a probability distribution has certain properties, does this imply that it is uniquely determined? If so, what is the density function?

Moments

A fair amount of information about a probability distribution is contained in its first two moments. The first moment is also called the **mean**, the **average**, the **expectation**, or the **expected value**. If the density function is $f(x)$ the first moment is defined as

$$\mu = E(x) = \int_{-\infty}^{+\infty} xf(x)dx$$

The variance is the second moment about the mean

$$\sigma^2 = E[(x - \mu)^2] = \int_{-\infty}^{+\infty} (x - \mu)^2 f(x)dx$$

The variance measures the dispersion of the distribution. If the variance is small then the distribution is concentrated about the mean. A mathematical version of this is given by Chebychev's inequality

$$Pr[\|x - \mu\| \geq \delta] \leq \frac{\sigma^2}{\delta^2}.$$

This inequality says it is unlikely for a member of the population to be a great distance from the mean.

Statistics

The purpose of this section is to present the basic ideas behind statistical techniques by means of concrete examples.

Sampling

Sampling consists of picking individual items from a population in order to measure the parameter in question. For the coin tossing experiment mentioned at the beginning of this chapter, an individual item is a toss of the coin and the parameter measured is heads or tails. If the matter of interest is the failure distribution for a class of devices, then a number of devices are selected and the parameter measured is the time until failure. Selecting and measuring an individual item is known as a trial.

The theoretical formulation arises from the assumptions that (1) selecting an individual from the population is a random event governed by the probability distribution for that population, (2) the results of one trial do not influence the results of another trial, and (3) the population (from which items are chosen)

remains the same for each trial. If these assumptions hold, then the samples are said to be independent and identically distributed.

Suppose $f(x)$ is the density function for the item being sampled. The probability that a sample lies in the interval $[a, b]$ is $\int_a^b f(x)dx$. By the assumption of independence, the density function for a sample of size n is the n -fold product

$$f(x_1)f(x_2)\cdots f(x_n)$$

The probability that a sample of size n , say, x_1, x_2, \dots, x_n , is in the set A is

$$\int \int \cdots \int f(x_1)f(x_2)\cdots f(x_n)dx_n \cdots dx_2dx_1$$

where the integral is taken over the (multidimensional) set A . This formulation for the probability of a sample (in terms of a multiple integral) provides a mathematical basis for statistics.

Estimators: Sample Average and Sample Variance

Estimators are functions of the sample values (and constants). Since samples are random variables, estimators are also random variables. For example, suppose g is a function of the sample x_1, x_2, \dots, x_n , where $f(x)$ is the density function for each of the x . Then the expectation of g is

$$E(g) = \int \int \cdots \int g(x_1, \dots, x_n) f(x_1)f(x_2)\cdots f(x_n)dx_n \cdots dx_2dx_1$$

To be useful, of course, estimators must have a good relationship to the unknown parameter we are trying to determine. There are a variety of criteria for estimators. We will only consider the simplest. If g is an estimator for the (unknown) parameter θ , then g is an *unbiased* estimator for θ if the expected value of g equals θ . That is

$$E(g) = \theta$$

In addition, we would like the variance of the estimator to be small since this improves the accuracy. Statistical texts devote considerable time on the efficiency (the **variance**) of estimators.

The most common statistic used is the sample average as an estimator for the mean of the distribution. For a sample of size n it is defined to be

$$\bar{x} = \frac{(x_1 + \cdots + x_n)}{n}$$

Suppose the distribution has mean, variance, and density function of μ, σ^2 and $f(x)$. To illustrate the mathematical formulation of the estimator, we will do a detailed derivation that the sample mean is an unbiased estimator for the mean of the underlying distribution. We have

$$\begin{aligned} E(\bar{x}) &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \cdots \int_{-\infty}^{+\infty} \left(\frac{x_1 + \cdots + x_n}{n} \right) f(x_n)\cdots f(x_2)f(x_1)dx_n \cdots dx_2dx_1 \\ &= \sum_{i=1}^n \frac{1}{n} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \cdots \int_{-\infty}^{+\infty} x_i f(x_n)\cdots f(x_2)f(x_1)dx_n \cdots dx_2dx_1 \end{aligned}$$

Writing the i th term in the last sum as an iterated integral and then as a product integral gives

$$\int_{-\infty}^{+\infty} 1 f(x_1)dx_1 \cdots \int_{-\infty}^{+\infty} x_i f(x_i)dx_i \int_{-\infty}^{+\infty} 1 f(x_{i+1})dx_{i+1} \cdots \int_{-\infty}^{+\infty} 1 f(x_n)dx_n$$

The factors with 1 in the integrand are equal to 1. The factor with x_i in the integrand is equal to μ , the mean of the distribution. Hence

$$E(\bar{x}) = \frac{1}{n} \sum_{i=1}^n \mu = \mu$$

The sample average also has a convenient expression for its variance. A derivation similar to, but more complicated than, the preceding one gives

$$\text{Var}(\bar{x}) = \frac{\sigma^2}{n}$$

where σ^2 is the variance of the underlying population. Hence, increasing the sample size n improves the estimate by decreasing the variance of the estimator. This is discussed at greater length in the section on confidence intervals.

We can also estimate the variance of the underlying distribution. Define the sample variance by

$$S^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1}$$

A similar derivation shows that

$$E(S^2) = \sigma^2$$

There is also an expression for $\text{Var}(S^2)$ in terms of the higher moments of the underlying distribution.

For emphasis, all of these results about estimators arrive from the formulation of a sample as a collection of independent and identically distributed random variables. Their joint distribution is derived from the n -fold product of the density function of the underlying distribution. Once these ideas are expressed as multiple integrals, deriving results in statistics are exercises in calculus and analysis.

The Density Function of an Estimator

This material motivates the central limit theorem presented in the next section, and it illustrates one of the major ideas in statistics. Since estimators are random variables, it is reasonable to ask about their density functions. If the density function can be computed we can determine the properties of the estimator.

This point of view permeates statistics, but it takes a while to get used to it. There is an underlying distribution. We take a random sample from this distribution. We consider a function of these sample points, which we call an estimator. This estimator is a random variable, and it has a distribution that is related to, but different from, the underlying distribution from which the samples were taken.

We will consider a very simple example for our favorite estimator—the sample average. Suppose the underlying distribution is a constant rate process with the density function $f(z) = e^{-z}$. Suppose the estimator is the average of a sample of size two $\bar{z} = (x + y)/2$. The distribution function for \bar{z} is $G(t) = Pr[x + y \leq 2t]$. The integration is carried out over the shaded area in Fig. 21.7 bounded by the line $y = -x + 2t$ and the axes.

FIGURE 21.7 $x + y \leq 2t$.

The probability that $x + y \leq 2t$ is given by the double integral

$$G(t) = \int_0^{2t} \int_0^{2t-x} e^{-x} e^{-y} dy dx = 1 - e^{-2t} - 2te^{-2t}$$

FIGURE 21.8 Density function: (a) underlying exponential distribution, (b) for the estimator of size 2.

which implies the density function is

$$g(t) = G'(t) = 4te^{-2t}$$

Hence, if x and y are sample points from a constant rate process with rate one, then the probability that $a \leq (x + y)/2 \leq b$ is $\int_a^b 4te^{-2t} dt$.

Figure 21.8 displays the density functions for the underlying exponential distribution and for the sample average of size 2. Obviously, we want the density function for a sample of size n , we want the density function of the estimator for other underlying distributions, and we want the density function for estimators other than the sample average. Statisticians have expended considerable effort on this topic, and this material can be found in statistics tests and monographs.

Consider the two density functions in Fig.21.8 from a different point of view. The first is the density function of the sample average when the sample size is 1. The second when the sample size is 2. As the sample size increases, the graph becomes more like the bell-shaped curve for the normal distribution. This is the content of the Central Limit Theorem in the next section. As the sample size increases, the distribution of the sample average becomes approximately normal.

The Central Limit Theorem

A remarkable result in probability is that for a large class of underlying distributions the sample average approaches one type of distribution as the sample size becomes large. The class is those distributions with finite mean and variance. The limiting distribution is the normal (Gaussian) distribution. The density function for the normal distribution with mean μ and variance σ^2 (Fig. 21.9) is

$$\frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/2\sigma^2}$$

where $\sigma = \sqrt{\sigma^2}$.

Theorem

Suppose a sample x_1, \dots, x_n is chosen from a distribution with mean μ and variance σ^2 . As n becomes large, the distribution for the sample average \bar{x} approaches the normal distribution with mean μ and variance σ^2/n .

This result is usually used in the following manner. As a consequence of the result, it can be shown that the function, $(\bar{x} - \mu)/\sqrt{\sigma^2/n}$, is (approximately) normal with mean zero and variance one (the standard normal). Extensive tables are available

FIGURE 21.9 A Gaussian distribution with mean μ and variance σ^2 .

that give the probability that $\alpha \leq Z \leq \beta$ if Z has the standard normal distribution. The probability that $a \leq \bar{x} \leq b$ can be computed from the inequalities

$$\frac{a - \mu}{\sqrt{\sigma^2/n}} \leq \frac{\bar{x} - \mu}{\sqrt{\sigma^2/n}} \leq \frac{b - \mu}{\sqrt{\sigma^2/n}}$$

and a table lookup. This will be illustrated in the next section on confidence intervals.

Confidence Intervals

It is possible for an experiment to mislead us. For example, when estimating the average lifetime for a certain type of device, the sample could contain an unusual number of the better components (or of the poorer components). We need a way to indicate the quality of an experiment—the probability that the experiment has not misled us. A quantitative method of measuring the quality of an experiment is by using a confidence interval, which usually consists of three parts:

1. The value of the **estimator**: \hat{x}
2. An interval (called the **confidence interval**) about the estimator: $[\hat{x} - \alpha, \hat{x} + \beta]$
3. The probability (called the **confidence level**) that this interval contains the true (but unknown) value

The confidence level in part three is usually conservative, the probability that the interval contains the true value is greater than or equal to the stated confidence level.

The confidence interval has the following frequency interpretation. Suppose we obtain a 95% confidence interval from an experiment and statistical techniques. If we performed this experiment many times, then at least 95% of the time the interval will contain the true value of the parameter. This discussion of the confidence interval sounds similar to the previous discussion about estimators; they are random variables, and they have a certain probability of being within certain intervals.

To illustrate the general procedure, suppose we wish a 95% confidence interval for the mean μ of a random variable. Suppose the sample size is n . As described earlier, the sample mean \bar{x} and the sample variance S^2 are unbiased estimators for the mean and variance of the underlying distribution. For a symmetric confidence interval the requirement is

$$Pr[|\bar{x} - \mu| \leq \alpha] \geq 0.95$$

It is necessary to solve for α . We will use the central limit theorem. Rewrite the preceding equation

$$Pr\left[\frac{-\alpha}{\sqrt{S^2/n}} \leq \frac{\bar{x} - \mu}{\sqrt{S^2/n}} \leq \frac{\alpha}{\sqrt{S^2/n}}\right]$$

The term in the middle of the inequality has (approximately) the standard normal distribution. Here, 95% of the standard normal lies between -1.96 and $+1.96$. Hence, set $t = \alpha/\sqrt{S^2/n} = 1.96$ and solve for α (Fig. 21.10).

As an example of what can be done with more information about the underlying distribution available, consider the exponential (constant rate) failure distribution with density function $f(t) = \lambda e^{-\lambda t}$. Suppose the requirement is to estimate the mean-time-to-failure within 10% with a 95% confidence level. We will use the central limit theorem to determine how many trials are needed. The underlying

FIGURE 21.10 $-1.96 \leq t \leq 1.96$.

population has mean and variance $\mu = 1/\lambda$ and $\sigma^2 = 1/\lambda^2$. For a sample of size n the sample average \bar{x} has mean and variance:

$$\mu(\bar{x}) = \frac{1}{\lambda} \quad \text{and} \quad \sigma^2(\bar{x}) = \frac{1}{n\lambda^2}$$

The requirement is

$$Pr[|\bar{x} - \mu| \leq 0.1\mu] \geq 0.95$$

Since the estimator is unbiased, $\mu = \mu(\bar{x})$. A little more algebra gives

$$Pr\left[\frac{-0.1\mu(\bar{x})}{\sqrt{\sigma^2(\bar{x})}} \leq \frac{\bar{x} - \mu(\bar{x})}{\sqrt{\sigma^2(\bar{x})}} \leq \frac{0.1\mu(\bar{x})}{\sqrt{\sigma^2(\bar{x})}}\right] \geq 0.95$$

Once again, the middle term of the inequality has (approximately) the standard normal distribution, and 95% percent of the standard normal lies between -1.96 and $+1.96$. Set

$$1.96 = \frac{0.1\mu(\bar{x})}{\sqrt{\sigma^2(\bar{x})}} = 0.1\sqrt{n}$$

write $\mu(\bar{x})$ and $\sigma^2(\bar{x})$ in terms of λ ; solve to get $n = 384$.

Opinion Surveys, Monte Carlo Computations, and Binomial Sampling

One of the sources for skepticism about statistical methods is one of the most common applications of statistics, the opinion survey where about 1000 people are polled to determine the preference of the entire population. How can a sample of size 1000 tell us anything about the preference of several hundred million people?

This question is more relevant to engineering applications of statistics than it might appear, because the answer lies in the general nature of binomial sampling. As a similar problem consider a **Monte Carlo** computation of the area enclosed in an irregular graph given in Fig. 21.11. Suppose the area of the square is A . Choose 1000 points at random in the square. If N of the chosen points lie within the enclosed graph, then the area of the graph is estimated to be $NA/1000$. This area estimation poses a greater problem than the opinion survey. Instead of a total population of several hundred million, the total population of points in the square is uncountably infinite. (How can 1000 points chosen at random tell us anything since 1000 is 0% of the population?) In both the opinion survey and the area problem we are after an unknown probability p , which reflects the global nature of the entire population. For the opinion survey

FIGURE 21.11 An area enclosed in an irregular graph.

$$p = \frac{\text{number of yeses}}{\text{total number of population}}$$

For the area problem

$$p = \frac{\text{area enclosed by graph}}{\text{area of square}}$$

Suppose the sampling technique makes it equally likely that any person or point is chosen when a random selection is made. Then p is the probability that the response is yes or inside the curve. Assign a numerical value of 1 to yes or inside the curve. Assign 0 to the complement. The average (the expected value) for the entire population is:

$$1(\text{probability of a 1}) + 0(\text{probability of a 0}) = 1p + 0(1 - p) = p$$

The population variance is

$$\begin{aligned} & (\text{probability of a 1})(1 - \text{average})^2 + (\text{probability of a 0})(0 - \text{average})^2 \\ & = p(1 - p)^2 + (1 - p)(0 - p)^2 = p(1 - p) \end{aligned}$$

Hence, for a sample of size n , the mean and variance of the sample average are $E(\bar{x}) = p$ and $\text{Var}(\bar{x}) = p(1 - p)/n$.

The last equation answers our question about how a sample that is small compared to the entire population can give an accurate estimate for the entire population. The last equation says the variance of the estimator (which measures the accuracy of the estimator) depends on the sample size, not on the population size. The population size does not appear in the variance, which indicates the accuracy is the same whether the population is ten thousand, or several hundred million, or uncountably infinite.

The next step is to use the **central limit theorem**. Since the binomial distribution has a finite mean and variance, the adjusted sample average

$$\frac{\bar{x} - \mu}{\sqrt{\sigma^2/n}} = \frac{\bar{x} - p}{\sqrt{p(1 - p)/n}}$$

converges to the standard normal distribution (which has mean zero and standard deviation one). The usual confidence level used for opinion surveys is 95%. A table with the normalized Gaussian distribution shows that 95% of the standard normal lies between -1.96 and $+1.96$. Hence

$$Pr \left[-1.96 \leq \frac{\bar{x} - p}{\sqrt{p(1 - p)/n}} \leq 1.96 \right] \geq 0.95$$

or

$$Pr \left[\frac{-1.96\sqrt{p(1 - p)}}{\sqrt{n}} \leq \bar{x} - p \leq \frac{1.96\sqrt{p(1 - p)}}{\sqrt{n}} \right] \geq 0.95$$

Instead of replacing $\sqrt{p(1 - p)}$ with an estimator, we will be more conservative and replace it with its maximum value, which is $\frac{1}{2}$. Approximating 1.96 by 2 and taking n to be 1000 gives

$$Pr[-0.03 \leq \bar{x} - p \leq 0.03] \geq 0.95$$

We have arrived at the news announcement that the latest survey gives some percentage, plus or minus 3%. The 3% error comes from a 95% confidence level with a sample size of 1000.

21.1.2 Components and Systems

Basics on Components

Quantitative reliability (the probability of failure by a certain time) begins by considering how fast and in what manner components fail. The source for this information is field data, past experience with classes of devices, and consideration of the manufacturing process. Good data are hard to get. For this reason, reliability analysts tend to be conservative in their assumptions about device quality and to use worst-case analyses when considering failure modes and their effects.

Failure Rates

There is a great body of statistical literature devoted to identifying the failure rate of devices under test. We just present a conceptual survey of rates.

Increasing Rate

There is an increasing failure rate if the device is wearing out. As the device ages, it is more likely to fail in the next increment of time. Most mechanical items have this property. For long-term reliability of a

system with such components, there is often a replace before failure strategy as in the streetlight example earlier.

Constant Rate

The device is not wearing out. The most prosaic example is the engineer's coffee mug. It fails by catastrophe (if we drop it), otherwise it is immortal. A constant failure rate model is often used for mathematical convenience when the wear out rate is small. This appears to be accurate for high-quality solid-state electronic devices during most of their useful life.

Decreasing Rate

The device is improving with age. Software is a (sometimes controversial) example, but this requires some discussion. Software does not break, but certain inputs will lead to incorrect output. The frequency of these critical inputs determines the frequency of failure. Debugging enables the software to handle more inputs correctly. Hence, the rate of failures decreases.

A major issue in software is the independence of different versions of the same program. Initially, software reliability was treated similarly to hardware reliability, but software is now recognized as having different characteristics. The main item is that hardware has components that are used over and over (tried and true), whereas most software is custom.

Mathematical Formulation of Rates

The occurrence rate $R(t)$ is defined to be the density function divided by the probability that the event has not yet occurred. Hence, if the density function and distribution functions are $f(t)$ and $F(t)$

$$R(t) = \frac{f(t)}{1 - F(t)}$$

It appears reasonable that a device that is neither wearing out nor improving with age has the memoryless property. This can be shown mathematically. If the failure rate is constant, then

$$\frac{f(t)}{1 - F(t)} = c$$

Since the density function is the derivative of the distribution function, we have the differential equation

$$F'(t) + cF(t) = c$$

with the initial condition $F(0) = 0$. The solution is $F(t) = 1 - e^{-ct}$.

There are infinitely many distributions with increasing or decreasing rates. The Weibull distributions are popular and can be found in any reliability text.

Component Failure Modes

In addition to failing at different rates, devices can exhibit a variety of behaviors once they have failed. One variety is the on-off cycle of faulty behavior. A device, when it fails, can exhibit constant faulty behavior. In some ways, this is best for overall reliability. These devices can be identified and replaced more quickly than devices that exhibit intermittent faulty behavior. There are transient failures, usually due to external shocks, where the device is temporarily faulty, but will perform correctly once it has recovered. It can be difficult to distinguish between a device that is intermittently faulty (which should be replaced) and a device that is transiently faulty (which should not be replaced). In addition, a constantly faulty device in a complicated system may only occasionally cause a measurable performance error.

Devices can exhibit different faulty behavior, some of them malicious. The most famous is the lying clock problem, which can occur in system synchronization when correcting for clock drift.

- Clock *A* is good, but slow, and sends 11 am to the other two clocks.
- Clock *B* is good, but fast, and sends 1 pm to the other two clocks.

- Clock *C* is faulty. It sends 6 am to clock *A* and 6 pm to clock *B*.
- Clock *A* averages the three times and resets itself to 10 am.
- Clock *B* averages the three times and resets itself to 2 pm.

Even though a majority of the components are good, the system will lose synchronization and fail. The general version of this problem is known as *Byzantine* agreement.

Designing systems to tolerate and diagnose faulty components is an open research area.

Systems

Redundancy

There are two strands in reliability—fault avoidance and fault tolerance. Fault avoidance consists of building high-quality components and designing systems in a conservative manner. Fault tolerance takes the point of view that, despite all our efforts, components will fail and highly reliable systems must function in the presence of these failed components. These systems attempt achieving reliability beyond the reach of any single component by using redundancy.

There is a price in efficiency, however, for using redundancy, especially if the attempt is made to achieve reliability far beyond the reliability of the individual components. This is illustrated in Fig. 21.12, which plots the survival probability of a simple redundant system against the mean-time-to-failure (MTTF) of a single component. The system consists of n components, and the system works if a majority of the components are good.

There are several methods of improving the efficiency. One is by reconfiguration, which remove faulty components from the working group. This lets the good components remain in the majority for a longer period of time. Another is to use spares that can replace failed members of the working group. For long-term reliability, the spares can be unpowered, which usually reduces their failure rate. Although reconfiguration improves efficiency, it introduces several problems. One is a more complex system with an increased design cost and an increased possibility of design error. It also introduces a new failure mode. Even if reconfiguration works perfectly, it takes time to detect, identify, and remove a faulty component. Additional component failures during this time span can overwhelm the working group before the faulty components are removed. This failure mode is called a *coverage failure* or a *coincident-fault failure*. Assessing this failure mode requires modeling techniques that reflect system dynamics. One appropriate technique is **Markov models** explained in the next section.

FIGURE 21.12 Reliability of n -modular redundant systems: (a) 3-MR, (b) 5-MR, (c) 7-MR.

Periodic Maintenance

In a sense, redundant systems have increasing failure rates. As individual components fail, the system becomes more and more vulnerable. Their reliability can be increased by periodic maintenance that replaces failed components. Figure 21.13 gives the reliability curve of a redundant system. The failure rate is small during the initial period of its life because it is unlikely that a significant number of its components fail in a short period of time. Figure 21.13 also gives the reliability curve of the same system with periodic maintenance. For simplicity, it is assumed that the maintenance restores the system as good as new. The reliability curve for the maintained system repeats the first part of the curve for the original system over and over.

FIGURE 21.13 Reliability curves of an *unmaintained* (left) redundant system and a *maintained* (right) system.

Modeling and Computation Methods

If a system consists of individual components, it is natural to attempt to derive the failure characteristics of the system from the characteristics of the components and the system structure. There are three major modeling approaches.

Combinatorial and Fault Trees

Combinatorial techniques are appropriate if the system is static (nonreconfigurable). The approach is to construct a function that gives the probability of system failure (or survival) in terms of component failure (or survival) and the system structure. Anyone who remembers combinatorial analysis from high school or a course in elementary probability can imagine that the combinatorial expressions for complex systems can become very complicated. Fault trees have been developed as a tool to help express the combinatorial structure of a system. Once the user has described the system, a program computes the combinatorial probability. Fault trees often come with a pictorial input.

Example

A system works if both its subsystems work. Subsystem *A* works if all three of its components A_1 , A_2 , and A_3 work. Subsystem *B* works if either of its subsystems B_1 or B_2 work. Fault trees can be constructed to compute either the probability of success or the probability of failure. Figure 21.14 gives both the success tree and the failure tree for this example.

FIGURE 21.14 Success tree (left) and failure tree (right).

Markov and Semi-Markov Models

Markov and semi-Markov models are convenient tools for dynamic (reconfigurable) systems because the states in the model correspond to system states and the transition between states in the model correspond to physical processes (fault occurrence or system recovery). Because of this correspondence, they have become very popular, especially for electronic systems where the devices can be assumed to have a constant failure rate. Their disadvantages stem from their successes. Because of their convenience, they are applied to large and complex systems, and the models have become hard to generate and compute because of their size (state-space explosion). Markov models assume that transitions between states do not depend on the time spent in the state. (The transitions are memoryless.) Semi-Markov models are more general and let the transition distributions depend on the time spent in the state. This survey dedicates a special section to Markov models.

Monte Carlo Methods

Monte Carlo is essentially computation by random sampling. The major concern is using sampling techniques that are efficient techniques that yield a small confidence interval for a given sample size.

Monte Carlo is often the technique of last resort. It is used when the probability distributions are too arbitrary or when the system is too large and complex to be modeled and computed by other approaches. The Monte Carlo approach is usually used when failure rates are time varying. It can be used when maintenance is irregular or imperfect. The last subsection on statistics gave a short presentation of the Monte Carlo approach.

Model Verification

Here is an area for anyone looking for a research topic. Models are based on a inspection of the system and on assumptions about system behavior. There is a possibility that important features of the system have been overlooked and that some of the assumptions are incorrect. There two remedies for these possibilities. One is a detailed examination of the system, a failure modes and effects analysis. The size and complexity of current electronic systems make this an arduous task. Experiments can estimate parameters, but conducting of extensive experiments can be expensive.

21.1.3 Markov Models

Markov models have become popular in both reliability and performance analysis. This section explains this technique from an engineering point of view.

Basic Constructions

It only takes an intuitive understanding of three basic principles to construct Markov models. These are (1) constant rate processes, (2) independent competing events, and (3) independent sequential events. These three principles are described, and it is shown (by several examples) that an intuitive understanding of these principles is sufficient to construct Markov models. A Markov model consists of states and transitions. The states in the model correspond to identifiable states in the system, and the transitions in the model correspond to transitions between the states of the system.

Conversely, constructing a Markov model assumes these three principles, which means assuming these properties about a system. These properties may not be true for all systems. Hence, one reason for a detailed examination of these principles is to understand what properties are being assumed about the system. This is essential for knowing when and when not to use Markov models. The validity of the model depends on a match between the assumptions of the model and the properties of the system.

As discussed in a previous section, constant rate processes are random events with the memoryless property. This probability distribution appears well suited to modeling the failures of high-quality devices operating in a benign environment. The constant rate probability distribution, however, does not appear to be well suited to such events as system reconfiguration. Some of these procedures, for example, are fixed time programs. If the system is halfway through a 10-ms procedure, then it is known that the procedure

will be completed in 5 ms. That is, this procedure has memory: how long it takes to complete the procedure depends on how long the procedure has been running. Despite this possible discrepancy, this exposition will describe Markov models because of their simplicity.

Competing events arise naturally in redundant and reconfigurable systems. An important example is the competition between the arrival of a second fault and system recovery from a first fault. Sequential events also arise naturally in redundant and reconfigurable systems. A component failure is followed by system recovery. Another component failure is followed by another system recovery.

The Markov model for an event that has rate λ is given by Fig. 21.15. In state S the event has not occurred. In state F the event has occurred.

Suppose A and B are independent events that occur at rates α and β , respectively. The model for A and B as competing events is given in Fig. 21.16. In state SS neither A nor B has occurred. In state SA , event A has occurred before event B , whereas event B may or may not have occurred. In state SB , event B has occurred before event A , whereas event A may or may not have occurred.

If A and B are independent, then the probability that one or the other or both have occurred can be modeled by adding their rate of occurrence. This is a standard result in probability (Rohatgi 1976; Hoel, Port, and Stone, 1972). For the two events depicted in Fig. 21.16, the sum is $\alpha + \beta$, and the model (for either one or both) is given in Fig. 21.17. The probability of being in state C in Fig. 21.17 is equal to the sum of the probabilities of being in states SA or SB in Fig. 21.16.

The model in Fig. 21.16 tells us whether or not an event has occurred and which event has occurred first. The model does not tell us whether or not both events have occurred. Models with this additional information require considering sequential events.

Figure 21.18 displays a model for two independent sequential events where the first event occurs at rate α and the second rate occurs at rate β . Such a model can arise when a device with failure rate α is operated until it fails, whereupon it is replaced by a device with failure rate β . State S represents the first device operating correctly; state A represents the first device having failed and the second device operating correctly; and state B represents the second device having failed.

Figure 21.19 displays a model with both competing and sequential events. Even though this model is simple, it uses all three of the basic principles. Suppose devices A and B with failure rates α and β are operating. In state S , there are two competing events, the failure of device A and the failure of device B . If device A fails first, the system is in state SA where device A has failed but device B has not failed.

FIGURE 21.15 Model of a device failing at a constant rate λ .

FIGURE 21.16 Model for independent competing events.

FIGURE 21.17 Model for occurrence of either independent event.

FIGURE 21.18 Model for sequential independent events.

In state SA , the memoryless property of a constant rate process is used to construct the transition to state SC . When it arrives in state SA , device B does not remember having spent some time in state S . Hence, for device B , the transition out of state SA is the same as the transition out of state S . If device B were a component that wore out, then the transition from state SA to SC in Fig. 21.19 would depend on the amount of time the system spent in state S . The modeling and computation would be more difficult. A similar discussion holds for state SB . In state SC , both devices have failed.

FIGURE 21.19 Model with both completing and sequential events.

Model for a Reconfigurable Fourplex

Having covered the three basic principles (constant rate processes, independent competing events, and independent sequential events), it is possible to construct Markov reliability models. This section describes the model for a reconfigurable fourplex. This fourplex uses majority voting to detect the presence of a faulty component. Faulty components are removed from the system.

The reconfiguration sequence for this fourplex is

$$\text{fourplex} \longrightarrow \text{threeplex} \longrightarrow \text{twoplex} \longrightarrow \text{failure}$$

This fourplex has two failure modes. The coincident-fault failure mode occurs when a second component fails before the system can remove a component that has previously failed. With two faulty components present, the majority voter cannot be guaranteed to return the correct answer. A coincident-fault failure is sometimes called a *coverage failure*. Since a failure due to lack of diagnostics is also called a coverage failure, this chapter will use the term coincident-fault failure for the system failure mode just described.

The exhaustion of parts failure mode occurs when too many components have failed for the system to operate correctly. In this reconfigurable fourplex, an exhaustion of parts failure occurs when one component of the final twoplex fails since this fourplex uses only majority voting to detect faulty components. A system using self-test diagnostics may be able to reconfigure to a simplex before failing. In general, a system can have a variety of reconfiguration sequences depending on design considerations, the sophistication of the operating system, and the inclusion of diagnostic routines. This first example will use a simple reconfiguration sequence.

The Markov reliability model for this fourplex is given in Fig. 21.20. Each component fails at rate λ . The system recovers from a fault at rate δ . This system recovery includes the detection, identification, and removal of the faulty component. The mnemonics in Fig. 21.20 are S for a fault free state, R for a recovery mode state, C for a coincident-fault failure state, and E for the exhaustion of parts failure state.

The initial states and transitions for the model of the fourplex will be examined in detail. In state S_1 there are four good components each failing at rate λ . Since these components are assumed to fail independently, the failure rates can be summed to get the rate for the failure of one of the four. This sum is 4λ , which is the transition rate from state S_1 to R_1 . State R_1 has a transition with rate 3λ to state C_1 which represents the failure of one of the three good components. Hence, in state R_1 precisely one component has failed because the 4λ transition (from S_1) has been taken, but the 3λ transition (out of R_1) has not been taken. There is also a δ transition out of state R_1 representing system recovery. System recovery transitions are usually regarded as independent of component failure transitions because system recovery depends on the architecture and software, whereas component failure depends on the quality of the devices. The system recovery procedure would not change if the devices were replaced by electronically equivalent devices with a higher or lower failure rate. Hence, state R_1 has the competing independent events of component failure and system recovery. If system recovery occurs first, the system goes to the fault free state S_2 where there are three good components in the system. The transition 3λ out of state S_2 represents the memoryless failure rate of these three good components. If, in state R_1 , component failure occurs before system recovery, then

FIGURE 21.20 Reliability model of a reconfigurable fourplex.

the system is in the failed state C_1 where there is the possibility of the faulty components overwhelming the majority voter. The descriptions of the remaining states and transitions in the model are similar to the preceding descriptions.

There are several additional comments about the system failure state C_1 . First, it is possible that the fourplex can survive a significant fraction of coincident faults. One possibility is that a fair amount of time elapses between the second fault occurrence and the faulty behavior of the second component. In this case, the system has time to remove the first faulty component before the majority is overwhelmed. Establishing this recovery mode, however, requires experiments with double fault injections, which may be expensive. It may be cheaper and easier to build a system that is more reliable than required instead of requiring an expensive set of experiments to establish the system’s reliability, although more extensive experiments are a possible option. Models, such as the one in Fig. 21.20, that overestimate the probability of system failure are said to be conservative. Most models tend to be conservative because of the cost of obtaining detailed information about system performance, especially about system fault recovery.

Correlated Faults

This example demonstrates that Markov models can depict correlated faults. The technique used in this model is to have transitions represent the occurrence of several faults at once. Figure 21.21 displays a model for a fiveplex subjected to shocks, which produce transient faults. These shocks arrive at some constant rate. During a shock, faults appear in 0–5 components with some probability. In Fig. 21.21, the system is in state S_i if it has i faulty components for $i = 0, 1, 2$. The system is in the failure state F if there are three or more faulty components. The system removes all transient faults at rate ρ .

FIGURE 21.21 Fiveplex subjected to shocks.

The Differential Equations for Markov Models

Markov processes are characterized by the manner in which the probabilities change in time. The rates give the flow for changes in probabilities. The flow for constant rate processes is smooth enough that the change in probabilities can be described by the (Chapman–Kolmogorov) differential equations. Solving the differential equations gives the probabilities of being in the states of the model.

One of the attractive features of Markov models is that numerical results can be obtained without an extensive knowledge of probability theory and techniques. The intuitive ideas of probability discussed in the previous section are sufficient for the construction of a Markov model. Once the model is constructed, it can be computed by differential equations. The solution does not require any additional knowledge of probability.

Writing the differential equations for a model can be done in a local manner. The equation for the derivative of a state depends only on the single step transitions into that state and the single step transitions out of that state. Suppose there are transitions from states $\{A_1, \dots, A_m\}$ into state B with rates $\{\alpha_1, \dots, \alpha_m\}$ respectively, and that these are the only transitions into state B . Suppose there are transitions from state B to states $\{C_1, \dots, C_n\}$ with rates $\{\beta_1, \dots, \beta_n\}$ respectively, and that these are the only transitions out of state B . This general condition is shown in Fig. 21.22.

The differential equation for state B is

$$p'_B(t) = \alpha_1 p_{A_1}(t) + \alpha_2 p_{A_2}(t) + \dots + \alpha_m p_{A_m}(t) - (\beta_1 + \dots + \beta_n) p_B(t)$$

This formula is written for every state in the model, and the equations are solved subject to the initial conditions. While writing the formula for state B , it is possible to ignore all of the other states and transitions.

Computational Examples

This section presents a conceptual example that relates Markov models to combinatorial events and a computational example for a reconfigurable system.

Combinatorial Failure of Components

The next example considers the failure of three identical components with failure rate α . This example uses the basic properties of competing events, sequential events, and memoryless processes. Figure 21.23 presents the model for the failure of at least one component. State A_2 represents the failure of one, two, or three components. In Fig. 21.23(b) state B_2 represents the failure of exactly one component, whereas state B_3 represent the failure of two or three components. Figure 21.23(c) gives all of the details.

Choosing the middle diagram in Fig. 21.23(b), the differential equations are

$$\begin{aligned} p'_1(t) &= -3\alpha p_1(t) \\ p'_2(t) &= 3\alpha p_1(t) - 2\alpha p_2(t) \\ p'_3(t) &= 2\alpha p_2(t) \end{aligned}$$

with the initial conditions $p_1(0) = 1$, $p_2(0) = 0$, and $p_3(0) = 0$.

Let Q be the probability that a single component has failed by time T . That is

$$Q = 1 - e^{-\alpha T}$$

FIGURE 21.22 General diagram for a state in a Markov model.

FIGURE 21.23 Markov models for combinatorial failures.

Solving the differential equations gives

$$Pr[B_3] = 3Q^2(1 - Q) + Q^3$$

which is the combinatorial probability that two or three components out of three have failed. A similar result holds for the other models in Fig. 21.23.

Computing the Fourplex

The model of the reconfigurable fourplex using numbers instead of mnemonics to label the states is represented by Fig. 21.24. The differential equations are

$$\begin{aligned}
 p'_1(t) &= -4\lambda p_1(t) \\
 p'_2(t) &= 4\lambda p_1(t) - (3\lambda + \delta)\lambda p_2(t) \\
 p'_3(t) &= 3\lambda p_2(t) \\
 p'_4(t) &= \delta p_2(t) - 3\lambda p_4(t) \\
 p'_5(t) &= 3\lambda p_4(t) - (2\lambda + \delta)\lambda p_5(t) \\
 p'_6(t) &= 2\lambda p_5(t) \\
 p'_7(t) &= 5\delta p_5(t) - 2\lambda p_7(t) \\
 p'_8(t) &= 2\lambda p_7(t)
 \end{aligned}$$

FIGURE 21.24 Original reliability model of a reconfigurable fourplex.

Once the parameter values are known, this set of equations can be computed by numerical methods. Suppose the parameter values are $\lambda = 10^{-4}/\text{h}$ and $\delta = 10^4/\text{h}$. Suppose the operating time is $T = 2$, and suppose the initial conditional is $p_1(0) = 1$. Then the probability of being in the failed states is

$$p_3(2) = 2.4 \times 10^{11}, \quad p_6(2) = 4.8 \times 10^{15}, \quad p_8(2) = 3.2 \times 10^{11}$$

21.1.4 Summary

An attempt has been made to accomplish two things, to explain the ideas underlying probability and statistics and to demonstrate some of the most useful techniques. Probability is presented as a method of describing phenomena in the presence of incomplete knowledge and uncertainty. Elementary events are assigned a likelihood of occurring. Complex events comprise these elementary events, and this is used to compute the probability of complex events. Statistical methods are a way of determining the probability of elementary events by experiment. Sampling and observation are emphasized. These two items are more important than fancy statistical techniques.

The analysis of fault-tolerant systems is presented in light of the view of probability described. Component failure and component behavior when faulty are the elementary events. System failure and behavior is computed according to how the system is built from its components. The text discussed some of the uncertainties and pathologies associated with component failure. It is not easy to design a system that functions as specified when all of the components are working correctly. It is even more difficult to accomplish this when some of the components are faulty.

Markov models of redundant and reconfigurable systems are convenient because states in the model correspond to states in the system and transitions in the model correspond to system processes. The Markov section gives an engineering presentation.

Defining Terms

Confidence interval and confidence level: Indicates the quality of an experiment. A confidence interval is an interval around the estimator. A confidence level is a probability. The interval contains the unknown parameter with this probability.

Central limit theorem: As the sample size becomes large, the distribution of the sample average becomes approximately normal.

Density function of a random variable: Defined implicitly: the probability that the random variable lies between a and b is the area under the density function between a and b . This approach introduces the methods of calculus and analysis into probability.

Estimator: Strictly speaking, any function of the sample points. Hence, an estimator is a random variable. To be useful an estimator must have a good relationship to some unknown quality that we are trying to determine by experiment.

Independent event: Events with the property that the occurrence of one event gives no information about the occurrence of the other events.

Markov model: A modeling techniques where the states of the model correspond to states of the system and transitions between the states in the model correspond to system processes.

Mean, average, expected value: The first moment of a distribution; the integral of x with respect to its density function $f(x)$.

Monte Carlo: Computation by statistical estimation.

Probability space: A set together with a distinguished collection of its subsets. A subset in this collection is called an event. Probabilities are assigned to events in a manner that preserves additive properties.

Sample: A set of items, each chosen independently from a distribution.

Variance: The second moment of a distribution about its mean; measures the dispersion of the distribution.

21.2 Electronic Hardware Reliability

Michael Pecht and Iuliana Bordelon

21.2.1 Introduction

Reliability is the ability of a product to perform as intended (i.e., without failure and within specified performance limits) for a specified life cycle. Reliability is a characteristic of a product, in the sense that reliability can be designed into a product, controlled in manufacture, measured during test, and sustained in the field.

To achieve **product performance** over time requires an approach that consists of tasks, each having total engineering and management commitment and enforcement. The tasks impact electronic hardware reliability through the selection of materials, structural geometries, design tolerances, manufacturing processes and tolerances, assembly techniques, shipping and handling methods, and maintenance and maintainability guidelines (Pecht, 1994). The tasks are as follows:

1. Define realistic system requirements determined by mission profile, required operating and storage life, performance expectations, size, weight, and cost. The design team must be aware of the environmental and operating conditions for the product. This includes all stress and loading conditions.
2. Characterize the materials and the manufacturing and assembly processes. Variabilities in material properties and manufacturing processes can induce failures. Although knowledge of variability may not be required for some engineering products, due to the inherent strength of the product compared to the stresses to which the product is subjected, concern with product weight, size, and cost often force the design team to consider such extreme margins as wasteful.
3. Identify the potential failure sites and **failure mechanisms**. Critical parts, part details, and the potential failure mechanisms and modes must be identified early in the design, and appropriate

measures must be implemented to assure control. Potential architectural and stress interactions must be defined and assessed.

4. Design to the usage and process capability (i.e., the quality level that can be controlled in manufacturing and assembly) considering the potential failure sites and failure mechanisms. The design stress spectra, the part test spectra, and the full-scale test spectra must be based on the anticipated life cycle usage conditions. Modeling and analysis are steps toward assessment. Tests are conducted to verify the results for complex structures. The goal is to provide a physics-of-failure basis for design decisions with the assessment of possible failure mechanisms for the anticipated product. The proposed product must survive the life cycle profile while being cost effective and available to the market in a timely manner.
5. Qualify the product manufacturing and assembly processes. If all the processes are in control and the design is proper, then product testing is not warranted and is therefore not cost effective. This represents a transition from *product* test, analysis, and screening, to *process* test, analysis, and screening.
6. Control the manufacturing and assembly processes addressed in the design. During manufacturing and assembly, each process must be monitored and controlled so that process shifts do not arise. Each process may involve screens and tests to assess statistical process control.
7. Manage the life cycle usage of the product using closed loop management procedures. This includes realistic inspection and maintenance procedures.

21.2.2 The Life Cycle Usage Environment

The life cycle usage environment or scenario for use of a product goes hand in hand with the product requirements. The life cycle usage information describes the storage, handling, and operating stress profiles and thus contains the necessary load input information for failure assessment and the development of design guidelines, screens, and tests. The stress profile of a product is based on the application profile and the internal stress conditions of the product. Because the performance of a product over time is often highly dependent on the magnitude of the stress cycle, the rate of change of the stress, and even the time and spatial variation of stress, the interaction between the application profile and internal conditions must be specified. Specific information about the product environment includes absolute temperature, temperature ranges, temperature cycles, temperature gradients, vibrational loads and transfer functions, chemically aggressive or inert environments, and electromagnetic conditions. The life cycle usage environment can be divided into three parts: the application and life profile conditions, the external conditions in which the product must operate, and the internal product generated stress conditions.

The application and life profile conditions include the application length, the number of applications in the expected life of the product, the product life expectancy, the product utilization or nonutilization (storage, testing, transportation) profile, the deployment operations, and the maintenance concept or plan. This information is used to group usage platforms (i.e., whether the product will be installed in a car, boat, satellite, underground), develop duty cycles (i.e., on–off cycles, storage cycles, transportation cycles, modes of operation, and repair cycles), determine design criteria, develop screens and test guidelines, and develop support requirements to sustain attainment of reliability and maintainability objectives.

The external operational conditions include the anticipated environment(s) and the associated stresses that the product will be required to survive. The stresses include temperature, vibrations, shock loads, humidity or moisture, chemical contamination, sand, dust and mold, electromagnetic disturbances, radiation, etc.

The internal operational conditions are associated with product generated stresses, such as power consumption and dissipation, internal radiation, and release or outgassing of potential contaminants. If the product is connected to other products or subsystems in a system, stresses associated with the interfaces (i.e., external power consumption, voltage transients, electronic noise, and heat dissipation) must also be included.

The life-cycle application profile is a time-sequential listing of all of the loads that can potentially cause failure. These loads constitute the parameters for quantifying the given application profile. For example, a flight application could be logged at a specified location and could involve engine warm-up, taxi, climb, cruising, high-speed maneuvers, gun firing, ballistic impact, rapid descent, and emergency landing. This information is of little use to a hardware designer unless it is associated with the appropriate application load histories, such as acceleration, vibration, impact force, temperature, humidity, and electrical power cycle.

21.2.3 Characterization of Materials, Parts, and the Manufacturing Processes

Design is intrinsically linked to the materials, parts, interfaces, and manufacturing processes used to establish and maintain functional and structural integrity. It is unrealistic and potentially dangerous to assume defect-free and perfect-tolerance materials, parts, and structures. Materials often have naturally occurring defects and manufacturing processes that can induce additional defects to the materials, parts, and structures. The design team must also recognize that the production lots or vendor sources for parts that comprise the design are subject to change. Even greater variability in parts characteristics is likely to occur during the fielded life of a product as compared to its design or production life cycle phases.

Design decisions involve the selection of components, materials, and controllable process techniques, using tooling and processes appropriate to the scheduled production quantity. Often, the goal is to maximize part and configuration standardization; increase package modularity for ease in fabrication, assembly, and modification; increase flexibility of design adaptation to alternate uses; and to utilize alternate fabrication processes. The design decisions also involve choosing the best materials interfaces and best geometric configurations, given the product requirements and constraints.

21.2.4 Failure Mechanisms

Failure mechanisms are the physical processes by which stresses can damage the materials included in the product. Investigating failure mechanisms aids in the development of failure-free, reliable designs. Numerous studies focusing on material failure mechanisms and physics-based damage models and their role in obtaining reliable electronic products have been extensively illustrated in a series of tutorials comprising all relevant **wearout** and **overstress failures** (Dasgupta and Pecht, 1991; Dasgupta and Hu, 1992a, 1992b, 1992c, 1992d; Dasgupta and Haslach, 1993; Engel, 1993; Li and Dasgupta, 1993, 1994; Dasgupta, 1993; Young and Christou, 1994; Rudra and Jennings, 1994; Al-Sheikhly and Christou, 1994; Diaz, Kang, and Duvvury 1995; Tullmin and Roberge, 1995).

Catastrophic failures that are due to a single occurrence of a stress event, when the intrinsic strength of the material is exceeded, are termed overstress failures. Failure mechanisms due to monotonic accumulation of incremental **damage** beyond the endurance of the material are termed wearout mechanisms. When the damage exceeds the endurance limit of the component, failure occurs. Unanticipated large stress events can either cause an overstress (catastrophic) failure or shorten life by causing the accumulation of wearout damage. Examples of such stresses are accidental abuse and acts of God. On the other hand, in well-designed and high-quality hardware, stresses should cause only uniform accumulation of wearout damage; the threshold of damage required to cause eventual failure should not occur within the usage life of the product.

The design team must be aware of all possible failure mechanisms in order to design hardware capable of withstanding loads without failing. Failure mechanisms and their related models are also important for planning tests and screens to audit the nominal design and manufacturing specifications, as well as the level of defects introduced by excessive variability in manufacturing and material parameters.

Electrical performance failures can be caused when individual components have incorrect resistance, impedance, voltage, current, capacitance, or dielectric properties or by inadequate shielding from electromagnetic interference (EMI) or particle radiation. The failure modes can be manifested as reversible drifts in electrical transient and steady-state responses such as delay time, rise time, attenuation, signal-to-noise

ratio, and cross talk. Electrical failures, common in electronic hardware, include overstress mechanisms due to *electrical overstress* (EOS) and *electrostatic discharge* (ESD) such as dielectric breakdown, junction breakdown, hot electron injection, surface and bulk trapping, and surface breakdown and wearout mechanisms such as electromigration.

Thermal performance failures can arise due to incorrect design of thermal paths in an electronic assembly. This includes incorrect conductivity and surface emissivity of individual components, as well as incorrect convective and conductive paths for the heat transfer path. Thermal overstress failures are a result of heating a component beyond such critical temperatures as the glass-transition temperature, melting point, fictive point, or flash point. Some examples of thermal wearout failures are aging due to depolymerization, intermetallic growth, and interdiffusion. Failures due to inadequate thermal design may be manifested as components running too hot or too cold, causing operational parameters to drift beyond specifications, although, the degradation is often reversible upon cooling. Such failures can be caused either by direct thermal loads or by electrical resistive loads, which in turn generate excessive localized thermal stresses. Adequate design checks require proper analysis for thermal stress and should include conductive, convective, and radiative heat paths.

Incorrect product response to mechanical overstress and wearout loads may compromise the product performance, without necessarily causing any irreversible material damage. Such failures include incorrect elastic deformation in response to mechanical static loads, incorrect transient response (such as natural frequency or damping) to dynamic loads, and incorrect time-dependent reversible (anelastic) response. Mechanical failure can also result from buckling, brittle and/or ductile fracture, interfacial separation, fatigue crack initiation and propagation, creep, and creep rupture. To take one example, excessive elastic deformations in slender structures in electronic packages due to overstress loads can sometimes constitute functional failure, such as excessive flexing of interconnection wires, package lids, or flex circuits in electronic devices, causing shorting and/or excessive cross talk. When the load is removed, however, the deformations disappear completely without any permanent damage. Examples of wearout failure mechanism include fatigue damage due to thermomechanical stresses during power cycling of electronic hardware, corrosion rate due to anticipated contaminants, and electromigration in high-power devices.

Radiation failures are principally caused by uranium and thorium contaminants and secondary cosmic rays. Radiation can cause wearout, aging, embrittlement of materials, or overstress soft errors in such electronic hardware as logic chips. Chemical failures occur in adverse chemical environments that result in corrosion, oxidation, or ionic surface dendritic growth. There may also be interactions between different types of stresses. For example, metal migration may be accelerated in the presence of chemical contaminants and composition gradients and a thermal load can accelerate the failure mechanism due to a thermal expansion mismatch.

21.2.5 Design Guidelines and Techniques

Generally, products replace other products. The replaced product can be used for comparisons (i.e., a baseline comparison product). Lessons learned from the baseline comparison product can be used to establish new product parameters, to identify areas of focus in the new product design, and to avoid the mistakes of the past.

Once the parts, materials, and processes are identified along with the stress conditions, the objective is to design a product using parts and materials that have been sufficiently characterized in terms of how they perform over time when subjected to the manufacturing and application profile conditions. Only through a methodical design approach using physics of failure and root cause analysis can a reliable and cost effective product be designed.

In using design guidelines, there may not be a unique path to follow. Instead, there is a general flow in the design process. Multiple branches may exist depending on the input design constraints. The design team should explore enough of the branches to gain confidence that the final design is the best for the prescribed input information. The design team should also assess the use of the guidelines for the complete design and not those limited to specific aspects of an existing design. This statement does not imply that

guidelines cannot be used to address only a specific aspect of an existing design, but the design team may have to trace through the implications that a given guideline suggests.

Design guidelines that are based on physics of failure models can also be used to develop tests, screens, and derating factors. Tests can be designed from the physics of failure models to measure specific quantities and to detect the presence of unexpected flaws or manufacturing or maintenance problems. Screens can be designed to precipitate failures in the weak population while not cutting into the design life of the normal population. Derating or safety factors can be determined to lower the stresses for the dominant failure mechanisms.

Preferred Parts

In many cases, a part or a structure much like the required one has already been designed and tested. This “preferred part or structure” is typically mature in the sense that variabilities in manufacturing, assembly, and field operation that can cause problems have been identified and corrected. Many design groups maintain a list of preferred parts and structures of proven performance, cost, availability, and reliability.

Redundancy

Redundancy permits a product to operate even though certain parts and interconnections have failed, thus increasing its reliability and availability. Redundant configurations can be classified as either active or standby. Elements in active redundancy operate simultaneously in performing the same function. Elements in standby redundancy are designed so that an inactive one will or can be switched into service when an active element fails. The reliability of the associated function is increased with the number of standby elements (optimistically assuming that the sensing and switching devices of the redundant configuration are working perfectly, and failed redundant components are replaced before their companion component fails). One preferred design alternative is that a failed redundant component can be repaired without adversely impacting the operation of the product and without placing the maintenance person or the product at risk.

A design team may often find that redundancy is

- The quickest way to improve product reliability if there is insufficient time to explore alternatives or if the part is already designed
- The cheapest solution, if the cost of redundancy is economical in comparison with the cost of redesign
- The only solution, if the reliability requirement is beyond the state-of-the-art

On the other hand, in weighing its disadvantages, the design team may find that redundancy will

- Prove too expensive, if the parts and redundant sensors and switching devices are costly
- Exceed the limitations on size and weight, particularly in avionics, missiles, and satellites
- Exceed the power limitations, particularly in active redundancy
- Attenuate the input signal, requiring additional amplifiers (which increase complexity)
- Require sensing and switching circuitry so complex as to offset the reliability advantage of redundancy.

Protective Architectures

It is generally desirable to include means in a design for preventing a part, structure, or interconnection from failing or from causing further damage if it fails. Protective architectures can be used to sense failure and protect against possible secondary effects. In some cases, self-healing techniques, in that they self-check and self-adjust to effect changes automatically to permit continued operation after a failure, are employed.

Fuses and circuit breakers are examples used in electronic products to sense excessive current drain and disconnect power from a failed part. Fuses within circuits safeguard parts against voltage transients or excessive power dissipation and protect power supplies from shorted parts. Thermostats may be used

to sense critical temperature limiting conditions and shutting down the product or a component of the system until the temperature returns to normal. In some products, self-checking circuitry can also be incorporated to sense abnormal conditions and operate adjusting means to restore normal conditions or activate switching means to compensate for the malfunction.

In some instances, means can be provided for preventing a failed part or structure from completely disabling the product. For example, a fuse or circuit breaker can disconnect a failed part from a product in such a way that it is possible to permit partial operation of the product after a part failure, in preference to total product failure. By the same reasoning, degraded performance of a product after failure of a part is often preferable to complete stoppage. An example is the shutting down of a failed circuit whose design function is to provide precise trimming adjustment within a deadband of another control product. Acceptable performance may thus be permitted, perhaps under emergency conditions, with the deadband control product alone.

Sometimes the physical removal of a part from a product can harm or cause failure of another part of the product by removing load, drive, bias, or control. In these cases, the first part should be equipped with some form of interlock to shut down or otherwise protect the second part. The ultimate design, in addition to its ability to act after a failure, would be capable of sensing and adjusting for parametric drifts to avert failures.

In the use of protective techniques, the basic procedure is to take some form of action, after an initial failure or malfunction, to prevent additional or secondary failures. By reducing the number of failures, such techniques can be considered as enhancing product reliability, although they also affect availability and product effectiveness. Another major consideration is the impact of maintenance, repair, and part replacement. If a fuse protecting a circuit is replaced, what is the impact when the product is re-energized? What protective architectures are appropriate for postrepair operations? What maintenance guidance must be documented and followed when fail-safe protective architectures have or have not been included?

Stress Margins

A properly designed product should be capable of operating satisfactorily with parts that drift or change with time, temperature, humidity, and altitude, for as long as the parameters of the parts and the interconnects are within their rated tolerances. To guard against out-of-tolerance failures, the designer must consider the combined effects of tolerances on parts to be used in manufacture, subsequent changes due to the range of expected environmental conditions, drifts due to aging over the period of time specified in the reliability requirement, and tolerances in parts used in future repair or maintenance functions. Parts and structures should be designed to operate satisfactorily at the extremes of the parameter ranges, and allowable ranges must be included in the procurement or reprocurement specifications.

Methods of dealing with part and structural parameter variations are statistical analysis and worst-case analysis. In statistical design analysis, a functional relationship is established between the output characteristics of the structure and the parameters of one or more of its parts. In worst-case analysis, the effect that a part has on product output is evaluated on the basis of end-of-life performance values or out-of-specification replacement parts.

Derating

Derating is a technique by which either the operational stresses acting on a device or structure are reduced relative to rated strength or the strength is increased relative to allocated operating stress levels. Reducing the stress is achieved by specifying upper limits on the operating loads below the rated capacity of the hardware. For example, manufacturers of electronic hardware often specify limits for supply voltage, output current, power dissipation, junction temperature, and frequency. The equipment designer may decide to select an alternative component or make a design change that ensures that the operational condition for a particular parameter, such as temperature, is always below the rated level. The component is then said to have been derated for thermal stress.

The derating factor, typically defined as the ratio of the rated level of a given stress parameter to its actual operating level, is actually a margin of safety or margin of ignorance, determined by the criticality of any

possible failures and by the amount of uncertainty inherent in the reliability model and its inputs. Ideally, this margin should be kept to a minimum to maintain the cost effectiveness of the design. This puts the responsibility on the reliability engineer to identify as unambiguously as possible the rated strength, the relevant operating stresses, and reliability.

To be effective, derating criteria must target the right stress parameter to address modeling of the relevant failure mechanisms. Field measurements may also be necessary, in conjunction with modeling simulations, to identify the actual operating stresses at the failure site. Once the failure models have been quantified, the impact of derating on the effective reliability of the component for a given load can be determined. Quantitative correlations between derating and reliability enable designers and users to effectively tailor the margin of safety to the level of criticality of the component, leading to better and more cost-effective utilization of the functional capacity of the component.

21.2.6 Qualification and Accelerated Testing

Qualification includes all activities that ensure that the nominal design and manufacturing specifications will meet or exceed the reliability targets. The purpose is to define the acceptable range of variabilities for all critical product parameters affected by design and manufacturing, such as geometric dimensions and material properties. Product attributes that are outside the acceptable ranges are termed defects because they have the potential to compromise the product reliability (Pecht et al., 1994).

Qualification validates the capacity of the design and manufacturing specifications of the product to meet customer's expectations. The goal of qualification testing is to verify whether the anticipated reliability is indeed achieved under actual life cycle loads. In other words, qualification tests are intended to assess the performance of survival of a product over the complete life cycle period of the product. Qualification testing thus audits the ability of the design specifications to meet reliability goals. A well-designed qualification procedure provides economic savings and quick turnaround during development of new products or mature products subject to manufacturing and process changes.

Investigating the failure mechanisms and assessing the reliability of products where long life is required may be a challenge because a very long test period under actual operating conditions is necessary to obtain sufficient data to determine actual failure characteristics. One approach to the problem of obtaining meaningful qualification test data for high-reliability devices is **accelerated testing** to achieve test-time compression, sometimes called *accelerated-stress life testing*. When qualifying the reliability for overstress mechanisms, however, a single cycle of the expected overstress load may be adequate, and acceleration of test parameters may not be necessary. This is sometimes called *proof-stress testing*.

Accelerated testing involves measuring the performance of the test product at accelerated conditions of load or stress that are more severe than the normal operating level, in order to induce failures within a reduced time period. The goal of such testing is to accelerate the time-dependent failure mechanisms and the accumulation of damage to reduce the time to failure. A requirement is that the failure mechanisms and modes in the accelerated environment are the same as (or can be quantitatively correlated with) those observed under usage conditions and it is possible to extrapolate quantitatively from the accelerated environment to the usage environment with some reasonable degree of assurance.

A scientific approach to accelerated testing starts with identifying the relevant wearout failure mechanism. The stress parameter that directly causes the time-dependent failure is selected as the acceleration parameter and is commonly called the accelerated stress. Common accelerated stresses include thermal stresses, such as temperature, temperature cycling, or rates of temperature change; chemical stresses, such as humidity, corrosives, acid, or salt; electrical stresses, such as voltage, current, or power; and mechanical stresses, such as vibration loading, mechanical stress cycles, strain cycles, and shock/impulse. The accelerated environment may include one or a combination of these stresses. Interpretation of results for combined stresses requires a very clear and quantitative understanding of their relative interactions and the contribution of each stress to the overall damage.

Once the failure mechanisms are identified, it is necessary to select the appropriate acceleration stress; determine the test procedures and the stress levels; determine the test method, such as constant stress

acceleration or step-stress acceleration; perform the tests; and interpret the test data, which includes extrapolating the accelerated test results to normal operating conditions. The test results provide designers with qualitative failure information for improving the hardware through design and/or process changes.

Failure due to a particular mechanism can be induced by several acceleration parameters. For example, corrosion can be accelerated by both temperature and humidity; creep can be accelerated by both mechanical stress and temperature. Furthermore, a single acceleration stress can induce failure by several wearout mechanisms simultaneously. For example, temperature can accelerate wearout damage accumulation not only due to electromigration, but also due to corrosion, creep, and so forth. Failure mechanisms that dominate under usual operating conditions may lose their dominance as stress is elevated. Conversely, failure mechanisms that are dormant under normal use conditions may contribute to device failure under accelerated conditions. Thus, accelerated tests require careful planning in order to represent the actual usage environments and operating conditions without introducing extraneous failure mechanisms or nonrepresentative physical or material behavior. The degree of stress acceleration is usually controlled by an *acceleration factor*, defined as the ratio of the life under normal use conditions to that under the accelerated condition. The acceleration factor should be tailored to the hardware in question and should be estimated from an acceleration transform that gives a functional relationship between the accelerated stress and reduced life, in terms of all of the hardware parameters.

Detailed failure analysis of failed samples is a crucial step in the qualification and validation program. Without such analysis and feedback to designers for corrective action, the purpose of the qualification program is defeated. In other words, it is not adequate simply to collect failure data. The key is to use the test results to provide insights into, and consequent control over, relevant failure mechanisms and ways to prevent them, cost effectively.

21.2.7 Manufacturing Issues

Manufacturing and assembly processes can impact the quality and reliability of hardware. Improper assembly and manufacturing techniques can introduce defects, flaws, and residual stresses that act as potential failure sites or stress raisers later in the life of the product. The fact that the defects and stresses during the assembly and manufacturing process can affect the product reliability during operation necessitates the identification of these defects and stresses to help the design analyst account for them proactively during the design and development phase. The task of auditing the merits of the manufacturing process involves two crucial steps. First, qualification procedures are required, as in design qualification, to ensure that manufacturing specifications do not excessively compromise the long-term reliability of the hardware. Second, lot-to-lot screening is required to ensure that the variabilities of all manufacturing-related parameters are within specified tolerances (Pecht et al., 1994). In other words, screening ensures the quality of the product and improves short-term reliability by precipitating latent defects before they reach the field.

Process Qualification

Like design qualification, process qualification should be conducted at the prototype development phase. The intent is to ensure that the nominal manufacturing specifications and tolerances produce acceptable reliability in the hardware. Once qualified, the process needs requalification only when process parameters, materials, manufacturing specifications, or human factors change.

Process qualification tests can be the same set of accelerated wearout tests used in design qualification. As in design qualification, overstress tests may be used to qualify a product for anticipated field overstress loads. Overstress tests may also be exploited to ensure that manufacturing processes do not degrade the intrinsic material strength of hardware beyond a specified limit. However, such tests should supplement, not replace, the accelerated wearout test program, unless explicit physics-based correlations are available between overstress test results and wearout field-failure data.

Manufacturability

The control and rectification of manufacturing defects has typically been the concern of production and process-control engineers, but not of the designer. In the spirit and context of concurrent product

development, however, hardware designers must understand material limits, available processes, and manufacturing process capabilities in order to select materials and construct architectures that promote producibility and reduce the occurrence of defects, and consequently increase yield and quality. Therefore, no specification is complete without a clear discussion of manufacturing defects and acceptability limits. The reliability engineer must have clear definitions of the threshold for acceptable quality, and of what constitutes nonconformance. Nonconformance that compromises hardware performance and reliability is considered a defect. Failure mechanism models provide a convenient vehicle for developing such criteria. It is important for the reliability analyst to understand what deviations from specifications can compromise performance or reliability, and what deviations are benign and can hence be accepted.

A *defect* is any outcome of a process (manufacturing or assembly) that impairs or has the potential to impair the functionality of the product at any time. The defect may arise during a single process or may be the result of a sequence of processes. The *yield* of a process is the fraction of products that are acceptable for use in a subsequent process in the manufacturing sequence or product life cycle. The *cumulative yield* of the process is determined by multiplying the individual yields of each of the individual process steps. The source of defects is not always apparent, because defects resulting from a process can go undetected until the product reaches some downstream point in the process sequence, especially if screening is not employed.

It is often possible to simplify the manufacturing and assembly processes in order to reduce the probability of workmanship defects. As processes become more sophisticated, however, process monitoring and control are necessary to ensure a defect-free product. The bounds that specify whether the process is within tolerance limits, often referred to as the *process window*, are defined in terms of the independent variables to be controlled within the process and the effects of the process on the product, or the dependent product variables. The goal is to understand the effect of each process variable on each product parameter in order to formulate control limits for the process, that is, the points on the variable scale where the defect rate begins to possess a potential for causing failure. In defining the process window, the upper and lower limits of each process variable, beyond which it will produce defects, have to be determined. Manufacturing processes must be contained in the process window by defect testing, analysis of the causes of defects, and elimination of defects by process control, such as closed-loop corrective action systems. The establishment of an effective feedback path to report process-related defect data is critical. Once this is done and the process window is determined, the process window itself becomes a feedback system for the process operator.

Several process parameters may interact to produce a different defect than would have resulted from the individual effects of these parameters acting independently. This complex case may require that the interaction of various process parameters be evaluated in a matrix of experiments. In some cases, a defect cannot be detected until late in the process sequence. Thus, a defect can cause rejection, rework, or failure of the product after considerable value has been added to it. These cost items due to defects can reduce yield and return on investments by adding to hidden factory costs. All critical processes require special attention for defect elimination by process control.

Process Verification Testing

Process verification testing is often called *screening*. Screening involves 100% auditing of all manufactured products to detect or precipitate defects. The aim is to preempt potential quality problems before they reach the field. In principle, this should not be required for a well-controlled process. When uncertainties are likely in process controls, however, screening is often used as a safety net.

Some products exhibit a multimodal probability density function for failures, with a secondary peak during the early period of their service life due to the use of faulty materials, poorly controlled manufacture and assembly technologies, or mishandling. This type of early-life failure is often called *infant mortality*. Properly applied screening techniques can successfully detect or precipitate these failures, eliminating or reducing their occurrence in field use. Screening should only be considered for use during the early stages of production, if at all, and only when products are expected to exhibit infant mortality field failures. Screening will be ineffective and costly if there is only one main peak in the failure probability density

function. Further, failures arising due to unanticipated events such as acts of God (lightning, earthquake) may be impossible to screen in a cost effective manner.

Since screening is done on a 100% basis it is important to develop screens that do not harm good components. The best screens, therefore, are nondestructive evaluation techniques, such as microscopic visual exams, X rays, acoustic scans, nuclear magnetic resonance (NMR), electronic paramagnetic resonance (EPR), and so on. Stress screening involves the application of stresses, possibly above the rated operational limits. If stress screens are unavoidable, overstress tests are preferred to accelerated wearout tests, since the latter are more likely to consume some useful life of good components. If damage to good components is unavoidable during stress screening, then quantitative estimates of the screening damage, based on failure mechanism models must be developed to allow the designer to account for this loss of usable life. The appropriate stress levels for screening must be tailored to the specific hardware. As in qualification testing, quantitative models of failure mechanisms can aid in determining screen parameters.

A stress screen need not necessarily simulate the field environment, or even utilize the same failure mechanism as the one likely to be triggered by this defect in field conditions. Instead, a screen should exploit the most convenient and effective failure mechanism to stimulate the defects that would show up in the field as infant mortality. Obviously, this requires an awareness of the possible defects that may occur in the hardware and extensive familiarity with the associated failure mechanisms.

Unlike qualification testing, the effectiveness of screens is maximized when screens are conducted immediately after the operation believed to be responsible for introducing the defect. Qualification testing is preferably conducted on the finished product or as close to the final operation as possible; on the other hand, screening only at the final stage, when all operations have been completed, is less effective, since failure analysis, defect diagnostics, and troubleshooting are difficult and impair corrective actions. Further, if a defect is introduced early in the manufacturing process, subsequent value added through new materials and processes is wasted, which additionally burdens operating costs and reduces productivity. Admittedly, there are also several disadvantages to such an approach. The cost of screening at every manufacturing station may be prohibitive, especially for small batch jobs. Further, components will experience repeated screening loads as they pass through several manufacturing steps, which increases the risk of accumulating wearout damage in good components due to screening stresses. To arrive at a screening matrix that addresses as many defects and failure mechanisms as feasible with each screen test, an optimum situation must be sought through analysis of cost-effectiveness, risk, and the criticality of the defects. All defects must be traced back to the root cause of the variability.

Any commitment to stress screening must include the necessary funding and staff to determine the root cause and appropriate corrective actions for all failed units. The type of stress screening chosen should be derived from the design, manufacturing, and quality teams. Although a stress screen may be necessary during the early stages of production, stress screening carries substantial penalties in capital, operating expense, and cycle time, and its benefits diminish as a product approaches maturity. If almost all of the products fail in a properly designed screen test, the design is probably incorrect. If many products fail, a revision of the manufacturing process is required. If the number of failures in a screen is small, the processes are likely to be within tolerances, and the observed faults may be beyond the resources of the design and production process.

21.2.8 Summary

Hardware reliability is not a matter of chance or good fortune; rather, it is a rational consequence of conscious, systematic, rigorous efforts at every stage of design, development, and manufacture. High product reliability can only be assured through robust product designs, capable processes that are known to be within tolerances, and qualified components and materials from vendors whose processes are also capable and within tolerances. Quantitative understanding and modeling of all relevant failure mechanisms provide a convenient vehicle for formulating effective design and processing specifications and tolerances for high reliability. Scientific reliability assessments may be supplemented by accelerated qualification testing.

The physics-of-failure approach is not only a tool to provide better and more effective designs, but it is also an aid for cost-effective approaches for improving the entire approach to building electronic systems. Proactive improvements can be implemented for defining more realistic performance requirements and environmental conditions, identifying and characterizing key material properties, developing new product architectures and technologies, developing more realistic and effective accelerated stress tests to audit reliability and quality, enhancing manufacturing-for-reliability through mechanistic process modeling and characterization to allow pro-active process optimization, and increasing first-pass yields and reducing hidden factory costs associated with inspection, rework, and scrap.

When utilized early in the concept development stage of a product's development, reliability serves as an aid to determine feasibility and risk. In the design stage of product development, reliability analysis involves methods to enhance performance over time through the selection of materials, design of structures, choice of design tolerance, manufacturing processes and tolerances, assembly techniques, shipping and handling methods, and maintenance and maintainability guidelines. Engineering concepts such as strength, fatigue, fracture, creep, tolerances, corrosion, and aging play a role in these design analyses. The use of physics-of-failure concepts coupled with mechanistic, as well as probabilistic, techniques is often required to understand the potential problems and tradeoffs and to take corrective actions when effective. The use of factors of safety and worst-case studies as part of the analysis is useful in determining stress screening and burn-in procedures, reliability growth, maintenance modifications, field testing procedures, and various logistics requirements.

Defining Terms

Accelerated testing: Tests conducted at higher stress levels than normal operation but in a shorter period of time for the specific purpose to induce failure faster.

Damage: The failure pattern of an electronic or mechanical product.

Failure mechanism: A physical or chemical defect that results in partial degradation or complete failure of a product.

Overstress failure: Failure mechanisms due to a single occurrence of a stress event when the intrinsic strength of an element of the product is exceeded.

Product performance: The ability of a product to perform as required according to specifications.

Qualification: All activities that ensure that the nominal design and manufacturing specifications will meet or exceed the reliability goals.

Reliability: The ability of a product to perform at required parameters for a specified period of time.

Wearout failure: Failure mechanisms caused by monotonic accumulation of incremental damage beyond the endurance of the product.

21.3 Software Reliability

Carol Smidts

21.3.1 Introduction

Software is without doubt an important element in our lives. Software systems are present in air traffic control systems, banking systems, manufacturing, nuclear power plants, medical systems, etc. Thus, software failures can have serious consequences: customer annoyance, loss of valuable data in information systems accidents, and so forth, which can result in millions of dollars in lawsuits. Hence, software development needs to be optimized, monitored, and controlled.

Models have been developed to characterize the quality of software development processes in industries. The capability maturity model (Paulk et al., 1993) is one such model. The CMM has five different levels, each of which distinguishes an organization's software process capability:

1. *Initial*: The software development process is characterized as ad hoc; few processes are defined and project outcomes are hard to predict.

2. *Repeatable*: Basic project management processes are established to track cost, schedule, and functionality; processes may vary from project to project, but management controls are standardized; current status can be determined across a project's life; with high probability, the organization can repeat its previous level of performance on similar projects. At level 2, the key process areas are as follows: requirements management, project planning, project tracking and oversight, subcontract management, quality assurance, and configuration management.
3. *Defined*: The software process for both management and engineering activities is documented, standardized, and integrated into an organization-wide software process; all projects use a documented and approved version of the organization's process for developing and maintaining software.
4. *Managed*: Detailed measures of the software process are collected; both the process and the product are quantitatively understood and controlled, using detailed measures.
5. *Optimizing*: Continuous process improvement is made possible by quantitative feedback from the process and from testing innovative ideas and technology.

21.3.2 Software Life Cycle Models

Knowledge of the software development life cycle is needed to understand **software reliability** concepts and techniques. Several life cycle models have been developed over the years: from the *code-and-fix* model to the *spiral model*. We will describe two such models, which have found a wide variety of applications: the *waterfall life cycle model* and the *spiral model*.

The Waterfall Life Cycle Model

The principal components of this software development process are presented in Fig. 21.25. Together they form the waterfall life cycle model (Royce, 1970, 1987). In actual implementations of the waterfall model variations in the number of phases may exist, naming of phases may differ, and who is responsible for what phase may change.

1. *Requirements definition and analysis* is the phase during which the analyst (usually a software engineer) will determine the user's requirements for the particular piece of software being developed. The notion of requirements will be examined in a later section.
2. *The preliminary design* phase consists of the development of a high-level design of the code based on the requirements.
3. *The detailed design* is characterized by increasing levels of detail and refinement to the preliminary design from the subsystem level to the subroutine level of detail. This implies describing in detail the user's inputs, system outputs, input/output files, and the interfaces at the module level.
4. *The implementation phase* consists of three different activities: coding, testing at the module level (an activity called *unit testing*), and integration of the modules into subsystems. This integration is usually accompanied by integration testing, a testing activity which will ensure compatibility of interfaces between the modules being integrated.

FIGURE 21.25 The waterfall life cycle.

5. *System testing* is defined as when the development team is in charge of testing the entire system from the point of view of the functions the software is supposed to fulfill. The validation process is completed when all tests required in the system test plan are satisfied. The development team will then produce a system description document.
6. *Acceptance testing* is defined as the point at which the development team relinquishes its testing responsibility to an independent acceptance test team. The independent acceptance test team is to determine whether or not the system now satisfies the original system requirements. An acceptance test plan is developed, and the phase ends with successful running of all tests in the acceptance test plan.
7. *Maintenance and operations* is the next phase. If the software requirements are stable, activities will be focused on fixing errors appearing in the exercise of the software or on fine tuning the software to enhance its performance. On the other hand, if the requirements continue to change in response to changing user needs, this stage could resemble to a minilife cycle in itself as software is modified to keep pace with the operational needs.
8. *Retirement* occurs when the user may decide at some point not to use the software anymore. Because of recurrent changes, the software might have become impossible to maintain.

The end of each phase of the life cycle should see the beginning of a new phase. Unfortunately, reality is often very different. Preliminary design will often start before the requirements have been completely analyzed. Actually, the real life cycle is characterized by a series of back-and-forth movements between the eight phases.

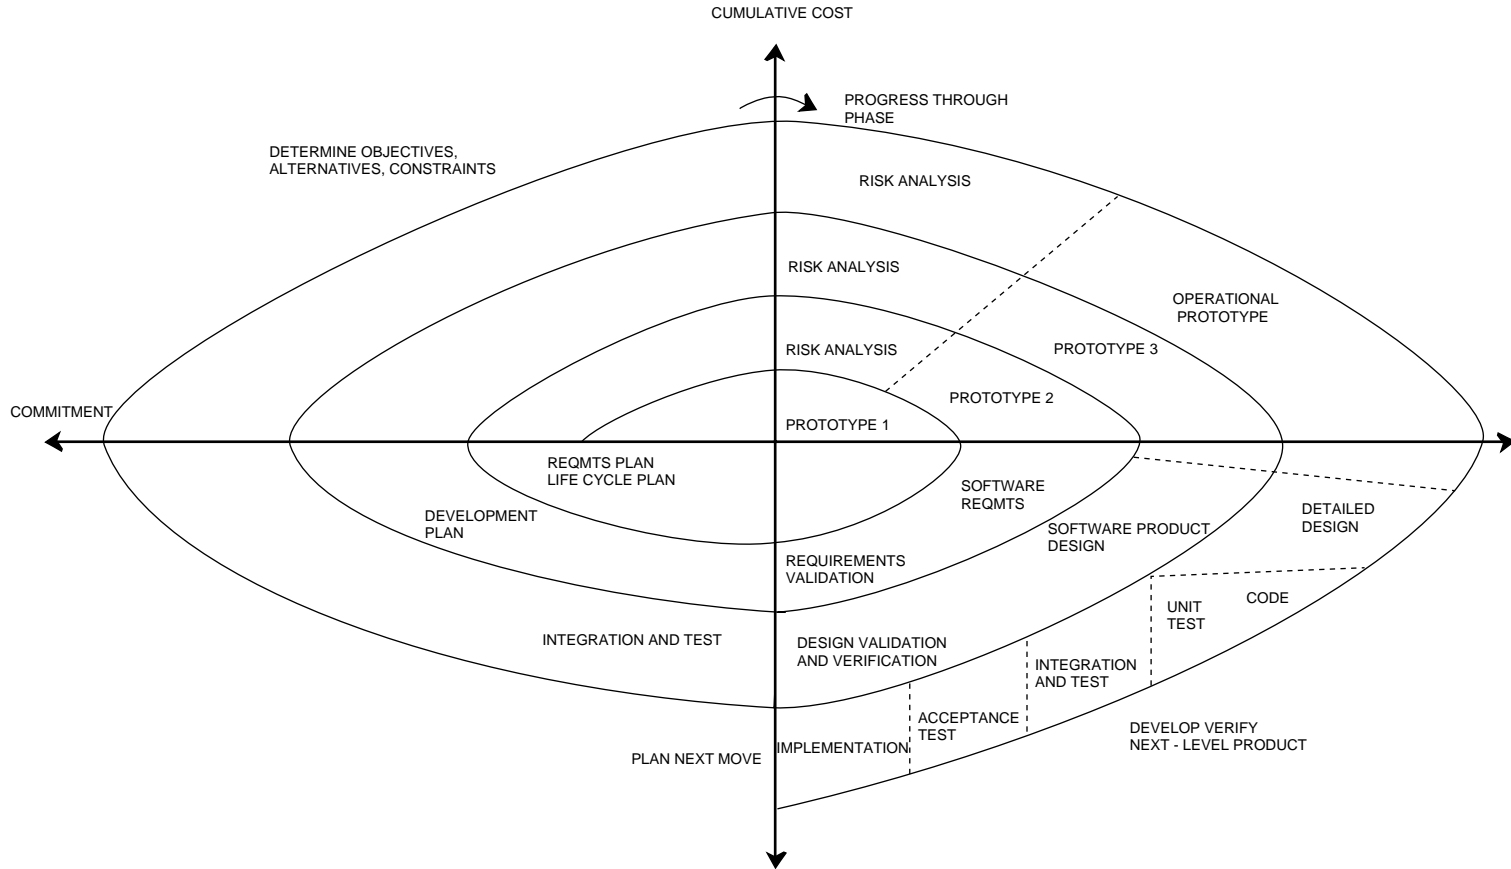

The Spiral Model

The waterfall model was extremely influential in the 1970s and still has widespread application today. However, the waterfall model has a number of limitations such as its heavy emphasis on fully developed documents as criteria of completion for early requirements and design phases. This constraint is not practical for many categories of software (for example, interactive end-user applications). Other process models were developed to remedy these weaknesses. The spiral model (Boehm, 1988) (see Fig. 21.26) is one such model. It is a risk-driven software development model that encompasses most existing process models. The software lifecycle model is not known *a priori*, and it is the risk that will dynamically drive selection of a specific process model or of the steps of such process. The spiral ceases when the risk is considered acceptable. In Fig. 21.26, the radial dimension represents the cost of development at that particular stage. The angular dimension describes the progress made in achieving each cycle of the spiral. A new spiral starts with assessing:

1. The objectives of the specific part of the product in development (functionality, required level of performance, etc.)
2. The alternative means of implementing the product (design options, etc.)
3. The constraints on the product development (schedule, cost, etc.)

Given the different objectives and constraints, one will select the optimal alternative. This selection process will usually uncover the principal sources of uncertainty in the development process. These sources of uncertainty are prime contributors to risk, and a cost-effective strategy will be formulated for their prompt resolution (for example, by prototyping, simulating, developing analytic models, etc.).

Once the risks have been evaluated, the next step is to determine the relative remaining risks and resolve them with the appropriate strategy. For example, if previous efforts (such as prototyping) have resolved to issues related to user interface or software performance and remaining risks can be tied to software development, a waterfall life cycle development will be selected and implemented as part of the next spiral. Finally, let us note that each cycle of the spiral ends with a review of the documents that were generated in the cycle. This review ensures that all parties involved in the software development are committed to the phase of the spiral.

SPIRAL MODEL OF THE SOFTWARE DEVELOPMENT LIFE CYCLE

FIGURE 21.26 The spiral model.

21.3.3 Software Reliability Models

Definitions

A number of definitions are needed to introduce the concept of software reliability. Following are IEEE (1983) definitions.

- **Errors** are human actions that result in the software containing a fault. Examples of such faults are the omission or misinterpretation of the user's requirements, a coding error, etc.
- **Faults** are manifestations of an error in the software. If encountered, a fault may cause a failure of the software.
- **Failure** is the inability of the software to perform its mission or function within specified limits. Failures are observed during testing and operation.
- **Software reliability** is the probability that software will not cause the failure of a product for a specified time under specified conditions; this probability is a function of the inputs to and use of the product, as well as a function of the existence of faults in the software; the inputs to the product will determine whether an existing fault is encountered or not.

The definition of software reliability is willingly similar to that of hardware reliability in order to compare and assess the reliability of systems composed of hardware and software components. One should note, however, that in some environments and for some applications such as scientific applications, time (and more precisely time between failures) is an irrelevant concept and should be replaced with a specified number of runs. The concept of software reliability is, for some, difficult to understand. For software engineers and developers, software has deterministic behavior, whereas hardware behavior is partly stochastic. Indeed, once a set of inputs to the software has been selected, once the computer and operating system with which the software will run is known, the software will either fail or execute correctly. However, our knowledge of the inputs selected, of the computer, of the operating system, and of the nature and position of the fault is uncertain. We can translate this uncertainty into probabilities, hence the notion of software reliability as a probability.

Classification of Software Reliability Models

Many software reliability models (SRMs) have been developed over the years. For a detailed description of most models see Musa, Iannino, and Okumoto (1987). Within these models one can distinguish two main categories: predictive models and assessment models.

- *Predictive models* typically address the reliability of the software early in the life cycle at the requirements or at the preliminary design level or even at the detailed design level in a waterfall life cycle process or in the first spiral of a spiral software development process (see next subsection). Predictive models could be used to assess the risk of developing software under a given set of requirements and for specified personnel before the project truly starts.
- *Assessment models* evaluate present and project future software reliability from failure data gathered when the integration of the software starts (discussed subsequently).

Predictive software reliability models are few in number; most models can be categorized in the assessment category. Different classification schemes for assessment models have been proposed in the past.

A classification of assessment models generalized from Goel's classification (1985) (see also Smidts and Kowalski (1995)) is presented later in this section. It includes most existing SRMs and provides guidelines for the selection of a software reliability model fitting a specific application.

Predictive Models: The Rome Air Development Center Reliability Metric

As explained earlier, predictive models are few. The Air Force's Development Center (RADC) proposed one of the first predictive models (ASFC, 1987). A large range of software programs and related failure data were analyzed in order to identify the characteristics that would influence software reliability. The

model identifies three characteristics: the application type (A), the development environment (D), and the software characteristics (S). A new software will be examined with reference to these different characteristics. Each characteristic will be quantified, and reliability R in faults per executable lines of code is obtained by multiplying these different metrics

$$R = A \times D \times S \quad (21.1)$$

A brief description of each characteristic follows:

The *application type* (A) is a basic characteristic of a software: it determines how a software is developed and run. Categories of applications considered by the Air Force were: airborne systems, strategic systems, tactical systems, process control systems, production systems (such as decision aids), and developmental systems (such as software development tools). An initial value for the reliability of the software to be developed is based only on the application type. This initial value is then modified when other factors characterizing the software development process and the product become available.

Different *development environments* (D) are at the origin of variations in software reliability. Boehm (1981) divides development environments into three categories:

- *Organic mode*: Small software teams develop software in a highly familiar, in-house environment. Most software personnel are extremely experienced and knowledgeable about the impact of this software development on the company's objectives.
- *Semidetached mode*: Team members have an intermediate level of expertise with related systems. The team is a mixture of experienced and inexperienced people. Members of the team have experience with some specific aspects of the project but not with others.
- *Embedded mode*: The software needs to operate under tight constraints. In other words, the software will function in a strongly coupled system involving software, hardware, regulations, and procedures. Because of the costs involved in altering other elements of this complex system, it is expected that the software developed will incur all required modifications due to unforeseen problems.

The *software characteristics* (S) metric includes all software characteristics that are likely to impact software reliability. This metric is subdivided into a *requirements and design representation metric* ($S1$) and a *software implementation metric* ($S2$) with

$$S = S1 \times S2 \quad (21.2)$$

The *requirements and design metric* ($S1$) is the product of the following subset of metrics.

The *anomaly management metric* (SA) degree to which fault tolerance exists in the software studied.

The *traceability metric* (ST) degree to which the software being implemented matches the user requirements.

The effect of traceability on the code is represented by a metric, ST

$$ST = \frac{k_{tc}}{TC} \quad (21.3)$$

where k_{tc} is a coefficient to be determined by regression and TC is the traceability metric calculated by

$$\frac{NR}{(NR - DR)} \quad (21.4)$$

where NR is the number of user requirements, and DR is the number of user requirements that cannot be found in design or code.

The last characteristic is the *quality review results metric* (SQ). During large software developments formal and informal reviews of software requirements and design are conducted. Any problems identified in the documentation or in the software design are recorded in discrepancy reports. Studies show a strong correlation between errors reported at these early phases and existence of unresolved problems that will be found later during test and operation. The quality review results metric is a measure of the effect of the

number of discrepancy reports found on reliability

$$SQ = k_q \frac{NR}{(NR - NDR)} \quad (21.5)$$

where k_q is a correlation coefficient to be determined, NR is the number of requirements and NDR is the number of discrepancy reports.

Finally

$$S1 = SA \times ST \times SQ \quad (21.6)$$

The *software implementation metric* ($S2$) is the product of SL , SS , SM , SU , SX , and SR , defined as follows.

A language type metric (SL): a significant correlation seems to exist between fault density and language type. The software implementation metric identifies two categories of language types: assembly languages ($SL = 1$) and high-order languages ($SL = 1.4$).

Program size metric (SS): Although fault density does account directly for the size of the software (i.e., fault density is the number of faults divided by the number of executable lines of code), nonlinear effects of size on reliability due to factors such as complexity and inability of humans to deal with large systems still need to be assessed. Programs are divided in four broad categories: smaller than 10,000 lines of code, between 10,000 and 50,000 lines of code, between 50,000 and 100,000 lines of code, and larger than 100,000 lines of code.

Modularity metric (SM): It is considered that smaller modules are generally more tractable, can be more easily reviewed, and hence will ultimately be more reliable. Three categories of module size are considered: (1) modules smaller than 200 lines of code, (2) modules between 200 and 3,000 lines of code and (3) modules larger than 3,000 lines of code. For a software composed of α modules in category 1, β modules in category 2, and γ modules in category 3,

$$SM = (\alpha \times SM(1) + \beta \times SM(2) + \gamma \times SM(3))/(\alpha + \beta + \gamma) \quad (21.7)$$

with $SM(i)$ the modularity metric for modules in category i .

Extent of reuse metric (SU): reused code is expected to have a positive impact on reliability because this reused code was part of an application that performed correctly in the field. Two cases need to be considered: (1) The reused code is to be used in an application of the same type as the application from which it originated. (2) The reused code is to be used in an application of a different type requesting different interfaces and so forth. In each case SU is a factor obtained empirically, which characterizes the impact of reuse on reliability.

Complexity metric (SX): it is generally considered that a correlation exists between a module's complexity and its reliability. Although complexity can be measured in different ways, the authors of the model define SX as

$$SX = k_x \cdot \frac{\sum_{i=1,n} SX_i}{n} \quad (21.8)$$

where k_x is a correlation coefficient determined empirically, n is the number of modules, and SX_i is module i McCabe's cyclomatic complexity. (McCabe's cyclomatic complexity (IEEE, 1989b) may be used to determine the structural complexity of a module from a graph of the module's operations. This measure is used to limit the complexity of a module in order to enhance understandability.)

Standards review results metric (SR): Reviews and audits are also performed on the code. The standards review results metric accounts for existence of problem discrepancy reports at the code level. A discrepancy report is generated each time a module meets one of the criteria given in [Table 21.1](#). SR is given by

$$SR = kv \cdot \frac{n}{(n - PR)} \quad (21.9)$$

TABLE 21.1 List of Criteria Determining Generation of a Discrepancy Report for a Code Module

<ul style="list-style-type: none"> • Design is not top down • Module is not independent • Module processing is dependent on prior processing • Module description does not include input, output, processing or limitations • Module has multiple entrances or multiple exits • Database is too large • Database is not compartmentalized • Functions are duplicated • Existence of global data
--

where n is the number of modules, PR is the number of modules with severe discrepancies, and $k\nu$ is a correlation coefficient.

Finally

$$S2 = SL \cdot SS \cdot SM \cdot SU \cdot SX \cdot SR \quad (21.10)$$

The RADC metric was developed from data taken from old projects much smaller than typical software developed today and in a lower level language. Hence its applicability to today's software is questionable.

Models for Software Reliability Assessment

Classification

Most existing SRMs may be grouped into four categories:

- *Times between failures category* includes models that provide estimates of the times between failures (see subsequent subsection, Jelinski and Moranda's model).
- *Failure count category* is interested in the number of faults or failure experienced in specific intervals of time (see subsequent subsection, Musa's basic execution time model and Musa–Okumoto logarithmic Poisson execution time model).
- *Fault seeding category* includes models to assess the number of faults in the program at time 0 via seeding of extraneous faults; (see subsequent subsection, Mills fault seeding model).
- *Input-domain based category* includes models that assess the reliability of a program when the test cases are sampled randomly from a well-known operational distribution of inputs to the program. The **clean room methodology** is an attempt to implement this approach in an industrial environment (the Software Engineering Laboratory, NASA) (Basili and Green, 1993). The reliability estimate is obtained from the number of observed failures during execution (see subsequent subsection, Nelson's model and Ramamoorthi and Bastani).

Table 21.2 lists the key assumptions on which each category of models is based, as well as representative models of the category. Additional assumptions specific to each model are listed in Table 21.3. Table 21.4 examines the validity of some of these assumptions (either the generic assumptions of a category or the additional assumptions of a specific model).

The software development process is environment dependent. Thus, even assumptions that would seem reasonable during the testing of one function or product may not hold true in subsequent testing. The ultimate decision about the appropriateness of the assumptions and the applicability of a model have to be made by the user.

Model Selection

To select an SRM for a specific application, the following practical approach can be used. First, determine to which category the software reliability model you are interested in belongs. Then, assess which specific

TABLE 21.2 Key Assumptions on Which Software Reliability Models Are Based

Key Assumptions	Specific Models
<i>Times between failures models</i>	
<ul style="list-style-type: none"> • Independent times between failures • Equal probability of exposure of each fault • Embedded faults are independent of each other • No new faults introduced during correction 	<ul style="list-style-type: none"> • Jelinski–Moranda’s de-eutrophication model (1972) • Schick and Wolvertson’s model (1973) • Goel and Okumoto’s imperfect debugging model (1979) • Littlewood–Verrall’s Bayesian model (1973)
<i>Fault count models</i>	
<ul style="list-style-type: none"> • Testing intervals are independent of each other • Testing during intervals is homogeneously distributed • Number of faults detected during nonoverlapping intervals are independent of each other 	<ul style="list-style-type: none"> • Shooman’s exponential model (1975) • Goel–Okumoto’s nonhomogeneous Poisson process (1979) • Goel’s generalized nonhomogeneous Poisson process model (1983) • Musa’s execution time model (1975) • Musa–Okumoto’s logarithmic Poisson execution time model (1983)
<i>Fault seeding models</i>	
<ul style="list-style-type: none"> • Seeded faults are randomly distributed in the program • Indigenous and seeded faults have equal probabilities of being detected 	<ul style="list-style-type: none"> • Mills seeding model (1972)
<i>Input-domain based models</i>	
<ul style="list-style-type: none"> • Input profile distribution is known • Random testing is used (inputs are selected randomly) • Input domain can be partitioned into equivalence classes 	<ul style="list-style-type: none"> • Nelson’s model (1978) • Ramamoorthy and Bastani’s model (1982)

model in a given category fits the application. Actually, a choice will only be necessary if the model is in one of the two first categories, that is, times between failures or failure count models. If this is the case, select a software reliability model based on knowledge of the software development process and environment. Collect such failure data as the number of failures, their nature, the time at which the failure occurred, failure severity level, and the time needed to isolate the fault and to make corrections. Plot the cumulative number of failures and the failure intensity as a function of time. Derive the different parameters of the models from the data collected and use the model to predict future behavior. If the future behavior corresponds to the model prediction, keep the model.

Models

Jelinski and Moranda’s Model (1972)

Jelinski and Moranda (1972) developed one of the earliest reliability models. It assumes that

- All faults in a program are equally likely to cause a failure during test.
- The hazard rate is proportional to the number of faults remaining.
- No new defects are incorporated into the software as testing and debugging occur.

Originally, the model assumed only one fault was removed after each failure, but an extension of the model, credited to Lipow (1974), permits more than one fault to be removed.

In this model, the hazard rate for the software is constant between failures and is

$$Z_i(T) = \phi[N - n_{i-1}], \quad i = 1, 2, \dots, m \quad (21.11)$$

TABLE 21.3 Specific Assumptions Related to Each Specific Software Reliability Model

Specific Representatives of a Model Category	Specific Assumptions
<i>Times between failures models</i>	
<ul style="list-style-type: none"> Jelinski and Moranda (JM) de-eutrophication model Schick and Wolverton model Goel and Okumoto imperfect debugging model Littlewood–Verrall Bayesian model 	<ul style="list-style-type: none"> N faults at time 0; detected faults are immediately removed; the hazard rate^a in the interval of time between two failures is proportional to the number of remaining faults Same as above with the hazard rate a function of both the number of faults remaining and the time elapsed since last failure Same as above, but the fault, even if detected, is not removed with certainty Initial number of failures is unknown, times between failures are exponentially distributed, and the hazard rate is gamma distributed
<i>Fault count models</i>	
<ul style="list-style-type: none"> Shooman’s exponential model Goel–Okumoto’s nonhomogeneous Poisson process (GONHPP) Goel’s generalized nonhomogeneous Poisson process model Musa’s execution time model Musa–Okumoto’s logarithmic Poisson time model 	<ul style="list-style-type: none"> Same assumptions as in the JM model The cumulative number of failures experienced follows a nonhomogeneous Poisson process (NHPP); the failure rate decreases exponentially with time Same assumptions as in the GONHPP, but the failure rate attempts better to replicate testing experiments results that show that failure rate first increases then decreases with time Same assumptions as in the JM model Same assumptions as in the GONHPP model, but the time element considered in the model is the execution time
<i>Fault seeding models</i>	
<ul style="list-style-type: none"> Mills’ seeding model 	
<i>Input domain based models</i>	
<ul style="list-style-type: none"> Nelson’s model Ramamoorthy and Bastani’s model 	<ul style="list-style-type: none"> The outcome of a test case provides some stochastic information about the behavior of the program for other inputs close to the inputs used in the test

^aSoftware hazard rate is $z(t) = f(t)/R(t)$, where $R(t)$ is the reliability at time t and $f(t) = -dR(t)/d(T)$. The software failure rate density is $\lambda(t) = d\mu(t)/d(t)$, where $\mu(t)$ is the mean value of the cumulative number of failures experienced by time t .

for the interval between the $(i - 1)$ st i th failures. In this equation, N is the initial number of faults in the software, ϕ is a proportionality constant, and n_{i-1} is the cumulative number of faults removed in the first $(i - 1)$ intervals.

The maximum likelihood estimates of N and ϕ are given by the solution of the following equations:

$$\sum_{i=1}^m \frac{1}{N - n_{i-1}} - \sum_{i=1}^m \phi x_{i-1} = 0 \tag{21.12}$$

and

$$\frac{n}{\phi} - \sum_{i=1}^m [N - n_{i-1}] x_{i-1} = 0 \tag{21.13}$$

where x_{i-1} is the length of the interval between the $(i - 1)$ st and i th failures, and n is the number of errors removed so far.

Once N and ϕ are estimated, the number of remaining errors is given by

$$N(\text{remaining}) = N - n_i \tag{21.14}$$

TABLE 21.4 Validity of Some Software Reliability Models Assumptions

Assumptions	Intrinsic Limitations of Such Assumptions
<ul style="list-style-type: none"> • Times between failures are independent 	<ul style="list-style-type: none"> • Only true if derivation of test cases is purely random (never the case)
<ul style="list-style-type: none"> • A detected fault is immediately corrected 	<ul style="list-style-type: none"> • Faults will not be removed immediately; they are usually corrected in batches; however, the assumption is valid as long as further testing avoids the path in which the fault is active
<ul style="list-style-type: none"> • No new faults are introduced during the fault removal process 	<ul style="list-style-type: none"> • In general, this is not true
<ul style="list-style-type: none"> • Failure rate decreases with test time 	<ul style="list-style-type: none"> • Reasonable approximation in most cases
<ul style="list-style-type: none"> • Failure rate is proportional to the number of remaining faults for all faults 	<ul style="list-style-type: none"> • A reasonable assumption if the test cases are chosen to ensure equal probability of testing different parts of code
<ul style="list-style-type: none"> • Time is used as a basis for failure rate 	<ul style="list-style-type: none"> • Usually time is a good basis for failure rate; if this is not true, the models are valid for other units
<ul style="list-style-type: none"> • Failure rate increases between failures for a given failure interval 	<ul style="list-style-type: none"> • Generally not the case unless testing intensity increases
<ul style="list-style-type: none"> • Testing is representative of the operational usage 	<ul style="list-style-type: none"> • Usually not the case since testing usually selects error-prone situations

The mean time to the next software failure is

$$MTTF = \frac{1}{(N - n_i)\phi} \quad (21.15)$$

The reliability is

$$R_{i+1}(t | t_i) = \exp[-(N - n_i)\phi(t - t_i)], \quad t \geq t_i \quad (21.16)$$

where $R_{i+1}(t/t_i)$ is the reliability of the software at time t in the interval (t_i, t_{i+1}) , given that the i th failure occurred at time t_i .

Musa Basic Execution Time Model (BETM) (Musa, 1975)

This model was first described by Musa in 1975. It assumes that failures occur as a nonhomogeneous Poisson process. The units of failure intensity are failures per central processing unit (CPU) time. This relates failure events to the processor time used by the software. In the BETM, the reduction in the failure intensity function remains constant, irrespective of whether the first or the N th failure is being fixed.

The failure intensity is a function of failures experienced:

$$\lambda(\mu) = \lambda_0(1 - \mu/\nu_0) \quad (21.17)$$

where $\lambda(\mu)$ is the failure intensity (failures per CPU hour at μ failures), λ_0 is the initial failure intensity (at $\tau_e = 0$), μ is the mean number of failures experienced at execution time and τ_e , and ν_0 is the total number of failures expected to occur in infinite time.

Then, the number of failures that need to occur to move from a present failure intensity, λ_p , to a target intensity, λ_F , is given by

$$\Delta\mu = \frac{\nu_0}{\lambda_0}(\lambda_p - \lambda_F) \quad (21.18)$$

and the execution time required to reach this objective is

$$\Delta\tau = \frac{\nu_0}{\lambda_0} \ln(\lambda_p/\lambda_F) \quad (21.19)$$

In practice, ν_0 and λ_0 can be estimated in three ways:

- Use previous experience with similar software. The model can then be applied prior to testing.
- Plot the actual test data to establish or update previous estimates. Plot failure intensity execution time; the y intercept of the straight line fit is an estimate of λ_0 . Plot failure intensity failure number; the x intercept of the straight line fits is an estimate of ν_0 .
- Use the test data to develop a maximum-likelihood estimate. The details of this approach are described in Musa et al. (1987).

Musa (1987) also developed a method to convert execution time predictions to calendar time. The calendar time component is based on the fact that available resources limit the amount of execution time that is practical in a calendar day.

Musa–Okumoto Logarithmic Poisson Execution Time Model (LPETM)

The logarithmic Poisson execution time model was first described by Musa and Okumoto (1983). In the LPETM, the failure intensity is given by

$$\lambda(\mu) = \lambda_0 \exp(-\theta\mu) \quad (21.20)$$

where θ is the failure intensity decay parameter and λ , μ , and λ_0 are the same as for the BETM. The parameter θ represents the relative change of failure intensity per failure experienced. This model assumes that repair of the first failure has the greatest impact in reducing failure intensity and that the impact of each subsequent repair decreases exponentially.

In the LPETM, no estimate of ν_0 is needed. The expected number of failures that must occur to move from a present failure intensity of λ_P to a target intensity of λ_F is

$$\Delta\mu = (1/\theta)\ln(\lambda_P/\lambda_F) \quad (21.21)$$

and the execution time to reach this objective is given by

$$\Delta\tau = \frac{1}{\theta} \left[\frac{1}{\lambda_F} - \frac{1}{\lambda_P} \right] \quad (21.22)$$

In these equations, λ_0 and θ can be estimated based on previous experience by plotting the test data to make graphical estimates or by making a least-squares fit to the data.

Mills Fault Seeding Model (IEEE, 1989a)

An estimate of the number of defects remaining in a program can be obtained by a seeding process that assumes a homogeneous distribution of a representative class of defects. The variables in this measure are: N_S the number of seeded faults, n_S the number of seeded faults found, and n_F the number of faults found that were not intentionally seeded.

Before seeding, a fault analysis is needed to determine the types of faults expected in the code and their relative frequency of occurrence. An independent monitor inserts into the code N_S faults that are representative of the expected indigenous faults. During reviews (or testing), both seeded and unseeded faults are identified. The number of seeded and indigenous faults discovered permits an estimate of the number of faults remaining for the fault type considered. The measure cannot be computed unless some seeded faults are found. The maximum likelihood estimate of the indigenous (unseeded) faults is given by

$$NF = n_F N_S / n_S \quad (21.23)$$

Example

Here, 20 faults of a given type are seeded and, subsequently, 40 faults of that type are uncovered: 16 seeded and 24 unseeded. Then, $NF = 30$, and the estimate of faults remaining is $NF(\text{remaining}) = NF - n_F = 6$.

Input Domain Models

Let us first define the notion of input domain. The input domain of a program is the set of all inputs to this program.

Nelson's Model

Nelson's model (TRW, 1976) is typically used for systems with ultrahigh-reliability requirements, such as software used in nuclear power plants and limited to 1000 lines of code (Goel, 1985; Ramamoorthy and Bastani, 1982). The model is applied to the validation phase of the software (acceptance testing) to estimate reliability. Typically during this phase, if any error is encountered, it will not be corrected (and usually no error will occur).

Nelson defines the reliability of a software run n times (for n test cases) and which failed n_f times as

$$R = 1 - n_f/n$$

where n is the total number of test cases and n_f is the number of failures experienced out of these test cases.

The Nelson model is the only model whose theoretical foundations are really sound. However, it suffers from a number of practical drawbacks.

- We need to run a huge number of test cases in order to reduce our uncertainty on the reliability R .
- Nelson's model assumes random sampling whereas testing strategies tend to use test cases that have a high probability of revealing errors.
- The model does not account for the characteristics of the program. One would expect that to reach an equal level of confidence in the reliability estimate, a logically complex program should be tested more often than a simple program.
- The model does not account for the notion of equivalence classes.

(Equivalence classes are subdomains of the input domain to the program. The expectation is that two sets of input selected from a same equivalence class will lead to similar output conditions.) The model was modified in order to account for these issues. The resulting model (Nelson, 1978) defines the reliability of the program as follows:

$$R = \sum_{j=1,m} P_j(1 - \epsilon_j)$$

where the program is divided in m equivalence classes, P_j is the probability that a set of user's inputs are selected from the equivalence class j and $(1 - \epsilon_j)$ is the probability that the program will execute correctly for any set of inputs in class j knowing that it executed correctly for any input randomly selected in j . Here $(1 - \epsilon_j)$ is the class j correctness probability.

The weakness of the model comes from the fact that values provided for ϵ_j are ad hoc and depend only on the functional structure of the program.

Empirical values for ϵ_j are

- If more than one test case belongs to G_j where G_j is the set of inputs that execute a given logic path L_j , then $\epsilon_j = 0.001$.
- If only one test case belongs to G_j , then $\epsilon_j = 0.01$.
- If no test case belongs to G_j but all segments (i.e., a sequence of executable statements between two branch points) and segment pairs in L_j have been exercised in the testing, then $\epsilon_j = 0.05$.
- If all segments L_j but not all segment pairs have been exercised in the testing, then $\epsilon_j = 0.1$.
- If m segments ($1 < m < 4$) of L_j have not been exercised in testing, then $\epsilon_j = 0.1 + 0.2m$.
- If more than 4 segments of L_j have not been exercised in the testing, then $\epsilon_j = 1$.

Ramamoorthy and Bastani

Ramamoorthy and Bastani (1982) developed an improved version of Nelson’s model. The model is an attempt to give an analytical expression of the correctness probability $1 - \epsilon_j$. To achieve this objective the authors introduce the notion of probabilistic equivalence class.

E is a probabilistic equivalence class if $E \subseteq I$, where I is the input domain of the program P and P is correct for all elements in E with probability $P\{X_1, X_2, \dots, X_d\}$ if P is correct for each $X_i \in E, i = 1, \dots, d$. Then $P\{E | X\}$ is the correctness probability of P based on the set of test cases X . Knowing the correctness probability one derives the reliability of the program easily,

$$R = \sum_{i=1,m} P(E_i | X_i)P(E_i)$$

where E_i is a probabilistic equivalence class, $P(E_i)$ is the probability that the user will select inputs from the equivalence class, and $P(E_i | X_i)$ is the correctness probability of E_i given the set of test cases X_i .

It is possible to estimate the correctness probability of a program using the continuity assumption (i.e., that closely related points in the input domain are correlated). This assumption holds especially for algebraic equations. Furthermore, we make the assumption that a point in the input domain depends only on its closest neighbors. Figure 21.27 shows the correctness probability for an equivalence class $E_i = (a, a + V)$ where only one test case is selected (Fig. 21.27(a)) and where two test cases are selected (Fig. 21.27(b)).

The authors show that, in general,

$$P\{E_i \text{ is correct} | 1 \text{ test case is correct}\} = e^{-\lambda V}$$

$$P(E_i \text{ is correct} | n \text{ test cases have successive distances } x_j \text{ are correct}$$

$$j = 1, 2, \dots, n - 1) = e^{(-\lambda v)} \prod_{j=1}^{n-1} \left(\frac{2}{1 + e^{-\lambda x_j}} \right)$$

where λ is a parameter of the equivalence class (Ramamoorthy and Bastani, 1982).

FIGURE 21.27 Interpretation of continuous equivalence classes: (a) single test case, (b) two test cases.

A good approximation of λV is found for

$$\lambda V \simeq (D - 1) // N$$

where N is the number of elements in the class (due to the finite word of the computer) and D is the degree of the equivalence class (i.e., number of distinct test cases that completely validate the class).

Ramamoorthy and Bastani warn that application of the model has several disadvantages. It can be relatively expensive to determine the equivalence classes and their complexity and the probability distribution of the equivalence classes.

Derived Software Reliability Models

From the basic models presented previously, models can be built for applications involving more than one software, such as models to assess the reliability of fault-tolerant software designs (Scott, Gault, and McAllister, 1987) or the reliability of a group of modules assembled during the integration phase.

Littlewood (1979) explicitly takes into account the structure (i.e., the modules) of the software, and models the exchange of control between modules (time of sojourn in a module and target of exchange) using a semi-Markovian process. The failure rates of a given module can be obtained from the basic reliability models applied to the module; interface failures are being modeled explicitly. This model can be used to study the integration process.

Data Collection

This subsection examines the data needed to perform a software reliability assessment with the models just described. In particular, we will define the concepts of criticality level and operational profiles. The complete list of data required by each model can be found in Table 21.5.

Criticality: The faults encountered in a software are usually placed in three or five categories called *severity levels* or *criticality levels*. This categorization helps distinguish those faults that are real contributors to software reliability from others such as mere enhancements. Such distinction is, of course, important

TABLE 21.5 Data Requirements for Each Model Category

Model Type	Minimal Data Required
Times between failures category	<ul style="list-style-type: none"> • Criticality level • Operational profile • Failure count • Time between two failures
Failure count category	<ul style="list-style-type: none"> • Criticality • Operational profile • Failure count • Time at which failure occurred
Fault seeding category	<ul style="list-style-type: none"> • Types of faults • Number of seeded faults of a given type • Number of seeded faults of a given type that were discovered • Number of indigenous faults of a given type that were discovered.
Input-domain based category	<ul style="list-style-type: none"> • Equivalence classes • Probability of execution of an equivalence class • Distance between test cases in an equivalence class or correctness probability

FIGURE 21.28 Input profile for a software program.

if we wish to make a correct assessment of the reliability of our software. The following is a classification with five criticality levels (Neufelder, 1993):

- *Catastrophic*: This fault may cause unrecoverable mission failure, a safety hazard or loss of life.
- *Critical*: This fault may lead to mission failure, loss of data, system downtime with consequences such as lawsuits or loss of business.
- *Moderate*: This fault may lead to a partial loss of functionalities and undesired downtimes. However, work-arounds exist, which can mitigate the effect of the fault.
- *Negligible*: This fault does generally not affect the software functionality. It is merely a nuisance to the user and may never be fixed.
- *All others*: This category includes all other faults.

It will be clear to the reader that the two first categories pertain without question to reliability assessment. But what is it of the three other categories?

Operational profile: A software's reliability depends inherently on its use. If faults exist in a region of the software never executed by its users and no faults exist in regions frequently executed, the software's perceived reliability will be high. On the other hand, if a software contains faults in regions frequently executed, the reliability will be perceived to be low. This remark leads to the concept of *input profile*. An input profile is the distribution obtained by putting the possible inputs to the software on the x -axis and the probability of selection of these inputs on the y -axis (see Fig. 21.28). As the reader will see the notion of input profile is extremely important: input profiles are needed for software reliability assessment but they also drive efficient software testing and even software design. Indeed, testing should start by exercising the software under sets of high probability inputs so that if the software has to be unexpectedly released early in the field, the reliability level achieved will be acceptable. It may even be that a reduced version of the software, the reduced operational software (ROS), constructed from the user's highly demanded functionalities, may be built first to satisfy the customer.

Because of the large number of possible inputs to the software, it would be an horrendous task to build a *pure input profile* (a pure input profile would spell out all combinations of input with their respective occurrence probabilities.) An approach to build a *tractable input profile* is proposed next. This approach assesses the operations that will be performed by the software and their respective occurrence probabilities. This profile is called an *operational profile*.

To build an operational profile five steps should be considered (Musa, 1993): establishing the customer's profile, and refinement to the user's profile, to the system-mode profile, to the functional profile, and finally to the operational profile itself.

Customer's profile: a customer is a person, group, or institution that acquires the software or, more generally, a system. A customer group is a set of customers who will use the software in an identical manner. The customer profile is the set of all customer groups with their occurrence probabilities.

User's profile: a user is a person, group, or institution that uses the software. The user group is then the set of users who use the system in an identical manner. The user profile is the set of users' groups (all users' groups through all customers' groups) and their probability of occurrence. If identical users' groups exist in two different customers' groups, they should be combined.

System mode profile: a system mode is a set of operations or functions grouped in analyzing system execution. The reliability analyst selects the level of granularity at which a system mode is defined. Some reference points for selecting system modes could be: *user group*, administration vs. students in a university; *environmental condition*; overload vs. normal load; *operational architectural structure*, network communications vs. stand-alone computations; *criticality*, normal nuclear power plant operation vs. after trip operations; *hardware components*, functionality is performed on hardware component 1 vs. component 2. The system mode profile is the set of all system modes and their occurrence probabilities.

Functional profile: functions contributing to the execution of a system mode are identified. These functions can be found at the requirements definition and analysis stage (see Fig. 21.25). They may also be identifiable in a prototype of the final software product if a spiral software development model was used. However, in such cases care should be exercised: most likely the prototype will not possess all of the functionalities of the final product. The number of functions to be defined varies from one application to another. It could range from 50 functions to several hundreds. The main criteria governing the definition of a function is the extent to which processing may differ. Let us consider a command C with input parameters X and Y . Three admissible values of X exist, x_1 , x_2 , and x_3 , and five admissible values of parameter Y exist, namely, y_1 , y_2 , y_3 , y_4 , and y_5 . From these different combinations of input parameters we could build 15 different functionalities (i.e., combinations (x_1, y_1) , (x_1, y_2) , \dots , (x_1, y_5) ; (x_2, y_1) , \dots , (x_2, y_5) , (x_3, y_1) , \dots , (x_3, y_5)). However, the processing may not differ significantly between these 15 different cases but only for cases that differ in variable X . Each variable defining a function is called a *key input variable*. In our example, the command C and the input X are two key input variables. Please note that even environmental variables could constitute candidate key input variables. The functional profile is the set of all functions identified (for all system modes) and their occurrence probability.

Operational profile: functions are implemented into code. The resulting implementation will lead to one or several operations that need to be executed for a function to be performed. The set of all operations obtained from all functions and their occurrence probability is the operational profile. To derive the operational profile, one will first divide execution into *runs*. A run can be seen as a set of tasks initiated by a given set of inputs. For example, sending e-mail to a specific address can be considered as a run. Note that a run will exercise different functionalities. Identical runs can be grouped into run types. Once the runs have been identified, the input state will be identified. The input state is nothing but the values of the input variables to the program at the initiation of the run. We could then build the input profile as the set of all input states and their occurrence probabilities and test the program for each such input state. However, this would be extremely expensive. Consequently, the run types are grouped into operations. The input space to an operation is called a *domain*. Run types that will be grouped share identical input variables. The set of operations should include all operations of high criticality.

Criticisms and Suggestion for New Approaches

Existing software reliability models will either base reliability predictions on historical data existing for similar ware (prediction models) or on failure data associated with the specific software being developed (software assessment models). A basic criticism held against these models is the fact that they are not

FIGURE 21.29 Sources of failures.

based on a depth of knowledge and understanding of software behavior. The problem resides in the inherent complexity of software. Too many factors seem to influence the final performance of a software. Furthermore, the software engineering process itself is not well defined. For instance, two programmers handed the same set of requirements and following the same detailed design will still generate different software codes.

Given these limitations, how can we modify our approach to the precision, assessment, and measurement of software reliability? How can we integrate our existing knowledge on software behavior in new models? The main issues we need to resolve are

- Why does software fail or how is a specific software failure mode generated?
- How does software fail or what are the different software failure modes?
- What is the likelihood of a given software failure mode?

Software failures are generated through the process of creating software. Consequently, it is in the software development process that lie the roots of software failures. More precisely, failures are generated either within a phase of the software development process or at the interface between two phases (see Fig. 21.29). To determine the ways in which software fail, we will then need to consider each phase of the software development process (for example, the requirements definition and analysis phase, the coding phase, etc.) and for each such phase identify the realm of failures that might occur. Then we will need to consider the interfaces between consequent phases and identify all of the failures that might occur at these interfaces: for example, at the interface between the requirements definition and analysis phase and the preliminary design phase.

To determine how software failure modes are created within a particular software development phase, we should first identify the activities and participants of a specific life cycle phase. For instance, let us consider the requirements definition and analysis phase of software S. Some of the activities involved in the software requirements definition phase are elicitation of the following:

1. Functional requirements: the different functionalities of the software.
2. Performance requirements: speed requirements.
3. Reliability and safety requirements: how reliable and how safe the software should be.
4. Portability requirements: the software should be portable from machine A to machine B.
5. Memory requirements.
6. Accuracy requirements.

An exhaustive list of the types of requirements can be found in Sage and Palmer (1990).

The participants of this phase are the user of the software and the software analyst, and generally a systems engineer working for a software development company. Note that the number of people involved in this phase may vary from one for each category (user category and analyst category) to several in each category. We will assume for the sake of simplicity that only one representative of each category is present.

We need now to identify the failure modes. These are the failure modes of the user, the failure modes of the analyst, and the failure modes of the communication between user and analyst (see Fig. 21.30).

FIGURE 21.30 Sources of failures in the requirements definition and analysis phase.

A preliminary list of user's failure modes are: omission of a known requirement (the user forgets), the user is not aware of a specific requirement, a requirement specified is incorrect (the user misunderstands his/her own needs), and the user specifies a requirement that conflicts with another requirement. Failure modes of the analyst are: the analyst omits (forgets) a specific user requirement, the analyst misunderstands (cognitive error) a specific user requirement, the analyst mistransposes (typographical error) a user requirement, the analyst fails to notice a conflict between two users' requirements (cognitive error). Communication failure is: requirement is misheard. Each such failure is applicable to all types of requirements.

As an example, let us consider the case of a software for which the user defined the following requirements:

- $R(f, 1)$ and $R(f, 2)$, two functional requirements
- A performance requirement $R(p, 1)$ on the whole software system
- A reliability requirement $R(r, 1)$ on the whole software
- One interoperability requirement $R(io, 1)$

Let us further assume for the sake of simplicity that there can only be four categories of requirements.

The failure modes in [Table 21.6](#) are obtained by affecting each requirement category by the failure modes identified previously. Note that we might need to further refine this failure taxonomy in order to correctly assess the impact of each failure mode on the software system. Let us, for instance, consider the case of a reliability requirement. From previous definitions, reliability is defined as the probability that the system will perform its mission under given conditions over a given period of time. Then if the analyst omits a reliability requirement, it might be either too low or too high. If the reliability requirement is too low, the system may still be functional but over a shorter period of time, which may be acceptable or unacceptable. If the reliability requirement is too high, there is an economic impact but the mission itself will be fulfilled.

Once the failure modes are identified, factors that influence their generation should be determined. For example, in the requirements definition and analysis phase, a failure mode such as "user is unaware of a requirement" is influenced by the user's level of knowledge in the task domain.

Once all failure modes and influencing factors have been established, data collection can start. Weakness areas can be identified and corrected. The data collected is meaningful because it ties directly into the failure generation process. Actually, it is likely that a generic set of failure modes can be developed for specific software life cycles and that this set would only need to be tailored for a specific application.

The next step is to find the combination of failure modes that will either fail the software or degrade its operational capabilities in an unacceptable manner. These failure modes are product (software) dependent. Let us focus only on functional requirements. Let us assume that the software will function satisfactorily if any of the two functional requirements $R(f, 1)$ and $R(f, 2)$ is carried out correctly. Hence, the probability

TABLE 21.6 Preliminary List of Failure Modes of the Software Requirements Definition and Analysis Phase

Category: By:	Functional Requirements	Performance Requirements	Reliability Requirements	Interoperability Requirements
User	<ul style="list-style-type: none"> • Omission of known requirement • Unaware of requirement • $R(f, 1)$ is incorrect • $R(f, 2)$ is incorrect • $R(f, 1)$ conflicts with other requirement. 	<ul style="list-style-type: none"> • Omission of known requirement • Unaware of requirement • $R(p, 1)$ is incorrect • $R(p, 1)$ conflicts with other requirement. 	<ul style="list-style-type: none"> • Omission of known requirement. • Unaware of requirement • $R(r, 1)$ is incorrect • $R(r, 1)$ conflicts with over requirement. 	<ul style="list-style-type: none"> • Omission of known requirement • Unaware of requirement • $R(po, 1)$ is incorrect • $R(po, 1)$ conflicts with other requirement.
Analyst	<ul style="list-style-type: none"> • Analyst omits $R(f, 1)$ • Analyst omits $R(f, 2)$ • Analyst does not notice conflict between $R(f, 1)$ and other requirements • Analyst does not notice conflict between $R(f, 2)$ and other requirements • Analyst misunderstands $R(f, 1)$ • Analyst misunderstands $R(f, 2)$ • Analyst mistransposed $R(f, 1)$ • Analyst mistransposed $R(f, 2)$ 	<ul style="list-style-type: none"> • Analyst omits $R(p, 1)$ • Analyst misunderstands $R(p, 1)$ • Analyst mistransposed $R(p, 1)$ • Analyst does not notice conflict between $R(p, 1)$ and other requirements 	<ul style="list-style-type: none"> • Analyst omits $R(r, 1)$ • Analyst misunderstands $R(r, 1)$ • Analyst mistransposed $R(r, 1)$ • Analyst does not notice conflict between $R(r, 1)$ and other requirements 	<ul style="list-style-type: none"> • Analyst omits $R(po, 1)$ • Analyst misunderstands $R(po, 1)$ • Analyst mistransposed $R(po, 1)$ • Analyst does not notice conflict between $R(po, 1)$ and other requirements
Communication between User and Analyst	<ul style="list-style-type: none"> • User's requirement $R(f, 1)$ is misheard • User's requirement $R(f, 2)$ is misheard 	<ul style="list-style-type: none"> • User's requirement $R(p, 1)$ is misheard 	<ul style="list-style-type: none"> • User's requirement $R(r, 1)$ is misheard 	<ul style="list-style-type: none"> • User's requirement $R(po, 1)$ is misheard

that the software will fail P_f if we take only into account the requirements and definition analysis phase is given by

$$P_f = P(E_{11} \cup (E_{12} \cap E_{13}) \cup E_{14} \cup E_{15} \cup E_{16} \cup E_{21} \cup (E_{22} \cap E_{23}) \cup E_{24} \cup E_{25} \cup E_{26})$$

where $E_{1i}, E_{2i}, i = 1, 6$ are defined in the fault tree given in Fig. 21.31. The actual fault tree will be more complex as failure modes generated by several phases of the software development process contribute to failure of functions 1 and 2. For instance, if we consider a single failure mode for coding such as “software developer fails to code $R(f, 1)$ correctly” and remove, for the sake of the example, contributions for all other phases, a new fault tree is obtained (see Fig. 21.31).

The last question is to determine if we could use such data for reliability prediction. Early in the process, for example, at the requirements definition and analysis phase, our knowledge of the attributes and characteristics of the software development process is limited: coding personnel and coding languages are undetermined, the design approach may not be defined, etc. Hence, our reliability assessment will be uncertain. The more we move into the life cycle process, the more information becomes available, and hence our uncertainty bound reduces. Let us call M the model of the process, that is, the set of characteristics that define the process. The characteristics of such model may include

- The process is a waterfall life cycle
- Top-down design is used
- Language selected is C++
- Number of programmers is 5, etc.

Our uncertainty is in M . Let $p(M)$ be the probability that the model followed is M . This probability is a function of the time into the life cycle, $p(M, t)$. A reasonable approximation of $p(M, t)$ is $p(M, k)$ where k is the k th life cycle phase. Let R_i be the reliability of the software at the end of the software development process if it was developed under model M_i . Initially, at the end of the requirements definition and analysis phase ($k = 1$), the expected reliability $\langle R \rangle$ is

$$\langle R \rangle = \sum_i p(M_i, 1) \cdot R_i$$

and the variance of R due to our uncertainty on the model is

$$\langle R^2 \rangle = \sum_i p(M_i, 1) (R_i - \langle R \rangle)^2$$

If information about the process becomes available, such as, for example, at the end of phase 2 (preliminary design), the process can be updated using Bayesian statistics

$$p(M_i, m+1) = \frac{\mathcal{L}(I | M_i) p(M_i, m)}{\sum_j p(M_j, m) \cdot \mathcal{L}(I | M_j)}$$

where I is information obtained between phase m and $m+1$ and where $\mathcal{L}(I | M_i)$ is the likelihood of information I if the model is M_i .

Defining Terms

Errors: Human actions that result in the software containing a fault. Examples of such errors are the omission or misinterpretation of the user’s requirements, coding error, etc.

Failure: The inability of the software to perform its mission or function within specified limits. Failures are observed during testing and operation.

Faults: Manifestations of an error in the software. If encountered, a fault may cause a failure of the software.

FIGURE 21.31 Software fault tree. The solid lines define the requirements definition and analysis phase fault tree. The requirements definition and analysis phase and coding phase fault tree is obtained by adding solid and dashed contributions.

Software reliability: The probability that software will not cause the failure of a product for a specified time under specified conditions. This probability is a function of the inputs to and use of the product, as well as a function of the existence of faults in the software. The inputs to the product will determine whether an existing fault is encountered or not.

22.1 Electric Shock

Clifford D. Ferris

22.1.1 Introduction

Human tissues, such as the skin and the muscles, as well as blood and other body fluids are classified as **electrolytes**. Consequently, they are electrical conductors that may be characterized in terms of ohmic resistances. Electric potential differences applied across human tissues, or at two locations on the external skin surface, generate response currents.

Electric shock can be divided into two classes: microshock and macroshock. Microshock describes an internal shock that may occur as a consequence of certain medical diagnostic procedures (such as cardiac catheterization) or surgical procedures in which electrically operated sensors are introduced into the human body. Electric current levels associated with microshock range from 10 to 100 μA . This phenomenon is specific to medical procedures and will not be addressed further in this chapter.

Macroshock, or simply electric shock, describes simultaneous contact between the body surface and two electrical conductors at different potentials, and the physiological consequences of this contact. The two conductors may be a hot conductor and ground, or two hot conductors, such as two of the phase wires in a three-phase power distribution system.

The severity of the consequences of electric shock depends on a variety of factors. The physiological effects of electrical shock are not produced by electric potential (voltage) *per se*, but rather by the electric current that is driven by the potential difference that is applied externally to the body surface. Consequently,

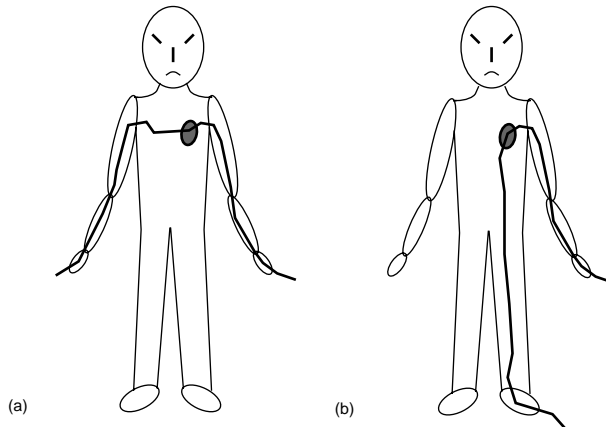

FIGURE 22.1 Most lethal paths for electric shock: (a) hand-to-hand path, (b) hand-to-foot path.

the combined effective electrical resistance of the body volume involved and the intimacy (surface area and pressure) of the skin-conductor contact have a major effect on the severity of electric shock. The paths through the body that the shock currents take determine the potential seriousness of the shock. Generally speaking, current paths that do not include the head or main trunk of the body are not fatal, although permanent damage may be produced in the form of scars, nerve or muscle impairment resulting in partially or fully paralyzed limbs, and loss of limbs. Electric shock currents that pass through the chest in the region of the heart or lungs may cause death, either by direct effect on the heart, or by paralysis of the nerves that control the breathing diaphragm. Severe electric shocks to the head may cause death or permanent brain damage. As illustrated in Fig. 22.1, the two most dangerous current paths are from hand-to-hand, and hand-to-foot (especially left hand to left foot) since the current passes through the chest and potentially through the heart.

Response to electric shock is subjective to some extent, with both physiological and psychological components. The condition of the skin surfaces that come into contact with the electrical conductors is an important factor. For example, if an adult grasps the probes of a digital ohmmeter tightly between the thumb and forefinger of each hand, the resistance displayed will vary widely among individuals. Those individuals who use their hands in activities that build up callouses may produce resistance readings on the order of 1 or 2 M Ω when the hands are dry, and perhaps 100 k Ω when the hands are wet. Other individuals with soft and pliant skin may register 5–10 k Ω with dry hands and significantly lower values when the hands are moist or wet. If the ohmmeter is powered by a 9-V battery, the maximum possible current sustained in the 1-M Ω case is 9 μ A, whereas it is 0.9 mA when the resistance is 10 k Ω (a thousandfold increase).

The sensation experienced by individuals exposed to the same low level of electric shock varies widely. Reported sensations range from buzzing, tingling (pins and needles), to burning or a jolt. The emotional state of the individual at the time that the shock was received and the body location of the shock also influence response. Shock response tends to be amplified in persons who are tense. If the shock site is near a nerve or nerve ending that is close to the surface of the skin, the perceived intensity of the shock is also amplified. A parallel situation is bumping one's elbow and triggering the funny-bone response. The physiological consequences of electric shock at different current levels (rms) for alternating current at 60 Hz are presented in Table 22.1. Threshold levels are shown. Refer to the section on Physiological Effects for additional information.

There are various secondary effects of electric shock that can cause serious injury even if the shock itself has produced no direct physiological damage. As with any sudden and unexpected sensory stimulus, the startle reflex may be triggered causing the person to fall down, flail limbs, drop objects, or otherwise sustain injury. High potentials, especially those produced by the discharge of a high-voltage capacitor, can induce

TABLE 22.1 Electric Shock Current Levels and Physiological Effects (AC 60 Hz)

Current Level	Effect
1 mA	Sensation that shock is occurring
5 mA	Upper limit of safe or harmless range
10–20 mA	Let-go threshold: flexor muscles are stronger than the extensor muscles; subject cannot shake loose from the shock source; perspiration
30–40 mA	Tetany : sustained muscle contraction and cramping
50–70 mA	Extreme pain, physical exhaustion, fainting, irreversible nerve damage; possibility of ventricular fibrillation (heart); respiratory arrest with possible asphyxiation
100 mA	Ventricular fibrillation (heart) and death if the current passes through the body trunk
>100 mA	Fibrillation, amnesia, burns, severe electrolysis at contact sites
>5 A	Little likelihood of survival

severe and generalized muscle contractions of sufficient intensity to propel an individual across a room. Because of the violence of the reaction, the person may sustain serious bone fractures (or even death) as a consequence of physical impact with objects in the trajectory path from the site of the shock. Even if the victim does not collide with an object, the force of the muscle contractions alone resulting from electrical shock may fracture spinal vertebrae or cause a shoulder dislocation.

22.1.2 Physiological Effects

As can be inferred from Table 22.1, the medical consequences of electric shock range in severity from no effect through minor burns, nerve and muscle damage, to death. Determining factors are

1. Effective electrical resistance of the body between the contact points
2. Portion of the body involved in the current path
3. Nature of the electrical source producing the shock
4. Body weight

Items 1 and 2 have been addressed to some extent in the Introduction. The lower the contact resistance, the higher is the resulting shock current and the possibility of severe damage. A current path through the body trunk is potentially the most lethal. The electrical resistance of the human body is a function of frequency. By a strange quirk of nature, it is lowest at 60 Hz and rises slightly as frequency decreases to 0 Hz or DC. The resistance also rises as frequency increases above 60 Hz. At frequencies on the order of 100 kHz, skin-surface (capacitance) effects commence such that electric conduction paths include the skin surface as well as bulk effects through the underlying body tissues. A shock that exceeds the let-go threshold is particularly dangerous because the victim begins to perspire, which then reduces the contact resistance between the body and the electrical source. When the contact resistance decreases, the shock current increases. The let-go threshold current level in women is about 30% lower than in men and may relate to differences in skin condition and resistance.

Generally speaking with regard to item 3, the effects of alternating current shock are more severe than direct current shock at the same current levels (rms and DC). The sensation level for DC is about 5 mA, as opposed to 1 mA (rms) for AC at 60 Hz. The let-go threshold shown in Table 22.1 for AC at 60 Hz is 10–20 mA (15 mA average). For DC, the let-go threshold is on the order of 75 mA, a figure that is higher than the corresponding maximum peak-to-peak AC value at the 20-mA rms level. When there is a direct current path through the heart, a momentary current of 60 mA (rms) at 60 Hz can induce **ventricular** fibrillation (defined subsequently), whereas a direct current in the range from 300 to 500 mA is required. A sustained shock at 120 V AC and 60 Hz is especially dangerous. The body resistance is at a minimum and the voltage level is not high enough to cause severe muscle contractions that might otherwise propel the victim away from the electrical source.

FIGURE 22.2 Stylized anatomical cross section of the heart.

As is discussed in the next section, electrical current that passes through the chest region may cause **cardiac arrest**. The intensity of the current required to produce this condition is a function of the time in the cardiac cycle at which the shock occurs and, to some degree, the victim's body weight. Heavy individuals present larger chest volumes, and the current paths are presumably more diffuse than the current paths through the chest region of a slender person.

Body Trunk (Heart and Lungs)

The human body runs on electricity. Sensory information received from our environment is translated into electrical pulses that are transmitted along nerve pathways to the brain. Muscle activity is initiated by electrical pulses that pass along nerves to sites called myoneural junctions where they trigger a muscle to extend or contract. From a mechanical point of view, the heart is simply a four-chambered pump composed of muscular tissue, as indicated in Fig. 22.2 (as viewed externally from the front).

The two upper chambers (left and right atria) are reservoirs that hold the blood that is returned to the heart from the body organs and the lungs. The main pump chambers are the left and right ventricles. The **atrial** chambers supply blood to the ventricles. When the ventricles (**ventricular** muscles) contract producing a heart beat, blood from the left ventricle is pumped through the aorta to the body organs (the systemic circulation); blood from the right ventricle is pumped through the pulmonary artery to the lungs (the pulmonary circulation). The beating of the heart is controlled by an electric **pacemaker** (analogous to a free-running multivibrator), called the sinoatrial or SA node, which is composed of a small volume of specialized tissue located at a site toward the top of the heart. The pacemaker generates regular pulses that cause the muscles of the ventricles to contract (one pulse per heart beat). In the normal heart, the pacemaker adjusts its output frequency according to the body's demand for oxygen.

The contraction and relaxation of muscles also generates electrical pulses. The beating of the heart is controlled by pulses from the pacemaker, while at the same time the contraction and relaxation of the heart-muscle tissues generate electrical pulses. Because the body is a volume conductor, these pulses can be detected on the surface of the body and recorded as an **electrocardiogram (ECG)**. If a sensing electrode is placed on the inside of each wrist with a third reference electrode on the inside of the right ankle, a signal of the form shown in Fig. 22.3 can be obtained. The signal shown represents one cardiac cycle (heart beat) in a normal heart and is designated as Lead II in the standard method of recording electrocardiograms. The time axis has been normalized to unity, and the major events (called waves) are denoted by P, Q, R, S, T, and U. The maximum peak value (R wave) on the skin surface is approximately 1.5 mV, although values on the order of 1 mV are usually recorded. The P wave represents the muscular contraction of the atrium (two atrial chambers) to force blood into the ventricles. The R wave (in the QRS complex) represents the contraction of the ventricles and the pumping of blood out of the heart into the aorta and pulmonary artery. The T wave is generated by the relaxation (called repolarization) of the ventricular muscles. The electrical signal from the relaxation of the atrium is masked by the high-intensity R wave.

FIGURE 22.3 ECG waveform for one cardiac cycle.

A severe shock current that passes through the chest cavity will cause the entire heart muscle to contract and stop beating while the current persists. If such a current is of short duration, normal heart rhythm begins again with no irreversible cardiac tissue damage. Lower levels of current can disrupt normal heart rhythm. The heart is most susceptible to electric shock during the occurrence of the T wave. Thus a current that just produces a shock response during the T wave typically will not generate any effect during another period of the cardiac cycle. The response of a normally beating heart to an above-threshold electric shock current is cardiac arrest.

The gross symptoms of cardiac arrest produced by electric shock are an unconscious subject who is not breathing, has no detectable pulse (cardiac arrest), and zero blood pressure. The heart, however, may be in either one of two states: standstill or ventricular **fibrillation**. In standstill, as the name implies, the heart is not beating and the ECG signal is a flat line. In fibrillation, the ventricular muscle groups contract randomly and out of unison such that the ventricles flutter. No blood is pumped, but a low-level electrical signal is produced. An ECG recorder is required to differentiate between flat line and ventricular fibrillation (VFIB). The respective ECG signals are illustrated in Fig. 22.4.

FIGURE 22.4 ECG waveforms in cardiac arrest.

A shock current that passes through the chest region may cause involuntary contraction of the respiratory muscles. The subject can no longer breathe voluntarily, and asphyxiation occurs if the current is not interrupted. Respiratory paralysis (cessation of breathing) may occur as a consequence of electric shock that takes a pathway through the body trunk. Typically, what occurs is the nerve that controls the diaphragm is paralyzed. When the shock occurs, the subject inhales sharply and the chest expands and then becomes rigid, even after the electric current has ceased. The heart may or may not be affected. In some cases, the heart initially continues to beat normally until the beats become erratic because the heart muscle itself is no longer receiving properly oxygenated blood. CO₂ builds up in the blood and produces acidosis, which causes irritability of the heart-muscle tissue and makes restoration of the normal heart beat difficult.

Tissue Damage

Except for very minor electric shocks, burns may be expected at the contact site(s) with the involvement of the skin surface and underlying tissues as a consequence of the penetration by the electric current. Traditional descriptions of the severity of thermal burns includes first-, second-, and third-degree burns. Some medical personnel have designated severe burns produced by electrical shock as fourth degree. First-degree burns are essentially superficial and are described by discoloration or redness of the skin, mild swelling, and associated pain. In subjects without underlying medical problems (such as diabetes), they normally heal quickly and without complications. Second-degree burns penetrate more deeply into the skin tissues than first-degree burns to produce a red or mottled appearance with blister formation and significant pain. Considerable swelling of the affected area occurs over a period of a few days, and the skin surface is usually wet from a loss of plasma from the damaged skin layers.

Third-degree burns involve deep penetration of the skin, frequently into underlying tissue, with coagulation of the skin, destruction of red blood cells, and charring of the skin. Initially the skin surface may appear white or charred, or it may resemble a second-degree burn. The risk of infection at the burn site is high, and full healing of the skin may occur only at the edges of the burned area with scar tissue replacing normal skin tissue in the main area of the injury.

The classification fourth-degree burn has been applied to electrical burns that char the overlying tissues in a manner that an underlying bone is exposed. This is the type of injury that can be produced by contact with high-voltage transmission lines. If death does not occur from the shock, permanent physical disability can be expected.

Whatever the apparent degree, burns resulting from electrical shock should not be taken lightly. With the exception of severe fires and explosions, accidental thermal burns typically affect the skin because they are produced by some hot object or liquid that contacts the skin surface. On the other hand, burns produced by electrical shock result from the passage of current through the skin and underlying tissues. Skin damage may appear to be slight, but there may be extensive tissue damage below the skin surface. Burns associated with electric shock tend to be deep, slow to heal, and subject to infection if not treated immediately. In some cases, both thermal and electrochemical burns can occur simultaneously if the subject accidentally touches an electrically energized hot conductor such as heating coil in an electric oven.

Depending on the nature of the electric shock, the tissues involved can be heated to temperatures as high as 5000°C, thus converting the water content of the body cells and fluids to superheated steam. There is progressive necrosis (death) and sloughing of the affected tissues. Damage is generally greater than that inferred from the initial examination of the burned area. This situation occurs because the electric current penetrates into the body, whereas thermal burns, such as those from contact with hot liquids or solid surfaces, generally occur at the body surface. The heat produced by the passage of electric current through biological tissues **coagulates** proteins, ruptures cells, and produces tissue death. When nerve and/or muscle tissues are involved, permanent effects may be expected that vary from partial impairment of function of the limb(s) involved to complete paralysis.

Biological tissues may be modeled electrically as parallel resistance-capacitance circuits. For DC and low-frequency AC currents, the resistive component controls the current levels produced by electric shocks. At audio frequencies and above, capacitive reactance decreases to values comparable to the resistive component of the tissue electrical impedance. This situation leads to the potential of very deep and searing burns when electric shock currents pass through tissues. The effects of high-frequency current are put to beneficial use in the now widely used electrosurgical apparatus (electrical scalpel). These instruments typically operate in the 300–400 kHz range, and by modulating the wave form of the signal, surgical cutting, cauterizing, or a combination of the two may be achieved.

22.1.3 First Aid

The best first aid for electric shock is prevention. In the event that an individual has sustained or is sustaining an electric shock in the work place, several guidelines are suggested:

1. *Shock in progress:* For the case when a coworker is receiving an electric shock and cannot let go of the electrical source, the safest action is to trip the circuit breaker that energizes the circuit involved, or to pull the power-line plug on the equipment involved if the latter can be accomplished safely. Under no circumstances should the rescuer touch the individual who is being shocked, since the rescuer's body may then also be in the dangerous current path. If the circuit breaker or equipment plug cannot be located, then an attempt can be made to separate the victim from the electrical source through the use of a nonconducting object such as a wooden stool or a wooden broom handle. Use only an *insulating* object and nothing that contains metal or other electrically conductive material. The rescuer must be very careful not to touch the victim or the electrical source and thus become a second victim. If such equipment is available, hot sticks used in conjunction with lineman's gloves may be applied to push or pull the victim away from the electrical source. Pulling the hot stick normally provides the greatest control over the victim's motion and is the safest action for

the rescuer. Once the the electrical source has been turned off, or the victim can be reached safely, immediate first aid procedures should be implemented as noted in paragraph 2.

2. *Shock no longer in progress:* (a) If the victim is conscious and moving about, have the victim sit down or lie down. Sometimes there is a delayed reaction to an electrical shock that causes the victim to collapse. Call 911 or the appropriate plant-site paramedical team immediately. If there is a delay in the arrival of medical personnel, check for electrical burns. In instances of severe shock, there will normally be burns at a minimum of two sites: the entry point for the current and the exit point(s). Cover the burns with dry (and sterile preferably) dressings. Check for possible bone fractures if the victim was violently thrown away from the electrical source and possibly impacted objects in the vicinity. Apply splints as required if suitable materials are available and you have appropriate training. Cover the victim with a coat or blanket if the environmental temperature is below room temperature, or the victim complains of feeling cold. (b) If the victim is unconscious, call 911 or the appropriate plant-site paramedical team immediately. In the interim, check to see if the victim is breathing and if a pulse can be felt at either the inside of a wrist above the thumb joint (radial pulse) or in the neck above and to either side of the Adam's apple (carotid pulse). It is usually easier to feel the pulse in the neck as opposed to the wrist pulse, which may be weak. The index and middle finger should be used to sense the pulse, and not the thumb. Many individuals have an apparent thumb pulse that can be mistaken for the victim's pulse. If a pulse can be detected but the victim is not breathing, begin mouth-to-mouth respiration if you know how to do so. If no pulse can be detected (presumably the victim will not be breathing), carefully move the victim to a firm surface and begin cardiopulmonary resuscitation if you have been trained in the use of CPR. Respiratory arrest and cardiac arrest are crisis situations. Because of loss of the oxygen supply to the brain, loss of memory or permanent brain damage may occur after several minutes even if the victim is successfully resuscitated. If the victim can be resuscitated and appears to be stable, follow the additional procedures indicated in paragraph 2(a) if the arrival of medical personnel is delayed.

Ironically, the treatment for cardiac arrest induced by an electric shock is a massive countershock, which causes the entire heart muscle to contract. The random and uncoordinated ventricular fibrillation contractions (if present) are thus stilled. Under ideal conditions, normal heart rhythm is restored once the shock current ceases. The countershock is generated by a cardiac defibrillator, various portable models of which are available for use by emergency medical technicians and other *trained* personnel. Although portable defibrillators may be available at industrial sites where there is a high risk of electrical shock to plant personnel, they should be used only by trained personnel. Application of a defibrillator to an unconscious subject whose heart is beating can induce cardiac standstill or ventricular fibrillation, just the conditions that the defibrillator was designed to correct.

22.1.4 Prevention of Electrical Shock

Electric shock is not a matter to be taken lightly, as death may be the consequence. Prevention of electric shock is far superior to remedial medical treatment. The subject of electrical safety is presented in a separate article, but a few items are outlined here to close the present discussion:

1. In the work place, observe all company and local regulations, and Occupational Safety and Health Administration (OSHA) regulations regarding electrical safety matters.
2. Always turn off and *disconnect* electrical equipment from the power mains before opening the equipment cabinet for servicing or calibration procedures. Do not rely on switches to disconnect power, as sometimes they are defective, and sometimes the switch has been miswired or mislabeled such that the off position is actually the on position.
3. Using cables designed for the purpose, always discharge high-voltage capacitors associated with radio transmitters, cathode-ray tubes, or other high-voltage circuits before attempting servicing. The external surface of cathode-ray tubes should also be discharged.

4. If diagnostic tests must be performed on energized equipment, use appropriate electrical safety procedures. Many modern switching/regulating power supplies are potentially lethal and power-line-isolation transformers *must* be used when servicing such equipment. The electrical hazard results from a bridge rectifier being connected directly across the 120-V AC power line when the equipment is energized. Consequently, the ground for the circuit board in the power supply in the equipment is not at power-line neutral or Earth ground potential. If no isolation transformer is used and the service person simultaneously contacts Earth ground and the circuit board ground, a high possibility exists for a fatal electric shock.
5. Do not disable or remove the Earth ground connectors on power cords and within equipment.
6. In the design or modification of electrical equipment and facilities, observe strict adherence to all of the appropriate codes and guidelines such as: the National Electrical Code of the National Fire Protection Association; Medical Device Safety Act of 1971, 1973, and subsequent amendments; industry standards for electronic equipment design and manufacture; other regulations as appropriate.

Defining Terms

Atrial: Pertaining to the atrium or the top reservoir chambers in the upper portion of the heart.

Cardiac: Pertaining to the heart.

Coagulation: The production or formation of a blood clot.

Electrocardiogram (ECG): The visual display of the electrical activity of the heart as recorded from electrodes placed on the skin surface.

Electrolyte: A substance that is electrically conductive and is broken down by the passage of electric current through it.

Extensor muscles: Muscles that extend a joint.

Fibrillation: Spontaneous and individual contraction of muscle fibers.

Flexor muscles: Muscles that flex a joint.

Pacemaker: A small area of specialized tissue near the top of the heart that generates the electrical pulses that initiate heart beats.

Tetany: The state of a muscle when it undergoes sustained contraction.

Ventricular: Pertaining to the ventricles or main pump chambers of the heart.

22.2 Nonionizing Electromagnetic Radiation

William F. Hammett

22.2.1 Definition of Nonionizing Electromagnetic Radiation (NIER)

An electric or magnetic current or potential of alternating polarity will create radiating electromagnetic fields (EMFs). The frequency of alternation is a chief characteristic, and EMF is generated across an enormous range of frequencies. This frequency spectrum is shown in Fig. 22.5, with several common identifiers noted for certain bands.

Electromagnetic radiation is a natural part of our existence, providing light, heat, and, relatively recently, power and communications. Visible light, for instance, occupies a very narrow band of electromagnetic radiation, with characteristic frequencies of $4-8 \times 10^{14}$ Hz. (Sound is not really part of the electromagnetic spectrum, since sound energy is carried by *pressure* waves in air or some other medium. Electromagnetic energy is carried by waves that do not require a medium for transport. Thus, sound can be considered naturally only an Earth-bound phenomenon, whereas EMF literally radiates throughout the universe. Nevertheless, the frequencies of pressure waves audible to humans are shown for interest.)

Electromagnetic waves radiate at, not surprisingly, the speed of light, approximately 300,000,000 m/s, and they behave like streams of particles (called photons). Each EMF has a characteristic quantum energy (also called photon energy), given by the equation

$$QE = hf$$

$$= 4.135 \times 10^{-15} f \text{ eV}$$

FIGURE 22.5 Electromagnetic frequency spectrum: (a) to light and beyond, (b) selected radio frequencies. (Source: 1996 Hammett & Edison, Inc. With permission.)

where h is Planck's constant 6.624×10^{-27} erg-s and f is the frequency of the wave, in hertz (cycles per second).

Quantum energies of at least 4–25 eV are required to break free an electron from an atom of matter, a process known as *ionization*. Therefore, frequencies above about $1\text{--}6 \times 10^{15}$ Hz are capable of this and so are known as *ionizing radiation*. This portion of the spectrum includes ultraviolet light, X-rays, gamma rays, and cosmic rays.

Nonionizing electromagnetic radiation (NIER), by definition, is characterized by quantum energies *below* the ionization threshold and therefore cannot break chemical bonds. Thus, the effects of exposure to NIER are not necessarily destructive or cumulative. This larger portion of the spectrum includes the familiar-sounding TV bands called VHF (very high frequency) and UHF (ultra high frequency). Radio frequencies (RF) are considered those between 300 Hz and 300 GHz.

Extremely low-frequency energy (ELF) is characterized by frequencies below about 100 Hz, which are believed to be similar to human biological electromagnetic activity. The study of ELF and its interaction with the human body is a separate field beyond the scope of this chapter.

Another way to consider EMF, less rigorously but perhaps more intuitively, is by its wavelength, which is proportional to the reciprocal of frequency. Atoms are tiny structures, with diameters of about 1–5 Å. Now, 1 Å equals 10^{-10} m, and so frequencies above about $0.6\text{--}3 \times 10^{18}$ Hz will have wavelengths small enough to get inside an atom and break loose an electron. This is ionizing energy. At frequencies below light, the EMF has wavelengths at least 8000 Å, that is, too big to fit into individual atoms; this is nonionizing energy. In fact, at 2 GHz, a common microwave frequency, the wavelength is 1.5×10^9 Å, or about 6 in.

22.2.2 Exposure Standards for NIER

Standards limiting human exposure to NIER have been promulgated by various organizations over the years, beginning with the Occupational Safety and Health Administration (OSHA) in the 1960s and now including, among others, the American National Standards Institute (ANSI), the National Council on Radiation Protection and Measurements (NCRP), the American Council of Government and Industrial Hygienists (ACGIH), the International Radiation Protection Association (IRPA), the Department of National Health and Welfare (Canada), and the European Committee for Electrotechnical Standardization (CENELEC). All of these are based on a large and still-growing body of research dating from the 1960s. Many of the studies relied on the use of laboratory animals, including primates, and many studies are epistemological, drawing conclusions from various occupational, residential, morphological, and mortality statistics. Tellingly, all metaanalyses performed by the standard-setting bodies find a similar threshold of exposure to NIER, below which no reliable evidence exists of adverse effects. This threshold is a **specific absorption rate (SAR)** of 4 W/kg, that is, 4 W of NIER power being absorbed for each kilogram of body mass. (Power being work *per unit time*, this figure is, indeed, a *rate* of energy absorption.)

The various standards then apply a safety factor of some magnitude to arrive at their **maximum permissible exposure (MPE)** guidelines. The three most relevant standards are ANSI C95.1-1982, the successor standard ANSI C95.1-1992, and NCRP-86 (adopted in 1986). Each has a safety factor of *10 times*, with ANSI-82, ANSI-92 (controlled environments), and NCRP-86 (occupational) reflecting a maximum SAR of 0.4 W/kg. In certain cases, a second tier is suggested, to reflect a possible (but not demonstrated) increase in susceptibility on the part of the infirm, the aged, or the very young. The second tier safety factor in ANSI-92 and NCRP-86 is *50 times*, that is, five times tighter than the controlled/occupational limit.

Because SAR is difficult to assess in conditions outside a laboratory, these standards are expressed in terms of field strength or equivalent **far-field** power density. Recognizing that the human body performs “better” as an antenna at certain frequencies and less well at others, the exposure guidelines are frequency dependent, as shown in Fig. 22.6. (ANSI-82 is followed exactly by the NCRP-86 occupational guidelines.) The similarity of the two should be immediately apparent; the later-issued ANSI-92 does extend the range of the guidelines at each end of the RF spectrum and also relaxes the limits at those frequencies, recognizing in particular the different manner in which electric fields and magnetic fields appear to interact with the human body below about 100 MHz (half-wavelength of about 5 ft). Both standards introduce a limit on

FIGURE 22.6 Comparison of ANSI C95.1-1992 and NCRP-86 (1986) standards. (Source: 1996 Hammett & Edison, Inc. With permission.)

current flowing in the human body, ANSI-92 including induced and contact current limits and NCRP-86 just contact current limits. Induced current refers to that flowing in a free-standing body, grounded or ungrounded but not in contact with any conductive object.

Strict compliance with ANSI-92 or NCRP-86 requires not only determination, by calculation or by measurement, of the total far-field equivalent power density from all nearby sources, but also measurement of body current from contact with potentially radiating objects and, for ANSI-92, measurement of body current induced by immersion in fields near such objects. Power density measurements are straightforward to take, using specialized broadband equipment calibrated in power density (or even in percent of some standard); such measurements can also be made using broadband or narrow-band equipment calibrated more traditionally in field strength. The conversion from field strength to equivalent far-field power density *S*, in **milliwatt per square centimeter (mW/cm²)**, uses the impedance of free space, 377 Ω, as follows:

$$S = \frac{E^2}{3770}$$

where the electric field strength *E* is in V/m, and

$$S = 37.7 H^2$$

where the magnetic field strength *H* is in A/m. Figure 22.7 is the tabular form of ANSI-92, providing the derivation for the limits, expressed as *E*, *H*, or *S*, at particular frequencies.

Frequency Applicable Range (MHz)	Electromagnetic Fields				Body Currents	
	Electric Field Strength (V/m)	Magnetic Field Strength (A/m)	Equivalent Far-Field Power Density (mW/cm ²)		Induced (Foot) or Contact (mA)	
0.003–0.1	614	163			1000f	450f
0.1–1.34	614	16.3/f			100	45
1.34–3.0	614	16.3/f			100	45
3.0–30	1842/f	16.3/f			100	45
30–100	61.4	16.3/f			100	45
100–300	61.4	0.163	1.0	0.2	no limit	
300–3,000		0.0729	f/300	f/1500	no limit	
3,000–15,000			10	f/1500	no limit	
15,000–300,000			10	10	no limit	

Note: f is frequency of emission, in MHz.

FIGURE 22.7 ANSI/IEEE C95.1-1992 radio frequency protection guide. Guidelines for controlled environments in plain text; guidelines for uncontrolled environments in italics.

22.2.3 Sources of NIER

As noted, NIER is a natural phenomenon, with the sun being the most important source. Man-made sources can be considered in two classes: intentional and unintentional. The most important intentional sources of NIER are broadcast antennas, designed to radiate a radio-frequency signal on which data have been encoded with some modulation scheme. FM radio stations are licensed by the FCC at powers up to (and exceeding, in a few instances) 100 kW effective radiated power, and VHF TV stations are licensed at powers up to 316 kW peak visual effective radiated power (or about 160 kW average power, with the inclusion of the aural signal). These stations operate in the frequency range at which the exposure guidelines are tightest. The FCC licenses AM radio stations at up to 50 kW input power, which can become, with a directional antenna array, effective radiated powers of up to several hundred kilowatts, and the FCC licenses UHF TV stations at peak visual powers of 5010 kW (or about 2500 kW average effective radiated power). At AM and UHF frequencies, the exposure guidelines do rise severalfold, so these higher power facilities are not necessarily of greater concern than are FM and VHF TV stations.

Microwave stations are licensed on frequencies from about 1 GHz up to about 40 GHz, although they generally do not send energy over a large area. Instead, this nonbroadcast service uses large dish antennas to focus the NIER tightly and direct it toward a similar receiving dish (known as *point-to-point* service). High radiated powers can be generated at microwave transmitting antennas, but exposures would be of concern generally only to tower riggers.

Other intentional sources include navigational aids for ships and planes, two-way paging, dispatch and emergency services, and signals from satellites. The power density levels experienced by anyone not actually operating that equipment would be very low. There are also household electronic devices, such as nursery monitors, cordless telephones, and garage door openers, that use RF EMF; the powers are generally so low that exposure conditions cannot exceed the standards. Communications devices such as amateur radio stations and cellular and PCS handsets may have the potential for creating localized fields that exceed the standards, but time and space averaging are generally presumed to limit self-exposures to conditions compliant with the standards. Another class of intentional radiators are medical devices, which have been developed for monitoring, for diagnosis, and for treatment.

Unintentional radiators include industrial applications, such as RF sealers and welders, and microwave ovens. Many such devices have emission standards, promulgated by the FCC, the Food and Drug Administration (FDA), or some other agency, limiting radiation from the device generally to avoid electromagnetic interference (EMI). NIER exposure standards apply to unintentional radiators, as well.

22.2.4 Avoidance of NIER

NIER at levels not exceeding the guidelines set forth in the exposure standards need *not* be avoided, as those guidelines are intended to apply for exposure conditions of unlimited duration, that is, 24 hours a day, 365 days a year, for a lifetime. The findings of the standard-setting bodies were that no credible evidence or theory exists for adverse health effects at compliant exposure levels. *Prudent avoidance* is the standard recommendation when findings are inconclusive, and the electric utility companies have taken to including EMF brochures with billing statements, recommending that their customers practice prudent avoidance of the ELF energy those companies supply. With RF radiation, the findings are widely believed to be conclusive already, so avoidance of NIER beyond the safety factors incorporated in the exposure guidelines should not be necessary.

At certain locations, generally near high-power broadcasting antennas or near high-power RF sealing or welding equipment, fields are likely to exceed the exposure guidelines. As NIER power radiates from a source, the spherical surface over which the wave spreads increases as the square of the distance from the source. This leads to the so-called *inverse square law* by which it is known that, in the far field of an antenna, the power density decreases rapidly. Calculation of RF exposure conditions relies on this fact from basic physics, and the incorporation of certain conservative assumptions set forth by the FCC in its

Office of Science and Technology (OST) Bulletin No. 65 allows computers to quickly estimate the NIER exposure conditions at even a multiuser broadcasting site, perhaps avoiding the need for power density measurements. The general form of the OST-65 formula is as follows:

$$\text{power density } S = \frac{2.56 \times 1.64 \times 100 \times \text{RFF}^2 \times [0.4 \times \text{VERP} + \text{AERP}]}{4\pi D^2} \quad \text{in mW/cm}^2$$

where

VERP = total peak visual ERP (all polarizations), kW

AERP = total aural ERP (all polarizations), kW

RFF = relative field factor at direction to actual point of calculation

D = distance from center of radiation to point of calculation, m

The factor of 2.56 accounts for the increase in power density due to ground reflection, assuming a reflection coefficient of 1.6 ($1.6 \times 1.6 = 2.56$). The factor of 1.64 is the gain of a half-wave dipole relative to an isotropic radiator. The factor of 0.4 converts peak visual ERP to an average RMS value; for FM and cellular stations, of course, the value of VERP is zero. The factor of 100 in the numerator converts to the desired units of power density.

Exposure situations exceeding the standards should be mitigated, which can be done in one of three ways: (1) reducing the field, (2) limiting access to the field, or (3) both. Reducing the field can be accomplished, depending on the circumstance, by improved antenna design, improved shielding, relocation of the source, or reduction in power. Limiting access to the field can be accomplished with barricades or, in controlled situations, by signs, markings, and protocols. In the latter situation, care must be exercised to be certain that all persons encountering the fields have been briefed on the appropriate protocols and markings. Figure 22.8 shows a typical warning sign using the ANSI RF symbol. Below this may be added further information such as “Stay Back 10 Feet” or “Check with Supervisor Before Entering Area” that are part of protocols established for ensuring compliance.

FIGURE 22.8 Standard RF warning sign.

Defining Terms

Far field: That region of space in which the electric field and magnetic field components of an electromagnetic wave are related by the impedance of free space. The far field is generally considered to begin no closer to the NIER source than a distance of several wavelengths or several times the antenna aperture.

Maximum permissible exposure (MPE): The limit adopted by a standards-setting body for exposures of unlimited duration. Generally, some allowance is made in the standard for time and/or space averaging of higher exposure conditions.

Milliwatts per square centimeter (mW/cm²): A measure of power density, that is, energy per unit time passing through a unit of surface area. This unit is commonly used to compare electric and magnetic field readings and to assess them against the exposure guidelines.

Nonionizing electromagnetic radiation (NIER): That portion of the electromagnetic spectrum below about 10^{15} Hz, characterized by waves of insufficient quantum energy to break electrons free from atoms.

Specific absorption rate (SAR): The deposition of energy over time into a body. The units are generally watts per kilogram of body mass. This is the attribute on which findings by various researchers can be compared and on which the exposure standards base their guidelines.

22.3 PCBs and Other Hazardous Substances

Jerry C. Whitaker

22.3.1 Introduction

Polychlorinated biphenyls (PCBs) belong to a family of organic compounds known as *chlorinated hydrocarbons*. Virtually all PCBs in existence today have been synthetically manufactured. PCBs are of a heavy, oil-like consistency and have a high boiling point, a high degree of chemical stability, low flammability, and low electrical conductivity. These characteristics led to the past widespread use of PCBs in high-voltage capacitors and transformers. Commercial products containing PCBs were distributed widely from 1957 to 1977 under several trade names including

- Aroclor
- Pyroclor
- Sanotherm
- Pyranol
- Askarel

Askarel also is a generic name used for nonflammable dielectric fluids containing PCBs. Table 22.2 lists some common trade names for Askarel. These trade names typically are listed on the nameplate of a PCB transformer or capacitor.

TABLE 22.2 Commonly Used Names for PCB Insulating Material

Apirolio	Abestol	Askarel	Aroclor B	Chlorextol	Chlophen
Chlorinol	Clorphon	Diaclor	DK	Dykanol	EEC-18
Elemex	Eucarel	Fenclor	Hyvol	Inclor	Inerteen
Kanechlor	No-Flamol	Phenodlor	Pydraul	Pyralene	Pyranol
Pyroclor	Sal-T-Kuhl	Santothern FR	Santovac	Solvol	Thermal

22.3.2 Health Risk

PCBs are harmful because, once they are released into the environment, they tend not to break apart into other substances. Instead, PCBs persist, taking several decades to slowly decompose. By remaining in the environment, they can be taken up and stored in the fatty tissues of all organisms, from which they are released slowly into the bloodstream. Therefore, because of the storage in fat, the concentration of PCBs in body tissues can increase with time, even though PCB exposure levels may be quite low. This process is called **bioaccumulation**. Furthermore, as PCBs accumulate in the tissues of simple organisms, which are consumed by progressively higher organisms, the concentration increases. This process is called **biomagnification**. These two factors are especially significant because PCBs are harmful even at low levels. Specifically, PCBs have been shown to cause chronic (long-term) toxic effects in some species of animals and aquatic life. Well-documented tests on laboratory animals show that various levels of PCBs can cause reproductive effects, gastric disorders, skin lesions, and cancerous tumors.

PCBs may enter the body through the lungs, the gastrointestinal tract, and the skin. After absorption, PCBs are circulated in the blood throughout the body and stored in fatty tissues and skin, as well as in a variety of organs, including the liver, kidneys, lungs, adrenal glands, brain, and heart.

The health risk lies not only in the PCB itself, but also in the chemicals developed when PCBs are heated. Laboratory studies have confirmed that PCB by-products, including *polychlorinated dibenzofurans* (PCDFs) and *polychlorinated dibenzo-p-dioxins* (PCDDs), are formed when PCBs or chlorobenzenes are heated to temperatures ranging from approximately 900 to 1300°F. Unfortunately, these products are more toxic than PCBs themselves.

22.3.3 Governmental Action

The Congress took action to control PCBs in October 1975, by passing the **Toxic Substances Control Act (TSCA)**. A section of this law specifically directed the EPA to regulate PCBs. Three years later, the EPA issued regulations to implement a congressional ban on the manufacture, processing, distribution, and disposal of PCBs. Since then, several revisions and updates have been issued by the EPA. One of these revisions, issued in 1982, specifically addressed the type of equipment used in industrial plants. Failure to properly follow the rules regarding the use and disposal of PCBs has resulted in high fines and some jail sentences.

Although PCBs no longer are being produced for electrical products in the U.S., the EPA estimates that thousands of PCB transformers and millions of PCB small capacitors may still be in use or in storage. The threat of widespread contamination from PCB fire-related incidents is one reason behind the EPA's efforts to reduce the number of PCB products in the environment. The users of high-power equipment are affected by the regulations primarily because of the widespread use of PCB transformers and capacitors in old equipment. [Table 22.3](#) lists the primary classifications of PCB devices.

PCB Components

The two most common PCB components are transformers and capacitors. A PCB transformer is one containing at least 500 ppm (parts per million) PCBs in the dielectric fluid. An Askarel transformer generally has 600,000 ppm or more. A PCB transformer may be converted to a *PCB-contaminated device* (50–500 ppm) or a *non-PCB device* (less than 50 ppm) by being drained, refilled, and tested. The testing must not take place until the transformer has been in service for a minimum of 90 days. Note that this is *not* something that a maintenance technician can do. It is the exclusive domain of specialized remanufacturing companies.

PCB transformers must be inspected quarterly for leaks. However, if an impervious dike (sufficient to contain all the liquid material) is built around the transformer, the inspections can be conducted yearly. Similarly, if the transformer is tested and found to contain less than 60,000 ppm, a yearly inspection is sufficient. Failed PCB transformers cannot be repaired; they must be disposed of properly.

If a leak develops, it must be contained and daily inspections must begin. A cleanup must be initiated as soon as possible, but no later than 48 h after the leak is discovered. Adequate records must be kept of all

TABLE 22.3 Definition of PCB Terms as Identified by the EPA

Term	Definition	Examples
<i>PCB</i>	Any chemical substance that is limited to the biphenyl molecule that has been chlorinated to varying degrees, or any combination of substances that contain such substances.	PCB dielectric fluids, PCB heat-transfer fluids, PCB hydraulic fluids, 2,2',4-trichlorobiphenyl
<i>PCB article</i>	Any manufactured article, other than a PCB container, that contains PCBs and whose surface has been in direct contact with PCBs.	Capacitors, transformers, electric motors, pumps, pipes
<i>PCB container</i>	A device used to contain PCBs or PCB articles and whose surface has been in direct contact with PCBs.	Packages, cans, bottles, bags, barrels, drums, tanks
<i>PCB article container</i>	A device used to contain PCB articles or equipment and whose surface has not been in direct contact with PCBs.	Packages, cans, bottles, bags, barrels, drums, tanks
<i>PCB equipment</i>	Any manufactured item, other than a PCB container or PCB article container, which contains a PCB article or other PCB equipment.	Microwave ovens, fluorescent light ballasts, electronic equipment
<i>PCB item</i>	Any PCB article, PCB article container, PCB container or PCB equipment that deliberately or unintentionally contains, or has as a part of it, any PCBs.	
<i>PCB transformer</i>	Any transformer that contains PCBs in concentrations of 500 ppm or greater.	
<i>PCB contaminated</i>	Any electric equipment that contains more than 50, but less than 500 ppm of PCBs. (Oil-filled electrical equipment other than circuit breakers, reclosers, and cable whose PCB concentration is unknown must be assumed to be PCB-contaminated equipment.)	Transformers, capacitors, circuit breakers, reclosers, voltage regulators, switches, cable, electromagnets

inspections, leaks, and actions taken for 3 years after disposal of the component. Combustible materials must be kept a minimum of 5 m from a PCB transformer and its enclosure.

As of October 1, 1990, the use of PCB transformers (500 ppm or greater) was prohibited in or near commercial buildings when the secondary voltages were 480 V AC or higher. The use of radial PCB transformers was allowed if specified electrical protection was provided. As of October 1, 1993, certain types of PCB transformers must have been removed from service or retrofitted to a lower PCB concentration. EPA regulations required that lower voltage network PCB transformers (those with secondary voltages of less than 480 V) could be used in and around commercial buildings for the rest of their useful life only if they were equipped with electrical protections, such as current-limiting fuses, to prevent ruptures caused by high current faults. If these protections were not installed before October 1, 1990, then the transformer should have been removed from service by October 1, 1993.

The EPA regulations also require that the operator notify others of the possible dangers. All PCB transformers (including those in storage for reuse) must be registered with the local fire department. Supply the following information:

- The location of the PCB transformer(s).
- Address(es) of the building(s). For outdoor PCB transformers, provide the outdoor location.
- Principal constituent of the dielectric fluid in the transformer(s).
- Name and telephone number of the contact person in the event of a fire involving the equipment.

Any PCB transformers used in a commercial building must be registered with the building owner. All owners of buildings within 30 m of such PCB transformers also must be notified. In the event of

a fire-related incident involving the release of PCBs, immediately notify the Coast Guard National Spill Response Center at 1-800-424- 8802. Also take appropriate measures to contain and control any possible PCB release into water.

Capacitors are divided into two size classes: *large* and *small*. The following are guidelines for classification:

- A PCB small capacitor contains less than 1.36 kg (3 lb) of dielectric fluid. A capacitor having less than 100 in.³ also is considered to contain less than the 3 lb of dielectric fluid.
- A PCB large capacitor has a volume of more than 200 in.³ and is considered to contain more than 3 lb of dielectric fluid. Any capacitor having a volume from 100 to 200 in.³ is considered to contain 3 lb of dielectric, provided the total weight is less than 9 lb.
- A PCB large *low-voltage capacitor* contains 3 lb or more of dielectric fluid and operates below 2 kV.
- A PCB large *high-voltage capacitor* contains 3 lb or more of dielectric fluid and operates at 2 kV or greater voltages.

The use, servicing, and disposal of PCB small capacitors is not restricted by the EPA unless there is a leak. In that event, the leak must be repaired or the capacitor disposed of properly. Disposal may be performed by an approved incineration facility, or the component may be placed in a specified container and buried in an approved chemical waste landfill. Typically, chemical waste landfills are only for disposal of liquids containing 50–500 ppm PCBs and for solid PCB debris. Items such as capacitors that are leaking oil containing greater than 500-ppm PCBs should be taken to an EPA-approved PCB disposal facility.

Identifying PCB Components

The first task for the facility manager is to identify any PCB items on the premises. Equipment built after 1979 probably does not contain any PCB-filled devices. Even so, inspect all capacitors, transformers, and power switches to be sure. A call to the manufacturer also may help. Older equipment (pre-1979) is more likely to contain PCB transformers and capacitors. A liquid-filled transformer usually has cooling fins, and the nameplate may provide useful information about its contents. If the transformer is not labeled or the fluid is not identified, it must be treated as a PCB transformer. Untested (not analyzed) mineral-oil-filled transformers are assumed to contain at least 50 ppm, but less than 500 ppm PCBs. This places them in the category of PCB-contaminated electric equipment, which has different requirements than PCB transformers. Older high-voltage systems are likely to include both large and small PCB capacitors. Equipment rectifier panels, exciter/modulators, and power-amplifier cabinets may contain a significant number of small capacitors. In older equipment, these capacitors often are Askarel filled. Unless leaking, these devices pose no particular hazard. If a leak does develop, follow proper disposal techniques. Also, liquid-cooled rectifiers may contain Askarel. Even though their use is not regulated, treat them as a PCB article, as if they contain at least 50 ppm PCBs. Never make assumptions about PCB contamination; check with the manufacturer to be sure.

Any PCB article or container being stored for disposal must be date tagged when removed, and inspected for leaks every 30 days. It must be removed from storage and disposed of within 1 year from the date it was placed in storage. Items being stored for disposal must be kept in a storage facility meeting the requirements of 40 Code of Federal Regulations (CFR), Part 761.65(b)(1) unless they fall under alternative regulation provisions. There is a difference between PCB items stored for disposal and those stored for reuse. Once an item has been removed from service and tagged for disposal, it cannot be returned to service.

Labeling PCB Components

After identifying PCB devices, proper labeling is the second step that must be taken by the facility manager. PCB article containers, PCB transformers, and large high-voltage capacitors must be marked with a standard 6- × 6-in. large marking label (ML) as shown in Fig. 22.9. Equipment containing these transformers or capacitors also should be marked. PCB large low-voltage (less than 2 kV) capacitors need not

FIGURE 22.9 Marking label (ML) used to identify PCB transformers and PCB large capacitors.

be labeled until removed from service. If the capacitor or transformer is too small to hold the large label, a smaller 1- × 2-in. label is approved for use. Labeling each PCB small capacitor is not required. However, any equipment containing PCB small capacitors should be labeled on the outside of the cabinet or on access panels. Properly label any spare capacitors and transformers that fall under the regulations. Identify with the large label any doors, cabinet panels, or other means of access to PCB transformers. The label must be placed so that it can be read easily by firefighters. All areas used to store PCBs and PCB items for disposal must be marked with the large (6- × 6-in.) PCB label.

Record Keeping

Inspections are a critical component in the management of PCBs. EPA regulations specify a number of steps that must be taken and the information that must be recorded. Table 22.4, which summarizes the schedule requirements, can be used as a checklist for each transformer inspection. This record must be retained for 3 years. In addition to the inspection records, some facilities may need to maintain an annual report. This report details the number of PCB capacitors, transformers, and other PCB items on the premises. The report must contain the dates when the items were removed from service, their disposition, and detailed information regarding their characteristics. Such a report must be prepared if the facility uses or stores at least one PCB transformer containing greater than 500 ppm PCBs, 50 or more PCB large capacitors, or at least 45 kg of PCBs in PCB containers. Retain the report for 5 years after the facility ceases using or storing PCBs and PCB items in the prescribed quantities. Table 22.5 lists the information required in the annual PCB report.

TABLE 22.4 The Inspection Schedule Required for PCB Transformers and Other Contaminated Devices

⇒ Standard PCB transformer	Quarterly
⇒ If full-capacity impervious dike added	Annually
⇒ If retrofitted to <60,000 ppm PCB	Annually
⇒ If leak discovered, clean up ASAP (retain these records for 3 years)	Daily
⇒ PCB article or container stored for disposal (remove and dispose of within 1 year)	Monthly
⇒ Retain all records for 3 years after disposing of transformer	

TABLE 22.5 Required Information for PCB Annual Report

Transformer location: _____

Date of visual inspection: _____

Leak discovered? _____(Yes/No)

If yes, date discovered (if different from inspection date): _____

Location of leak: _____

Person performing inspection: _____

Estimate of the amount of dielectric fluid released from leak: _____

Date of cleanup, containment, repair, or replacement: _____

Description of cleanup, containment, or repair performed: _____

Results of any containment and daily inspection required for uncorrected active leaks: _____

Disposal

Disposing of PCBs is not a minor consideration. Before contracting with a company for PCB disposal, verify its license with the area EPA office. That office also can supply background information on the company’s compliance and enforcement history.

The fines levied for improper disposal are not mandated by federal regulations. Rather, the local EPA administrator, usually in consultation with local authorities, determines the cleanup procedures and costs. Civil penalties for administrative complaints issued for violations of the PCB regulations are determined according to a matrix provided in the PCB penalty policy. This policy, published in the Federal Register, considers the amount of PCBs involved and the potential for harm posed by the violation.

Proper Management

Properly managing the PCB risk is not difficult. The keys are to understand the regulations and to follow them carefully. A PCB management program should include the following steps:

- Locate and identify all PCB devices. Check all stored or spare devices.
- Properly label PCB transformers and capacitors according to EPA requirements.
- Perform the required inspections, and maintain an accurate log of PCB items, their location, inspection results, and actions taken. These records must be maintained for 3 years after disposal of the PCB component.
- Complete the annual report of PCBs and PCB items by July 1 of each year. This report must be retained for 5 years.
- Arrange for any necessary disposal through a company licensed to handle PCBs. If there are any doubts about the company’s license, contact the EPA.
- Report the location of all PCB transformers to the local fire department and owners of any nearby buildings.

The importance of following the EPA regulations cannot be overstated.

22.3.4 Equipment Operating Hazards

Particular hazards exist in the operation and maintenance of high-power equipment. Maintenance personnel must exercise extreme care around such hardware. Consider the following items:

- Use caution around the high voltage stages of the equipment. Many power supplies operate at voltages high enough to kill through electrocution. Always break the primary AC circuit of the power supply and discharge all high-voltage capacitors.
- Minimize exposure to RF radiation. Do not permit personnel in the vicinity of open energized RF generating circuits, RF transmission systems (waveguides, cables, or connectors), or energized

antennas. High levels of radiation can result in severe bodily injury, including blindness. Cardiac pacemakers may also be affected.

- Avoid contact with **beryllium oxide** (BeO) ceramic dust or fumes. BeO ceramic material is often used as a thermal link to carry heat from a tube or transistor to the heat sink. Do not perform any operation on any BeO ceramic that might produce dust or fumes, such as grinding, grit blasting, or acid cleaning. Beryllium oxide dust or fumes are highly toxic and breathing them can result in serious injury or death. BeO ceramics must be disposed of only in a manner prescribed by the device manufacturer.
- Avoid contact with hot surfaces within the equipment. The anode portion of most power tubes are air-cooled. The external surface normally operates at a high temperature (up to 250°C). Other portions of the tube may also reach high temperatures, especially the cathode insulator and the cathode/heater surfaces. All hot surfaces may remain hot for an extended time after the tube is shut off. To prevent serious burns, avoid bodily contact with these surfaces both during and for a reasonable cool-down period after tube operation.

Beryllium Oxide Ceramics

Some power vacuum tubes, both power grid and microwave, contain beryllium oxide (BeO) ceramics, typically at the output waveguide window or around the cathode. Never perform any operations on BeO ceramics that produce dust or fumes; for example, grinding, grit blasting, or acid cleaning. Beryllium oxide dust and fumes are highly toxic and breathing them can result in serious personal injury or death.

If a broken window is suspected on a microwave tube, carefully remove the device from its waveguide and seal the output flange of the tube with tape. Because BeO warning labels may be obliterated or removed, maintenance personnel should contact the tube manufacturer before performing any work on the device. Some tubes have BeO internal to the vacuum envelope.

Take precautions to protect personnel working in the disposal or salvage of tubes containing BeO. All such personnel should be made aware of the deadly hazards involved and the necessity for great care and attention to safety precautions. Some tube manufacturers will dispose of tubes without charge, provided they are returned to the manufacturer prepaid, with a written request for disposal.

Corrosive and Poisonous Compounds

The external output waveguides and cathode high-voltage bushings of microwave tubes are sometimes operated in systems that use a dielectric gas to impede microwave or high-voltage breakdown. If breakdown does occur, the gas may decompose and combine with impurities, such as air or water vapor, to form highly toxic and corrosive compounds. Examples include Freon gas, which may form lethal *phosgene*, and sulfur hexafluoride (SF₆) gas, which may form highly toxic and corrosive sulfur or fluorine compounds such as *beryllium fluoride*. When breakdown does occur in the presence of these gases, proceed as follows:

- Ventilate the area to outside air.
- Avoid breathing any fumes or touching any liquids that develop.
- Take precautions appropriate for beryllium compounds and for other highly toxic and corrosive substances.

FC-75 Toxic Vapor

The decomposition products of FC-75 are highly toxic. Decomposition may occur as a result of any of the following:

- Exposure to temperatures above 200°C
- Exposure to liquid fluorine or alkali metals (lithium, potassium, or sodium)
- Exposure to ionizing radiation

Known thermal decomposition products include *perfluoroisobutylene* (PFIB; $(CF_3)_2C=CF_2$), which is highly toxic in small concentrations.

If FC-75 has been exposed to temperatures above 200°C through fire, electric heating, or prolonged electric arcs, or has been exposed to alkali metals or strong ionizing radiation, take the following steps:

- Strictly avoid breathing any fumes or vapors
- Thoroughly ventilate the area
- Strictly avoid any contact with the FC-75

Under such conditions, promptly replace the FC-75 and handle and dispose the contaminated FC-75 as a toxic waste.

Defining Terms

Askarel: A common trade name for PCB fluid.

Beryllium oxide: A compound commonly used in the production of ceramics for electrical applications and whose dust or fumes are toxic.

Bioaccumulation: The process whereby a harmful substance is increased in concentration in an organism through ingestion of small amounts over a long period of time.

Biomagnification: The process whereby a harmful substance is increased in concentration as contaminated simpler organisms are consumed by progressively higher organisms.

Polychlorinated biphenyls (PCBs): A family of organic compounds known as *chlorinated hydrocarbons* and used as an insulating material for electrical devices until the late 1970s.

Toxic Substances Control Act (TSCA): A federal law passed by the Congress in 1975 to control PCBs and ultimately eliminate them from use.

22.4 Facility Grounding Principles

William. E. DeWitt

22.4.1 Introduction

Grounding is a very broad and complex subject. The material presented here will introduce the reader to facility grounding principles. It is not intended to represent code requirements or recommended practice. Specific code requirements are contained in the current edition of the National Electrical Code and the

National Electrical Code Handbook. Recommended practice is covered in the current edition of the Institute of Electrical and Electronic Engineers (IEEE) and other industry standards.

A facility can be defined as something built, installed, or established to serve a particular purpose [1]. A facility is usually thought of as a single building or group of buildings. The National Electrical Code (NEC) [2] uses the term *premises* to refer to a facility when it defines premises wiring as the interior and exterior wiring, such as power, lighting, control, and signal systems. Premises wiring includes the service and all permanent and temporary wiring between the service and the load equipment. Premises wiring does not include wiring internal to any load equipment.

This article will define grounding, list the reasons for grounding, discuss grounding methods, and present grounding terminology. Applicable codes and industry standards will be referenced.

22.4.2 Grounding Terminology [2]

Grounded conductor—A system or circuit conductor that is intentionally grounded.

Grounding conductor—A conductor used to connect equipment or the grounded circuit of a wiring system to a grounding electrode or electrodes.

Equipment grounding conductor—The conductor used to connect the noncurrent-carrying metal parts of equipment, raceways, and other enclosures to the system grounded conductor, the grounding electrode conductor, or both, at the service equipment or at the source of a separately derived system.

Grounding electrode conductor—The conductor used to connect the grounding electrode(s) to the equipment grounding conductor to the grounded conductor, or to both, at the service, at each building or structure where supplied from a common service, or at the source of a separately derived system.

Ground-fault protection of equipment—A system intended to provide protection of equipment from damaging line-to-ground fault currents by operating to cause a disconnecting means to open all ungrounded conductors of the faulted circuit. This protection is provided at current levels less than those required to protect conductors from damage through the operation of a supply circuit overcurrent device.

Main bonding jumper—The connection between the grounded circuit conductor and the equipment grounding conductor at the service.

Service—The conductors and equipment for delivering energy from the electricity supply system to the wiring system of the premises served.

Service conductors—The conductors from the service point to the service disconnecting means.

Service equipment—The necessary equipment, usually consisting of a circuit breaker(s) or switch(es) and fuse(s) and their accessories, connected to the load end of service conductors to a building or other structure, or an otherwise designated area, and intended to constitute the main control and cutoff of the supply.

Separately derived system—A premises wiring system whose power is derived from a battery, from a solar photovoltaic system, or from a generator, transformer, or converter windings, and that has no direct electrical connection, including a solidly connected grounded circuit conductor, to supply conductors originating in another system.

22.4.3 Reasons for Grounding

The Institute of Electrical and Electronic Engineers (IEEE) defines grounding as a conducting connection, whether intentional or accidental, by which an electric circuit or equipment is connected to the earth, or to some conducting body of relatively large extent that serves in place of the earth. It is used for establishing and maintaining the same or approximately the same potential as that of the earth (or of the conducting body), on conductors connected to it, and for conducting ground current to and from the earth (or the conducting body) [3].

Based on the IEEE definition, the reasons for grounding can be identified as (1) personnel safety by limiting potentials between non-current-carrying metal parts of an electrical distribution system, (2) personnel safety and control of electrostatic discharge by limiting potentials between noncurrent-carrying metal parts of an electrical distribution system and the earth, and (3) fault isolation for equipment and personnel safety by providing a low-impedance fault return path to the power source to facilitate the operation of overcurrent devices during a ground fault.

The IEEE definition implies an important distinction between *ground* and *earth*. *Earth* refers to planet earth, and *ground* refers to the equipment grounding system, which includes equipment grounding conductors, metallic raceways, cable armor, enclosures, cabinets, frames, building steel, and all other noncurrent-carrying metal parts of the electrical distribution system.

Other reasons for grounding are not as implicit in the IEEE definition. Overvoltage control has long been a benefit of power system grounding, and is described in IEEE Std 142, the Green Book [4]. Beeman presents an excellent discussion of overvoltage control in the *Industrial Power Systems Handbook* [5]. With the increasing use of electronic and computer systems, noise control has become associated with the subject of grounding, and is described in IEEE Std 1100, the *Emerald Book*. [6].

22.4.4 Equipment Grounding

Equipment grounding is the process of interconnecting the noncurrent-carrying metal parts of an electrical distribution system, and then connecting the interconnected metal parts to the earth. Equipment grounding insures that there is no difference of potential, and thus no shock hazard between noncurrent-carrying metal parts in the electrical distribution system. Connecting the equipment grounding system to earth insures that there is no difference of potential between the earth and the equipment grounding system. This also prevents static charge build-up. Specific requirements for equipment grounding are contained in Article 250 of the NEC [2].

22.4.5 System Grounding

System grounding is the process of intentionally connecting one of the current-carrying conductors of the electrical distribution system to ground. This conductor is called the *grounded* conductor because it is intentionally grounded. The purpose of system grounding is overvoltage control and equipment and personnel safety through fault isolation. An ungrounded system is subject to serious overvoltages under conditions such as intermittent ground faults, resonant conditions, and contact with higher voltage systems. Fault isolation is achieved by providing a low-impedance ground return path from the load back to the source that will ensure operation of overcurrent devices in case of ground fault. Methods of system grounding include solidly-grounded, ungrounded, and impedance-grounded. Specific requirements for system grounding are also contained in Article 250 of the NEC [2].

Solidly-grounded means that an intentional zero-impedance connection is made between the grounded conductor and the equipment grounding conductor at the service. In a solidly-grounded, three-phase, four-wire, wye system, the neutral is connected directly to ground with no impedance installed in the neutral circuit. The NEC permits this connection to be made at the service only using the main bonding jumper. The advantages of a solidly-grounded wye system include reduced magnitude of transient overvoltages, improved fault protection, and faster location of ground faults. There is one disadvantage of the solidly-grounded wye system. For low-level arcing ground faults, the application of sensitive, properly-coordinated, ground fault protection (GFP) devices is necessary to prevent equipment damage from arcing ground faults. The NEC requires separate arcing ground fault protection at certain points in 480Y/277V systems. Arcing damage is less a problem at the lower voltage 208Y/120V systems, where the arc may be self-extinguishing. The specific GFP requirements are contained in various articles of the NEC [2].

Ungrounded means that there is no intentional connection between a current-carrying conductor and ground. However, charging capacitance will create unintentional capacitive coupling from each phase to ground, making the system essentially a capacitance-grounded system. The most common ungrounded

system is the three-phase, three-wire delta system. The most important advantage of an ungrounded system is that an accidental ground fault in one phase does not require immediate removal. This allows for continuity of service that made the ungrounded-delta system very popular in the past. However, ungrounded systems have serious disadvantages. Since there is no fixed system ground point, it is difficult to locate the first ground fault and to sense the magnitude of the fault current. As a result, the fault is often permitted to remain on the system for a long time. If a second fault should occur before the first one is removed, and the second fault is on a different phase, the result will be a double line-to-ground fault causing serious arcing damage. Another problem with the ungrounded-delta system is the occurrence of high transient overvoltages from phase-to-ground. Transient overvoltages are caused by intermittent ground faults, with overvoltages capable of reaching a phase-to-ground voltage of six to eight times the phase-to-neutral voltage. Sustained overvoltages may ultimately result in insulation failure and thus more ground faults.

Impedance-grounded means that an intentional nonzero impedance connection is made between the neutral conductor and the equipment grounding conductor at the service. The high-resistance grounded wye system is an alternative to solidly-grounded and ungrounded systems. High-resistance grounding will limit ground fault current to a few amperes, thus removing the potential for arcing damage inherent in solidly-grounded systems. The ground reference point is fixed, and relaying methods can locate first faults before damages from second faults occur. Internally-generated transient overvoltages are reduced since the neutral to ground resistor dissipates any charge that may build-up on system charging capacitance.

There is no one *best* system grounding method for all applications. In choosing among the various options, the designer must consider the requirements for safety, continuity of service, and cost. Generally, low-voltage systems are operated solidly-grounded. For applications involving continuous processes in industrial plants or where shutdown might create a hazard, a high-resistance grounded wye system, or a solidly-grounded wye system with an alternate power supply, may be used. The high-resistance grounded wye system combines many advantages of the ungrounded-delta system and the solidly-grounded wye system. Recommended practice for system grounding of low and medium-voltage systems is contained in IEEE Std 142 [4].

22.4.6 Earth Connections

The process of connecting the grounding system to earth is called earthing, and consists of immersing a metal electrode or system of electrodes into the earth. The conductor that connects the grounding system to earth is called the *grounding electrode conductor*. Its function is to keep the entire grounding system at earth potential (i.e., voltage equalization during lightning and other transients) rather than for conducting ground fault current. Therefore, the NEC allows reduced sizing requirements for that portion of the grounding electrode conductor that is the sole connection to certain types of electrodes. Refer to the NEC [2] for specific sizing requirements and electrode types.

The basic measure of effectiveness of an earth electrode system is called *earth electrode resistance*. Earth electrode resistance is the resistance, in ohms, between the point of connection and a distant point on the earth called *remote earth*. Remote earth, about 25 ft from a single driven electrode, is a point from the driven electrode where earth electrode resistance does not increase appreciably when this distance is increased. Earth electrode resistance consists of the sum of the resistance of the metal electrode (negligible) plus the contact resistance between the electrode and the soil (negligible) plus the soil resistance itself. Thus, for all practical purposes, earth electrode resistance equals the soil resistance. The soil resistance is nonlinear, with most of the resistance contained within several feet of the electrode. Furthermore, current flows only through the electrolyte portion of the soil, not the soil itself. Thus, soil resistance varies as the electrolyte content (moisture and salts) of the soil varies. Without electrolyte, soil resistance would be essentially infinite.

Soil resistance is a function of soil resistivity. A 1 m³ sample of soil with a resistivity of one 1 Ω·m will present a resistance of 1 Ω between opposite faces. A broad variation of soil resistivity occurs as a function of soil types, and soil resistivity can be estimated or measured directly. The most commonly used method

of measuring soil resistivity injects a known current into a given volume of soil and measures the resulting voltage drop. When soil resistivity is known, the earth electrode resistance of any given configuration (single rod, multiple rods, or ground ring) may be determined by using standard equations developed by Sunde [7], Schwarz [8], and others.

Earth resistance values should be as low as practicable, but are a function of the application. The NEC requires single rod, pipe, or plate electrodes, that do not have a resistance to ground of 25 ohms or less, to be augmented by one additional approved electrode. Recommended practice for earth electrode resistance is contained in the IEEE and other standards. Methods of reducing earth resistance values include the use of multiple electrodes, the use of ground rings, increased ground rod lengths, installation of ground rods to the permanent water level, increased area of coverage of ground rings, and the use of concrete-encased electrodes, ground wells, and electrolytic electrodes.

22.4.7 Earth Electrodes

Historically, earth electrodes were classified as *made* electrodes, *natural* electrodes, and *special-purpose* electrodes. The term, made electrode, was used in the 1999 NEC but is not used in the 2002 NEC. The term is found once in the 2002 NEC Handbook in reference to a ground rod. Made electrodes include driven rods and pipes, buried conductors, ground mats, buried plates, and ground rings. The electrode selected is a function of the type of soil and the available depth. Driven electrodes are used where the bedrock is well below the earth surface. Mats or buried conductors are used for lesser depths. Buried plates are not widely used because of the higher cost as compared to rods. Ground rings employ equally-spaced driven electrodes interconnected with buried bare conductors. Ground rings are used around buildings, around pad-mounted equipment, and in areas having high soil resistivity.

Natural electrodes could include metal underground water pipe electrodes and concrete-encased electrodes. The NEC lists a metal underground water pipe, available on the premises, in direct contact with the earth for 10-ft or more, and electrically continuous as part of the grounding electrode system. The NEC also lists a concrete-encased electrode (meeting the detailed specifications listed in the code) as part of the grounding electrode system. The application of concrete-encased electrodes is also covered in IEEE Std 142 [4].

A special-purpose electrode called the electrolytic electrode, consists of a ground rod installed in a canister containing an electrolytic salt. The salt absorbs moisture from the atmosphere through *breather* holes at the top of the unit. The salt combines and dissolves with the moisture and forms a constant electrolytic solution. Gravity and changes in atmospheric pressure cause the electrolytic solution to seep out through *weep* holes at the bottom of the unit. The electrolytic solution constantly seeps into the surrounding soil, reducing the soil resistivity, and helps keep the soil resistivity relatively constant. The result is a consistently low and constant earth electrode resistance. Made electrodes can also be backfilled with a material called bentonite to achieve a similar effect.

Specific requirements for the installation of earth electrodes are contained in the NEC [2]. Manufacturer's handling and installation instructions should also be consulted and followed.

22.4.8 Facilities Grounding for Computer and Electronics Equipment

Noise control is an important aspect of computer and electronic systems. The process of noise control through proper grounding techniques is more correctly called *referencing*. IEEE Std 1100 [6] covers the referencing and grounding of sensitive electronics equipment.

22.4.9 Isolated Grounding

Isolated grounding schemes, where the signal reference plane of an electronic system is isolated from equipment ground but connected to an *isolated* electrode in the earth, do not work, are unsafe, and violate the NEC. It was thought by some people that the isolated earth connection is *clean* since there is no

connection between it and the *dirty* system ground connection at the service entrance. The clean, isolated earth connection was also viewed (incorrectly) as a point where noise currents can flow into the earth and be dissipated. Kirchoff's current law teaches that any current flowing into the isolated ground must return to the source through another earth connection. Current cannot be dissipated. It must always return to its source. Even lightning current is not dissipated into the earth. It must have a return path (i.e., the electrostatic and electromagnetic fields that created the charge build-up and the lightning strike in the first place). Fine print note (FPN) No. 2 at NEC 250–260 states that the connecting all the grounding electrodes will limit potential differences between them and between their associated wiring systems [2].

Isolated ground (IG) receptacles, which are a version of single-point grounding, are permitted by the NEC where required for the reduction of electrical noise (electromagnetic interference) on grounding circuits. Proper application of IG receptacles is very important, and the specific NEC requirements must be followed.

23.1 Systems Engineering Concepts

Gene DeSantis

23.1.1 Introduction

Modern systems engineering emerged during World War II as, due to the degree of complexity in design, development, and deployment, weapons evolved into weapon systems. The complexities of the space program made a systems engineering approach to design and problem solving even more critical. Indeed, the Department of Defense and NASA are two of the staunchest practitioners. With the growth of digital systems, the need for systems engineering has gained increased attention. Today, most large engineering organizations utilize a systems engineering process. Much has been published about system engineering practices in the form of manuals, standards, specifications, and instruction. In 1969, MIL-STD-499 was published to help government and contractor personnel involved in support of defense acquisition programs. In 1974 this standard was updated to MIL-STD-499A, which specifies the application of system engineering principles to military development programs. The tools and techniques of this processes continue to evolve in order to do each job a little better, save time, and cut costs. This chapter will first describe systems theory in a general sense followed by its application in systems engineering and some practical examples and implementations of the process.

23.1.2 Systems Theory

Though there are other areas of application outside of the electronics industry, we will be concerned with systems theory as it applies to electrical systems engineering. Systems theory is applicable to engineering of control, information processing, and computing systems. These systems are made up of component elements that are interconnected and programmed to function together. Many systems theory principles are routinely applied in the aerospace, computer, telecommunications, transportation, and manufacturing industries.

For the purpose of this discussion a *system* is defined as a set of related elements that function together as a single entity.

Systems theory consists of a body of concepts and methods that guide the description, analysis, and design of complex entities.

Decomposition is an essential tool of systems theory. The systems approach attempts to apply an organized methodology to completing large complex projects by breaking them down into simpler and more manageable component elements. These elements are treated separately, analyzed separately, and designed separately. In the end, all of the components are recombined to build the whole.

Holism is an element of systems theory in that the end product is greater than the sum of its component elements. In systems theory, the modeling and analytical methods enable all essential effects and interactions within a system and those between a system and its surroundings to be taken into account. Errors resulting from the idealization and approximation involved in treating parts of a system in isolation, or reducing consideration to a single aspect, are thus avoided.

Another holistic aspect of system theory describes **emergent properties**. Properties that result from the interaction of system components, properties that are not those of the components themselves, are referred to as emergent properties.

Though dealing with concrete systems, **abstraction** is an important feature of systems models. Components are described in terms of their function rather than in terms of their form. Graphical models such as block diagrams, flow diagrams, timing diagrams, and the like are commonly used.

Mathematical models may also be employed. Systems theory shows that, when modeled in abstract formal language, apparently diverse kinds of systems show significant and useful **isomorphisms** of structure and function. Similar interconnection structures occur in different types of systems. Equations that describe the behavior of electrical, thermal, fluid, and mechanical systems are essentially identical in form.

FIGURE 23.1 Systems engineering: (a) product development process, (b) requirements documentation process.

Isomorphism of structure and function implies isomorphism of behavior of a system. Different types of systems exhibit similar dynamic behavior such as response to stimulation.

The concept of **hard** and **soft systems** appears in system theory. In hard systems, the components and their interactions can be described by mathematical models. Soft systems cannot be described as easily. They are mostly human activity systems, which imply unpredictable behavior and nonuniformity. They introduce difficulties and uncertainties of conceptualization, description, and measurement. The kinds of system concepts and methodology described earlier cannot be applied.

23.1.3 Systems Engineering

Systems engineering depends on the use of a process methodology based on systems theory. To deal with the complexity of large projects, systems theory breaks down the process into logical steps.

Even though underlying requirements differ from program to program, there is a consistent, logical process, which can best be used to accomplish system design tasks. The basic product development process is illustrated in Fig. 23.1. The systems engineering starts at the beginning of this process to describe the product to be designed. It includes four activities:

- Functional analysis
- Synthesis
- Evaluation and decision
- Description of system elements

The process is iterative, as shown in Fig. 23.2. That is, with each successive pass, the product element description becomes more detailed. At each stage in the process a decision is made whether to accept,

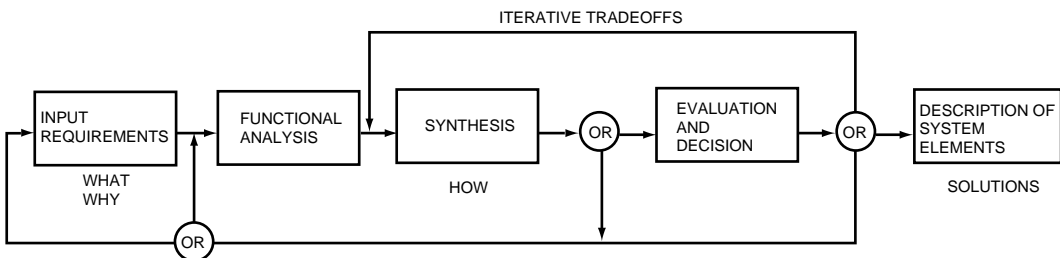

FIGURE 23.2 The systems engineering process. (Source: Adapted from Hoban, F.T. and Lawbaugh, W.M. 1993. *Readings In Systems Engineering*, p. 10. NASA, Washington, DC.)

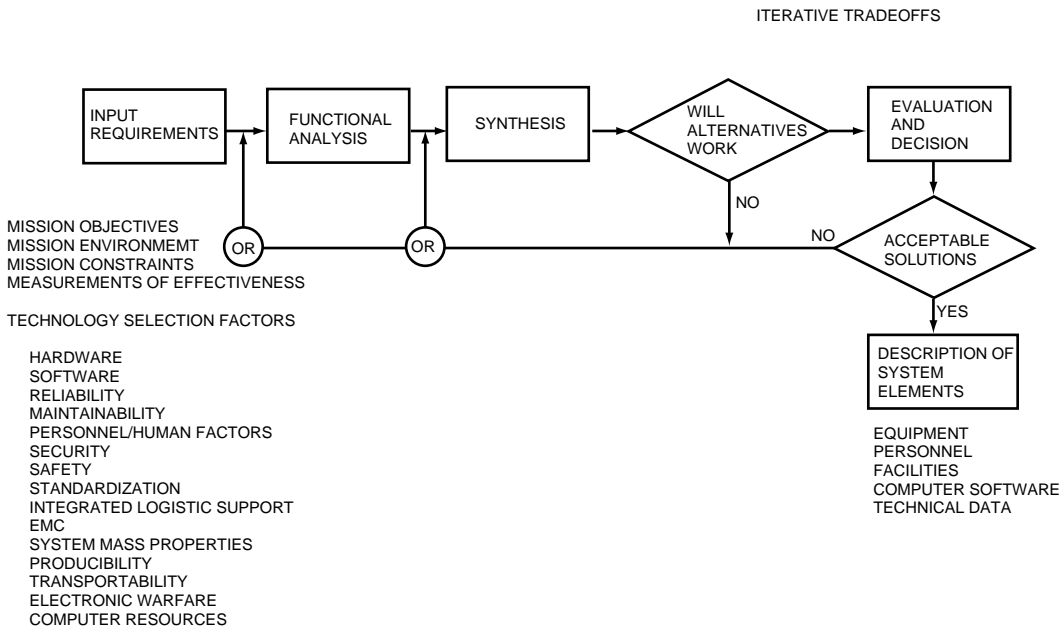

FIGURE 23.3 The systems engineering decision process. (Source: Adapted from Hoban, F.T. and Lawbaugh, W.M. 1993. *Readings In Systems Engineering*, p. 12. NASA, Washington, DC.)

make changes, or return to an earlier stage of the process and produce new documentation. The result of this activity is documentation that fully describes all system elements and that can be used to develop and produce the elements of the system. The systems engineering process does not produce the actual system itself.

Functional Analysis

A systematic approach to systems engineering will include elements of systems theory (see Fig. 23.3). To design a product, hardware and software engineers need to develop a vision of the product, the product requirements. These requirements are usually based on customer needs researched by a marketing department. An organized process to identify and validate customer needs will help minimize false starts. System objectives are first defined. This may take the form of a mission statement, which outlines the objectives, the constraints, the mission environment, and the means of measuring mission effectiveness. The purpose of the system is defined, and analysis is carried out to identify the requirements and what essential functions the system must perform and why. The *functional flow block diagram* is a basic tool used to identify functional needs. It shows logical sequences and relationships of operational and support functions at the system level. Other functions, such as maintenance, testing, logistics support, and productivity, may also be required in the functional analysis. The functional requirements will be used during the synthesis phase to show the allocation of the functional performance requirements to individual system elements or groups of elements. Following evaluation and decision, the functional requirements provide the functionally oriented data required in the description of the system elements.

Analysis of time critical functions is also a part of this functional analysis process when functions have to take place sequentially, or concurrently, or on a particular schedule. Time line documents are used to support the development of requirements for the operation, testing, and maintenance functions.

Synthesis

Synthesis is the process by which concepts are developed to accomplish the functional requirements of a system. Performance requirements and constraints, as defined by the functional analysis, are applied to

each individual element of the system, and a design approach is proposed for meeting the requirements. Conceptual schematic arrangements of system elements are developed to meet system requirements. These documents can be used to develop a description of the system elements and can be used during the acquisition phase.

Modeling

The concept of **modeling** is the starting point of synthesis. Since we must be able to weigh the effects of different design decisions in order to make choices between alternative concepts, modeling requires the determination of those quantitative features that describe the operation of the system. We would, of course, like a very detailed model with as much detail as possible describing the system. Reality and time constraints, however, dictate that the simplest possible model be selected to improve our chances of design success. The model itself is always a compromise. The model is restricted to those aspects that are important in the evaluation of system operation. A model might start off as a simple block diagram with more detail being added as the need becomes apparent.

Dynamics

Most system problems are **dynamic** in nature. The signals change over time and the components determine the dynamic response of the system. The system behavior depends on the signals at a given instant, as well as on the rates of change of the signals and their past values. The term signals can be replaced by substituting human factors such as the number of users on a computer network, for example.

Optimization

The last concept of synthesis is **optimization**. Every design project involves making a series of compromises and choices based on relative weighting of the merit of important aspects. The best candidate among several alternatives is selected. Decisions are often subjective when it comes to deciding the importance of various features.

Evaluation and Decision

Program costs are determined by the tradeoffs between operational requirements and engineering design. Throughout the design and development phase, decisions must be made based on evaluation of alternatives and their effect on cost. One approach attempts to correlate the characteristics of alternative solutions to the requirements and constraints that make up the selection criteria for a particular element. The rationale for alternative choices in the decision process are documented for review. Mathematical models or computer simulations may be employed to aid in this evaluation decision making process.

Trade Studies

A structured approach is used in the trade study process to guide the selection of alternative configurations and ensure that a logical and unbiased choice is made. Throughout development, **trade studies** are carried out to determine the best configuration that will meet the requirements of the program. In the concept exploration and demonstration phases, trade studies help define the system configuration. Trade studies are used as a detailed design analysis tool for individual system elements in the full-scale development phase. During production, trade studies are used to select alternatives when it is determined that changes need to be made. [Figure 23.4](#) illustrates the relationship of the various types of elements that may be employed in a trade study.

[Figure 23.5](#) is a flow diagram of the trade study process. To provide a basis for the selection criteria, the objectives of the trade study must first be defined. Functional flow diagrams and system block diagrams are used to identify trade study areas that can satisfy certain requirements. Alternative approaches to achieving the defined objectives can then be established.

Complex approaches can be broken down into several simpler areas, and a decision tree constructed to show the relationship and dependences at each level of theselection process. This *trade tree*, as it is called, is illustrated in [Fig. 23.6](#). Several trade study areas may be identified as possible candidates for accomplishing

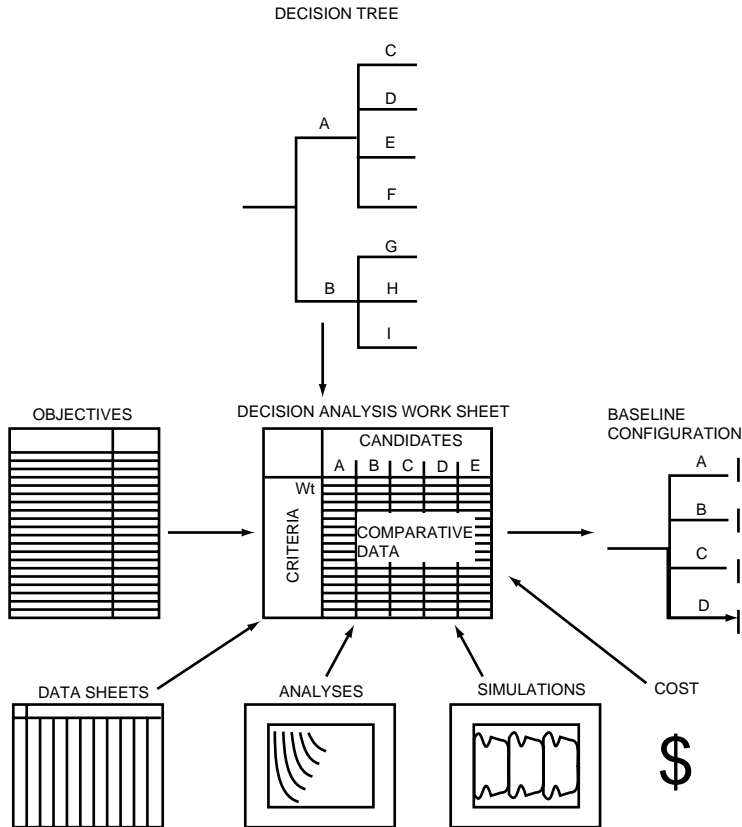

FIGURE 23.4 Trade studies using a systematic approach to decision making. (Source: Adapted from Defense Systems Management, 1983. *Systems Engineering Management Guide*. Contract No. MDA 903-82-C-0339. Defense Systems Management College, Fort Belvoir, VA.)

a given function. A trade tree is constructed to show relationships and the path through selected candidate trade areas at each level to arrive at a solution.

Several alternatives may be candidates for solutions in a given area. The selected candidates are then submitted to a systematic evaluation process intended to weed out unacceptable candidates. Criteria are determined, which are intended to reflect the desirable characteristics. Undesirable characteristics may also be included to aid in the evaluation process. Weights are assigned to each criteria to reflect its value or impact on the selection process. This process is subjective. It should also take into account cost, schedule, and hardware availability restraints that may limit the selection.

The criteria data on the candidates are then collected and tabulated on a decision analysis work sheet (Fig. 23.7). The attributes and limitations are listed in the first column and the data for each candidate listed in adjacent columns to the right. The performance data are available from vendor specification sheets or may require laboratory testing and analysis to determine. Each attribute is given a relative score from 1 to 10 based on its comparative performance relative to the other candidates. Utility function graphs (Fig. 23.8) can be used to assign logical scores for each attribute. The utility curve represents the advantage rating for a particular value of an attribute. A graph is made of ratings on the y axis vs. attribute value on the x axis. Specific scores can then be applied, which correspond to particular performance values. The shape of the curve may take into account requirements, limitations, and any other factor that will influence its value regarding the particular criteria being evaluated. The limits to which the curves should be extended should run from the minimum value, below which no further benefit will accrue, to the maximum value, above which no further benefit will accrue.

TOTAL WEIGHTED SCORE:		241				234				(243)		

FIGURE 23.7 Decision analysis work sheet example. (Source: Adapted from Defense Systems Management. 1983. *Systems Engineering Management Guide*. Contract No. MDA 903-82-C-0339. Defense Systems Management College, Fort Belvoir, VA.)

The scores are filled in on the decision analysis work sheet and multiplied by the weights to calculate the weighted score. The total of the weighted scores for each candidate then determines their ranking. As a rule, at least a 10% difference in score is acceptable as meaningful.

Further analysis can be applied in terms of evaluating the sensitivity of the decision to changes in the value of attributes, weights, subjective estimates, and cost. Scores should be checked to see if changes in weights or scores would reverse the choice. How sensitive is the decision to changes in the system requirements or technical capabilities?

A **trade table** (Fig. 23.9) can be prepared to summarize the selection results. Pertinent criteria are listed for each alternative solution. The alternatives may be described in a quantitative manner, such as high, medium, or low.

Finally, the results of the trade study are documented in the form of a report, which discusses the reasons for the selections and may include the trade tree and the trade table.

There has to be a formal system of change control throughout the systems engineering process to prevent changes from being made without proper review and approval by all concerned parties and to keep all parties informed. Change control also ensures that all documentation is kept up to date and can help to eliminate redundant documents. Finally, change control helps to control project costs.

Description of System Elements

Five categories of interacting system elements can be defined: equipment (hardware), software, facilities, personnel, and procedural data. Performance, design, and test requirements must be specified and

FIGURE 23.8 Attribute utility trade curve example.

CRITERIA	COOL ROOM ONLY. ONLY NORMAL CONVECTION COOLING WITHIN ENCLOSURES	FORCED COLD AIR VENTILATION THROUGH RACK THEN DIRECTLY INTO RETURN	FORCED COLD AIR VENTILATION THROUGH RACK, EXHAUSTED INTO THE ROOM, THEN RETURNED THRU THE NORMAL PLENUM
COST	LOWEST. CONVENTIONAL CENTRAL AIR CONDITIONING SYSTEM USED.	HIGH. DEDICATED DUCTING REQUIRED. SEPARATE SYSTEM REQUIRED TO COOL ROOM	MODERATE. DEDICATED DUCTING REQUIRED FOR INPUT AIR.

FIGURE 23.9 Trade table example.

documented for equipment, components, and computer software elements of the system. It may be necessary to specify environmental and interface design requirements, which are necessary for proper functioning of system elements within a facility.

The documentation produced by the systems engineering process controls the evolutionary development of the system. Figure 23.10 illustrates the special purpose documentation used by one organization in each step of the systems engineering process.

The requirements are formalized in written specifications. In any organization, there should be clear standards for producing specifications. This can help reduce the variability of technical content and improve product quality as a result. It is also important to make the distinction here that the product should not be overspecified to the point of describing the design or making it too costly. On the other hand, requirements should not be too general or so vague that the product would fail to meet the customer needs. In large departmentalized organizations, commitment to schedules can help assure that other members of the organization can coordinate their time.

The system engineering process does not actually design the system. The system engineering process produces the documentation necessary to define, design, develop, and test the system. The technical integrity provided by this documentation ensures that the design requirements for the system elements reflect the functional performance requirements, that all functional performance requirements are satisfied by the combined system elements, and that such requirements are optimized with respect to system performance requirements and constraints.

23.1.4 Phases of a Typical System Design Project¹

The television industry has always been a dynamic industry because of the rapid advancement of communications technology. The design of complex modern video facility can be used to illustrate the systems engineering approach.

Design Development

System design is carried out in a series of steps that lead to an operational unit. Appropriate research and preliminary design work is completed in the first phase of the project, the design development phase. It is the intent of this phase to fully delineate all requirements of the project and to identify any constraints. Based on initial concepts and information, the design requirements are modified until all concerned parties are satisfied and approval is given for the final design work to proceed. The first objective of this phase is to answer the following questions:

- What are the functional requirements of the product of this work?
- What are the physical requirements of the product of this work?
- What are the performance requirements of the product of this work?
- Are there any constraints limiting design decisions?
- Will existing equipment be used?
- Is the existing equipment acceptable?
- Will this be a new facility or a renovation?
- Will this be a retrofit or upgrade to an existing system?
- Will this be a stand alone system?

Working closely with the customer’s representatives, the equipment and functional requirements of each of the major technical areas of the facility are identified. In the case of facility renovation, the systems engineer’s first order of business is to analyze existing equipment. A visit is made to the site to gather detailed

information about the existing facility. Usually confronted with a mixture of acceptable and unacceptable equipment, the systems engineer must sort out those pieces of equipment that meet current standards and determine which items should be replaced. Then, after soliciting input from the facility's technical personnel, the systems engineer develops a list of needed equipment.

One of the systems engineer's most important contributions is the ability to identify and meet the needs of the customer and do it within the project budget. Based on the customer's initial concepts and any subsequent equipment utilization research conducted by the systems engineer, the desired capabilities are identified as precisely as possible. Design parameters and objectives are defined and reviewed. Functional efficiency is maximized to allow operation by a minimum number of personnel. Future needs are also investigated at this time. Future technical systems expansion is considered.

After the customer approves the equipment list, preliminary system plans are drawn up for review and further development. If architectural drawings of the facility are available, they can be used as a starting point for laying out an equipment floor plan. The systems engineer uses this floor plan to be certain that adequate space is provided for present and future equipment, as well as adequate clearance for maintenance and convenient operation. Equipment identification is then added to the architect's drawings.

Documentation should include, but not be limited to, the generation of a list of major equipment including:

- Equipment prices
- Technical system functional block diagrams
- Custom item descriptions
- Rack and console elevations
- Equipment floor plans

The preliminary drawings and other supporting documents are prepared to record design decisions and to illustrate the design concepts to the customer. Renderings, scale models, or full-size mock ups may also be needed to better illustrate, clarify, or test design ideas.

Ideas and concepts have to be exchanged and understood by all concerned parties. Good communication skills are essential. The bulk of the creative work is carried out in the design development phase. The physical layout—the look and feel—and the functionality of the facility will all have been decided and agreed upon by the completion of this phase of the project. If the design concepts appear feasible, and the cost is within the anticipated budget, management can authorize work to proceed on the final detailed design.

Electronic System Design

Performance standards and specifications have to be established up front in a technical facility project. This will determine the performance level of equipment that will be acceptable for use in the system and effect the size of the budget. Signal quality, stability, reliability, and accuracy are examples of the kinds of parameters that have to be specified. Access and processor speeds are important parameters when dealing with computer-driven products. The systems engineer has to confirm whether selected equipment conforms to the standards.

At this point it must be determined what functions each component in the system will be required to fulfill and how each will function together with other components in the system. The management and operation staff usually know what they would like the system to do and how they can best accomplish it. They have probably selected equipment that they think will do the job. With a familiarity of the capabilities of different equipment, the systems engineer should be able to contribute to this function-definition stage of the process. Questions that need to be answered include

- What functions must be available to the operators?
- What functions are secondary and therefore not necessary?
- What level of automation should be required to perform a function?
- How accessible should the controls be?

Overengineering or overdesign must be avoided. This serious and costly mistake can be made by engineers and company staff when planning technical system requirements. A staff member may, for example, ask for a seemingly simple feature or capability without fully understanding its complexity or the additional cost burden it may impose on a project. Other portions of the system may have to be compromised to implement the additional feature. An experienced systems engineer will be able to spot this and determine if the tradeoffs and added engineering time and cost is really justified.

When existing equipment is going to be used, it will be necessary to make an inventory list. This list will be the starting point for developing a final equipment list. Usually, confronted with a mixture of acceptable and unacceptable equipment, the systems engineer must sort out what meets current standards and what should be replaced. Then, after soliciting input from facility technical personnel, the systems engineer develops a summary of equipment needs, including future acquisitions. One of the systems engineer's most important contributions is the ability to identify and meet these needs within the facility budget.

A list of major equipment is prepared. The systems engineer selects the equipment based on experience with the products, and on customer preferences. Often some existing equipment may be reused. A number of considerations are discussed with the facility customer to arrive at the best product selection. Some of the major points include

- Budget restrictions
- Space limitations
- Performance requirements
- Ease of operation
- Flexibility of use
- Functions and features
- Past performance history
- Manufacturer support

The goal of the systems engineer is the design of equipment to meet the functional requirements of a project efficiently and economically. Simplified block diagrams for the video, audio, control, data, and communication systems are drawn. They are discussed with the customer and presented for approval.

Detailed Design

With the research and preliminary design development completed, the details of the design must now be concluded. The design engineer prepares complete detailed documentation and specifications necessary for the fabrication and installation of the technical systems, including all major and minor components. Drawings must show the final configuration and the relationship of each component to other elements of the system, as well as how they will interface with other building services, such as air conditioning and electrical power. This documentation must communicate the design requirements to the other design professionals, including the construction and installation contractors.

In this phase, the systems engineer develops final, detailed flow diagrams and schematics that show the interconnection of all equipment. Cable interconnection information for each type of signal is taken from the flow diagrams and recorded on the cable schedule. Cable paths are measured and timing calculations performed. Timed cable lengths (used for video and other special services) are entered onto the cable schedule.

The flow diagram is a schematic drawing used to show the interconnections between all equipment that will be installed. It is different from a block diagram in that it contains much more detail. Every wire and cable must be included on the drawings. A typical flow diagram for a video production facility is shown in [Fig. 23.11](#).

The starting point for preparing a flow diagram can vary depending on the information available from the design development phase of the project and on the similarity of the project to previous projects. If a similar system has been designed in the past, the diagrams from that project can be modified to include the equipment and functionality required for the new system. New models of the equipment can be shown

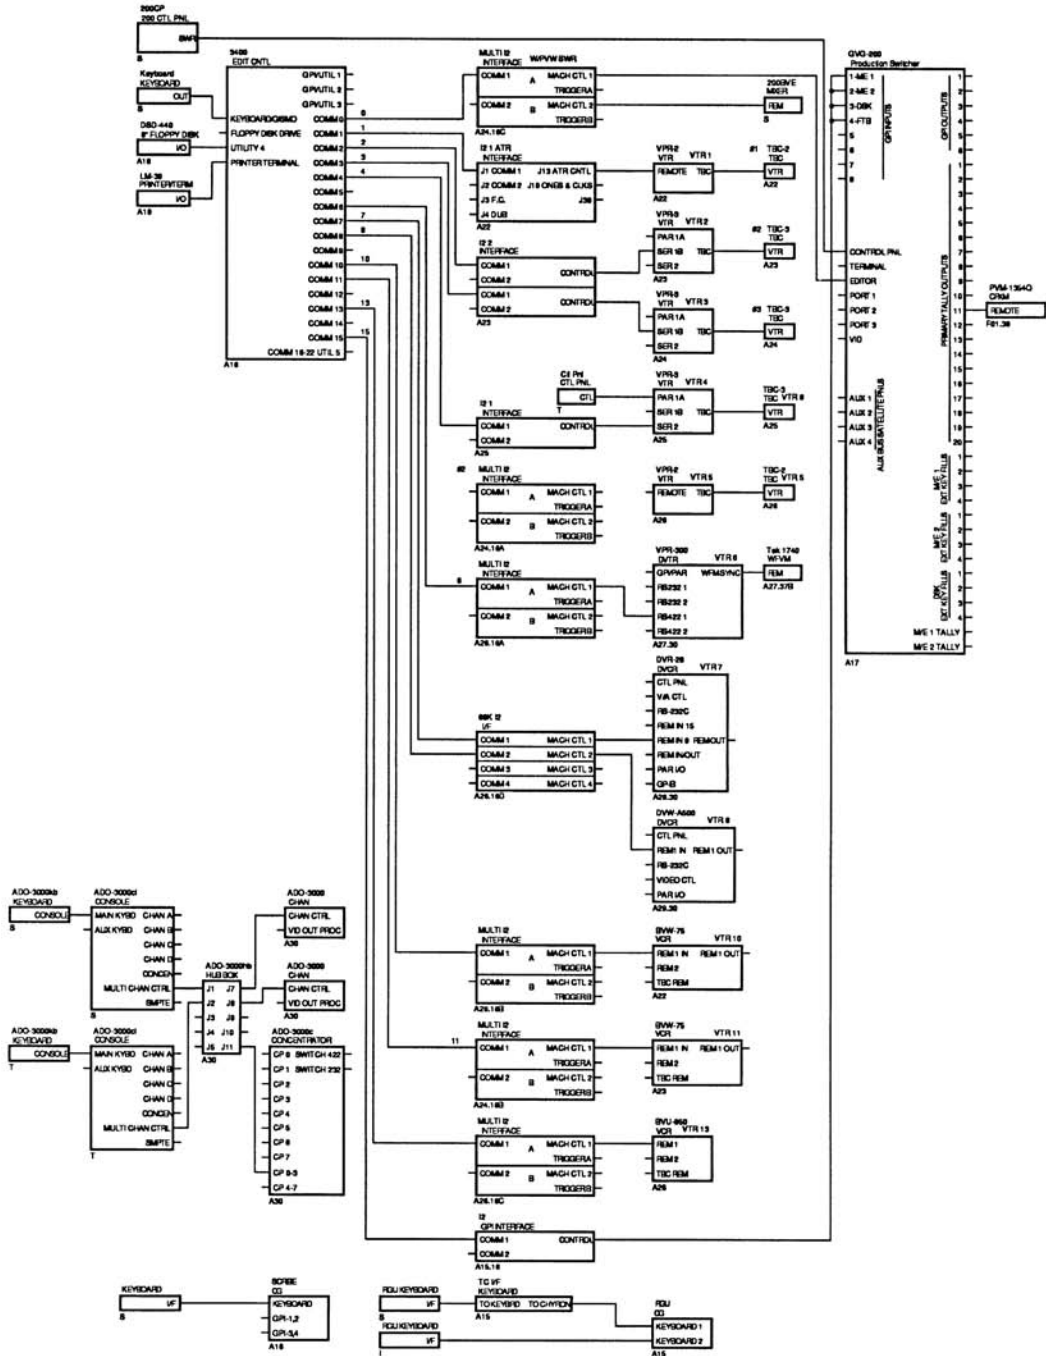

FIGURE 23.11 Video system control flow diagram.

in place of their counterparts on the diagram, and minor wiring changes can be made to reflect the new equipment connections and changes in functional requirements. This method is efficient and easy to complete.

If the facility requirements do not fit any previously completed design, the block diagram and equipment list are used as a starting point. Essentially, the block diagram is expanded and details added to show all

of the equipment and their interconnections and to show any details necessary to describe the installation and wiring completely.

An additional design feature that might be desirable for specific applications is the ability to easily disconnect a rack assembly from the system and relocate it. This would be the case if the system were to be prebuilt at a systems integration facility and later moved and installed at the client's site. When this is a requirement, the interconnecting cable harnessing scheme must be well planned in advance and identified on the drawings and cable schedules.

Special custom items are defined and designed. Detailed schematics and assembly diagrams are drawn. Parts lists and specifications are finalized, and all necessary details worked out for these items. Mechanical fabrication drawings are prepared for consoles and other custom-built cabinetry.

The systems engineer provides layouts of cable runs and connections to the architect. Such detailed documentation simplifies equipment installation and facilitates future changes in the system. During preparation of final construction documents, the architect and the systems engineer can firm up the layout of the technical equipment wire ways, including access to flooring, conduits, trenches, and overhead wire ways.

Dimensioned floor plans and elevation drawings are required to show placement of equipment, lighting, electrical cable ways, duct, conduit, and heating, ventilation, and air conditioning (HVAC) ducting. Requirements for special construction, electrical, lighting, HVAC, finishes, and acoustical treatments must be prepared and submitted to the architect for inclusion in the architectural drawings and specifications. This type of information, along with cooling and electrical power requirements, also must be provided to the mechanical and electrical engineering consultants (if used on the project) so that they can begin their design calculations.

Equipment heat loads are calculated and submitted to the HVAC consultant. Steps are taken when locating equipment to avoid any excessive heat buildup within the equipment enclosures, while maintaining a comfortable environment for the operators.

Electrical power loads are calculated and submitted to the electrical consultant and steps taken to provide for sufficient power and proper phase balance.

Customer Support

The systems engineer can assist in purchasing equipment and help to coordinate the move to a new or renovated facility. This can be critical if a great deal of existing equipment is being relocated. In the case of new equipment, the customer will find the systems engineer's knowledge of prices, features, and delivery times to be an invaluable asset. A good systems engineer will see to it that equipment arrives in ample time to allow for sufficient testing and installation. A good working relationship with equipment manufacturers helps guarantee their support and speedy response to the customer's needs.

The systems engineer can also provide engineering management support during planning, construction, installation, and testing to help qualify and select contractors, resolve problems, explain design requirements, and assure quality workmanship by the contractors and the technical staff.

The procedures described in this section outline an ideal scenario. In reality, management may often try to bypass many of the foregoing steps to save money. This, the reasoning goes, will eliminate unnecessary engineering costs and allow construction to start right away. Utilizing in-house personnel, a small company may attempt to handle the job without professional help. With inadequate design detail and planning, which can result when using unqualified people, the job of setting technical standards and making the system work then defaults to the construction contractors, in-house technical staff, or the installation contractor. This can result in costly and uncoordinated work-arounds and, of course, delays and added costs during construction, installation, and testing. It makes the project less manageable and less likely to be completed successfully.

The complexity of a project can be as simple as interconnecting a few pieces of computer equipment together to designing software for the Space Shuttle. The size of a technical facility can vary from a small one room operation to a large multimillion dollar plant or large area network. Where large amounts of money and other resources are going to be involved, management is well advised to recruit the services of qualified system engineers.

Budget Requirements Analysis

The need for a project may originate with customers, management, operations staff, technicians, or engineers. In any case, some sort of logical reasoning or a specific production requirement will justify the cost. On small projects, like the addition of a single piece of equipment, money only has to be available to make the purchase and cover installation costs. When the need may justify a large project, it is not always immediately apparent how much the project will cost to complete. The project has to be analyzed by dividing it up into its constituent elements. These elements include

- Equipment and parts
- Materials
- Resources (including money and time needed to complete the project)

An executive summary or capital project budget request containing a detailed breakdown of these elements can provide the information needed by management to determine the return on investment and to make an informed decision on whether or not to authorize the project.

A capital project budget request containing the minimum information might consist of the following items:

- Project name. Use a name that describes the result of the project, such as control room upgrade.
- Project number (if required). A large organization that does many projects will use a project numbering system of some kind or may use a budget code assigned by the accounting department.
- Project description. A brief description of what the project will accomplish, such as design the technical system upgrade for the renovation of production control room 2.
- Initiation date. The date the request will be submitted.
- Completion date. The date the project will be completed.
- Justification. The reason the project is needed.
- Material cost breakdown. A list of equipment, parts, and materials required for construction, fabrication, and installation of the equipment.
- Total material cost.
- Labor cost breakdown. A list of personnel required to complete the project, their hourly pay rates, the number of hours they will spend on the project, and the total cost for each.
- Total project cost. The sum of material and labor costs.
- Payment schedule. Estimation of individual amounts that will have to be paid out during the course of the project and the approximate dates each will be payable.
- Preparer's name and the date prepared.
- Approval signature(s) and date(s) approved.

More detailed analysis, such as return on investment, can be carried out by an engineer, but financial analysis should be left to the accountants who have access to company financial data.

Feasibility Study and Technology Assessment

Where it is required that an attempt be made to implement new technology and where a determination must be made as to whether certain equipment can perform a desired function, it will be necessary to conduct a feasibility study. The systems engineer may be called upon to assess the state-of-the-art to develop a new application. An executive summary or a more detailed report of evaluation test results may be required, in addition to a budget request, to help management make a decision.

Planning and Control of Scheduling and Resources

Several planning tools have been developed for planning and tracking progress toward the completion of projects and scheduling and controlling resources. The most common graphical project management tools are the Gantt chart and the *critical path method* (CPM) utilizing the *project evaluation and review*

(PERT) technique. Computerized versions of these tools have greatly enhanced the ability of management to control large projects.

Project Tracking and Control

A project team member may be called upon by the project manager to report the status of the work during the course of the project. A standardized project status report form can provide consistent and complete information to the project manager. The purpose is to supply information to the project manager regarding work completed and money spent on resources and materials.

A project status report containing the minimum information might contain the following items:

- Project number (if required)
- Date prepared
- Project name
- Project description
- Start date
- Completion date (the date this part of the project was completed)
- Total material cost
- Labor cost breakdown
- Preparer's name

Change Control

After part or all of a project design has been approved and money allocated to build it, any changes may increase or decrease the cost. Factors that effect the cost include

- Components and material
- Resources, such as labor and special tools or construction equipment
- Costs incurred because of manufacturing or construction delays

Management will want to know about such changes and will want to control them. For this reason, a method of reporting changes to management and soliciting approval to proceed with the change may have to be instituted. The best way to do this is with a *change order request* or *change order*. A change order includes a brief description of the change, the reason for the change and a summary of the effect it will have on costs and on the project schedule.

Management will exercise its authority and approve or disapprove each change based on its understanding of the cost and benefits and the perceived need for the modification of the original plan. Therefore, it is important that the systems engineer provide as much information and explanation as may be necessary to make the change clear and understandable to management.

A change order form containing the minimum information might contain the following items:

- Project number
- Date prepared
- Project name
- Labor cost breakdown
- Preparer's name
- Description of the change
- Reason for the change
- Equipment and materials to be added or deleted
- Material costs or savings
- Labor costs or savings
- Total cost of this change (increase or decrease)
- Impact on the schedule

Program Management

The Defense Systems Management College (Hoban, F.T. and Lawbaugh, W.M. 1993. *Readings in Systems Engineering Management*. NASA Science and Technical Information Program, Washington, D.C., p. 9.) favors the management approach and defines systems engineering as follows:

Systems engineering is the management function which controls the total system development effort for the purpose of achieving an optimum balance of all system elements. It is a process which transforms an operational need into a description of system parameters and integrates those parameters to optimize the overall system effectiveness.

Systems engineering is both a technical process and a management process. Both processes must be applied throughout a program if it is to be successful. The persons who plan and carry out a project constitute the project team. The makeup of a project team will vary depending on the size of the company and the complexity of the project. It is up to the management to provide the necessary human resources to complete the project.

Executive Management

The executive manager is the person who can authorize that a project be undertaken. This person can allocate funds and delegate authority to others to accomplish the task. Motivation and commitment is toward the goals of the organization. The ultimate responsibility for a project's success is in the hands of the executive manager. This person's job is to get tasks completed through other people by assigning group responsibilities, coordinating activities between groups, and resolving group conflicts. The executive manager establishes policy, provides broad guidelines, approves the project master plan, resolves conflicts, and assures project compliance with commitments.

Executive management delegates the project management functions and assigns authority to qualified professionals, allocates a capital budget for the project, supports the project team, and establishes and maintains a healthy relationship with project team members.

Management has the responsibility to provide clear information and goals, up front, based on their needs and initial research. Before initiating a project, the company executive should be familiar with daily operation of the facility and analyze how the company works, how jobs are done by the staff, and what tools are needed to accomplish the work. Some points that may need to be considered by an executive before initiating a project include

- What is the current capital budget for equipment?
- Why does the staff currently use specific equipment?
- What function of the equipment is the weakest within the organization?
- What functions are needed but cannot be accomplished with current equipment?
- Is the staff satisfied with current hardware?
- Are there any reliability problems or functional weaknesses?
- What is the maintenance budget and is it expected to remain steady?
- How soon must the changes be implemented?
- What is expected from the project team?

Only after answering the appropriate questions will the executive manager be ready to bring in expert project management and engineering assistance. Unless the manager has made a systematic effort to evaluate all of the obvious points about the facility requirements, the not so obvious points may be overlooked. Overall requirements must be broken down into their component parts. Do not try to tackle ideas that have too many branches. Keep the planning as basic as possible. If the company executive does not make a concerted effort to investigate the needs and problems of a facility thoroughly before consulting experts, the expert advice will be shallow and incomplete, no matter how good the engineer.

Engineers work with the information they are given. They put together plans, recommendations, budgets, schedules, purchases, hardware, and installation specifications based on the information they receive from interviewing management and staff. If the management and staff have failed to go through the planning, reflection, and refinement cycle before those interviews, the company will likely waste time and money.

Project Manager

Project management is an outgrowth of the need to accomplish large complex projects in the shortest possible time, within the anticipated cost, and with the required performance and reliability. Project management is based on the realization that modern organizations may be so complex as to preclude effective management using traditional organizational structures and relationships. Project management can be applied to any undertaking that has a specific end objective.

The project manager must be a competent systems engineer, accountant, and manager. As systems engineer, there must be understanding of analysis, simulation, modeling, and reliability and testing techniques. There must be awareness of state-of-the-art technologies and their limitations. As accountant, there must be awareness of the financial implications of planned decisions and knowledge of how to control them. As manager, the planning and control of schedules is an important part of controlling the costs of a project and completing it on time. Also, as manager, there must be the skills necessary to communicate clearly and convincingly with subordinates and superiors to make them aware of problems and their solutions.

The project manager is the person who has the authority to carry out a project. This person has been given the legitimate right to direct the efforts of the project team members. The manager's power comes from the acceptance and respect accorded by superiors and subordinates. The project manager has the power to act and is committed to group goals.

The project manager is responsible for getting the project completed properly, on schedule, and within budget, by utilizing whatever resources are necessary to accomplish the goal in the most efficient manner. The manager provides project schedule, financial, and technical requirement direction and evaluates and reports on project performance. This requires planning, organizing, staffing, directing, and controlling all aspects of the project.

In this leadership role, the project manager is required to perform many tasks including the following:

- Assemble the project organization.
- Develop the project plan.
- Publish the project plan.
- Set measurable and attainable project objectives.
- Set attainable performance standards.
- Determine which scheduling tools (PERT, CPM, and/ or Gantt) are right for the project.
- Using the scheduling tools, develop and coordinate the project plan, which includes the budget, resources, and the project schedule.
- Develop the project schedule.
- Develop the project budget.
- Manage the budget.
- Recruit personnel for the project.
- Select subcontractors.
- Assign work, responsibility, and authority so that team members can make maximum use of their abilities.
- Estimate, allocate, coordinate, and control project resources.
- Deal with specifications and resource needs that are unrealistic.
- Decide on the right level of administrative and computer support.
- Train project members on how to fulfill their duties and responsibilities.

- Supervise project members, giving them day-to-day instructions, guidance, and discipline as required to fulfill their duties and responsibilities.
- Design and implement reporting and briefing information systems or documents that respond to project needs.
- Control the project.

Some basic project management practices can improve the chances for success. Consider the following:

- Secure the necessary commitments from top management to make the project a success.
- Set up an action plan that will be easily adopted by management.
- Use a work breakdown structure that is comprehensive and easy to use.
- Establish accounting practices that help, not hinder, successful completion of the project.
- Prepare project team job descriptions properly up front to eliminate conflict later on.
- Select project team members appropriately the first time.

After the project is under way, follow these steps:

- Manage the project, but make the oversight reasonable and predictable.
- Get team members to accept and participate in the plans.
- Motivate project team members for best performance.
- Coordinate activities so they are carried out in relation to their importance with a minimum of conflict.
- Monitor and minimize interdepartmental conflicts.
- Get the most out of project meetings without wasting the team's productive time. Develop an agenda for each meeting and start on time. Conduct one piece of business at a time. Assign responsibilities where appropriate. Agree on follow up and accountability dates. Indicate the next step for the group. Set the time and place for the next meeting. End on time.
- Spot problems and take corrective action before it is too late.
- Discover the strengths and weaknesses in project team members and manage them to get desired results.
- Help team members solve their own problems.
- Exchange information with subordinates, associates, superiors, and others about plans, progress, and problems.
- Make the best of available resources.
- Measure project performance.
- Determine, through formal and informal reports, the degree to which progress is being made.
- Determine causes of and possible ways to act upon significant deviations from planned performance.
- Take action to correct an unfavorable trend or to take advantage of an unusually favorable trend.
- Look for areas where improvements can be made.
- Develop more effective and economical methods of managing.
- Remain flexible.
- Avoid activity traps.
- Practice effective time management.

When dealing with subordinates, each person must

- Know what is to be done, preferably in terms of an end product.
- Have a clear understanding of the authority and its limits for each individual.
- Know what the relationship with other people is.

- Know what constitutes a job well done in terms of specific results.
- Know when and what is being done exceptionally well.
- Be shown concrete evidence that there are just rewards for work well done and for work exceptionally well done.
- Know where and when expectations are not being met.
- Be made aware of what can and should be done to correct unsatisfactory results.
- Feel that the supervisor has an interest in each person as an individual.
- Feel that the supervisor both believes in each person and is anxious for individual success and progress.

By fostering a good relationship with associates, the manager will have less difficulty communicating with them. The fastest, most effective communication takes place among people with common points of view.

The competent project manager watches what is going on in great detail and can, therefore, perceive problems long before they flow through the paper system. Personal contact is faster than filing out forms. A project manager who spends most of the time in the management office instead of roaming through the places where the work is being done is headed for catastrophe.

Systems Engineer

The term *systems engineer* means different things to different people. The systems engineer is distinguished from the engineering specialist, who is concerned with only one aspect of a well-defined engineering discipline, in that the systems engineer must be able to adapt to the requirements of almost any type of system. The systems engineer provides the employer with a wealth of experience gained from many successful approaches to technical problems developed through hands-on exposure to a variety of situations. This person is a professional with knowledge and experience, possessing skills in a specialized and learned field or fields. The systems engineer is an expert in these fields; highly trained in analyzing problems and developing solutions that satisfy management objectives. The systems engineer takes data from the overall development process and, in return, provides data in the form of requirements and analysis results to the process.

Education in electronics theory is a prerequisite for designing systems that employ electronic components. As a graduate engineer, the systems engineer has the education required to design electronic systems correctly. Mathematics skill acquired in engineering school is one of the tools used by the systems engineer to formulate solutions to design problems and analyze test results. Knowledge of testing techniques and theory enables this individual to specify system components and performance and to measure the results. Drafting and writing skills are required for efficient preparation of the necessary documentation needed to communicate the design to technicians and contractors who will have to build and install the system.

A competent systems engineer has a wealth of technical information that can be used to speed up the design process and help in making cost effective decisions. If necessary information is not at hand, the systems engineer knows where to find it. The experienced systems engineer is familiar with proper fabrication, construction, installation, and wiring techniques and can spot and correct improper work.

Training in personnel relations, a part of the engineering curriculum, helps the systems engineer communicate and negotiate professionally with subordinates and management.

Small in-house projects can be completed on an informal basis and, indeed, this is probably the normal routine where the projects are simple and uncomplicated. In a large project, however, the systems engineer's involvement usually begins with preliminary planning and continues through fabrication, implementation, and testing. The degree to which program objectives are achieved is an important measure of the systems engineer's contribution.

During the design process the systems engineer:

- Concentrates on results and focuses work according to the management objectives.
- Receives input from management and staff.

- Researches the project and develops a workable design.
- Assures balanced influence of all required design specialties.
- Conducts design reviews.
- Performs tradeoff analyses.
- Assists in verifying system performance.
- Resolves technical problems related to the design, interface between system components, and integration of the system into any facility.

Aside from designing a system, the systems engineer has to answer any questions and resolve problems that may arise during fabrication and installation of the hardware. Quality and workmanship of the installation must be monitored. The hardware and software will have to be tested and calibrated upon completion. This, too, is the concern of the systems engineer. During the production or fabrication phase, systems engineering is concerned with

- Verifying system capability
- Verifying system performance
- Maintaining the system baseline
- Forming an analytical framework for producibility analysis

Depending on the complexity of the new installation, the systems engineer may have to provide orientation and operating instruction to the users. During the operational support phase, system engineers

- Receive input from users
- Evaluate proposed changes to the system
- Establish their effectiveness
- Facilitates the effective incorporation of changes, modifications and updates

Depending on the size of the project and the management organization, the systems engineer's duties will vary. In some cases the systems engineer may have to assume the responsibilities of planning and managing smaller projects.

Other Project Team Members

Other key members of the project team where building construction may be involved include the following:

- Architect, responsible design of any structure.
- Electrical engineer, responsible for power system design if not handled by the systems engineer.
- Mechanical engineer, responsible for HVAC, plumbing, and related designs.
- Structural engineer, responsible for concrete and steel structures.
- Construction contractors, responsible for executing the plans developed by the architect, mechanical engineer, and structural engineer.
- Other outside contractors, responsible for certain specialized custom items which can not be developed or fabricated internally or by any of the other contractors.

23.1.5 Conclusion

Systems theory is the theoretical basis of systems engineering that is an organized approach to the design of complex systems. The key components of systems theory applied in systems engineering are a holistic approach, the decomposition of problems, the exploitation of analogies, and the use of models.

A formalized technical project management technique used to define systems includes three major steps.

- Define the requirements in terms of functions to be performed and measurable and testable requirements describing how well each function must be performed.

- Synthesize a way of fulfilling the requirements.
- Study the tradeoffs and select one solution from among the possible alternative solutions.

In the final analysis, beyond any systematic approach to systems engineering, engineers have to engineer. Robert A. Frosch, a former NASA Administrator, in a speech to a group of engineers in New York, urged a common sense approach to systems engineering (Frosch, R.A. 1969. A Classic Look at System Engineering and Management. In *Readings In Systems Engineering*. ed. F.T. Hoban and W.M. Lawbaugh, pp. 1–7. NASA Science and Technical Information Program, Washington, D.C.):

Systems, even very large systems, are not developed by the tools of systems engineering, but only by the engineers using the tools. . . . I can best describe the spirit of what I have in mind by thinking of a music student who writes a concerto by consulting a check list of the characteristics of the concerto form, being careful to see that all of the canons of the form are observed, but having no flair for the subject, as opposed to someone who just knows roughly what a concerto is like, but has a real feeling for music. The results become obvious upon hearing them. The prescription of technique cannot be a substitute for talent and capability. . . .

Defining Terms

Abstraction: Though dealing with concrete systems, abstraction is an important feature of systems models. Components are described in terms of their function rather than in terms of their form. Graphical models such as block diagrams, flow diagrams, timing diagrams, and the like are commonly used. Mathematical models may also be employed. Systems theory shows that, when modeled in abstract formal language, apparently diverse kinds of systems show significant and useful isomorphisms of structure and function. Similar interconnection structures occur in different types of systems. Equations that describe the behavior of electrical, thermal, fluid, and mechanical systems are essentially identical in form.

Decomposition: The systems approach attempts to apply an organized methodology to completing large complex projects by breaking them down into simpler more manageable component elements. These elements are treated separately, analyzed separately, and designed separately. In the end, all of the components are recombined to build the whole.

Dynamics: Most system problems are dynamic in nature. The signals change over time and the components determine the dynamic response of the system. The system behavior depends on the signals at a given instant, as well as on the rates of change of the signals and their past values. The term signals can be replaced by substituting human factors such as the number of users on a computer network, for example.

Emergent properties: A holistic aspect of system theory describes emergent properties. Properties which result from the interaction of system components, properties which are not those of the components themselves, are referred to as emergent properties.

Hard and soft systems: In hard systems, the components and their interactions can be described by mathematical models. Soft systems can not be described as easily. They are mostly human activity systems, which imply unpredictable behavior and non-uniformity. They introduce difficulties and uncertainties of conceptualization, description, and measurement. Usual system concepts and methodology can not be applied.

Holism: Holism is an element of systems theory in that the end product is greater than the sum of its component elements. In systems theory, the modeling and analytical methods enable all essential effects and interactions within a system and those between a system and its surroundings to be taken into account. Errors resulting from the idealization and approximation involved in treating parts of a system in isolation, or reducing consideration to a single aspect are thus avoided.

Isomorphism: Similarity in elements of different kinds. Similarity of structure and function in elements implies isomorphism of behavior of a system. Different types of systems exhibit similar dynamic behavior such as response to stimulation.

Modeling: The concept of modeling is the starting point of synthesis of a system. Since we must be able to weigh the effects of different design decisions in order to make choices between alternative concepts, modeling requires the determination of those quantitative features that describe the operation of the system. We would, of course, like a very detailed model with as much detail as possible describing the system. Reality and time constraints, however, dictate that the simplest possible model be selected to improve our chances of design success. The model itself is always a compromise. The model is restricted to those aspects that are important in the evaluation of system operation. A model might start off as a simple block diagram with more detail being added as the need becomes apparent.

Optimization: Making an element as perfect, effective, or functional as possible. Every design project involves making a series of compromises and choices based on relative weighting of the merit of important aspects. The best candidate among several alternatives is selected.

Synthesis: This is the process by which concepts are developed to accomplish the functional requirements of a system. Performance requirements and constraints, as defined by the functional analysis, are applied to each individual element of the system, and a design approach is proposed for meeting the requirements. Conceptual schematic arrangements of system elements are developed to meet system requirements. These documents are used to develop a description of the system elements.

Trade Studies: A structured approach to guide the selection of alternative configurations and ensure that a logical and unbiased choice is made. Throughout development, trade studies are carried out to determine the best configuration that will meet the requirements of the program. In the concept exploration and demonstration phases, trade studies help define the system configuration. Trade studies are used as a detailed design analysis tool for individual system elements in the full-scale development phase. During production, trade studies are used to select alternatives when it is determined that changes need to be made. Alternative approaches to achieving the defined objectives can thereby be established.

Trade Table: A trade table is used to summarize selection results of a trade study. Pertinent criteria are listed for each alternative solution. The alternatives may be described in a qualitative manner, such as high, medium, or low.

23.2 Concurrent Engineering

Francis Long

23.2.1 Introduction

Concurrent engineering (CE) is a method used to shorten the time to market for new or improved products. Let it be assumed that a product will, upon reaching the marketplace, be competitive in nearly every respect, such as quality and cost, for example. But the marketplace has shown that products, even though competitive, must not be late to market, because market share, and therefore profitability, will be adversely affected. Concurrent engineering is the technique that, today, is most likely to result in acceptable profits for a given product.

A number of proactive companies began, in the late 1970s and early 1980s, to use what were then innovative techniques to improve their competitive position. But it was not until 1986 that a formal definition of concurrent engineering was published by the Defense Department:

A systematic approach to the integrated, concurrent design of products and their related processes, including manufacture, and support. This approach is intended to cause the developers, from the outset, to consider all elements of the product life cycle from concept through disposal including quality, cost, schedule, and user requirements.

This definition was printed in the Institute for Defense Analyses Report R-338, 1986. The key words are seen to be *integrated*, *concurrent design* and *all elements of the product life cycle*. Implicit in this definition is the concept that in addition to input from the originators of the concept, input should come from users of the product, from those who install and maintain the product, from those who manufacture and test the product, as well as from the designers of the product. Such input, as appropriate, should be in every phase of the product life cycle, even the very earliest design work.

This approach is implemented by bringing specialists from manufacturing, test, procurement, field service, etc., into the earliest design considerations. It is very different from the process so long used by industry. The earlier process, now known as the *over the wall* process, was a serial or sequential process. The product concept, formulated at a high level of company management, was then turned over to a design group. The design group completed its design effort, tossed it over the wall to manufacturing, and proceeded to an entirely new and different product design. Manufacturing tossed its product to test, and so on through the chain. The unfortunate result of this sequential process was the necessity for redesign, which happened with great regularity.

Traditional designers too frequently have limited knowledge of a manufacturing process, especially its capabilities and limitations. This may lead to a design that cannot be made economically or made in the time scheduled, or perhaps cannot be made at all. The same can be said of the specialists in the processes of test, marketing, and field service, as well as parts and material procurement. A problem in any of these areas might well require that the design be returned to the design group for redesign. The same result might come from a product that cannot be repaired. The outcome is a redesign effort required to correct the deficiencies found during later processes in the product cycle. Such redesign effort is costly in both economic and time to market terms. Another way to view these redesign efforts is that they are not *value added*. Value added is a particularly useful parameter by which to evaluate a process or practice.

This presence of redesign in the serial process can be illustrated as in Fig. 23.12, showing that even feedback from field service might be needed in a redesign effort. When the process is illustrated in this manner, the presence of redesign can be seen to be less efficient than a process in which little or no redesign is required. A common projection of the added cost of redesign is that changes made in a following process step are about 10 times more costly than correctly designing the product in the first place. If the product should be in the hands of a customer when a failure occurs, the results can be disastrous, both in direct costs to accomplish the repair and in possible lost sales due to a tarnished reputation.

There are two major facets of concurrent engineering that must be kept in mind at all times. The first is that a concurrent engineering process requires team effort. This is more than the customary committee.

FIGURE 23.12 The serial design process.

Although the team is composed of specialists from the various activities, the team members are not there as representatives of their organizational home. They are there to cooperate in the delivery of product to the market place by contributing their expertise in the task of eliminating the redesign loops shown in Fig. 23.12. Formation of the proper team is critical to the success of most CE endeavors. The second facet is to keep in mind that concurrent engineering is information and communication intensive. There must be no barriers of any kind to complete and rapid communication among all parts of a process, even if they are located at geographically dispersed sites. If top management has access to and uses information relevant to the product or process, this same information must be available to all in the production chain, including the line workers.

An informed and knowledgeable workforce at all levels is essential, so that they may use their efforts to the greatest advantage. The most effective method to accomplish this is to form, as early as possible in the product life cycle, a team composed of knowledgeable people from all aspects of the product life cycle. This team should be able to *anticipate and design out* most if not all possible problems before they actually occur. Figure 23.13 suggests many of the communication pathways that must be freely available to the members of the team. Others will surface as the project progresses. The inputs to the design process are sometimes called the “design for . . .,” inserting the requirement.

The top management that assigns the team members must also be the *coaches* for the team, making certain that the team members are properly trained and then allowing the team to proceed with the project. There is no place here for the traditional *bossism* of the past. The team members must be selected to have the best combination of recognized expertise in their respective fields and the best team skills. It is not always the one most expert in a specialty who will be the best team member. Team members, however, must have the respect for all other team members, not only for their expertise, but also for their interpersonal skills. Only then will the best products result. This concurrency of design, to include these and all other parts of the cycle, can measurably reduce time to market and overall investment in the product.

Preventing downstream problems has another benefit in that employee morale is very likely to be enhanced. People almost universally want to take pride in what they do and produce. Few people want to support or work hard in a process or system that they believe results in a poor product. Producing a

FIGURE 23.13 Concurrency of design is communication intensive.

defective or shoddy product does not give them this pride. Quite often it destroys pride in workmanship and creates a disdain for the management that asks them to employ such processes or systems. The use of concurrent engineering is a very effective technique for producing a quality product in a competitive manner. Employee morale is nearly always improved as a result.

Perhaps the most important aspect of using concurrent engineering is that the design phase of a product cycle will nearly always take more time and effort than the original design would have expended in the serial process. However, most organizations that have used concurrent engineering report that the overall time to market is measurably reduced because product redesign is greatly reduced or eliminated entirely. The time-worn phrase *time is money* takes on added meaning in this context.

Concurrent engineering can be thought of as an evolution rather than a revolution of the product cycle. As such, the principles of **total quality management (TQM)** and *continuous quality improvement (CQI)*, involving the ideas of robust design and reduction of variation, are not to be ignored. They continue to be important in process and product improvement. Nor is concurrent engineering, of itself, a type of re-engineering. The concept of re-engineering in today's business generally implies a massive restructuring of the organization of a process, or even a company, probably because the rate of improvement of a process using traditional TQM and CQI is deemed to be too slow or too inefficient or both to remain competitive. Still, the implementation of concurrent engineering does require and demand a certain and often substantial change in the way a company does business.

Concurrent engineering is as much a cultural change as it is a process change. For this reason it is usually achieved with some trauma. The extent of the trauma is dependent on the willingness of people to accept change, which in turn is dependent on the commitment and sales skills of those responsible for installing the concurrent engineering culture. Although it is not usually necessary to re-engineer, that is, to restructure, an entire organization to install concurrent engineering, it is also true that it cannot be installed like an overlay on top of most existing structures. Although some structural changes may be necessary, the most important change is in attitude, in culture. Yet it must also be emphasized that there is no *one size fits all* pattern. Each organization must study itself to determine how best to install concurrent engineering. However, there are some considerations that are helpful in this study. A discussion of many fine ideas can be found in Salomone (1995). The importance of commitment to a concurrent engineering culture from top management to line workers cannot be emphasized too strongly.

23.2.2 The Process View of Production

If production is viewed as a process, the product cycle becomes a seamless movement through the design, manufacture, test, sales, installation, and field maintenance activities. There is no competition within the organization for resources. The team has been charged with the entire product cycle such that allocation of resources is seen from a holistic view rather than from a departmental or specialty view. The needs of each activity are evident to all team members. The product and process are seen as more than the sum of the parts.

The usual divisions of the process cycle can be viewed in a different way. Rather than discuss the obvious activities of manufacturability and testability and the others shown in Fig. 23.13, the process can be viewed in terms of functional techniques that are used to accomplish the process cycle. Such a view might be as shown in Fig. 23.14.

In this view, it is the functions of *quality function deployment (QFD)*, *design of experiments (DOE)*, and *process control (PC)* that are emphasized rather than the design, manufacturing, test, etc. activities. It is the manner in which the processes of design, manufacturing, and other elements are

FIGURE 23.14 Functional view of the process cycle.

accomplished that is described. In this description, QFD is equated to analysis in the sense that the customers' needs and desires must be the driver in the design of today's products. Through the use of QFD, not only is the customer input, often referred to as the *voice of the customer*, heard, it is translated into a process to produce the product. Thus, both initial product and process design are included in QFD in this view. It is important to note that the product and the process to produce the product are designed together, not just at the same time.

DOE can be used in one of two ways. First is the optimization of an existing process by removing any causes of defects and determining the best target value of the parameters. The purpose of this is to maximize the yield of a process, which frequently involves continuous quality improvement techniques. The second is the determination of a process for a new product by optimization of a proposed process before it is implemented. Today, simulation of processes is becoming increasingly important as the processes become increasingly complex. DOE, combined with simulation, is the problem solving technique, both for running processes and proposed processes.

PC is a monitoring process to insure that the optimized process remains an optimized process. Its primary purpose is to issue an alarm signal when a process is moving away from its optimized state. Often, this makes use of statistical methods and is then called *statistical process control* (SPC). PC is not a problem solving technique, although some have tried to use it for that purpose. When PC signals a problem, then problem solving techniques, possibly involving DOE, must be implemented. The following sections will expand on each of these functional aspects of a product cycle.

Quality Function Deployment

QFD begins with a determination of the customers' needs and desires. There are many ways that raw data can be gathered. Two of these are questionnaires and focus groups. Obtaining the data is a well-developed field. The details of these techniques will not be discussed here as much has been written on the subject. It is important, however, that professionals are involved in the design of such data acquisition because of the many nuances that are inherent in such methods.

The data obtained must be translated into language that is understood by the company and its people. It is this translation that must extract the customers' needs and wants and put them in words that the designers, manufacturers, etc., can use in their tasks. Yet, the intent of the customers' words must not be lost. This is not always an easy task, but is a vitally important one. Another facet of this is the determination of unstated but pleasing qualities of a product that might provide a marketing edge. This idea has been sketched by the Kano model, shown in Fig. 23.15.

The Kano model, developed by Noriaki Kano, a Japanese professor, describes these pleasers as the *wows*. The model also shows that some characteristics of a product are not even mentioned by customers or potential customers, yet they must be present or the product will be deemed unsatisfactory. The *wows* are not even thought of by the customers but give the product a competitive advantage. An often cited example is the net in the trunk of the Ford Taurus that can be used to secure loose cargo such as grocery bags.

Translating the customers' responses into useable items is usually accomplished by application of the *house of quality*. The house of quality is a matrix, or perhaps more accurately an augmented matrix. Two important attributes of the house of quality are (1) its capability for ranking the various inputs in terms of perceived importance and (2) the data in the completed house that shows much of the decision making that went into the translation of customers' wants and need into useable task descriptions. The latter attribute

FIGURE 23.15 The Kano model.

is often called the archival characteristic and is especially useful when product up grades are designed or when new products of a similar nature are designed.

Constructing the house of quality matrix begins by identifying each horizontal row of the main or correlation matrix with a customer input, called the *customer attribute* (CA). These CAs are entered on the left side of the matrix row. Each vertical column of the matrix is assigned an activity, called the *engineering characteristic* (EC). The ECs are entered at the top of the columns. Together, the ECs are believed by the team to be able to produce the CAs. Because a certain amount of judgment is required in determining the ECs, such TQM techniques as brainstorming are often used by the team at this time. The team must now decide the relative importance of the ECs in realizing the CAs. Again, the techniques of TQM are used. The relative importance is indicated by assigning the box that is the intersection of an EC with a CA a numerical value, using an agreed upon rating scale, such as blank for no importance to 5 or 10 as very important. Each box in the matrix is then assigned a number. Note that an EC may affect more than one CA and that one CA may require more than one EC to be realized. An example of a main matrix with ranking information in the boxes and a summary at the bottom is shown in Fig. 23.16. In this example the rankings of the ECs are assigned only three relative values rather than a full range of 0–9. This is frequently done to reduce the uncertainty and lost time as a result of trying to decide, for example, between a 5 or a 6 for the comparisons. Also, weighting the three levels unequally will give emphasis to the more important relationships.

		ECs										
		A	B	C	D	E	F	G	H	I	J	
CAs	1	9		3	3		1					
	2		3	1			9					
	3	3	3		1	1		3		9	1	
	4			1					1			
	5	1	1			3				1		
	6			3			1				3	
	7				9			3		1		
	8	9				3			3			
	9		3		1			1			3	
	10	3		9								
TOTAL		25	10	20	14	7	11	7	4	11	7	116
%		21	9	17	12	6	10	6	3	10	6	100

FIGURE 23.16 The house of quality main matrix.

Following completion of the main matrix, the augmentation portions are added. The first is usually the planning matrix that is added to the right side of the main matrix. Each new column added by the planning matrix lists items that have a relationship to one or more of the CAs but are not ECs. Such items might be: assumed customer relative importance, current company status, estimated competitor’s status, sales positives (wows), improvement needed, etc. Figure 23.17 shows a planning matrix with relative weights of the customer attributes for each added relationship. The range of weights for each column is arbitrary, but the relationships between columns should be such that a row total can be assigned to each CA and each row given a relative weight when compared to other CA rows.

Another item of useful information is the interaction of the ECs because some of these can be positive, reinforcing each other, whereas others can be negative: improving one can lower the effect of another. Again,

CAs										IMPORTANCE	OUR STATUS	IMPROVEMENT NEEDED	COMPETITIVE ADVANTAGE	OVERALL WEIGHT	%	COMPETITOR	
Att 1											5	3	1.7	1.0	5.1	21	4
Att 2											3	3	1.0	1.5	4.5	19	3
Att 3											5	4	1.3	1.0	5.2	22	4
Att 4											2	3	1.0	1.0	3.0	13	2
Att 5											1	4	1.0	1.5	6.0	25	3

FIGURE 23.17 CAs and the planning matrix.

the house of quality can be augmented to indicate these interactions and their relative importance. This is accomplished by adding a roof. Such a roof is shown in Fig. 23.18. This is very important information to the design effort, helping to guide the designers as to where special effort might be needed in the optimization of the product.

It is very likely that the ECs used in the house of quality will need to be translated into other requirements. A useful way to do this is to use the ECs from this first house as the inputs to a second house, whose output might be cost or parts to accomplish the ECs. It is not unusual to have a sequence of several houses of quality, as shown in Fig. 23.19.

The final output of a QFD utilization should be a product description and a first pass at a process description to produce the product. The product description should be traceable to the original customer inputs so that this product will be competitive in those terms. The process description should be one that will produce the product in a competitive time and cost framework. It is important to note that the QFD process, to be complete, requires input from all parts of a product cycle.

This brief look at QFD hopefully indicates the power that this tool has. Initial use of this tool will most likely be more expensive than currently used methods because of the familiarization that must take place. It should not be used for small tasks, those with fewer than 10 input statements. It should probably not be used if the number of inputs exceeds 50 because the complexity makes the relative weightings difficult to manage with a satisfactory degree of confidence. Those who have learned to use QFD do find it efficient and valuable as well as cost effective.

Design of Experiments

DOE is an organized procedure for identifying those parts of a process that are causing less than satisfactory product and then optimizing the process. The process might be one already in production or it might be one that is proposed for a new product. A complex process cannot be studied effectively by using the simple technique of varying one parameter while holding all others fixed. Such a procedure, though historically taught in most science and engineering classes, totally ignores the possibility of interactions between parameters, a condition that very often prevails in the real world. However, if all interactions as well as primary parameters are to be tested, the number of experiments rapidly becomes large enough to be out of the question for only a few variables. DOE has been developed to help reduce the number of experiments required to uncover a problem parameter. As DOE developed, it became clear that some method of

FIGURE 23.18 The house of quality with a roof.

FIGURE 23.19 A series of houses of quality.

determining the relative importance of some relationships of parameters needed to be found. Thus, DOE became based in statistics and became the task of statisticians trained in advanced methods of statistics.

Factorial analysis, the study of all parameters and all their interactions, is not time efficient for hand calculations involving more than four parameters. From this, the fractional factorial method of analysis developed, where only the primary parameters and a selected set of their interactions are studied. How to select the interactions, which to study, and which to omit, is the problem. Use of brainstorming and other like techniques from TQM to select the interactions can help but do not remove the nagging questions about those that are left out. Were they left out because of ignorance of them by the team, or by a member of the team dominating the selection because of preconceived, perhaps, erroneous ideas?

An attempt to simplify the selection of parameters for a fractional factorial study was introduced by Taguchi in a technique called *orthogonal arrays* (1993). Much has been written about this technique. A few references are given at the end of this chapter. Use of the technique is not simple and requires more than a passing acquaintance with the method. A major shortcoming of the technique is that there are no guidelines for selecting among the possible interactions, much the same as that for the original fractional factorial method. The response of some to this criticism is that most problems are due to one of the main parameters anyway, leaving the nagging question of the interaction effects that may be important but were excluded.

Because of the large volume written about orthogonal arrays and the difficulties outlined previously, this chapter will discuss a lesser known but simpler system introduced by Dorian Shainin (Bhote, 1991). Only simple hand calculations are required. The techniques are based on valid statistical grounds, but their application require very little knowledge of statistics. To begin, only a knowledge of mean, median, and standard deviation is required. It is important to realize that because of the limited knowledge of statistics required to follow the rules to be described, a professional statistician should be available to answer questions that may arise when application is made to systems slightly different from the simple ones described in the subsequent discussion.

The general procedure to be followed is that of first reducing a large number of possible causes of problems to a few, typically four or fewer if possible, and then use the full factorial method of analysis to identify the most likely culprit or culprits. The principle is that most real life problems are the result of four or fewer primary variables plus their interactions, a situation that can be handled quite nicely by full factorial analysis. Once the culprits have been identified, the next step is to optimize their values so that the process is producing the very best product that it can.

Seven different procedures make up this system. These are shown in Fig. 23.20. In this structure, there are three ways to attack a many variable, more than 20, problem. The basic concept is first to eliminate those

FIGURE 23.20 The procedures of Shainin.

variables that can be shown not to be a cause because they are of the wrong type. For example, *multivari charts* are useful in defining what type, or family, the variation is, eliminating those that are not in this family. *Multivari charts* may be used with one of the other two shown as first level procedures. However, the other two are mutually exclusive. *Components search* requires that the product can be disassembled and reassembled. *Paired comparisons* is the method to use if the product cannot be disassembled but must be studied as a unit.

Colorful language was introduced by Shainin to help users remember the methods. The purpose of the procedures is to find the *red X* or the *pink Xs* or the *pale pink Xs*. The red X is the one primary cause with all other possible causes of much lesser importance. If one cause cannot be found, then the two or more that must be considered are called the pink Xs, or the pale pink Xs if they are of lesser importance.

Multivari Chart

The multivari chart is used to classify the family into which the red X or pink Xs fall. A parameter that is indicative of the problem, and can be measured, is chosen for study. Sets of samples are then taken and the variation noted. The categories used to distinguish the parameter output variation are: (1) variation within sample sets (cyclical variation) is larger than variation within samples or variation over time, (2) time variation (temporal variation) between sample sets is larger than variation within sample sets or variation of the samples, and (3) variations within samples (positional variation) are larger than variation of sample sets over time or variation within the sample sets. These are demonstrated in Fig. 23.21.

To illustrate, assume a process has been producing defective product at a known historical rate, that is, at an average rate of X ppm, for the past weeks or months. Begin the study by collecting, *consecutively*, three to five products from the process. At a later time, after a number of units have been produced in the interim, collect three to five products again. Repeat this again and again, as often as necessary; three to five times is frequently sufficient to capture at least 80% of the historical defect rate in the samples, that is, these samples should include defects at least at 80% of the historical rate, X, that the process has produced defects in historical samples. This is an important rule to observe, to provide statistical validity to the samples collected.

In the language of statistics, this is a stratified experiment, that is, the samples are grouped according to some criteria. In this case, the criteria is consecutive production of the units. This is not, therefore, a random selection of samples as is required in many statistical methods. It also is not a control chart even though the plot may resemble one. It is a *snapshot* of the process taken at the time of the sampling. Incidentally, the multivari chart is not a new procedure, dating from the 1950s, but it has been incorporated into this system by Shainin.

The purpose of the multivari chart is to discover the *family* of the red X, although on rare occasions the red X itself may become evident. The anticipated result of a successful multivari experiment is a set, the family, of possible causes that includes the red X, the pink Xs, or the pale pink Xs. The family will normally include possible causes numbering from a few up to about 20. Further experiments will be necessary to determine the red X or the pink Xs from this set.

The following example displays in Fig. 23.22 the variations of four 98- Ω nominal valued resistors screen printed on a single ceramic substrate. They will later be separated from each other by scribing. Data recorded over a two shift period, from units from more than 2800 substrate printings, are shown in the chart.

FIGURE 23.21 Multivari types of variation.

FIGURE 23.22 Example resistor value variation: (a) table of data, (b) graph of data.

A graph of these data is also shown, with the range of data for each substrate indicated and the average of the four resistors for each substrate, as well as the overall average for the three substrates sampled at that time.

Note:

1. Unit-to-unit variation within a group is the largest.
2. Time variation is also serious as the time averages increase sharply.

With this information about the family of the cause(s) of defects, additional experiments to find the cause(s) of the variation can be designed according to the methodology to be described later.

Components Search

Components search is used only when a product can be disassembled and then reassembled. It is a parts swapping procedure that is familiar to many who have done field repair. The first step is to select a performance parameter by which good and bad units can be identified. A good unit is chosen at random, measured, then disassembled and reassembled two times, measuring the performance parameter each time. This establishes a range of variability of the performance parameter that is related to the assembly operation for good units. Repeat this for a randomly selected bad unit, once again establishing the range of variability of the performance parameter for assembly of bad units. The good unit must remain a good unit after disassembly and reassembly, just as the bad unit must remain a bad unit after disassembly and reassembly. If this is not the case, then the parameter chosen as performance indicator needs to be reviewed.

Because there are only three data points for each type of unit, the statistics of small samples is useful. The first requirement here is that the three performance parameter measurements for the good unit must all yield values that are more acceptable than the three for the bad unit. If this is so, then there is only

1 chance in 20 that this ranking of measurements could happen by accident, giving a 95% confidence in this comparison. The second requirement is that the minimum separation between the medians of variability of the good unit and the bad unit exceeds a minimum. This is illustrated in Fig. 23.23, showing the three data points for the good and bad units. The value of 1.25 for the ratio D/d is based on the classical F Table at the 0.05 level. This means that the results of further tests conducted by swapping parts have at least a 95% level of confidence in the results.

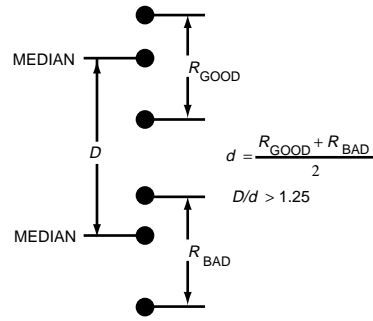

FIGURE 23.23 Test of acceptability of data for component search.

The next step is to identify the parts to be swapped and begin doing so, keeping a chart of the results, such as that in Fig. 23.24. In this plot, the left three data points are those of the original good and bad units, plus their disassembly and reassembly two times. The remaining data points represent those measurements for swapping one part for parts labeled A, etc.

Three results are possible: (1) no change, indicating the part is not at fault, (2) change in one of the units outside its limits but the other unit remains within its limits; or (3) the units flip-flop, the good unit becoming a bad unit and vice versa. A complete flip-flop indicates a part that is seriously at fault—call it a red X. Parts with measurements that are outside the limits but do not cause a complete reversal of good and bad are deemed pink Xs, worthy of further study. A pink X is a partial cause, so that one or more additional pink Xs should be found. Finally, if pink Xs are found, they should be bundled together, that is, all the parts with a pink X result should be swapped as a block between units. This is called a *capping run* and is illustrated as well. A capping run should result in a complete reversal, as shown, indicating that there are no other causes. Less than a full reversal indicates that other, not identified, causes exist or the performance measure is not the best that could have been chosen.

If a single cause, a red X has been found, then remedial action can be initiated. If two to four pink Xs are found, a full factorial analysis, to be described later, should be done to determine the relative importance of the revealed causes and their interactions. Once the importance has been determined, then allocation of resources can be guided by the relative importance of the causes.

FIGURE 23.24 Components search.

Paired Comparisons

If the product cannot be disassembled and reassembled, the technique to use is paired comparisons. The concept is to select pairs of good and bad units and compare them, using whatever visual, mechanical, electrical, chemical, etc., comparisons are possible, recording whatever differences are noticed. Do this for several pairs, continuing until a pattern of differences becomes evident. In many cases, a half-dozen paired comparisons is enough to detect repeatable differences. The units chosen for this test should be selected at random to establish statistical confidence in the results. If the number of differences detected is more than four, then use of *variables search* is indicated. For four or fewer, a full factorial analysis can be done.

Variables Search

Variables search is best applied when there are 5 or more variables with a practical limit of about 20. It is a binary process. It begins by determining a performance parameter and defining a *best* and a *worst* result. Then a ranking of the variables as possible causes is done, followed by assigning for each variable two levels, call them best and worst or good and bad, or some other distinguishing pair. For all variables simultaneously at the best level, the expected result is the best for the performance parameter chosen, similarly for the worst levels. Run two experiments, one with all variables at their best levels and one with all variables at their worst levels. Do this two more times, randomizing the order of best and worst combinations. Use this set of data in the same manner as that for components search using the same requirements and the same limits formula.

If the results meet the best and worst performance, proceed to the next step. If the results do not meet these requirements, interchange the best and worst levels of one parameter at a time until the requirements are met or until all pair reversals are used. If the requirements are still not met, an important factor has been left out of the original set and additional factors must be added until all important requirements are met.

When the requirements are met, then proceed to run pairs of experiments, choosing first the most likely cause and exchanging it between the two groupings. Let the variables be designated as A , B , etc., and use subscripts B and W to indicate the best and worst levels. Let R designate the remainder of the variables. If A is deemed the most likely cause, then this pair of experiments would use $A_W R_B$ and $A_B R_W$, where R is all remaining variables B , C , etc. Observe whether the results fall within the limits, outside the limits but not reversal, or complete reversal, as before. Use a capping run if necessary. If the red X is found, proceed to remedial efforts. If up to four variables are found, proceed to a full factorial analysis.

Full Factorial Analysis

After the number of possible causes, variables, has been reduced to four or fewer but more than one, a full factorial analysis is used to determine the relative importance of these variables and their interactions. Once again, the purpose of DOE is to direct the allocation of resources in the effort to improve a product and a process. One use of the results is to open tolerances on the lesser important variables if there is economic advantage in doing so.

The simplest four factor factorial analysis is to use two levels for each factor, requiring that 16 experiments be performed in random order. Actually, for reasons of statistical validity, it is better to perform each experiment a second time, again in a different random order, requiring a total of 32 experiments. If there are fewer than four factors, then correspondingly fewer experiments would need to be performed. The data from these experiments are used to generate two charts, a full factorial chart and an *analysis of variance* (ANOVA) chart. Examples of these two are shown in Fig. 23.25 and Fig. 23.26, where the factors are A , B , C , and D with the two levels denoted by $+$ and $-$. The numbers in the circles represent the average or mean of the data for the two performances of that particular combination of variables. These numbers are then the data for the input column of the ANOVA chart. The numbers in the upper left hand corner are the cell or box number corresponding to the cell number in the left-hand column of the ANOVA chart. In the ANOVA chart, the $+$ and $-$ signs in the boxes indicate whether the output is to be added to or subtracted from the other outputs in that column, with the sum given at the bottom of that column. A column sum with small net, plus or minus, compared to other columns is deemed to be of little importance. The columns

FIGURE 23.25 Full factorial chart.

with large nets, plus or minus, are deemed the ones that require attention. These two charts contain the data necessary to make a determination of resource allocation.

B vs. C Method

At this point it might be desirable to validate these findings by an independent means. The *B (better) vs. C (current)* method is useful for this purpose. There are two parts to this validation: (1) rank a series of samples to see if *B* is better than *C* and (2) determine the degree of risk of assuming that the results are valid. For example, if there are two *B* and two *C*, then there is only one ranking of these four parameters in which the two *B* outrank the two *C*. Therefore, there is only a one in six probability that this ranking occurred by chance. There is a 16.7% risk in assuming that this ranking actually occurred when it should not have. If there are three *B* and three *C*, then requiring that the three *B* outrank the three *C* has only a 1 in 20 probability of happening by chance, a 5% risk. These risk numbers are simply the calculation of the number of combinations of the inputs that can result in the required ranking vs. the total number of combinations that exist. This risk is called the α risk. A definition of an α risk is the risk of assuming improvement when none exists. This is also referred to as a type I error risk. There is also a β risk that is the risk of assuming no improvement when improvement actually does exist, referred to as a type II error risk. It is worthy of note that decreasing one type of risk increases the other for a given sample size. Increasing the sample size may permit decreasing both. It is also true that increasing the sample size may allow some overlap in the *B vs. C* ranking, that is, some *C* may be better than some *B* in a larger sample size. Please refer to the references for further discussion.

Realistic Tolerances Parallelogram Plots

The final step in this set of DOE procedures is the optimization of the variables of the process. The tool for this is the *realistic tolerances parallelogram plot*, often called the *scatter plot*. The purpose is to establish the variables at their optimum target values. Although there are a number of other techniques for doing this, the use of scatter plots is a simpler process than most, generally with equally acceptable results.

The procedure begins with acquiring 30 output data points by varying the variable over a range of values that is assumed to include the optimum value and plotting the output for these 30 data points vs. the variable under study. An ellipse can be drawn around the data plot so as to identify a major axis. Two lines parallel to the major axis of the ellipse are then drawn on either side of the ellipse to include all but one or one and one-half of the data points. Assuming that specification limits exist for the output, these are drawn on the plot. Then vertical lines are drawn to intersect these specification limit lines at the same point that the parallelogram lines intersect the specification limits, as shown in Fig. 23.27. The intersection of these vertical lines with the variable axis determines the realistic tolerance for the variable.

FIGURE 23.27 Scatter plot (realistic tolerance parallelogram plot).

Additional information can be found in this plot. Small vertical scatter of the data indicates that indeed this is an important variable, that most of the variation of the output is caused by this variable. Conversely, large vertical scatter indicates that other variables are largely responsible for variation of the output. Also, little or no slope to the major axis of the ellipse indicates little or no importance of this variable in influencing the output. The actual slope is not important as it depends on the scale of the plot. Scatter plots can be made for each of the variables to determine their optimum, target value.

The techniques presented here are intended to be easy to implement with pencil and paper. As such, they may not be the best, although they are very likely the most economical. The use of recently developed software programs is gaining acceptance, some of these programs able to do very sophisticated data manipulation and plotting. As mentioned previously, the advice or direction of a professional statistician is always to be considered, especially for very complex problems.

Process Control

Once the process has been optimized and is in operation, the task becomes that of maintaining this optimized condition. Here Shainin makes use of two tools, *positrol* and *precontrol*. Again, these are easy to use and understand, and provide in many instances better results than previously used tools, such as control charts from TQM.

Positrol

In simple terms, positrol (short for positive control) is a plan, with appropriate documentation recorded in a log, that identifies *who* is to make *what* measurements, *how* these measurements are to be made, and *when* and *where* they are to be measured. It establishes the responsibility for and the program of measurements that are to be a part of the process control plan. A simple log, though sometimes with detailed entries, is kept so that information about the process is available at any time to operators and managers. Those responsible for keeping the log must be given a short training period on how to keep the log, with emphasis on the importance of making entries promptly and accurately.

An example of a positrol log entry for a surface mount soldering process would be

<u>What</u>	<u>Who</u>	<u>How</u>	<u>Where</u>	<u>When</u>
Copper patterns	Etcher	Visual	Etcher	After Etch

Such a positrol log contains complex steps, each of which might well be kept in its own log. For example, the reflow soldering operation could have a number of what steps, such as belt speed; furnace zone temperatures for preheat; soldering zone; cool down zone; atmosphere chemistry control; atmosphere flow speed; visual inspection for missing, misaligned, or tombstoned parts; solder bridges; and solder opens.

A positrol log should contain whatever steps or specifications (whats) in a process are to be monitored. As such, it should be the best log or record of the process that the team, in consultation with the operators, can devise. It should be clear that no important steps are to be omitted. The log provides documentation that could be invaluable should the process develop problems. However, it is not the purpose of the log to identify people to blame, but rather to know the people who might have information to offer in finding a solution to the problem.

Precontrol

The second procedure in process control is precontrol, developed by Frank Satterthwaite and described in the 1950s. One of the problems with control charts of the TQM type is that they are slow to indicate a process that is moving to an out of control state. In part this is because of the way the limits on the variability of a process are determined. Satterthwaite suggested that it would be better if the specification limits were used rather than the traditional control limits. He then divided the range between the *upper specification limit* (USL) and the *lower specification limit* (LSL) into four equal-sized regions. The two in the middle on either side of the center of the region between the limits were called the *green zones*, indicating a satisfactory process. The two regions bordering the green zones on one side and the USL and LSL on the other were called the *yellow zones*. Zones outside the limits were called the *red zones*. For an existing process being studied, simple rules for an operator to follow are

1. If two consecutive samples fall in the green zones, the process may continue.
2. If one sample falls in a green zone and one in a yellow zone, the process is still OK.
3. If both are in the same yellow zone, the process needs adjustment but does not need to be stopped.
4. If the two are in different yellow zones, the process is going out of control and must be stopped.
5. Even one in red zones the process must be stopped.

A stopped process must then be brought back to control.

A new process must be in control before it is brought into production. Here, the procedure is to select five samples. If all five are in green zones, the process may be implemented. If even one is not in the green zones, the process is not yet ready for production and must be further studied.

Another important aspect of precontrol is that, for a process that is in control, the time between samples can be increased the longer it remains in control. The rule is that the time between samples is the time between the prior two consecutive stops divided by six. If it is determined that a more conservative sampling is in order, then divide by a larger number.

Experience has shown that the α risk of precontrol is less than 2%, that is, the risk of stopping a good process. The β risk, not stopping a bad process, is less than 1.5%. These are more than acceptable risks for most real processes.

23.2.3 Robust Design

Because design determines so much of the ultimate expenditure in producing a product, there is increasing interest in process and product designs that can survive in many different environments while maintaining their design performance with quality and production costs that are competitive in the global market. Taguchi (1993) has suggested that the *goal posts* mentality of design, accepting values anywhere within the design specifications, is harmful to society as well as to the producer and the user.

Customers generally want products to be as identical as clones. This implies that the products should have zero variability of a parameter that is important. Its value should be the target value. Any product that does not exhibit this value, even though it remains within specifications, is a loss to society in that the customer/user is not getting from the product the very best that could be delivered.

The Loss Function

Taguchi proposed that a measure of the loss to society, and to the customer, be a quadratic (square law) function of the difference between the target value and the actual value of the parameter of interest. This has become known as *Taguchi's loss function*. The goal posts idea just does not address this loss to society; it does not penalize a product with a parameter that is not the target value. The loss function has been used as a measure of monetary loss associated with less than optimal performance as well as higher maintenance and repair costs.

The formula that is the basis of the loss function is

$$L(y) = (A/\Delta^2)(y - m)^2$$

where L is loss function; A cost of repair or replacement, the failure loss; Δ functional limit of the product, the deviation at which failure occurs; y product value; and m target value. Note that $(y - m)^2$ is the square of the deviation from the target value and could be replaced by the mean squared deviation of the parameter.

Also, Taguchi recognized that any real process has variability, that it is not possible to have ideal clones. To quantify this inherent variability of a process, he chose a measure that he calls signal to noise. (This is not to be confused with the same terminology used in electrical engineering to describe the power in a signal compared to the power in the noise that accompanies the signal.) In the sense used here, noise can be thought of as the uncontrollable factors.

The formulas for signal to noise do use the base 10 logarithm and the units of the signal-to-noise ratio (S/N) are decibel (dB). The purpose is to give a measure of the factor so that comparisons can be made. The basic formula is

$$S/N = 10 \log_{10} (Y^2/\sigma^2)$$

for nominal is best. Taguchi uses S/N in connection with his orthogonal arrays technique. That is a complicated process and will not be discussed here. The reader is referred to the literature for further information on the loss function and the various formula modifications for specific applications.

Process Capability

Process capability C_p is defined as the *specification width* divided by the process width. The main assumption for all of this is that many physical processes have sample distributions that are described by the Gaussian or normal distribution. A second assumption is that the 3σ points of the process normal distribution describe the process width. If the process width coincides with the **specification limits**, then the $C_p = 1.0$. This is somewhat arbitrary but has been the standard usage for many years and continues to be accepted. If $C_p = 1$, the defect rate is approximately 2700 parts per million (ppm), a generally unacceptable defect rate for most products in today's competitive marketplace. If the center of the process is not coincident with the center of the specification width, the process capability is reduced and must be calculated by $C_{pk} = C_p(1 - K)$ where K is the difference between the target value and the process mean divided by one-half the specification width.

Worst Case and Monte Carlo Design

Many designs have been made using the designer's best estimates of the worst possible combination of parameters and attempting to create a design that will still meet the specifications. For those products that demand a high degree of reliability, there is no possibility to be allowed for a defective product. For these, a **worst case design** is mandatory. The major difficulty in doing worst case design is to guarantee that the combination of parameters chosen does in fact result in the worst case. The more the parameters, the more difficult it is to guarantee this. Design of experiments might be used to determine the combinations that will result in the worst case. Then, simulations should be employed to verify the choices. It can be seen that worst case design can be quite expensive, in terms of time as well as dollars. However, most products do not require such high reliability. A method of accepting less than 100% yield might be cost effective for

products that experience an occasional failure without catastrophic repercussions, especially if it can be repaired easily.

Still, with the customer demanding higher quality, some form of organized design for quality and reliability must be employed. One method for doing this is to simulate the product variability using **Monte Carlo** statistical analysis of the designs. The specifications are set for the product and tolerances are chosen for the components. Then, the component values of the product are made to vary according to a selected statistical distribution, such as a normal (Gaussian) or a uniform distribution. The components can be varied one at a time or multiple components can be varied at the same time. Generally, varying one component at a time is not the best technique, because interactions between components can be the cause of a defective product. Again, the techniques of design of experiments can aid greatly in selecting the components to be varied. Then, the Monte Carlo analysis becomes a verification of the results obtained from DOE.

The key to successful use of Monte Carlo simulation and analysis is to determine the tolerances to be used and to match the statistical distribution to be used to that of the real component. Then a realistic C_{pk} can be chosen that will guarantee an acceptable level of defect rate. The concurrent engineering team can then determine whether or not such a design can be built and tested.

Monte Carlo simulation and analysis can become expensive if many variables are allowed to vary. The simulation must be run many times. This is another reason to do design of experiments as outlined earlier and incorporate those results with the Monte Carlo analysis. Just as scatter plots can indicate when tolerances might be tightened or loosened or that the original target value is not the best, Monte Carlo analysis can also point out tolerances that might be loosened so as to reduce the costs of the components. Thus, Monte Carlo analysis and design of experiments are seen to be complementary, one yielding verification of the other, as well as presenting a different view of the processes.

Expert Systems and Artificial Intelligence

The advent of **artificial intelligence (AI)** in the world of business in the 1970s and 1980s has begun a new approach to some of the problems of the day. Some companies became acutely aware of the loss of very valuable expertise with the retirement of their most valued employees. Many managers, and often engineers, those who were aware of artificial intelligence research in the university communities and in the fledgling consulting companies offering their systems, anticipated the improved productivity that these so far esoteric studies might produce. The most used part of AI became the *expert system*, which could become the repository of the knowledge and expertise of these soon to retire most valued employees.

The history and applications around the world make a fascinating story that is told in the literature. The struggles against the entrenched bureaucratic structures and the doubting managers who must finance the ventures are a classic tale. Some of these pioneers devoted their own time to the venture, while others bootlegged it unbeknownst to their managers. It is the story of many new technologies.

The greatest immediate benefit for many of the companies was the capturing of the knowledge, the heuristics, and the thought processes of the retiring experts. These were then converted to a set of rules that the engine considers in presenting the alternatives to a human decision maker, or even in some instances making a single recommendation. What the expert systems also made possible was the training and assistance of new employees in these critical fields, making the transition from apprentice to expert in a much shorter time than had been possible without the expert system. In other cases, the utility was the uniformity of the decision making process across several workers, such as approving purchases on a credit card or denying the credit, or the increased speed with which such decisions could be made.

Defining Terms

Artificial intelligence: A branch of computer science that attempts to devise computer hardware and software that emulates human intelligence.

Artificial neural networks: Hardware and software that are based on a model of neural synapse data processing.

Control limits: The limits on a process that are determined by running the process, measuring a performance parameter, and determining the limits according to preset formulas based on the output data

of the process. A satisfactory process will have control limits that are usually somewhat narrower than the specification limits.

Expert system: A system that uses a computer program containing the knowledge and problem solving techniques of experts in a field.

Knowledge engineers: Those who translate the expertise and knowledge of experts into the software of expert systems.

Monte Carlo design: A method of design that assigns parts a tolerance with variation such as Gaussian or uniform and then studies an output performance parameter to determine if a yield is deemed satisfactory.

Specification limits: The limits on a performance parameter or a part that are set by the designers.

Total quality management (TQM): A philosophy and set of guiding principles required by any organization attempting to compete in today's global-based economy, built upon the work of Deming, Juran, and others.

Worst case design: A method for determining the worst performance values of parameters and assigning all parameters these values while still having the product meet specifications, presumably resulting in a product that will never fail to meet specifications under all operating conditions.

23.3 Engineering Documentation

Fred Baumgartner and Terrence M. Baun

23.3.1 Introduction

Video facilities are designed to have as little down-time as possible. Yet, inadequate documentation is a major contributor to the high cost of systems maintenance and the resulting widespread replacement of poorly documented facilities. The cost of neglecting *hours* of engineering documentation is paid in *weeks* of reconstruction.

Documentation is a management function every bit as important as project design, budgeting, planning, and quality control; it is often the difference between an efficient and reliable facility and a misadventure. If the engineer does not feel qualified to attempt documentation of a project, the engineer must at the very least oversee and approve the documentation developed by others.

Within the last few years the need for documentation has increased with the complexity of the broadcast systems. Fortunately, the power of documentation tools has kept pace.

23.3.2 Basic Concepts

The first consideration in the documentation process is the complexity of the installation. A basic video editing station may require almost no formal documentation, while a large satellite or network broadcast facility may require computerized databases and a full time staff doing nothing but documentation updates. Most facilities will fall somewhere in the middle of that spectrum.

A second concern is the need for flexibility at the facility. Seldom does a broadcast operation get “completely rewired” because the cabling wears out or fails. More often, it is the supporting documentation that has broken down, frustrating the maintainability of the system. Retroactive documentation is physically difficult and emotionally challenging, and seldom generates the level of commitment required to be entirely successful or accurate; hence, a total rebuild is often the preferred solution to documentation failure. Documentation must be considered a hedge against such unnecessary reconstruction.

Finally, consider efficiency and speed. Documentation is a prepayment of time. Repairs, rerouting, replacements, and reworking all go faster and smoother with proper documentation. If your installation is one in which any downtime or degradation of service is unacceptable, then budgeting sufficient time for the documentation process is critically important.

Because, in essence, documentation is education, knowing “how much is enough” is a difficult decision. We will begin by looking at the basics, and then expand our view of the documentation process to fit specialized situations.

The Manuals

Even if you never take a pen to paper, you do have one source of documentation to care for, since virtually every piece of commercial equipment comes with a manual.

Place those manuals in a centralized location, and arrange them in an order that seems appropriate for your facility. Most engineering shops file manuals alphabetically, but some prefer a filing system based on equipment placement. (For example, production studio equipment manuals would be filed together under a “Production Studio” label and might even be physically located in the referenced studio.) But whatever you do, be consistent. Few things are as frustrating to a technician as being unable to locate a manual when needing something as simple as a part number or the manufacturer’s address.

Equipment manuals are the first line of documentation and deserve our attention and respect.

Documentation Conventions

The second essential item of documentation is the statement of “conventions.” By this we mean a document containing basic information essential to an understanding of the facility, posted in an obvious location

and available to all who maintain the plant. Consider the following examples of conventions:

- Where are the equipment manuals and how are they organized?
- What is the architecture of the ground system? Where is the central station ground and is it a star, grid, or other distribution pattern? Are there separate technical and power grounds? Are audio shield grounded at the source, termination, or both locations?
- What is the standard audio input/output architecture? Is this a +8, +4, or 0 dBm facility? Is equipment sourced at 600 Ω terminated at its destination, or left unterminated? Are unbalanced audio sources wired with the shield as ground or is the low side of a balanced pair used for that purpose? How are XLR-type connectors wired—pin 2 high or low?
- How can a technician disconnect utility power to service line voltage wiring within racks? Where are breakers located, and how are they marked? What equipment is on the UPS power, generator, or utility power? Whom do you call for power and building systems maintenance?
- Where are the keys to the transmitter? Is the site alarmed?

For such an essential information source, you will find it takes very little time to generate the conventions document. Keep it short—it is not meant to be a book. A page or two should be sufficient for most installations and, if located in a obvious place, this document will keep the technical staff on track and will save service personnel from stumbling around searching for basic information. This document is the key to preventing many avoidable embarrassments.

The next step beyond the conventions document is a documentation *system*. There are three primary methods:

- Self documentation
- Database documentation
- Graphic documentation

In most cases, a mixture of all three is necessary and appropriate. In addition to documenting the physical plant and its interconnections, each piece of equipment, whether commercially produced or custom made, must be documented in an organized manner.

Self Documentation

In situations where the facility is small and very routine, self documentation is possible. Self documentation relies on a set of standard practices that are repeated. Telephone installations, for example, appear as a mass of perplexing wires. In reality, the same simple circuits are simply repeated in an organized and universal manner. To the initiated, any telephone installation that follows the rules is easy to understand and repair or modify, no matter where or how large. Such a system is truly self documenting. Familiarity with telephone installations is particularly useful, because the telephone system was the first massive electronic installation. It is the telephone system that gave us “relay” racks, grounding plans, demarcation points, and virtually all of the other concepts that are part of today’s electronic control or communications facility.

The organization, color codes, terminology, and layout of telephone systems is recorded in minute detail. Once a technician is familiar with the rules of telephone installations, drawings and written documentation are rarely required for routine expansion and repair. The same is true for many parts of other facilities. Certainly, much of the wiring in any given rack of equipment can be self documenting. For example, a video tape recorder will likely be mounted in a rack with a picture monitor, audio monitor, waveform monitor, and vectorscope. The wiring between each of these pieces of equipment is clearly visible, with all wires short and their purpose obvious to any technician familiar with the rules of video. Furthermore, each video cable will conform to the same standards of level or data configuration. Additional documentation, therefore, is largely unnecessary.

By convention, there are rules of grounding, power, and signal flow in all engineering facilities. In general, it can be assumed that in most communications facilities, the ground will be a star system, the

power will be individual 20 amp feeds to each rack, and the signal flow within each rack will be from top to bottom. Rules that might vary from facility to facility include color coding, connector pin outs, and rules for shield and return grounding.

To be self documenting, the rules must be determined and all of the technicians working on the facility must know and follow the conventions. The larger the number of technicians, or the higher the rate of staff turn-over, the more important it is to have a readily available document that clearly covers the conventions in use.

One thing must be very clear: a facility that does not have written documentation is not automatically self documenting. Quite the contrary. A written set of conventions and unfaltering adherence to them are the trade marks of a self documenting facility.

While it is good engineering practice to design all facilities to be as self documenting as possible, there are limits to the power of self documentation. In the practical world, self documentation can greatly reduce the amount of written documentation required, but can seldom replace it entirely.

Database Documentation

As facilities expand in size and complexity, a set of conventions will no longer answer all of the questions. At some point, a wire leaves an equipment rack and its destination is no longer obvious. Likewise, equipment will often require written documentation as to its configuration and purpose, especially if it is utilized in an uncharacteristic way.

Database documentation records the locations of both ends of a given circuit. For this, each cable must be identified individually. There are two common systems for numbering cables: *ascension numbers*, and *from-to coding*. In ascension numbering schemes, each wire or cable is numbered in increasing order, one, two, three, and so on. In from-to coding, the numbers on each cable represent the source location, the destination location, and normally some identification as to purpose and/or a unique identifier. For example, a cable labeled 31–35-B6 might indicate that cable went from a piece of equipment in rack 31 to another unit in rack 35 and carries black, it is also the sixth cable to follow the same route and carry the same class of signal.

Each method has its benefits. Ascension numbering is easier to assign, and commonly available preprinted wire labels can be used. On the other hand, ascension numbers contain no hints as to wire purpose or path, and for that reason “purpose codes” are often added to the markings.

From-to codes can contain a great deal more information without relying on the printed documentation records, but often space does not permit a full delineation on the tag itself. Here again, supplemental information may still be required in a separate document or database.

Whatever numbering system is used, a complete listing must be kept in a database of some type. In smaller installations, this might simply be a spiral notebook that contains a complete list of all cables, their source, destination, any demarcations, and signal parameters.

Because all cabling can be considered as a transmission line, all cabling involves issues of termination. In some data and analog video applications, it is common for a signal to “loop-through” several pieces of equipment. Breaking or tapping into the signal path often has consequences elsewhere, resulting in unterminated or double-terminated lines. While more forgiving, analog audio has similar concerns. Therefore, documentation must include information on such termination.

Analog audio and balanced lines used in instrumentation have special concerns of their own. It is seldom desirable to ground both ends of a shielded cable. Again, the documentation must reflect which end(s) of a given shield is grounded.

In many cases, signal velocity is such that the length of the lines and the resulting propagation delay is critical. In such circumstances, this is significant information that should be retained. In cases where differing signal levels or configurations are used (typical in data and control systems), it is the documentor’s obligation to record those circumstances as well.

However or wherever the database documentation is retained, it represents the basic information that defines the facility interconnections and must be available for updating and duplication as required.

Graphic Documentation

Electronics is largely a graphical language. Schematics and flow charts are more understandable than net lists or cable interconnection lists. Drawings, either by hand—done with the aid of drafting machines and tools—or accomplished on CAD (computer aided design) programs are highly useful in conveying overall facility design quickly and clearly. Normally, the wire numbering scheme will follow that used in the database documentation, so that the graphic and text documentation can be used together.

CAD drawings are easy to update and reprint. For this reason, documentation via CAD is becoming more popular, even in smaller installations. Because modern CAD programs not only draw but also store information, they can effectively serve as an electronic file cabinet for documentation. While there have been attempts to provide electronic/telecommunications engineering documentation “templates” and corresponding technical graphics packages for CAD programs, most of the work in this area has been done by engineers working independently to develop their own systems. Obviously, the enormous scope of electronic equipment and telecommunications systems make it impractical for a “standard” CAD package to suit every user.

Update Procedures

Because documentation is a dynamic tool, as the facility changes, so too must the documentation. It is common for a technician to “improve” conditions by reworking a circuit or two. Most often this fixes a problem that should be corrected as a maintenance item. But sometimes, it plants a “time bomb” wherein a future change, based on missing or incomplete documentation of the previous work, will cause problems.

It is essential that there be a means of consistently updating the documentation. The most common way of accomplishing this is the mandatory “change sheet.” Here, whenever a technician makes a change it is reported back to those who keep the documentation. If the changes are extensive, the use of the “red-line” drawing and “edit sheet” come into play; the original drawing and database, respectively, are printed and corrected with a “red pen.” This document then is used to update the original documentation.

In some cases, the updating process can be tied to the engineering reports or discrepancy process. Most facilities use some form of “trouble ticket” to track equipment and system performance and to report and track maintenance. This same form may be used to report changes required of the documentation or errors in existing documentation.

Equipment Documentation

Plant documentation does not end when all of the circuit paths in the facility are defined. Each circuit begins and ends at a piece of equipment, which can be modified, reconfigured, or removed from service. Keep in mind that unless the lead technician lives forever, never changes jobs, and never takes a day off, someone unfamiliar with the equipment will eventually be asked to return it to service. For this reason, a documentation file for each piece of equipment must be maintained.

Equipment documentation contains these key elements:

- The equipment manual
- Modification record
- Configuration information
- Maintenance record

The equipment manual is the manufacturer’s original documentation. As mentioned previously, the manuals must be organized in such a manner that they can be easily located. Typically, the manuals are kept at the site where the equipment is installed (if practical). Remember that equipment with two “ends” such as STLs, RPU’s, or remote control systems need manuals at *each* location.

Of course, if a piece of equipment is of custom construction, there must be particular attention paid to creating a manual. For this reason, a copy of the key schematics and documentation is often attached directly to the equipment. This “built-in manual” may be the only documentation to survive over the years.

Many pieces of equipment, over time, will require modification. Typically, the modification is recorded in three ways. First, internally to the equipment. A simple note glued into the chassis may be suitable, or a marker pen is used to write on a printed circuit board or other component. Second, the changes can be recorded in the manual, either inside the cover, or on the schematic or relevant pages. If the manual serves several machines, this may not be appropriate. If this is the case, a third option is to keep the modification information in a separate *equipment file*.

Equipment files are typically kept in standard file folders, and may be filed with the pertinent equipment manuals. Ideally, the equipment file is started when the equipment is purchased, and should contain purchase date, serial number, all modifications, equipment location(s), and a record of service.

The equipment file is the proper place to keep the configuration information. An increasingly large amount of equipment is microprocessor based or otherwise configurable for a specific mode of operation. Having a record of the machine’s default configuration is extremely helpful when a power glitch (or an operator) reconfigures a machine unexpectedly.

Equipment files should also contain repair records. With most equipment, documenting failures, major part replacements, operating time, and other service-related events serves a valuable purpose. Nothing is more useful in troubleshooting than a record of previous failures, configuration, modifications, and—of course—a copy of the original manual.

Operator/User Documentation

User documentation provides, at its most basic level, instructions on how to use a system. While most equipment manufacturers provide reasonably good instruction and operations manuals for their products, when those products are integrated into a system another level of documentation may be required. Complex equipment may require interface components that need to be adjusted from time to time, or various machines may be incompatible in some data transmission modes—all of which is essential to the proper operation of the system.

Such information often resides only in the heads of certain key users and is passed on by word of mouth. This level of informality can be dangerous, especially when changes take place in the users or maintenance staff, resulting in differing interpretations between operators and maintenance people about how the system normally operates. Maintenance personnel will then spend considerable time tracking hypothetical errors reported by misinformed users.

A good solution is to have the operators write an operating manual, providing a copy to the maintenance department. Such documentation will go a long way toward improving inter-departmental communications and should result in more efficient maintenance as well.

The True Cost of Documentation

There is no question that documentation is expensive—in some cases it can equal the cost of installation. Still, both installation and documentation expenses pale in comparison to the cost of equipment and potential revenue losses resulting from system down-time.

Documentation must be seen as a management and personnel issue of the highest order. Any lapse in the documentation updating process can result in disaster. Procrastination and the resulting lack of follow through will destroy any documentation system and ultimately result in plant failures, extend down-time, and premature rebuilding of the facility.

Making a business case for documentation is similar to making any business case. Gather together all the costs in time, hardware, and software on one side of the equation, and balance this against the savings in time and lost revenue on the other side. Engineering managers are expected to project costs accurately, and the allocation of sufficient resources for documentation and its requisite updating is an essential part of that responsibility.

23.4 Disaster Planning and Recovery

Richard Rudman

23.4.1 Introduction

Disaster-readiness must be an integral part of the design process. You cannot protect against every possible risk.

Earthquakes, hurricanes, tornados, and floods come to mind when we talk about risks that can disable a facility and its staff. Risk can also be man made. Terrorist attack, arson, utility outage, or even simple accidents that get out of hand are facts of everyday life. Communications facilities, especially those that convey information from government to the public during major catastrophes, must keep their people and systems from becoming disaster victims. No major emergency has yet cut all communications to the public. We should all strive to maintain that record.

Employees all too often become crash dummies when disaster disrupts the workplace. During earthquakes, they sometimes have to dodge falling ceiling tiles, elude objects hurled off shelves, watch computers and work stations dance in different directions, breathe disturbed dust, and suffer the indignities of failed plumbing. This chapter does not have ready-to-implement plans for people, facilities, or systems. It does outline major considerations for disaster planning. It is then up to you to be the champion for emergency preparedness and planning on mission critical projects.

A Short History of Disaster Communications

When man lived in caves, every day was an exercise in disaster planning and recovery. There were no “All Cave News” stations for predator reports. The National Weather Service was not around yet to warn about rain that might put out the community camp fire. We live in an increasingly interdependent information-driven society. Modern information systems managers have an absolute social, technical, and economic responsibility to get information to the public when disaster strikes. Designers of these facilities must do their part to build workplaces that will meet the special needs of the lifeline information mission during major emergencies.

The U.S. recognized the importance of getting information to the public during national emergencies in the 1950s when it devised a national warning system in case of enemy attack. This effort was and still is driven by a belief that a government that loses contact with its citizens during an emergency could fall. The emergency broadcast system (EBS), began life as control of electromagnetic radiation (CONELRAD). It was devised to prevent enemy bombers from homing in on AM broadcast stations. It was conceived amid Cold War fears of nuclear attack, and was born in 1951 to allow government to reach the public rapidly through designated radio stations. EBS replaced CONELRAD and its technical shortcomings. EBS is being replaced by emergency alert system (EAS). EAS introduces multiple alerting paths for redundancy as well as some digital technology. It strengthens the emergency communication partnerships beyond broadcasting, federal government, National Weather Service, local government, and even the Internet.

Major disasters such as Hurricane Andrew and the Northridge (CA) earthquake help us focus on assuring that information systems will work during emergencies. These events expose our weaknesses. They can also be rare windows of opportunity to learn from our mistakes and make improvements for the future.

23.4.2 Emergency Management 101 for Designers

There is a government office of emergency services (or management) in each state. Within each state, *operational areas* for emergency management have been defined. Each operational area has a person or persons assigned to emergency management, usually under the direction of an elected or appointed public safety official. There is usually a mechanism in place to announce when an emergency condition exists. *Declared* has a special meaning when used with the word *emergency*. An operational area normally has a formal method, usually stated in legislation, to announce to the world that it is operating under emergency conditions. That legislation places management of the emergency under a specially trained person or organization. During declared emergencies, operational areas usually open a special management office that is usually called an **emergency operations center (EOC)**. Some large businesses with a lot at stake have emergency management departments with full-time employees and rooms set aside to be their EOC. These departments usually use the same management philosophy as government emergency organizations. They also train their people to understand how government manages emergencies. The unprepared business exists in a vacuum without an understanding of how government is managing the emergency. Misunderstandings are created when people do not know the language. An emergency, when life and property are at stake, is the wrong time to have misunderstandings. Organizations that have to maintain services to the public, have outside plant responsibilities, or have significant responsibilities to the public when on their property should have their plans, people, and purpose in place when disaster strikes.

A growing number of smaller businesses which have experienced serious business disruptions during emergencies, or wish to avoid that unpleasant experience, are writing their own emergency plans and building their own emergency organizations. Broadcasters, information companies, cable systems, and other travellers on the growing information superhighway should do likewise. There are national organizations and possibly local emergency-minded groups you can contact. In Los Angeles, there is the Business and Industry Council for Emergency Planning and Preparedness (BICEPP). A more complete listing of resource organizations follows this chapter.

Figure 23.28 shows the cyclical schematic of emergency management. After an emergency has been declared, *response* deals with immediate issues that have to do with saving lives and property. Finding out what has broken and who has been hurt is called *damage assessment*. Damage assessment establishes the dimensions of the response that are needed. Once you know what is damaged and who is injured, trapped, or killed, you have a much better idea of how much help you need. You also know if you have what you need on hand to meet the challenge. Another aspect of response is to provide the basics of human existence: water, food, and shelter. An entire industry has sprung up to supply such special needs. Water is available packaged to stay drinkable for years. The same is true for food. Some emergency food is based on the old military K rations or the more modern meals ready to eat (MREs). MREs became widely known during the Gulf War.

The second phase of the emergency cycle is called *recovery*. Recovery often begins after immediate threats to life safety have been addressed. This is difficult to determine during an earthquake or flood. A series of life threats may span hours, days, or weeks. It is not uncommon for business and government emergency management organizations to be engaged in recovery and response at the same time.

In business, response covers these broad topics:

- Restoring lost capacity to your production and distribution capabilities
- Getting your people back to work

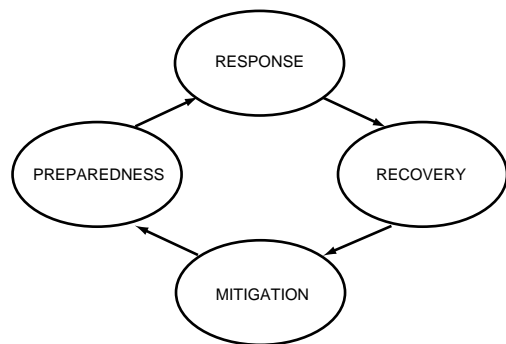

FIGURE 23.28 The response, recovery, mitigation, and preparedness cycle.

- Contacting customers and/or alternate vendors
- Contacting insurers and processing claims

A business recovery team's mission is to get the facility back to 100% capacity, or as close to it as possible. Forming a *business recovery team* should be a key action step along with conducting the *business impact analysis*, discussed later in this chapter. Major threats must be eliminated or stabilized so that employees or outside help can work safely. Salvage missions may be necessary to obtain critical records or equipment. Reassurance should also be a part of the mission. Employees may be reluctant to return to work or customer may be loathe to enter even if the building is not *red tagged*. Red tagging is a term for how inspectors identify severely damaged buildings, an instant revocation of a building's certificate of occupancy until satisfactory repairs take place. Entry, even for salvage purposes by owners or tenants, may be prohibited or severely restricted. Recovery will take a whole new turn if the facility is marked unfit for occupancy.

The third stage of the cycle is *mitigation*. Sometimes called lessons learned, mitigation covers a wide range of activities that analyze what went wrong and what went right during response and recovery. Accurate damage assessment records, along with how resources were allocated, are key elements reviewed during mitigation. At the business level, mitigation debriefings might uncover how and why the emergency generator did not start automatically. You might find that a microwave dish was knocked out of alignment by high winds or seismic activity or that a power outage disabled critical components such as security systems. On the *people* side, a review of the emergency might show that no one was available to reset circuit breakers or unlock normally locked doors. There may have been times when people on shift were not fed in a timely manner. Stress, an often overlooked factor that compounds emergencies and emergency response, may have affected performance. In the *what went right* column, you might find that certain people rose above the occasion and averted added disaster, that money spent on preparing paid off, or that you were able to resume 100% capacity much faster than expected.

Be prepared should be the watch-phrase of emergency managers and facilities designers. Lessons learned during mitigation should be implemented in the *preparedness* phase. Procedures that did not work are rewritten. Depleted supplies are replenished and augmented if indicated. New resources are ordered and stored in safe places. Training in new procedures, as well as refresher training, is done. Mock drills and exercises may be carried out. The best test of preparedness is the next actual emergency. Preparedness is the one element of the four you should adopt as a continuous process.

Emergency management, from a field incident to the state level, is based on the **incident command system (ICS)**. ICS was pioneered by fire service agencies in California as an emergency management model. Its roots go further back into military command and control. ICS has been adopted by virtually every government and government public safety emergency management organization in the country as a standard.

ICS depends on simple concepts. One is *span of control*. Span of control theory states that a manager should not directly manage more than seven people. The optimum number is five. Another ICS basic is that an emergency organization builds up in stages, from the bottom up, from the field up, in response to need. For example, a wastebasket fire in your business may call for your fire response team to activate. One trained member on the team may be all that is required to identify the source of the fire, go for a fire extinguisher on the wall, and put it out. A more serious fire may involve the entire team. The team *stages up* according to the situation.

23.4.3 The Planning Process

It is impossible to separate emergency planning from the facility where the plan will be put into action. Emergency planning must be integral to a functional facility. It must support the main mission and the people who must carry it out. It must work when all else fails. Designers first must obtain firm commitment and backing from top management. Commitment is always easier to get if top management has experienced first-hand a major earthquake or powerful storm. Fear is a powerful source of motivation.

Disaster planning and recovery is an art, a science, and a technology. Like entities such as the Institute of Electrical and Electronics Engineers (IEEE) or the Society of Broadcast Engineers (SBE), disaster planners have their own professional groups and certification standards. States such as California provide year-round classroom training for government disaster planners. Many planners work full time for the military or in the public safety arenas of government. Others have found homes in businesses who recognize that staying in business after a major disaster is smart business. Still others offer their skills and services as consultants to entities who need to *jump start* their disaster planning process.

The technical support group should have responsibility or supervision over the environmental infrastructure of a critical communications facility. Without oversight, electronic systems are at the mercy of whomever controls that environment. Local emergencies can be triggered by preventable failures in air supply systems, roof leaks, or uncoordinated telephone, computer, or AC wiring changes. Seemingly harmless acts such as employees plugging electric heaters into the wrong AC outlet have brought down entire facilities. Successful practitioners of systems design and support must take daily emergencies into account in the overall planning process. To do otherwise risks rapid doom, if not swift unemployment.

Starting Your Planning Process: Listing Realistic Risks

Your realistic risk list should contain specific hazards based on local conditions such as

- Regional high water marks for the 100 and 150 year storms
- Regional social, political, and governmental conditions
- Regional commercial electrical power reliability
- Regional weather conditions
- Regional geography
- Regional geology

You should assess specific local hazards that could be triggered by

- Threats from present or former employees who may hold grudges
- External parties who are likely to get mad at your organization
- Other factors that could make you an easy target
- Nearby man-made hazards
- Special on-site hazards
- Neighbors
- Construction of your facility
- Hazardous materials on the premises
- Communications links to the outside world
- Electrical power
- Other utilities
- Buried pipelines

For example, information from the Northridge earthquake could rewrite seismic building codes for many types of structures. The Northridge quake showed that some high rise structures thought to be earthquake safe are not. Designers should be aware that seismic building codes usually allow for safe evacuation. They do not embody design criteria to prevent major structural damage. Earthquake safe is not earthquake proof.

If possible, get help from emergency planning professionals when you finish your list. They can help you devise a well-written and comprehensive emergency plan. They can also help with detailed research on factors such as geology and hazardous materials. For instance, you may be located near a plant that uses hazardous materials. The ultimate expert advice might be to move before something bad happens! Once there is an agreement on the major goals for operations under emergency conditions, you will have a clear direction for *emergency-ready* facilities planning.

Risk Assessment and Business Resumption Planning

Perform a realistic assessment of the risks that your list suggests. Do not overlook the obvious. If computers, transmitters, or telephone equipment depend on cool air, how can they continue to operate during a heat wave when your one air conditioner has malfunctioned?

What level of reliability should a designer build into a lifeline communications facility? Emergencies introduce *chaos* into the reliability equation. Most engineers are quite happy when a system achieves 99.9999% reliability. Although the glass is more than half full, *four nines reliability* still means eight minutes of outage over a one year period! Reliability is an educated prediction based on a number of factors.

Believers in Murphy's law (anything that can go wrong, will go wrong) know that the 0.0001% outage will occur at the worst possible time. Design beyond that stage of reliability so that you can have a greater chance to cheat Murphy and stay on line during major emergencies. Double, triple, and even quadruple redundancy become realistic options when 100% uptime is the goal.

The new Los Angeles County Emergency Operations Center has three diesel generators. Air handling equipment is also built in triplicate. The building rests on huge rubber isolators at the base of each supporting column. These rubber shock mounts are sometimes called *base isolators*. They are built using laminated layers of Neoprene® rubber and metal. The entire structure floats on 26 of these isolators, designed to let the earth move beneath a building during an earthquake, damping transmission of rapid and damaging acceleration. The Los Angeles County EOC is designed to allow 16 in. of lateral movement from normal, or as much as 32 in. of total movement in one axis. LA County emergency planners are hoping there will not be an earthquake that produces more than 16 in. of lateral displacement. The isolators protect the structure and its contents from most violent lateral movement during earthquakes. The design mandate for this structure came directly from the Board of Supervisors and the Sheriff for the County of Los Angeles.

Can that building or a key system still fail? Of course. It is possible, though unlikely, that all three generators will fail to start. Diminishing returns set in beyond a certain point. Designers must balance realistic redundancy with the uptime expectations for the facility.

A facility designer must have a clear understanding of how important continued operation during and after a major catastrophe will be to its future survival. Disaster planning for facilities facing a hurricane with 125-mi/h winds may well entail boarding up the windows and leaving town for the duration. Others facilities will opt for uninterrupted operation, even in the face of nature's fury. Some will do nothing, adding to the list of victims who sap the resources of those who did prepare. The facility's mission may be critical to local government emergency management. For example, the public tunes to radio and television when disaster strikes. Government emergency managers tune in too.

A **business resumption plan (BRP)** is just as important as an organization's disaster plan. Both are just as essential as having an overall strategic business plan. Some experts argue these three elements should be formulated and updated in concert. When disaster strikes, the first concern of an organization must be for the safety of its employees, customers, vendors, and visitors.

Once *life safety* issues have been addressed, the next step is to perform damage assessments, salvage operations, and, if needed, relocation of critical functions. The BRP is activated once these basic requirements have been met and may influence how they are met.

The focus of business resumption planning is maintaining or resuming core business activities following a disaster. The three major goals of the BRP are: resumption of production and delivery, customer service and notification, and cash flow. A comprehensive BRP can accelerate recovery, saving time, money, and jobs. Like any insurance policy or any other investment, a properly designed BRP will cost you both in time and money. A BRP is an insurance policy, if not a major investment. The following actions are the backbone of a BRP:

- Conduct a **business impact analysis (BIA)**
- Promote employee buy-in and participation
- Seek input starting at the lowest staff levels

- Build a recovery strategy and validation process
- Test your BRP
- Assure a continuous update of the BRP²

Most companies do not have the staff to do a proper BIA. If a BIA becomes a top management goal, retain an experienced consultant. Qualified consultants can also conduct training and design test exercises. The BIA process does work. Oklahoma City businesses that had BIAs in place recovered faster than their competitors after the terrorist bombing in 1995. First Interstate Bank was able to open for business the very next day after a fire shut down their Los Angeles highrise headquarters in 1988. On January 17, 1994, the day of the Northridge earthquake, Great Western Bank headquarters suffered major structural damage. They made an almost seamless transition to their Florida operations.

23.4.4 Workplace Safety

Employers must always assure safety in the workplace at all times. Some states such as California have passed legislation that mandates that most employers identify hazards and protect their workers from them. Natural emergencies create special hazards that can maim or kill. A *moment magnitude 7.4* earthquake can hurl heavy objects such as computer monitors and daggerlike shards from plate glass windows lethally through the air. The Richter Scale is no longer used by serious seismic researchers. Moment magnitude calculates energy release based on the surface area of the planes of two adjacent rock structures (an earthquake fault) and the distance these structures will move in relation to one another. Friction across the surface of the fault holds the rocks until enough stress builds to release energy. Some of the released energy travels via low-frequency wave motion through the rock. These low-frequency waves cause the shaking and sometimes violent accelerations that occur during an earthquake. For more on modern seismic research and risk, please refer to the Reference section for this chapter. A strong foundation of day-to-day safety can lessen the impact of major emergencies. For instance, assuring that plate glass in doors has a safety rating could avoid an accidental workplace injury.

Special and dangerous hazards are found in the information and communications workplace. Tall equipment racks are often not secured to floors, much less secured to load-bearing walls. Preventing equipment racks from tipping over during an earthquake may avoid crippling damage to both systems and people. Bookcases and equipment storage shelves should be secured to walls. Certain objects should be *tethered*, rather than firmly bolted. Although securing heavy objects is mostly common sense, consult experts for special cases. Do not forget seismic-rated safety chains for heavy objects like television studio lights and large speakers.

Computers and monitors are usually not secured to work surfaces. A sudden drop from work station height would ruin the day's output for most computers, video monitors, and their managers. An industry has sprung up that provides innovative fasteners for computer and office equipment. Special Velcro® quick-release anchors and fasteners can support the entire weight of a personal computer or printer, even if the work surface falls over.

Bolting work stations to the floor and securing heavy equipment with properly rated fasteners can address major seismic safety issues. *G* forces measured in an upper story of a high rise building during the Northridge quake were greater than 2.7 times the force of gravity; 1 *g* is of course equal to the force of Earth's gravity. An acceleration of 2 *g* doubles the effective force of a person or object in motion, and nullifies the effectiveness of restraints that worked fine just before the earthquake (Force = (mass) × (acceleration)). Seismic accelerations cause objects to make sudden stops: 60 to zero in 1 sec. A room full of unsecured work stations could do a fair imitation of a slam dance contest, even at lower accelerations. Cables can be pulled loose, monitors can implode, and delicate electronics can be smashed into scrap.

²The author thanks Mary Carrido, President, MLC & Associates of Irvine, CA, for core elements of business resumption. It is far beyond the scope of this chapter to go into more detail on the BIA process

Even regions to the Earth where there has not been recent seismic activity, have been given a *long overdue* rating by respected seismologists. May be you will be the only one on your block to take such warnings seriously. May be you will be the only one left operational on your block!

Maintaining safety standards is difficult in any size organization. A written safety manual that has specific practices and procedures for normal workplace hazards as well as the emergency-related hazards you identify is not only a good idea, it may lower your insurance rates. If outside workers set foot in your facility, prepare a special safety manual for contractors. Include in it installation standards, compliance with *lock-out/tag-out*, and emergency contact names, and phone numbers. (Lock-out/tag-out is a set of standard safety policies that assure that energy is removed from equipment during installation and maintenance. It assures that every member of a work detail is clear before power is reapplied.) Make sure outside contractors carry proper insurance and are qualified, licensed, or certified to do the work for which you contract.

23.4.5 Outside Plant Communications Links

Your facility may be operational, but failure of a wire, microwave, or fiber communications link could be devastating. All outside plant links discussed next presuppose proper installation. For wire and fiber, this means adequate *service loops* (coiled slack) so quake and wind stresses will not snap taut lines. It means that the telephone company has installed terminal equipment so it will not fall over in an earthquake or be easily flooded out. A range of backup options are available.

Outside Plant Wire

Local telephone companies still use a lot of wire. If your facility is served only by wire on telephone poles or underground in flood-prone areas, you may want what the telephone industry calls *alternate routing*. Alternate routing from your location to another **central office (CO)** may be very costly since the next nearest CO is rarely close. Ask to see a map of the proposed alternate route. If it is alternate only to the next block, or duplicates your telephone pole or underground risk, the advantage you gain will be minimal.

Most telephone companies can designate as an *essential service* a limited block of telephone numbers at a given location for lifeline communications. Lines so designated are usually found at hospitals and public safety headquarters. Contact your local phone company representative to see if your facility can qualify. Many broadcasters who have close ties to local government emergency management should easily qualify.

Microwave Links

Wind and seismic activity can cause microwave dishes to go out of alignment. Earthquake-resistant towers and mounts can help prevent alignment failure, even for wind-related problems. Redundant systems should be considered part of your solution. A duplicate microwave system might lead to a false sense of security. Consider a nonmicrowave backup, such as fiber, for a primary microwave link. Smoke, heavy rain, and snow storms can cause enough path loss to disable otherwise sound wireless systems.

Fiber Optics Links

If you are not a fiber customer today, you will be tomorrow. Telephone companies will soon be joined by other providers to seek your fiber business. You may be fortunate enough to be served by separate fiber vendors with separate fiber systems and routing to enhance reliability and uptime. Special installation techniques are essential to make sure fiber links will not be bothered by earth movement, subject to vandalism, or vulnerable to single-point failure. Single-point failure can occur in any system. Single-point failure analysis and prevention is based on simple concepts: A chain is only as strong as its weakest link, but two chains, equally strong, may have the same weak link. The lesson may be make one chain much stronger, or use three chains of a material that has different stress properties.

Fiber should be installed underground in a sturdy plastic sheath, called an interliner. Interliners are usually colored bright orange to make them stand out in trenches, manholes and other places where

careless digging and prodding could spell disaster. This sheath offers protection from sharp rocks or other forces that might cause a nick or break in the armor of the cable, or actually sever one or more of the bundled fibers. Cable systems that only have aerial rights-of-way on utility poles for their fiber may not prove as reliable in some areas as underground fiber. Terminal equipment for fiber should be installed in earthquake-secure equipment racks away from flooding hazards. Fiber electronics should have a minimum of two parallel DC power supplies, which are in turn paralleled with rechargeable battery backup.

Sonet[®] technology is a proven approach you should look for from your fiber vendor. This solution is based on topology that looks like a circle or ring. A fiber optics cable could be cut just like a wire or cable. A ringlike network will automatically provide a path in the other direction, away from the break. Caution! Fiber installations that run through unsealed access points, such as manholes, can be an easy target for terrorism or vandalism.

Satellite

Ku- or C-band satellite is a costly but effective way to link critical communications elements. C band has an added advantage over Ku during heavy rain or snow storms. Liquid or frozen water can disrupt Ku-band satellite transmission. A significant liability of satellite transmission for ultrareliable facilities is the possibility that a storm could cause a deep fade, even for C-band links. Another liability is short but deep semiannual periods of sun outage when a link is lost while the sun is focused directly into a receive dish. Although these periods are predictable and last for only a minute or two, there is nothing that can prevent their effect unless you have alternate service on another satellite with a different sun outage time, or terrestrial backup.

23.4.6 Emergency Power and Batteries

Uninterruptable power supplies (UPS) are common in the information workplace. From small UPS that plug into wall outlets at a personal computer work station, to giant units that can power an entire facility, they all have one thing in common, batteries. UPS batteries have a finite life span. Once exceeded, a UPS is nothing more than an expensive door stop. UPS batteries must be tested regularly. Allow the UPS to go on line to test it. Some UPS test themselves automatically. Routinely pull the UPS AC plug out of the wall for a manual test. Some UPS applications require hours of power, whereas some only need several minutes. Governing factors are

- Availability of emergency power that can be brought on line fast
- A need to keep systems alive long enough for a graceful shutdown
- Systems so critical that they can never go down

Although UPS provide emergency power when the AC mains are dead, many are programmed with another electronic agenda: Protect the devices plugged in from what the UPS thinks is *bad power*. Many diesel generators in emergency service are not sized for the load they have to carry, or may not have proper power factor correction. Computers and other devices with switching power supplies can distort AC power wave forms; the result: bad power.

After a UPS comes on line, it should shut down after the emergency generator picks up the load and charges its batteries. If it senses the AC equivalent of poison, it stays on or cycles on and off. Its battery eventually runs down. Your best defense is to test your entire emergency power system under full load. If a UPS cycles on and off to the point that its batteries run down, you must find out why. Consult your UPS manufacturer, service provider, or service manual to see if your UPS can be adjusted to be more tolerant. Some UPS cycling cannot be avoided with engine-based emergency power, especially if heavy loads such as air conditioner compressors switch on and off line.

Technicians sometimes believe that starting an emergency generator with no equipment load is an adequate weekly test. Even a 30-min test will not get the engine up to proper operating temperature. If your generator is diesel driven, this may lead to *wet stacking*, cylinder glazing, and piston rings that can lose proper seating. Wet stacking occurs when a generator is run repeatedly with no load or a light load.

When the generator is asked to come on line to power a full equipment load, deposits that build up during no-load tests prevent it from developing full power. The engine will also not develop full power if its rings are misseated and there is significant cylinder glazing. The cure is to always test with the load your diesel has to carry during an emergency. If that is not possible, obtain a resistive load bank so you can simulate a full load for an hour or two of hard running several times per year. A really hard run should burn out accumulated carbon, reseat rings, and deglaze cylinder walls.

Fuel stored in tanks gets old and old fuel is unreliable. Gum and varnish can form. Fuel begins to break down. Certain forms of algae can grow in diesel oil, especially at the boundary layer between fuel and the water that can accumulate at the bottom of most tanks. Fuel additives can extend the storage period and prevent algae growth. A good filtering system, and a planned program of cycling fuel through it, can extend storage life dramatically. Individual fuel chemical composition, fuel conditioners, and the age and type of storage tank all affect useful fuel life.

There are companies that will analyze your fuel. They can filter out dirt, water, and debris that can rob your engine of power. The cost of additives and fuel filtering is nominal compared to the cost of new fuel plus hazardous material disposal charges for old fuel. Older fuel tanks can spring leaks that either introduce water into the fuel, or introduce you to a costly hazardous materials clean up project, your tank will be out of service while it is being replaced, and fuel carrying dirt or water can stop the engine.

While you are depending on an emergency generator for your power, you would hate to see it stop. A running generator will consume fuel, crankcase oil, and possibly radiator coolant. You should know your generator's crankcase oil consumption rate so you can add oil well before the engine grinds to a screeching, nonlubricated halt. Water-cooled generators must to be checked periodically to make sure there is enough coolant in the radiator. Make sure you have enough coolant and oil to get the facility through a minimum of one week of constant duty.

Most experts recommend a generator health check every six months. Generators with engine block heaters put special stress on fittings and hoses. Vibration can loosen bolts, crack fittings, and fatigue wires and connectors. If your application is supercritical, a second generator may give you a greater margin of safety. Your generator maintenance technician should take fuel and crankcase oil samples for testing at a qualified laboratory. The fuel report will let you know if your storage conditions are acceptable. The crankcase oil report might find microscopic metal particles, early warning of a major failure. How long will a generator last? Some engine experts say that a properly maintained diesel generator set can run in excess of 9,000 h before it would normally need to be replaced.

Mission dictates need. Need dictates reliability. If the design budget permits, a second or even third emergency generator is a realistic insurance policy. When you are designing a facility you know must never fail, consider redundant UPS wired in parallel. Consult the vendor for details on wiring needs for multiphase parallel UPS installations. During major overhauls and generator work, make sure you have a local source for reliable portable power. High-power diesel generators on wheels are common now to supply field power for events from rock concerts to movie shoots. Check your local telephone directory. If you are installing a new diesel, remember that engines over a certain size may have to be licensed by your local air quality management district and that permits must be obtained to construct and store fuel in an underground tank.

23.4.7 Air Handling Systems

Equipment crashes when it gets too hot. Clean, cool, dry, and pollutant-free air in generous quantities is critical for modern communications facilities. If you lease space in a high-rise, you may not have your own air system. Many building systems often have no backup, are not supervised nights and weekends, and may have uncertain maintenance histories. Your best protection is to get the exact terms for air conditioning nailed down in your lease. You may wish to consider adding your own backup system, a costly but essential strategy if your building air supply is unreliable or has no backup. Several rental companies specialize in emergency portable industrial-strength air conditioning. An emergency contract for **heating ventilating and air conditioning (HVAC)** that can be invoked with a phone call could save you hours or even days of downtime. Consider buying a portable HVAC unit if you are protecting a supercritical facility.

Wherever cooling air comes from, there are times when you need to make sure the system can be forced to recirculate air within the building, temporarily becoming a closed system. Smoke or toxic fumes from a fire in the neighborhood can enter an open system. Toxic air could incapacitate your people in seconds. With some advanced warning, forcing the air system to full recirculation could avoid or forestall calamity. It could buy enough time to arrange an orderly evacuation and transition to an alternate site.

23.4.8 Water Hazards

Water in the wrong place at the wrong time can be part of a larger emergency or be its own emergency. A simple mistake such as locating a water heater where it can flood out electrical equipment can cause short circuits when it finally wears out and begins to leak. Unsecured water heaters can tear away from gas lines, possibly causing an explosion or fire in an earthquake. The water in that heater could be lost, depriving employees of a source of emergency drinking water.

Your facility may be located near a source of water that could flood you out. Many businesses are located in flood plains that see major storms once every 100 or 150 years. If you happen to be on watch at the wrong time of the century, you may wish that you had either located elsewhere, or stocked a very large supply of sand bags.

Remember to include any wet or dry pipe fire sprinkler systems as potential water hazards.

23.4.9 Electromagnetic Pulse Protection (EMP)

The **electromagnetic pulse (EMP)** phenomenon associated with nuclear explosions can disable almost any component in a communications system. EMP energy can enter any component or system coupled to a wire or metal surface directly, capacitively, or inductively. Some chemical weapons can produce EMP, but on a smaller scale. The Federal Emergency Management Agency (FEMA) publishes a three volume set of documents on EMP. They cover the theoretical basis for EMP protection, protection applications, and protection installation. FEMA has been involved in EMP protection since 1970 and is charged at the federal level with the overall direction of the EMP program. FEMA provides detailed guidance and, in some cases, direct assistance on EMP protection to critical communications facilities in the private sector. AM, FM, and television transmitter facilities that need EMP protection should discuss EMP protection tactics with a knowledgeable consultant before installing protection devices on radio frequency (RF) circuitry. EMP devices such as gas discharge tubes can fail in the presence of high-RF voltage conditions and disable facilities through such a failure.

23.4.10 Alternate Sites

No matter how well you plan, something still could happen that will require you to abandon your facility for some period of time. Government emergency planners usually arrange for an alternate site for their EOCs. Communications facilities can sign mutual aid agreements. Sometimes this is the only way to access telephone lines, satellite uplink equipment, microwave, or fiber on short notice. If management shows reluctance to share, respectfully ask what they would do if their own facility is rendered useless.

23.4.11 Security

It is a fact of modern life that man-caused disasters must now enter into the planning and risk assessment process. Events ranging from terrorism to poor training can cause the most mighty organization to tumble. The World Trade Center and Oklahoma City bombings are a warning to us all. Your risk assessment might even prompt you to relocate if you are too close to *ground zero*.

Federal Communications Commission (FCC) rules still state that licensees of broadcast facilities must protect their facilities from hostile takeover. Breaches in basic security have often led to serious incidents

at a number of places throughout the county. It has even happened at major market television stations. Here are the basics:

- Approve visits from former employees through their former supervisors.
- Escort nonemployees in critical areas.
- Assure that outside doors are never propped open.
- Secure roof hatches from the inside and have alarm contacts on the hatch.
- Use identification badges when employees will not know each other by sight.
- Check for legislation that may require a written safety and security plan.
- Use video security and card key systems where warranted.
- Repair fences, especially at unmanned sites.
- Install entry alarms at unattended sites; test weekly.
- Redesign to limit the places bombs could be planted.
- Redesign to prevent unauthorized entry.
- Redesign to limit danger from outside windows.
- Plan for fire, bomb threats, hostage situations, terrorist takeovers.
- Plan a safe way to shut the facility down in case of invasion.
- Plan guard patrol schedules to be random, not predictable.
- Plan for off-site relocation and restoration of services on short notice.

California Senate Bill 198 mandates that California businesses with more than 100 employees write an industrial health and safety plan for each facility addressing workplace safety, hazardous materials spills, employee training, and emergency response.

23.4.12 Workplace and Home: Hand-in-Hand Preparedness

A critical facility deprived of its staff will be paralyzed just as surely as if all of the equipment suddenly disappeared. Employees may experience guilt if they are at work when a regional emergency strikes, and they do not know what is happening at home. The first instinct is to go home. This is often the wrong move. Blocked roads, downed bridges, and flooded tunnels are dangerous traps, especially at night. People who leave work during emergencies, especially people experiencing severe stress, often become victims. Encourage employees to prepare their homes, families, and pets for the same types of risks the workplace will face. Emergency food and water and a supply of fresh batteries in the refrigerator are a start. Battery-powered radios and flashlights should be tested regularly. If employees or their families require special foods, prescription drugs, eyewear, oxygen, over-the-counter pharmaceuticals, sun block or bug repellent, remind them to have an adequate supply on hand to tide them over for a lengthy emergency.

Heavy home objects like bookcases should be secured to walls so they will not tip over. Secure or move objects mounted on walls over beds. Make sure someone in the home knows how to shut off natural gas. An extra long hose can help for emergency fire fighting or help drain flooded areas. Suggest family *hazard hunts*. Educate employees on what you are doing to make the workplace safe. The same hazards that can hurt, maim, or kill in the workplace can do the same at home. Personal and company vehicles should all have emergency kits that contain basic home or business emergency supplies. Food, water, comfortable shoes, and old clothes should be added. If their families are prepared at home or on the road, employees will have added peace of mind. It may sustain them until they can get home safely.

An excellent home family preparedness measure is to identify a distant relative or friend who can be the emergency message center. Employees may be able to call a relative from work to find out their family is safe and sound. Disasters that impair telephone communications teach us that it is often possible to make and receive long distance calls when a call across the street will not get through. Business emergency planners should not overlook this hint. A location in another city, or a key customer or supplier may make a good out-of-area emergency contact.

23.4.13 Expectations, 9-1-1, and Emergencies

Television shows depicting 9-1-1 saving lives over the telephone are truly inspirational. But during a major emergency, resources normally available to 9-1-1 services, including their very telephone system, may be unavailable. Emergency experts used to tell us to be prepared to be self-sufficient at the neighborhood and business level for 72 h or more. Some now suggest a week or longer. Government will not respond to every call during a major disaster. That is a fact.

Even experienced communications professionals sometimes forget that an overloaded telephone exchange cannot supply dial tone to all customers at once. Emergency calls will often go through if callers wait patiently for dial tone. If callers do not hear dial tone after 10 or 15 min, it is safe to assume that there is a more significant problem.

23.4.14 Business Rescue Planning for Dire Emergencies

When people are trapped and professionals cannot get through, our first instinct may be to attempt a rescue. Professionals tell us that more people are injured or killed in rescue attempts during major emergencies than are actually saved. Experts in **urban search and rescue (USAR)** not only have the know-how to perform their work safely, but have special tools that make this work possible under impossible conditions. The *jaws of life*, hydraulic cutters used to free victims from wrecked automobiles, is a common USAR tool. Pneumatic jacks that look like large rubber pillows can lift heavy structural members in destroyed buildings to free trapped people.

You, as a facilities designer, may never be faced with a life-or-death decision concerning a rescue when professionals are not available. Those in the facilities you design may be faced with tough decisions. Consider that your design could make their job easier or more difficult. Also consider recommending USAR training for those responsible for on-line management and operations of the facility as a further means to ensure readiness.

23.4.15 Managing Fear

Anyone who says they are not scared while experiencing a hurricane, tornado, flood, or earthquake is either lying or foolish. Normal human reactions when an emergency hits are colored by a number of factors, including fear. As the emergency unfolds, we progress from fear of the unknown, to fear of the known. While preparedness, practice, and experience may help keep fears in check, admitting fear and the normal human response to fear can help us keep calm.

Some people prepare mentally by reviewing their behavior during personal, corporate, or natural emergencies. Then they consider how they could have been better prepared to transition from *normal* human reactions like shock, denial, and panic, to abnormal reactions like grace, acceptance, and steady performance. The latter behaviors reassure those around them and encourage an effective emergency team. Grace under pressure is not a bad goal.

Another normal reaction most people experience is a rapid change of focus toward one's own personal well being. "Am I OK?" is a very normal question at such times. Even the most altruistic people have moments during calamities when they regress. They temporarily become selfish children. Once people know they do not require immediate medical assistance, they can usually start to focus again on others and on the organization.

Defining Terms

Business impact analysis (BIA): A formal study of the impact of a risk or multiple risks on a specific business. A properly conducted BIA becomes critical to the *business recovery plan*.

Business resumption planning (BRP): A blueprint to maintain or resume core business activities following a disaster. Three major goals of BRP are resumption of products and services, customer service, and cash flow.

Central office (CO): Telephone company jargon for the building where local switching is accomplished.

Electromagnetic pulse (EMP): A high burst of energy associated most commonly with nuclear explosions. EMP can instantly destroy many electronic systems and components.

Emergency operations center (EOC): A location where emergency managers receive damage assessments, allocate resources, and begin recovery.

Heating, ventilation, and air conditioning (HVAC): Architectural acronym.

Incident commander (IC): The title of the person in charge at an emergency scene from the street corner to an emergency involving an entire state or region.

Incident command system (ICS): An effective emergency management model invented by fire fighters in California.

Urban Search and Rescue (USAR): Emergency management acronym.

23.5 Conversion Factors

Jerry C. Whitaker

23.5.1 Introduction

Engineers often find it necessary to convert from one unit of measurement to another. The following table of conversion factors provides a convenient method of accomplishing the task. In the following table, a more complete listing of conversion factors is presented, grouped in alphabetical order.

To Convert	Into	Multiply by
	A	
abcoulomb	statcoulombs	2.998×10^{10}
acre	square chain (Gunters)	10
acre	rods	160
acre	square links (Gunters)	1×10^5
acre	hectare or square hectometer	0.4047
acres	square feet	43,560.0
acres	square meters	4,047
acres	square miles	1.562×10^{-3}
acres	square yards	4,840
acre-feet	cubic feet	43,560.0
acre-feet	gallons	3.259×10^5
amperes per square centimeter	ampere per square inch	6.452
amperes per square centimeter	ampere per square meter	10^4
amperes per square inch	ampere per square centimeter	0.1550
amperes per square inch	ampere per square meter	1,550.0
amperes per square meter	ampere per square centimeter	10^{-4}
amperes per square meter	ampere per square inch	6.452×10^{-4}
ampere-hours	coulombs	3,600.0
ampere-hours	faradays	0.03731

(continued)

To Convert	Into	Multiply by
ampere-turns	gilberts	1.257
ampere-turns per centimeter	ampere-turns per inch	2.540
ampere-turns per centimeter	ampere-turns per meter	100.0
ampere-turns per centimeter	gilberts per centimeter	1.257
ampere-turns per inch	ampere-turns per centimeter	0.3937
ampere-turns per inch	ampere-turns per meter	39.37
ampere-turns per inch	gilberts per centimeter	0.4950
ampere-turns per meter	ampere-turns per centimeter	0.01
ampere-turns per meter	ampere-turns per inch	0.0254
ampere-turns per meter	gilberts per centimeter	0.01257
Angstrom unit	inch	3937×10^{-9}
Angstrom unit	meter	1×10^{-10}
Angstrom unit	micron or μ	1×10^{-4}
are	acre (U.S.)	.02471
ares	square yards	119.60
ares	acres	0.02471
ares	square meters	100.0
astronomical unit	kilometers	1.495×10^8
atmospheres	ton per square inch	0.007348
atmospheres	centimeter of mercury	76.0
atmospheres	foot of water (at 4°C)	33.90
atmospheres	inch of mercury (at 0°C)	29.92
atmospheres	kilogram per square centimeter	1.0333
atmospheres	kilogram per square meter	10,332
atmospheres	pounds per square inch	14.70
atmospheres	tons per square foot	1.058
B		
barrels (U.S., dry)	cubic inch	7056
barrels (U.S., dry)	quarts (dry)	105.0
barrels (U.S., liquid)	gallons	31.5
barrels (oil)	gallons (oil)	42.0
bars	atmospheres	0.9869
bars	dyne per square centimeter	10^4
bars	kilogram per square meter	1.020×10^4
bars	pound per square foot	2,089
bars	pound per square inch	14.50
Baryl	dyne per square centimeter	1.000
bolt (U.S., cloth)	meter	36.576
British thermal unit	liter-atmosphere	10.409
British thermal unit	erg	1.0550×10^{10}
British thermal unit	foot-pound	778.3

Temperature Factors

$$^{\circ}\text{F} = 9/5(^{\circ}\text{C}) + 32$$

$$\text{Fahrenheit temperature} = 1.8 (\text{temperature in kelvins}) - 459.67$$

$$^{\circ}\text{C} = 5/9[(^{\circ}\text{F}) - 32]$$

$$\text{Celsius temperature} = \text{temperature in kelvin} - 273.15$$

$$\text{Fahrenheit temperature} = 1.8 (\text{Celsius temperature}) + 32$$

Conversion of Temperatures

From	To	
°Celsius	°Fahrenheit	$t_F = (t_C \times 1.8) + 32$
	Kelvin	$T_K = t_C + 273.15$
	°Rankine	$T_R = (t_C + 273.15) \times 1.8$
°Fahrenheit	°Celsius	$t_C = \frac{t_F - 32}{1.8}$
	Kelvin	$T_K = \frac{t_F - 32}{1.8} + 273.15$
	°Rankine	$T_R = t_F + 459.67$
Kelvin	°Celsius	$t_C = T_K - 273.15$
	°Rankine	$T_R = T_K \times 1.8$
°Rankine	°Fahrenheit	$t_F = T_R - 459.67$
	Kelvin	$T_K = \frac{T_R}{1.8}$

23.6 General Mathematical Tables⁴

William F. Ames and George Cain

23.6.1 Introduction to Mathematics Chapter

Mathematics has been defined as “the logic of drawing unambiguous conclusions from arbitrary assumptions.” The assumptions do not come from the mathematics but arise from the engineering or scientific discipline. Mathematical models of real world phenomena have been remarkably useful. The simplest of these express various physical *laws* in mathematical form. For example, Ohms law ($V = IR$), Newton’s second law ($F = ma$) and the ideal gas law ($pV = nRT$) provide starting points for many theories. More complicated models employ difference, differential, or integral equations. Whatever the model, the conclusions drawn from it are unambiguous!

In this mathematics chapter we provide for an extensive review of algebra and geometry in the first section. One feature is the collection of common geometric figures together with their areas, volumes, and other data.

The second section reviews the fundamentals of trigonometry and presents the myriad of identities, which are very useful but very easy to forget. The third section presents tables of various series for a number of useful functions, followed by the theory of how these series are calculated.

The next section gives the elements of the differential calculus, discusses the calculation and theory of maxima and minima, and contains a table of derivatives. The fifth section provides a summary of the integral calculus including formulas for calculating such fundamental physical ideas as arclength, area, volume, work, centroids, etc.

Special functions constitute [Sec. 23.6.7](#). Here are the Bessel functions and various basic polynomials. A special feature found here is the table of three-dimensional quadratic figures.

Because linear algebra and vector calculus are so basic Secs. 23.6.8 and 23.6.9 are devoted to their summaries. The last section presents the various Fourier transforms and their properties in table form.

Throughout the chapter various references are provided.

23.6.2 Elementary Algebra and Geometry

Fundamental Properties (Real Numbers)

$a + b = b + a$	Commutative law for addition
$(a + b) + c = a + (b + c)$	Associative law for addition
$a + 0 = 0 + a$	Identity law for addition
$a + (-a) = (-a) + a = 0$	Inverse law for addition
$a(bc) = (ab)c$	Associative law for multiplication
$a(\frac{1}{a}) = (\frac{1}{a})a = 1, a \neq 0$	Inverse law for multiplication
$(a)(1) = (1)(a) = a$	Identity law for multiplication
$ab = ba$	Commutative law for multiplication
$a(b + c) = ab + ac$	Distributive law

Division by zero is not defined.

⁴The material in this chapter was previously published by CRC Press in *The Engineering Handbook*, pp. 2037–2079, 2187–2192, and 2196–2202, 1996.

Exponents

For integers m and n

$$\begin{aligned}a^n a^m &= a^{n+m} \\ a^n / a^m &= a^{n-m} \\ (a^n)^m &= a^{nm} \\ (ab)^m &= a^m b^m \\ (a/b)^m &= a^m / b^m\end{aligned}$$

Fractional Exponents

$$a^{p/q} = (a^{1/q})^p$$

where $a^{1/q}$ is the positive q th root of a if $a > 0$ and the negative q th root of a if a is negative and q is odd. Accordingly, the five rules of exponents just given (for integers) are also valid if m and n are fractions, provided a and b are positive.

Irrational Exponents

If an exponent is irrational (e.g., $\sqrt{2}$), the quantity, such as $a^{\sqrt{2}}$, is the limit of the sequence $a^{1.4}, a^{1.41}, a^{1.414}, \dots$

Operations with Zero

$$0^m = 0 \quad a^0 = 1$$

Logarithms

If x , y , and b are positive and $b \neq 1$

$$\begin{aligned}\log_b(xy) &= \log_b x + \log_b y \\ \log_b(x/y) &= \log_b x - \log_b y \\ \log_b x^p &= p \log_b x \\ \log_b(1/x) &= -\log_b x \\ \log_b b &= 1 \\ \log_b 1 &= 0 \quad \text{Note: } b^{\log_b x} = x\end{aligned}$$

Change of Base ($a \neq 1$)

$$\log_b x = \log_a x \log_b a$$

Factorials

The factorial of a positive integer n is the product of all of the positive integers less than or equal to the integer n and is denoted $n!$. Thus

$$n! = 1 \cdot 2 \cdot 3 \cdot \dots \cdot n$$

Factorial 0 is defined: $0! = 1$

Stirling's Approximation

$$\lim_{n \rightarrow \infty} (n/e)^n \sqrt{2\pi n} = n!$$

Binomial Theorem

For positive integer n

$$(x + y)^n = x^n + nx^{n-1}y + \frac{n(n-1)}{2!}x^{n-2}y^2 + \frac{n(n-1)(n-2)}{3!}x^{n-3}y^3 + \dots + nxy^{n-1} + y^n$$

Factors and Expansion

$$(a + b)^2 = a^2 + 2ab + b^2$$

$$(a - b)^2 = a^2 - 2ab + b^2$$

$$(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$$

$$(a - b)^3 = a^3 - 3a^2b + 3ab^2 - b^3$$

$$(a^2 - b^2) = (a - b)(a + b)$$

$$(a^3 - b^3) = (a - b)(a^2 + ab + b^2)$$

$$(a^3 + b^3) = (a + b)(a^2 - ab + b^2)$$

Progression

An *arithmetic progression* is a sequence in which the difference between any term and the preceding term is a constant (d):

$$a, a + d, a + 2d, \dots, a + (n - 1)d$$

If the last term is denoted $l (= a + (n - 1)d)$, then the sum is

$$s = \frac{n}{2}(a + l)$$

A *geometric progression* is a sequence in which the ratio of any term is a constant r . Thus, for n terms

$$a, ar, ar^2, \dots, ar^{n-1}$$

The sum is

$$S = \frac{a - ar^n}{1 - r}$$

Complex Numbers

A complex number is an ordered pair of real numbers (a, b).

Equality:

$$(a, b) = (c, d) \quad \text{if and only if } a = c \text{ and } b = d$$

Addition:

$$(a, b) + (c, d) = (a + c, b + d)$$

Multiplication:

$$(a, b)(c, d) = (ac - bd, ad + bc)$$

The first element (a, b) is called the *real* part, the second the *imaginary* part. An alternative notation for (a, b) is $a + bi$, where $i^2 = (-1, 0)$, and $i = (0, 1)$ or $0 + 1i$ is written for this complex number as a convenience. With this understanding, i behaves as a number, that is, $(2 - 3i)(4 + i) = 8 - 12i + 2i - 3i^2 = 11 - 10i$. The conjugate of $a + bi$ is $a - bi$, and the product of a complex number and its conjugate is $a^2 + b^2$. Thus, *quotients* are computed by multiplying numerator and denominator by the conjugate of the denominator,

illustrated as follows:

$$\frac{2 + 3i}{4 + 2i} = \frac{(4 - 2i)(2 + 3i)}{(4 - 2i)(4 + 2i)} = \frac{14 + 8i}{20} = \frac{7 + 4i}{10}$$

Polar Form

The complex number $x + iy$ may be represented by a plane vector with components x and y :

$$x + iy = r(\cos \theta + i \sin \theta)$$

(See Fig. 23.29.) Then, given two complex numbers $z_1 = r_1(\cos \theta_1 + i \sin \theta_1)$, and $z_2 = r_2(\cos \theta_2 + i \sin \theta_2)$, the product and quotient are as follows.

Product:

$$z_1 z_2 = r_1 r_2 (\cos(\theta_1 + \theta_2) + i \sin(\theta_1 + \theta_2))$$

Quotient:

$$z_1 / z_2 = (r_1 / r_2) [\cos(\theta_1 - \theta_2) + i \sin(\theta_1 - \theta_2)]$$

Powers:

$$z^n = [r \cos \theta + i \sin \theta]^n = r^n [\cos n\theta + i \sin n\theta]$$

Roots:

$$z^{1/n} = [r \cos \theta + i \sin \theta]^{1/n} = r^{1/n} \left[\cos \frac{\theta + k \cdot 360}{n} + i \sin \frac{\theta + k \cdot 360}{n} \right] \quad k = 0, 1, 2, \dots, n - 1$$

Permutations

A permutation is an ordered arrangement (sequence) of all or part of a set of objects. The number of permutations of n objects taken r at a time is

$$p(n, r) = n(n - 1)(n - 2) \cdots (n - r + 1) = \frac{n!}{(n - r)!}$$

A permutation of positive integers is *even* or *odd* if the total number of inversions is an even integer or an odd integer, respectively. Inversions are counted relative to each integer j in the permutation by counting the number of integers that follow j and are less than j . These are summed to give the total number of inversions. For example, the permutation 4132 has four inversions: three relative to 4 and one relative to 3. This permutation is therefore even.

FIGURE 23.29 Polar form of complex number.

Combinations

A combination is a selection of one or more objects from among a set of objects regardless of order. The number of combinations of n different objects taken r at a time is

$$C(n, r) = \frac{P(n, r)}{r!} = \frac{n!}{r!(n - r)!}$$

Algebraic Equations

Quadratic

If $ax^2 + bx + c = 0$, and $a \neq 0$, then roots are

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Cubic

To solve $x^3 + bx^2 + cx + d = 0$, let $x = y - b/3$. Then the *reduced cubic* is obtained

$$y^3 + py + q = 0$$

where $p = c - (1/3)b^2$ and $q = d - (1/3)bc + (2/27)b^3$. Solutions of the original cubic are then in terms of the reduced cubic roots y_1, y_2, y_3

$$x_1 = y_1 - (1/3)b \quad x_2 = y_2 - (1/3)b \quad x_3 = y_3 - (1/3)b$$

The three roots of the reduced cubic are

$$y_1 = (A)^{1/3} + (B)^{1/3}$$

$$y_2 = W(A)^{1/3} + W^2(B)^{1/3}$$

$$y_3 = W^2(A)^{1/3} + W(B)^{1/3}$$

where

$$A = -\frac{1}{2}q + \sqrt{(1/27)p^3 + \frac{1}{4}q^2}$$

$$B = -\frac{1}{2}q - \sqrt{(1/27)p^3 + \frac{1}{4}q^2}$$

$$W = \frac{-1 + i\sqrt{3}}{2}, \quad W^2 = \frac{-1 - i\sqrt{3}}{2}$$

When $(1/27)p^3 + (1/4)q^2$ is negative, A is complex; in this case A should be expressed in trigonometric form: $A = r(\cos \theta + i \sin \theta)$ where θ is a first or second quadrant angle, as q is negative or positive. The three roots of the reduced cubic are

$$y_1 = 2(r)^{1/3} \cos(\theta/3)$$

$$y_2 = 2(r)^{1/3} \cos\left(\frac{\theta}{3} + 120^\circ\right)$$

$$y_3 = 2(r)^{1/3} \cos\left(\frac{\theta}{3} + 240^\circ\right)$$

Geometry

Figures 23.30–23.40 are a collection of common geometric figures. Area (A), volume (V), and other measurable features are indicated.

FIGURE 23.30 Rectangle: $A = bh$

FIGURE 23.31 Parallelogram: $A = bh$

FIGURE 23.32 Triangle: $A = \frac{1}{2}bh$

FIGURE 23.33 Trapezoid: $A = \frac{1}{2}(a + b)h$

FIGURE 23.34 Circle: $A = \pi R^2$;
circumference = $2\pi R$;
arc length $S = R\theta$ (θ in radians)

FIGURE 23.35 Sector of a circle:
 $A_{\text{sector}} = \frac{1}{2}R^2\theta$;
 $A_{\text{segment}} = \frac{1}{2}R^2(\theta - \sin \theta)$

FIGURE 23.39 Right circular cone:
 $V = \frac{1}{3}\pi R^2 h$;
lateral surface area = $\pi R l = \pi R \sqrt{R^2 + h^2}$

FIGURE 23.40 Sphere: $V = \frac{4}{3}\pi R^3$; surface area = $4\pi R^2$

23.6.3 Trigonometry

Triangles

In any triangle (in a plane) with sides a , b , and c and corresponding opposite angles A , B , and C

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C} \quad (\text{Law of sines})$$

$$a^2 = b^2 + c^2 - 2cb \cos A \quad (\text{Law of cosines})$$

$$\frac{a+b}{a-b} = \frac{\tan \frac{1}{2}(A+B)}{\tan \frac{1}{2}(A-B)} \quad (\text{Law of Tangents})$$

$$\sin \frac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{bc}} \quad \text{where } s = \frac{1}{2}(a+b+c)$$

$$\cos \frac{1}{2}A = \sqrt{\frac{s(s-a)}{bc}}$$

$$\tan \frac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}$$

$$\begin{aligned} \text{area} &= \frac{1}{2}bc \sin A \\ &= \sqrt{s(s-a)(s-b)(s-c)} \end{aligned}$$

If the vertices have coordinates (x_1, y_1) , (x_2, y_2) , (x_3, y_3) , the area is the *absolute value* of the expression

$$\frac{1}{2} \begin{vmatrix} x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \end{vmatrix}$$

Trigonometric Functions of an Angle

With reference to Fig. 23.41, $P(x, y)$ is a point in any one of the four quadrants and A is an angle whose initial side is coincident with the positive x axis and whose terminal side contains the point $P(x, y)$. The distance from the origin $P(x, y)$ is denoted by r and is positive. The trigonometric functions of the angle

FIGURE 23.41 The trigonometric point: angle A is taken to be positive when the rotation is counterclockwise and negative when the rotation is clockwise. The plane is divided into quadrants as shown.

A are defined as

$$\begin{aligned} \sin A &= \text{sine } A &&= y/r \\ \cos A &= \text{cosine } A &&= x/r \\ \tan A &= \text{tangent } A &&= y/x \\ \text{ctn } A &= \text{cotangent } A &&= x/y \\ \sec A &= \text{secant } A &&= r/x \\ \csc A &= \text{cosecant } A &&= r/y \end{aligned}$$

Angles are measured in degrees or radians; $180^\circ = \pi$ radians; $1 \text{ radian} = 180/\pi^\circ$.

The trigonometric functions of $0, 30,$ and 45° , and integer multiples of these are directly computed.

	0°	30°	45°	60°	90°	120°	135°	150°	180°
sin	0	$\frac{1}{2}$	$\frac{\sqrt{2}}{2}$	$\frac{\sqrt{3}}{2}$	1	$\frac{\sqrt{3}}{2}$	$\frac{\sqrt{2}}{2}$	$\frac{1}{2}$	0
cos	1	$\frac{\sqrt{3}}{2}$	$\frac{\sqrt{2}}{2}$	$\frac{1}{2}$	0	$-\frac{1}{2}$	$-\frac{\sqrt{2}}{2}$	$-\frac{\sqrt{3}}{2}$	-1

Trigonometric Identities

$$\begin{aligned} \sin A &= \frac{1}{\csc A} \\ \cos A &= \frac{1}{\sec A} \\ \tan A &= \frac{1}{\text{ctn } A} = \frac{\sin A}{\cos A} \\ \csc A &= \frac{1}{\sin A} \end{aligned}$$

$$\sec A = \frac{1}{\cos A}$$

$$\operatorname{ctn} A = \frac{1}{\tan A} = \frac{\cos A}{\sin A}$$

$$\sin^2 A + \cos^2 A = 1$$

$$1 + \tan^2 A = \sec^2 A$$

$$1 + \operatorname{ctn}^2 A = \operatorname{csc}^2 A$$

$$\sin(A \pm B) = \sin A \cos B \pm \cos A \sin B$$

$$\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B$$

$$\tan(A \pm B) = \frac{\tan A \pm \tan B}{1 \mp \tan A \tan B}$$

$$\sin 2A = 2 \sin A \cos A$$

$$\sin 3A = 3 \sin A - 4 \sin^3 A$$

$$\sin nA = 2 \sin(n-1)A \cos A - \sin(n-2)A$$

$$\cos 2A = 2 \cos^2 A - 1 = 1 - 2 \sin^2 A$$

$$\cos 3A = 4 \cos^3 A - 3 \cos A$$

$$\cos nA = 2 \cos(n-1)A \cos A - \cos(n-2)A$$

$$\sin A + \sin B = 2 \sin \frac{1}{2}(A+B) \cos \frac{1}{2}(A-B)$$

$$\sin A - \sin B = 2 \cos \frac{1}{2}(A+B) \sin \frac{1}{2}(A-B)$$

$$\cos A + \cos B = 2 \cos \frac{1}{2}(A+B) \cos \frac{1}{2}(A-B)$$

$$\cos A - \cos B = -2 \sin \frac{1}{2}(A+B) \sin \frac{1}{2}(A-B)$$

$$\tan A \pm \tan B = \frac{\sin(A \pm B)}{\cos A \cos B}$$

$$\operatorname{ctn} A \pm \operatorname{ctn} B = \pm \frac{\sin(A \pm B)}{\sin A \sin B}$$

$$\sin A \sin B = \frac{1}{2} \cos(A-B) - \frac{1}{2} \cos(A+B)$$

$$\cos A \cos B = \frac{1}{2} \cos(A-B) + \frac{1}{2} \cos(A+B)$$

$$\sin A \cos B = \frac{1}{2} \sin(A+B) + \frac{1}{2} \sin(A-B)$$

$$\sin \frac{A}{2} = \pm \sqrt{\frac{1 - \cos A}{2}}$$

$$\cos \frac{A}{2} = \pm \sqrt{\frac{1 + \cos A}{2}}$$

$$\tan \frac{A}{2} = \frac{1 - \cos A}{\sin A} = \frac{\sin A}{1 + \cos A} = \pm \sqrt{\frac{1 - \cos A}{1 + \cos A}}$$

$$\sin^2 A = \frac{1}{2}(1 - \cos 2A)$$

$$\cos^2 A = \frac{1}{2}(1 + \cos 2A)$$

$$\sin^3 A = \frac{1}{4}(3 \sin A - \sin 3A)$$

$$\cos^3 A = \frac{1}{4}(\cos 3A + 3 \cos A)$$

$$\sin ix = \frac{1}{2i}(e^x - e^{-x}) = i \sinh x$$

$$\cos ix = \frac{1}{2}(e^x + e^{-x}) = \cosh x$$

$$\tan ix = i \frac{(e^x - e^{-x})}{e^x + e^{-x}} = i \tanh x$$

$$e^{x+iy} = e^x(\cos y + i \sin y)$$

$$(\cos x \pm i \sin x)^n = \cos nx \pm i \sin nx$$

Inverse Trigonometric Functions

The inverse trigonometric functions are multiple valued, and this should be taken into account in the use of the following formulas:

$$\begin{aligned} \sin^{-1} x &= \cos^{-1} \sqrt{1 - x^2} \\ &= \tan^{-1} \frac{x}{\sqrt{1 - x^2}} = \operatorname{ctn}^{-1} \frac{\sqrt{1 - x^2}}{x} \\ &= \sec^{-1} \frac{1}{\sqrt{1 - x^2}} = \operatorname{csc}^{-1} \frac{1}{x} \\ &= -\sin^{-1}(-x) \end{aligned}$$

$$\begin{aligned} \cos^{-1} x &= \sin^{-1} \sqrt{1 - x^2} \\ &= \tan^{-1} \frac{\sqrt{1 - x^2}}{x} = \operatorname{ctn}^{-1} \frac{x}{\sqrt{1 - x^2}} \\ &= \sec^{-1} \frac{1}{x} = \operatorname{csc}^{-1} \frac{1}{\sqrt{1 - x^2}} \\ &= \pi - \cos^{-1}(-x) \end{aligned}$$

$$\begin{aligned} \tan^{-1} x &= \operatorname{ctn}^{-1} \frac{1}{x} \\ &= \sin^{-1} \frac{x}{\sqrt{1 + x^2}} = \cos^{-1} \frac{1}{\sqrt{1 + x^2}} \\ &= \sec^{-1} \sqrt{1 + x^2} = \operatorname{csc}^{-1} \frac{\sqrt{1 + x^2}}{x} \\ &= -\tan^{-1}(-x) \end{aligned}$$

23.6.4 Series

Bernoulli and Euler Numbers

A set of numbers, $B_1, B_3, \dots, B_{2n-1}$ (Bernoulli numbers) and B_2, B_4, \dots, B_{2n} (Euler numbers) appear in the series expansions of many functions. A partial listing follows; these are computed from the following equations:

$$B_{2n} - \frac{2n(2n-1)}{2!}B_{2n-2} + \frac{2n(2n-1)(2n-2)(2n-3)}{4!}B_{2n-4} - \dots + (-1)^n = 0$$

and

$$\frac{2^{2n}(2^{2n}-1)}{2n}B_{2n-1} = (2n-1)B_{2n-2} - \frac{(2n-1)(2n-2)(2n-3)}{3!}B_{2n-4} + \dots + (-1)^{n-1}$$

$B_1 = 1/6$	$B_2 = 1$
$B_3 = 1/30$	$B_4 = 5$
$B_5 = 1/42$	$B_6 = 61$
$B_7 = 1/30$	$B_8 = 1385$
$B_9 = 5/66$	$B_{10} = 50521$
$B_{11} = 691/2730$	$B_{12} = 2\,702\,765$
$B_{13} = 7/6$	$B_{14} = 199\,360\,981$
\vdots	\vdots

Series of Functions

In the following, the interval of convergence is indicated; otherwise it is all x . Logarithms are to the base e . Bernoulli and Euler numbers (B_{2n-1} and B_{2n}) appear in certain expressions.

$$(a+x)^n = a^n + na^{n-1}x + \frac{n(n-1)}{2!}a^{n-2}x^2 + \frac{n(n-1)(n-2)}{3!}a^{n-3}x^3 + \dots + \frac{n!}{(n-j)!j!}a^{n-j}x^j + \dots \quad [x^2 < a^2]$$

$$(a-bx)^{-1} = \frac{1}{a} \left[1 + \frac{bx}{a} + \frac{b^2x^2}{a^2} + \frac{b^3x^3}{a^3} + \dots \right] \quad [b^2x^2 < a^2]$$

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{2!}x^2 \pm \frac{n(n-1)(n-2)x^3}{3!} + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-n} = 1 \mp nx + \frac{n(n+1)}{2!}x^2 \mp \frac{n(n+1)(n+2)}{3!}x^3 + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{\frac{1}{2}} = 1 \pm \frac{1}{2}x - \frac{1}{2 \cdot 4}x^2 \pm \frac{1 \cdot 3}{2 \cdot 4 \cdot 6}x^3 - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 8}x^4 \pm \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-\frac{1}{2}} = 1 \mp \frac{1}{2}x + \frac{1 \cdot 3}{2 \cdot 4}x^2 \mp \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6}x^3 + \frac{1 \cdot 3 \cdot 5 \cdot 7}{2 \cdot 4 \cdot 6 \cdot 8}x^4 \pm \dots \quad [x^2 < 1]$$

$$(1 \pm x^2)^{\frac{1}{2}} = 1 \pm \frac{1}{2}x^2 - \frac{x^4}{2 \cdot 4} \pm \frac{1 \cdot 3}{2 \cdot 4 \cdot 6}x^6 - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 8}x^8 \pm \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-2} = 1 \mp 2x + 3x^2 \mp 4x^3 + 5x^4 \mp \dots \quad [x^2 < 1]$$

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots$$

$$e^{-x^2} = 1 - x^2 + \frac{x^4}{2!} - \frac{x^6}{3!} + \frac{x^8}{4!} - \dots$$

$$a^x = 1 + x \log a + \frac{(x \log a)^2}{2!} + \frac{(x \log a)^3}{3!} + \dots$$

$$\log x = (x - 1) - \frac{1}{2}(x - 1)^2 + \frac{1}{3}(x - 1)^3 - \dots \quad [0 < x < 2]$$

$$\log x = \frac{x - 1}{x} + \frac{1}{2}\left(\frac{x - 1}{x}\right)^2 + \frac{1}{3}\left(\frac{x - 1}{x}\right)^3 + \dots \quad \left[x > \frac{1}{2}\right]$$

$$\log x = 2 \left[\left(\frac{x - 1}{x + 1}\right) + \frac{1}{3}\left(\frac{x - 1}{x + 1}\right)^3 + \frac{1}{5}\left(\frac{x - 1}{x + 1}\right)^5 + \dots \right] \quad [x > 0]$$

$$\log(1 + x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \frac{1}{4}x^4 + \dots \quad [x^2 < 1]$$

$$\log\left(\frac{1 + x}{1 - x}\right) = 2 \left[x + \frac{1}{3}x^3 + \frac{1}{5}x^5 + \frac{1}{7}x^7 + \dots \right] \quad [x^2 < 1]$$

$$\log\left(\frac{x + 1}{x - 1}\right) = 2 \left[\frac{1}{x} + \frac{1}{3}\left(\frac{1}{x}\right)^3 + \frac{1}{5}\left(\frac{1}{x}\right)^5 + \dots \right] \quad [x^2 < 1]$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \dots + \frac{2^{2n}(2^{2n} - 1)B_{2n-1}x^{2n-1}}{2n!} \quad \left[x^2 < \frac{\pi^2}{4}\right]$$

$$\text{ctn } x = \frac{1}{x} - \frac{x}{3} - \frac{x^3}{45} - \frac{2x^5}{945} - \dots - \frac{B_{2n-1}(2x)^{2n}}{(2n)!x} - \dots \quad [x^2 < \pi^2]$$

$$\sec x = 1 + \frac{x^2}{2!} + \frac{5x^4}{4!} + \frac{61x^6}{6!} + \dots + \frac{B_{2n}x^{2n}}{(2n)!} + \dots \quad \left[x^2 < \frac{\pi^2}{4}\right]$$

$$\csc x = \frac{1}{x} + \frac{x}{3!} + \frac{7x^3}{3 \cdot 5!} + \frac{31x^5}{3 \cdot 7!} + \dots + \frac{2(2^{2n+1} - 1)}{(2n + 2)!}B_{2n+1}x^{2n+1} + \dots \quad [x^2 < \pi^2]$$

$$\sin^{-1} x = x + \frac{x^3}{6} + \frac{(1 \cdot 3)x^5}{(2 \cdot 4)5} + \frac{(1 \cdot 3 \cdot 5)x^7}{(2 \cdot 4 \cdot 6)7} + \dots \quad [x^2 < 1]$$

$$\tan^{-1} x = x - \frac{1}{3}x^3 + \frac{1}{5}x^5 - \frac{1}{7}x^7 + \dots \quad [x^2 < 1]$$

$$\begin{aligned} \sec^{-1} x &= \frac{\pi}{2} - \frac{1}{x} - \frac{1}{6x^3} - \frac{1 \cdot 3}{(2 \cdot 4)5x^5} - \frac{1 \cdot 3 \cdot 5}{(2 \cdot 4 \cdot 6)7x^7} - \dots & [x^2 < 1] \\ \sinh x &= x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \dots \\ \cosh x &= 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \frac{x^8}{8!} + \dots \\ \tanh x &= (2^2 - 1)2^2 B_1 \frac{x}{2!} - (2^4 - 1)2^4 B_3 \frac{x^3}{4!} + (2^6 - 1)2^6 B_5 \frac{x^5}{6!} - \dots & \left[x^2 < \frac{\pi^2}{4} \right] \\ \operatorname{ctnh} x &= \frac{1}{x} \left(1 + \frac{2^2 B_1 x^2}{2!} - \frac{2^4 B_3 x^4}{4!} + \frac{2^6 B_5 x^6}{6!} - \dots \right) & [x^2 < \pi^2] \\ \operatorname{sech} x &= 1 - \frac{B_2 x^2}{2!} + \frac{B_4 x^4}{4!} - \frac{B_6 x^6}{6!} + \dots & \left[x^2 < \frac{\pi^2}{4} \right] \\ \operatorname{csch} x &= \frac{1}{x} - (2 - 1)2 B_1 \frac{x}{2!} + (2^3 - 1)2 B_3 \frac{x^3}{4!} - \dots & [x^2 < \pi^2] \\ \sinh^{-1} x &= x - \frac{1}{2} \frac{x^3}{3} + \frac{1 \cdot 3}{2 \cdot 4} \frac{x^5}{5} - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6} \frac{x^7}{7} + \dots & [x^2 < 1] \\ \tanh^{-1} x &= x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \dots & [x^2 < 1] \\ \operatorname{ctnh}^{-1} x &= \frac{1}{x} + \frac{1}{3x^3} + \frac{1}{5x^5} + \dots & [x^2 > 1] \\ \operatorname{csch}^{-1} x &= \frac{1}{x} - \frac{1}{2 \cdot 3x^3} + \frac{1 \cdot 3}{2 \cdot 4 \cdot 5x^5} - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 7x^7} + \dots & [x^2 > 1] \\ \int_0^x e^{-t^2} dt &= x - \frac{1}{3}x^3 + \frac{x^5}{5 \cdot 2!} - \frac{x^7}{7 \cdot 3!} + \dots \end{aligned}$$

Error Function

The following function, known as the error function, $\operatorname{erf} x$, arises frequently in applications:

$$\operatorname{erf} x = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt$$

The integral cannot be represented in terms of a finite number of elementary functions; therefore, values of $\operatorname{erf} x$ have been compiled in tables. The following is the series for $\operatorname{erf} x$:

$$\operatorname{erf} x = \frac{2}{\sqrt{\pi}} \left[x - \frac{x^3}{3} + \frac{x^5}{5 \cdot 2!} - \frac{x^7}{7 \cdot 3!} + \dots \right]$$

There is a close relation between this function and the area under the standard normal curve. For evaluation it is convenient to use z instead of x ; then $\operatorname{erf} z$ may be evaluated from the area $F(z)$ by use of the relation

$$\operatorname{erf} z = 2F(\sqrt{2}z)$$

Example

$$\operatorname{erf}(0.5) = 2F[(1.414)(0.5)] = 2F(0.707)$$

By interpolation, $F(0.707) = 0.260$; thus, $\operatorname{erf}(0.5) = 0.520$.

Series Expansion

The expression in parentheses following certain series indicates the region of convergence. If not otherwise indicated, it is understood that the series converges for all finite values of x .

Binomial

$$(x + y)^n = x^n + nx^{n-1}y + \frac{n(n-1)}{2!}x^{n-2}y^2 + \frac{n(n-1)(n-2)}{3!}x^{n-3}y^3 + \dots \quad (y^2 < x^2)$$

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)x^2}{2!} \pm \frac{n(n-1)(n-2)x^3}{3!} + \dots \quad (x^2 < 1)$$

$$(1 \pm x)^{-n} = 1 \mp nx + \frac{n(n+1)x^2}{2!} \mp \frac{n(n+1)(n+2)x^3}{3!} + \dots \quad (x^2 < 1)$$

$$(1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 + \dots \quad (x^2 < 1)$$

$$(1 \pm x)^{-2} = 1 \mp 2x + 3x^2 \mp 4x^3 + 5x^4 \mp 6x^5 + \dots \quad (x^2 < 1)$$

Reversion of Series

Let a series be represented by

$$y = a_1x + a_2x^2 + a_3x^3 + a_4x^4 + a_5x^5 + a_6x^6 + \dots \quad (a_1 \neq 0)$$

To find the coefficients of the series

$$\begin{aligned} x &= A_1y + A_2y^2 + A_3y^3 + A_4y^4 + \dots \\ A_1 &= \frac{1}{a_1} \quad A_2 = -\frac{a_2}{a_1^3} \quad A_3 = \frac{1}{a_1^5}(2a_2^2 - a_1a_3) \\ A_4 &= \frac{1}{a_1^7}(5a_1a_2a_3 - a_1^2a_4 - 5a_2^3) \\ A_5 &= \frac{1}{a_1^9}(6a_1^2a_2a_4 + 3a_1^2a_3^2 + 14a_2^4 - a_1^3a_5 - 21a_1a_2^2a_3) \\ A_6 &= \frac{1}{a_1^{11}}(7a_1^3a_2a_5 + 7a_1^3a_3a_4 + 84a_1a_2^3a_3 - a_1^4a_6 - 28a_1^2a_2^2a_4 - 28a_1^2a_2a_3^2 - 42a_2^5) \\ A_7 &= \frac{1}{a_1^{13}}(8a_1^4a_2a_6 + 8a_1^4a_3a_5 + 4a_1^4a_4^2 + 120a_1^2a_2^3a_4 + 180a_1^2a_2^2a_3^2 + 132a_2^6 - a_1^5a_7 \\ &\quad - 36a_1^3a_2^2a_5 - 72a_1^3a_2a_3a_4 - 12a_1^3a_3^3 - 330a_1a_2^4a_3) \end{aligned}$$

Taylor

1.

$$f(x) = f(a) + (x-a)f'(a) + \frac{(x-a)^2}{2!}f''(a) + \frac{(x-a)^3}{3!}f'''(a) + \dots + \frac{(x-a)^n}{n!}f^{(n)}(a) + \dots$$

2. (Increment form)

$$\begin{aligned} f(x+h) &= f(x) + hf'(x) + \frac{h^2}{2!}f''(x) + \frac{h^3}{3!}f'''(x) + \dots \\ &= f(h) + xf'(h) + \frac{x^2}{2!}f''(h) + \frac{x^3}{3!}f'''(h) + \dots \end{aligned}$$

3. If $f(x)$ is a function possessing derivatives of all orders throughout the interval $a \leq x \leq b$, then there is a value X , with $a < X < b$, such that

$$\begin{aligned} f(b) &= f(a) + (b-a)f'(a) + \frac{(b-a)^2}{2!}f''(a) + \dots \\ &\quad + \frac{(b-a)^{n-1}}{(n-1)!}f^{(n-1)}(a) + \frac{(b-a)^n}{n!}f^{(n)}(X) \\ f(a+h) &= f(a) + hf'(a) + \frac{h^2}{2!}f''(a) + \dots + \frac{h^{n-1}}{(n-1)!}f^{(n-1)}(a) \\ &\quad + \frac{h^n}{n!}f^{(n)}(a+\theta h), \quad b = a+h, \quad 0 < \theta < 1 \end{aligned}$$

or

$$f(x) = f(a) + (x-a)f'(a) + \frac{(x-a)^2}{2!}f''(a) + \dots + (x-a)^{n-1}\frac{f^{(n-1)}(a)}{(n-1)!} + R_n$$

where

$$R_n = \frac{f^{(n)}(a + \theta \cdot (x-a))}{n!}(x-a)^n, \quad 0 < \theta < 1$$

The preceding forms are known as Taylor's series with the remainder term.

4. Taylor's series for a function of two variables: If

$$\begin{aligned} \left(h\frac{\partial}{\partial x} + k\frac{\partial}{\partial y}\right)f(x,y) &= h\frac{\partial f(x,y)}{\partial x} + k\frac{\partial f(x,y)}{\partial y}; \\ \left(h\frac{\partial}{\partial x} + k\frac{\partial}{\partial y}\right)^2 f(x,y) &= h^2\frac{\partial^2 f(x,y)}{\partial x^2} + 2hk\frac{\partial^2 f(x,y)}{\partial x \partial y} + k^2\frac{\partial^2 f(x,y)}{\partial y^2} \end{aligned}$$

and so forth, and if

$$\left(h\frac{\partial}{\partial x} + k\frac{\partial}{\partial y}\right)^n f(x,y) \Big|_{\substack{x=a \\ y=b}}$$

where the bar and subscripts mean that after differentiation we are to replace x by a and y by b ,

$$\begin{aligned} f(a+h, b+k) &= f(a,b) + \left(h\frac{\partial}{\partial x} + k\frac{\partial}{\partial y}\right)f(x,y) \Big|_{\substack{x=a \\ y=b}} + \dots \\ &\quad + \frac{1}{n!} \left(h\frac{\partial}{\partial x} + k\frac{\partial}{\partial y}\right)^n f(x,y) \Big|_{\substack{x=a \\ y=b}} + \dots \end{aligned}$$

MacLaurin

$$f(x) = f(0) + xf'(0) + \frac{x^2}{2!}f''(0) + \frac{x^3}{3!}f'''(0) + \dots + x^{n-1}\frac{f^{(n-1)}(0)}{(n-1)!} + R_n$$

where

$$R_n = \frac{x^n f^{(n)}(\theta x)}{n!}, \quad 0 < \theta < 1$$

Exponential

$$e = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \dots$$

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots \quad (\text{all real values of } x)$$

$$a^x = 1 + x \log_e a + \frac{(x \log_e a)^2}{2!} + \frac{(x \log_e a)^3}{3!} + \dots$$

$$e^x = e^a \left[1 + (x - a) + \frac{(x - a)^2}{2!} + \frac{(x - a)^3}{3!} + \dots \right]$$

Logarithmic

$$\log_e x = \frac{x-1}{x} + \frac{1}{2} \left(\frac{x-1}{x} \right)^2 + \frac{1}{3} \left(\frac{x-1}{x} \right)^3 + \dots \quad \left(x > \frac{1}{2} \right)$$

$$\log_e x = (x-1) - \frac{1}{2}(x-1)^2 + \frac{1}{3}(x-1)^3 - \dots \quad (2 \geq x > 0)$$

$$\log_e x = 2 \left[\frac{x-1}{x+1} + \frac{1}{3} \left(\frac{x-1}{x+1} \right)^3 + \frac{1}{5} \left(\frac{x-1}{x+1} \right)^5 + \dots \right] \quad (x > 0)$$

$$\log_e(1+x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \frac{1}{4}x^4 + \dots \quad (-1 < x \leq 1)$$

$$\log_e(n+1) - \log_e(n-1) = 2 \left[\frac{1}{n} + \frac{1}{3n^3} + \frac{1}{5n^5} + \dots \right]$$

$$\log_e(a+x) = \log_e a + 2 \left[\frac{x}{2a+x} + \frac{1}{3} \left(\frac{x}{2a+x} \right)^3 + \frac{1}{5} \left(\frac{x}{2a+x} \right)^5 + \dots \right] \quad (a > 0, -a < x < +\infty)$$

$$\log_e \frac{1+x}{1-x} = 2 \left[x + \frac{x^3}{3} + \frac{x^5}{5} + \dots + \frac{x^{2n-1}}{2n-1} + \dots \right] \quad (-1 < x < 1)$$

$$\log_e x = \log_e a + \frac{(x-a)}{a} - \frac{(x-a)^2}{2a^2} + \frac{(x-a)^3}{3a^3} - \dots \quad (0 < x \leq 2a)$$

Trigonometric

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots \quad (\text{all real values of } x)$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \quad (\text{all real values of } x)$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \dots$$

$$+ \frac{(-1)^{n-1} 2^{2n} (2^{2n} - 1) B_{2n}}{(2n)!} x^{2n-1} + \dots$$

$(x^2 < \pi^2/4, \text{ and } B_n \text{ represents the } n\text{th Bernoulli number})$

$$\cot x = \frac{1}{x} - \frac{x}{3} - \frac{x^3}{45} - \frac{2x^5}{945} - \frac{x^7}{4725} - \dots$$

$$- \frac{(-1)^{n+1} 2^{2n}}{(2n)!} B_{2n} x^{2n-1} + \dots$$

$(x^2 < \pi^2, \text{ and } B_n \text{ represents the } n\text{th Bernoulli number})$

23.6.5 Differential Calculus

Notation

For the following equations, the symbols $f(x)$, $g(x)$, and so forth represent functions of x . The value of a function $f(x)$ at $x = a$ is denoted $f(a)$. For the function $y = f(x)$ the derivative of y with respect to x is denoted by one of the following:

$$\frac{dy}{dx}, \quad f'(x), \quad D_x y, \quad y'$$

Higher derivatives are as follows:

$$\begin{aligned} \frac{d^2y}{dx^2} &= \frac{d}{dx} \left(\frac{dy}{dx} \right) = \frac{d}{dx} f'(x) = f''(x) \\ \frac{d^3y}{dx^3} &= \frac{d}{dx} \left(\frac{d^2y}{dx^2} \right) = \frac{d}{dx} f''(x) = f'''(x) \\ &\vdots \end{aligned}$$

and values of these at $x = a$ are denoted $f''(a)$, $f'''(a)$, and so on (see [Table 23.1](#), Table of Derivatives).

Slope of a Curve

The tangent line at point $P(x, y)$ of the curve $y = f(x)$ has a slope $f'(x)$ provided that $f'(x)$ exists at P . The slope at P is defined to be that of the tangent line at P . The tangent line at $P(x_1, y_1)$ is given by

$$y - y_1 = f'(x_1)(x - x_1)$$

The *normal line* to the curve at $P(x_1, y_1)$ has slope $-1/f'(x_1)$ and thus obeys the equation

$$y - y_1 = [-1/f'(x_1)](x - x_1)$$

(The slope of a vertical line is not defined.)

Angle of Intersection of Two Curves

Two curves, $y = f_1(x)$ and $y = f_2(x)$, that intersect at a point $P(X, Y)$ where derivatives $f_1'(X)$, $f_2'(X)$ exist have an angle (α) of intersection given by

$$\tan \alpha = \frac{f_2'(X) - f_1'(X)}{1 + f_2'(X) \cdot f_1'(X)}$$

If $\tan \alpha > 0$, then α is the acute angle; if $\tan \alpha < 0$, then α is the obtuse angle.

Radius of Curvature

The radius of curvature R of the curve $y = f(x)$ at the point $P(x, y)$ is

$$R = \frac{\{1 + [f'(x)]^2\}^{3/2}}{f''(x)}$$

In polar coordinates (θ, r) the corresponding formula is

$$R = \frac{\left[r^2 + \left(\frac{dr}{d\theta} \right)^2 \right]^{3/2}}{r^2 + 2 \left(\frac{dr}{d\theta} \right)^2 - r \frac{d^2r}{d\theta^2}}$$

The *curvature* K is $1/R$.

TABLE 23.1 Table of Derivatives*

1. $\frac{d}{dx}(a) = 0$	20. $\frac{d}{dx} \cos^{-1} u = \frac{-1}{\sqrt{1-u^2}} \frac{du}{dx}, \quad (0 \leq \cos^{-1} u \leq \pi)$
2. $\frac{d}{dx}(x) = 1$	21. $\frac{d}{dx} \tan^{-1} u = \frac{1}{1+u^2} \frac{du}{dx}$
3. $\frac{d}{dx}(au) = a \frac{du}{dx}$	22. $\frac{d}{dx} \text{ctn}^{-1} u = \frac{-1}{1+u^2} \frac{du}{dx}$
4. $\frac{d}{dx}(u+v) = \frac{du}{dx} + \frac{dv}{dx}$	23. $\frac{d}{dx} \sec^{-1} u = \frac{1}{u\sqrt{u^2-1}} \frac{du}{dx},$ $\left(-\pi \leq \sec^{-1} u < -\frac{1}{2}\pi; \quad 0 \leq \sec^{-1} u < \frac{1}{2}\pi\right)$
5. $\frac{d}{dx}(uv) = u \frac{dv}{dx} + v \frac{du}{dx}$	24. $\frac{d}{dx} \csc^{-1} u = \frac{-1}{u\sqrt{u^2-1}} \frac{du}{dx},$ $\left(-\pi \leq \csc^{-1} u \leq -\frac{1}{2}\pi; \quad 0 < \csc^{-1} u \leq \frac{1}{2}\pi\right)$
6. $\frac{d}{dx} \frac{u}{v} = \frac{v \frac{du}{dx} - u \frac{dv}{dx}}{v^2}$	25. $\frac{d}{dx} \sinh u = \cosh u \frac{du}{dx}$
7. $\frac{d}{dx}(u^n) = nu^{n-1} \frac{du}{dx}$	26. $\frac{d}{dx} \cosh u = \sinh u \frac{du}{dx}$
8. $\frac{d}{dx} e^u = e^u \frac{du}{dx}$	27. $\frac{d}{dx} \tanh u = \text{sech}^2 u \frac{du}{dx}$
9. $\frac{d}{dx} a^u = (\log_e a) a^u \frac{du}{dx}$	28. $\frac{d}{dx} \text{ctnh} u = -\text{csch}^2 u \frac{du}{dx}$
10. $\frac{d}{dx} \log_e u = \frac{1}{u} \frac{du}{dx}$	29. $\frac{d}{dx} \text{sech} u = -\text{sech} u \tanh u \frac{du}{dx}$
11. $\frac{d}{dx} \log_a u = (\log_a e) \frac{1}{u} \frac{du}{dx}$	30. $\frac{d}{dx} \text{csch} u = -\text{csch} u \text{ctnh} u \frac{du}{dx}$
12. $\frac{d}{dx} u^v = vu^{v-1} \frac{du}{dx} + u^v (\log_e u) \frac{dv}{dx}$	31. $\frac{d}{dx} \sinh^{-1} u = \frac{1}{\sqrt{u^2+1}} \frac{du}{dx}$
13. $\frac{d}{dx} \sin u = \cos u \frac{du}{dx}$	32. $\frac{d}{dx} \cosh^{-1} u = \frac{1}{\sqrt{u^2-1}} \frac{du}{dx}$
14. $\frac{d}{dx} \cos u = -\sin u \frac{du}{dx}$	33. $\frac{d}{dx} \tanh^{-1} u = \frac{1}{1-u^2} \frac{du}{dx}$
15. $\frac{d}{dx} \tan u = \sec^2 u \frac{du}{dx}$	34. $\frac{d}{dx} \text{ctnh}^{-1} u = \frac{-1}{u^2-1} \frac{du}{dx}$
16. $\frac{d}{dx} \text{ctn} u = -\text{csc}^2 u \frac{du}{dx}$	35. $\frac{d}{dx} \text{sech}^{-1} u = \frac{-1}{u\sqrt{1-u^2}} \frac{du}{dx}$
17. $\frac{d}{dx} \sec u = \sec u \tan u \frac{du}{dx}$	36. $\frac{d}{dx} \text{csch}^{-1} u = \frac{1}{u\sqrt{u^2+1}} \frac{du}{dx}$
18. $\frac{d}{dx} \csc u = -\csc u \text{ctn} u \frac{du}{dx}$	
19. $\frac{d}{dx} \sin^{-1} u = \frac{1}{\sqrt{1-u^2}} \frac{du}{dx}, \quad \left(-\frac{1}{2}\pi \leq \sin^{-1} u \leq \frac{1}{2}\pi\right)$	

*In this table, a and n are constants, e is the base of the natural logarithms, and u and v denote functions of x .

Relative Maxima and Minima

The function f has a relative maximum at $x = a$ if $f(a) \geq f(a + c)$ for all values of c (positive or negative) that are sufficiently near zero. The function f has a relative minimum at $x = b$ if $f(b) \leq f(b + c)$ for all values of c that are sufficiently close to zero. If the function f is defined on the closed interval $x_1 \leq x \leq x_2$ and has a relative maximum or minimum at $x = a$, where $x_1 < a < x_2$, and if the derivative $f'(x)$ exists at $x = a$, then $f'(a) = 0$. It is noteworthy that a relative maximum or minimum may occur at a point where the derivative does not exist. Further, the derivative may vanish at a point that is neither a maximum nor a minimum for the function. Values of x for which $f'(x) = 0$ are called *critical values*. To determine whether a critical value of x , say

x_c , is a relative maximum or minimum for the function at x_c , one may use the second derivative test:

1. If $f''(x_c)$ is positive, $f(x_c)$ is a minimum.
2. If $f''(x_c)$ is negative, $f(x_c)$ is a maximum.
3. If $f''(x_c)$ is zero, no conclusion may be made.

The sign of the derivative as x advances through x_c may also be used as a test. If $f'(x)$ changes from positive to zero to negative, then a maximum occurs at x_c , whereas a change in $f'(x)$ from negative to zero to positive indicates a minimum. If $f'(x)$ does not change sign as x advances through x_c , then the point is neither a maximum nor a minimum.

Points of Inflection of a Curve

The sign of the second derivative of f indicates whether the graph of $y = f(x)$ is concave upward or concave downward:

$$f''(x) > 0: \text{concave upward}$$

$$f''(x) < 0: \text{concave downward}$$

A point of the curve at which the direction of concavity changes is called a point of inflection (Fig. 23.42). Such a point may occur where $f''(x) = 0$ or where $f''(x)$ becomes infinite. More precisely, if the function $y = f(x)$ and its first derivative $y' = f'(x)$ are continuous in the interval $a \leq x \leq b$, and if $y'' = f''(x)$ exists in $a < x < b$, then the graph of $y = f(x)$ for $a < x < b$ is concave upward if $f''(x)$ is positive and concave downward if $f''(x)$ is negative.

FIGURE 23.42 Point of inflection.

Taylor's Formula

If f is function that is continuous on an interval that contains a and x , and if its first $(n + 1)$ derivatives are continuous on this interval, then

$$f(x) = f(a) + f'(a)(x - a) + \frac{f''(a)}{2!}(x - a)^2 + \frac{f'''(a)}{3!}(x - a)^3 + \dots + \frac{f^{(n)}(a)}{n!}(x - a)^n + R$$

where R is called the *remainder*. There are various common forms of the remainder.

Lagrange's form:

$$R = f^{(n+1)}(\beta) \cdot \frac{(x - a)^{n+1}}{(n + 1)!}, \quad \beta \text{ between } a \text{ and } x$$

Cauchy's form:

$$R = f^{(n+1)}(\beta) \cdot \frac{(x - B)^n(x - a)}{n!}, \quad \beta \text{ between } a \text{ and } x$$

Integral form:

$$R = \int_a^x \frac{(x - t)^n}{n!} f^{(n+1)}(t) dt$$

Indeterminant Forms

If $f(x)$ and $g(x)$ are continuous in an interval that includes $x = a$, and if $f(a) = 0$ and $g(a) = 0$, the limit $\lim_{x \rightarrow a} (f(x)/g(x))$ takes the form $0/0$, called an *indeterminant form*. *L'Hôpital's rule* is

$$\lim_{x \rightarrow a} \frac{f(x)}{g(x)} = \lim_{x \rightarrow a} \frac{f'(x)}{g'(x)}$$

Similarly, it may be shown that if $f(x) \rightarrow \infty$ and $g(x) \rightarrow \infty$ as $x \rightarrow a$, then

$$\lim_{x \rightarrow a} \frac{f(x)}{g(x)} = \lim_{x \rightarrow a} \frac{f'(x)}{g'(x)}$$

(This holds for $x \rightarrow \infty$.)

Examples

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = \lim_{x \rightarrow 0} \frac{\cos x}{1} = 1$$

$$\lim_{x \rightarrow \infty} \frac{x^2}{e^x} = \lim_{x \rightarrow \infty} \frac{2x}{e^x} = \lim_{x \rightarrow \infty} \frac{2}{e^x} = 0$$

Numerical Methods

1. *Newton's method* for approximating roots of the equation $f(x) = 0$: A first estimate x_1 of the root is made; then, provided that $f'(x_1) \neq 0$, a better approximation is x_2 ,

$$x_2 = x_1 - \frac{f(x_1)}{f'(x_1)}$$

The process may be repeated to yield a third approximation, x_3 , to the root

$$x_3 = x_2 - \frac{f(x_2)}{f'(x_2)}$$

provided $f'(x_2)$ exists. The process may be repeated. (In certain rare cases the process will not converge.)

2. *Trapezoidal rule for areas* (Fig. 23.43): For the function $y = f(x)$ defined on the interval (a, b) and positive there, take n equal subintervals of width $\Delta x = (b - a)/n$. The area bounded by the curve between $x = a$ and $x = b$ (or definite integral of $f(x)$) is approximately the sum of trapezoidal areas, or

$$A \sim \left(\frac{1}{2}y_0 + y_1 + y_2 + \dots + y_{n-1} + \frac{1}{2}y_n \right) (\Delta x)^2$$

FIGURE 23.43 Trapezoidal rule for area.

Estimation of the error (E) is possible if the second derivative can be obtained:

$$E = \frac{b-a}{12} f''(c)(\Delta x)^2$$

where c is some number between a and b .

Functions of Two Variables

For the function of two variables, denoted $z = f(x, y)$, if y is held constant, say at $y = y_1$, then the resulting function is a function of x only. Similarly, x may be held constant at x_1 , to give the resulting function of y .

The Gas Laws

A familiar example is afforded by the ideal gas law relating the pressure p , the volume V , and the absolute temperature T of an ideal gas:

$$pV = nRT$$

where n is the number of moles and R is the gas constant per mole, $8.31 \text{ (J} \cdot \text{K}^{-1} \cdot \text{mole}^{-1})$. By rearrangement, any one of the three variables may be expressed as a function of the other two. Further, either one of these two may be held constant. If T is held constant, then we get the form known as Boyle's law:

$$p = kV^{-1} \quad (\text{Boyle's law})$$

where we have denoted nRT by the constant k and, of course, $V > 0$. If the pressure remains constant, we have Charles' law:

$$V = bT \quad (\text{Charles' law})$$

where the constant b denotes nR/p . Similarly, volume may be kept constant:

$$p = aT$$

where now the constant, denoted a , is nR/V .

Partial Derivatives

The physical example afforded by the ideal gas law permits clear interpretations of processes in which one of the variables is held constant. More generally, we may consider a function $z = f(x, y)$ defined over some region of the xy plane in which we hold one of the two coordinates, say y , constant. If the resulting function of x is differentiable at a point (x, y) , we denote this derivative by one of the notations.

$$f_x, \quad \frac{\partial f}{\partial x}$$

called the *partial derivative with respect to x* . Similarly, if x is held constant and the resulting function of y is differentiable, we get the *partial derivative with respect to y* , denoted by one of the following:

$$f_y, \quad \frac{\partial f}{\partial y}$$

Example

Given $z = x^4 y^3 - y \sin x + 4y$, then

$$\frac{\partial z}{\partial x} = 4(xy)^3 - y \cos x$$

$$\frac{\partial z}{\partial y} = 3x^4 y^2 - \sin x + 4$$

In [Table 23.1](#), a and n are constants, e is the base of the natural logarithms, and u and v denote functions of x .

Additional Relations with Derivatives

$$\frac{d}{dt} \int_a^t f(x) dx = f(t) \quad \frac{d}{dt} \int_t^a f(x) dx = -f(t)$$

If $x = f(y)$, then

$$\frac{dy}{dx} = \frac{1}{\frac{dx}{dy}}$$

If $y = f(u)$ and $u = g(x)$, then

$$\frac{dy}{dx} = \frac{dy}{du} \cdot \frac{du}{dx} \quad (\text{chain rule})$$

If $x = f(t)$ and $y = g(t)$, then

$$\frac{dy}{dx} = \frac{g'(t)}{f'(t)}, \quad \text{and} \quad \frac{d^2}{dx^2} = \frac{f'(t)g''(t) - g'(t)f''(t)}{(f'(t))^3}$$

(Note: Exponent in denominator is 3.)

23.6.6 Integral Calculus

Indefinite Integral

If $F(x)$ is differentiable for all values of x in the interval (a, b) and satisfies the equation $dy/dx = f(x)$, then $F(x)$ is an integral of $f(x)$ with respect to x . The notation is $F(x) = \int f(x) dx$ or, in differential form, $dF(x) = f(x) dx$.

For any function $F(x)$ that is an integral of $f(x)$, it follows that $F(x) + C$ is also an integral. We thus write

$$\int f(x) dx = F(x) + C$$

Definite Integral

Let $f(x)$ be defined on the interval (a, b) which is partitioned by points $x_1, x_2, \dots, x_j, \dots, x_{n-1}$ between $a = x_0$ and $b = x_n$. The j th interval has length $\Delta x_j = x_j - x_{j-1}$, which may vary with j . The sum $\sum_{j=1}^n f(v_j)\Delta x_j$, where v_j is arbitrarily chosen in the j th subinterval, depends on the numbers x_0, \dots, x_n and the choice of the v as well as f ; but if such sums approach a common value as all Δx approach zero, then this value is the definite integral of f over the interval (a, b) and is denoted $\int_a^b f(x) dx$. The *fundamental theorem of integral calculus* states that

$$\int_a^b f(x) dx = F(b) - F(a)$$

where F is any continuous indefinite integral of f in the interval (a, b) .

Properties

$$\int_a^b (f_1(x) + f_2(x) + \dots + f_j(x)) dx = \int_a^b f_1(x) dx + \int_a^b f_2(x) dx + \dots + \int_a^b f_j(x) dx$$

$$\int_a^b c f(x) dx = c \int_a^b f(x) dx, \quad \text{if } c \text{ is a constant}$$

$$\int_a^b f(x) dx = - \int_b^a f(x) dx$$

$$\int_a^b f(x) dx = \int_a^c f(x) dx + \int_c^b f(x) dx$$

Common Applications of the Definite Integral

Area (Rectangular Coordinates)

Given the function $y = f(x)$ such that $y > 0$ for all x between a and b , the area bounded by the curve $y = f(x)$, the x axis, and the vertical lines $x = a$ and $x = b$ is

$$A = \int_a^b f(x) dx$$

Length of Arc (Rectangular Coordinates)

Given the smooth curve $f(x, y) = 0$ from point (x_1, y_1) to point (x_2, y_2) , the length between these points is

$$L = \int_{x_1}^{x_2} \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx$$

$$L = \int_{y_1}^{y_2} \sqrt{1 + \left(\frac{dx}{dy}\right)^2} dy$$

Mean Value of a Function

The mean value of a function $f(x)$ continuous on (a, b) is

$$\frac{1}{(b-a)} \int_a^b f(x) dx$$

Area (Polar Coordinates)

Given the curve $r = f(\theta)$, continuous and nonnegative for $\theta_1 \leq \theta \leq \theta_2$, the area enclosed by this curve and the radial lines $\theta = \theta_1$ and $\theta = \theta_2$ is given by

$$A = \int_{\theta_1}^{\theta_2} \frac{1}{2} [f(\theta)]^2 d\theta$$

Length of Arc (Polar Coordinates)

Given the curve $r = f(\theta)$ with continuous derivative $f'(\theta)$ on $\theta_1 \leq \theta \leq \theta_2$, the length of arc from $\theta = \theta_1$ to $\theta = \theta_2$ is

$$L = \int_{\theta_1}^{\theta_2} \sqrt{[f(\theta)]^2 + [f'(\theta)]^2} d\theta$$

Volume of Revolution

Given a function $y = f(x)$ continuous and nonnegative on the interval (a, b) , when the region bounded by $f(x)$ between a and b is revolved about the x axis, the volume of revolution is

$$V = \pi \int_a^b [f(x)]^2 dx$$

Surface Area of Revolution (Revolution about the x axis, between a and b)

If the portion of the curve $y = f(x)$ between $x = a$ and $x = b$ is revolved about the x axis, the area A of the surface generated is given by the following:

$$A = \int_a^b 2\pi f(x) \{1 + [f'(x)]^2\}^{\frac{1}{2}} dx$$

FIGURE 23.44 Cylindrical coordinates.

Work

If a variable force $f(x)$ is applied to an object in the direction of motion along the x axis between $x = a$ and $x = b$, the work done is

$$W = \int_a^b f(x) dx$$

Cylindrical and Spherical Coordinates

1. Cylindrical coordinates (Fig. 23.44):

$$x = r \cos \theta$$

$$y = r \sin \theta$$

Element of volume $dV = r dr d\theta dz$.

2. Spherical coordinates (Fig. 23.45):

$$x = \rho \sin \phi \cos \theta$$

$$y = \rho \sin \phi \sin \theta$$

$$z = \rho \cos \phi$$

Element of volume $dV = \rho^2 \sin \phi d\rho d\phi d\theta$.

FIGURE 23.45 Spherical coordinates.

FIGURE 23.46 Region R bounded by $y_2(x)$ and $y_1(x)$.

Double Integration

The evaluation of a double integral of $f(x, y)$ over a plane region R ,

$$\iint_R f(x, y) dA$$

is practically accomplished by iterated (repeated) integration. For example, suppose that a vertical straight line meets the boundary of R in at most two points so that there is an upper boundary, $y = y_2(x)$, and a lower boundary, $y = y_1(x)$. Also, it is assumed that these functions are continuous from a to b (see Fig. 23.46). Then

$$\iint_R f(x, y) dA = \int_a^b \left(\int_{y_1(x)}^{y_2(x)} f(x, y) dy \right) dx$$

If R has left-hand boundary $x = x_1(y)$ and a right-hand boundary $x = x_2(y)$, which are continuous from c to d (the extreme values of y in R), then

$$\iint_R f(x, y) dA = \int_c^d \left(\int_{x_1(y)}^{x_2(y)} f(x, y) dx \right) dy$$

Such integrations are sometimes more convenient in polar coordinates, $x = r \cos \theta$, $y = r \sin \theta$, $dA = r dr d\theta$.

Surface Area and Volume by Double Integration

For the surface given by $z = f(x, y)$, which projects onto the closed region R of the xy plane, one may calculate the volume V bounded above by the surface and below by R , and the surface area S by the following:

$$V = \iint_R z dA = \iint_R f(x, y) dx dy$$

$$S = \iint_R (1 + (\partial z / \partial x)^2 + (\partial z / \partial y)^2)^{\frac{1}{2}} dx dy$$

(In polar coordinates, (r, θ) , we replace dA by $r dr d\theta$.)

Centroid

The centroid of a region R of the xy plane is a point (x', y') where

$$x' = \frac{1}{A} \int_R \int x \, dA, \quad y' = \frac{1}{A} \int_R \int y \, dA$$

and A is the area of the region.

Example

For the circular sector of angle 2α and radius R , the area A is αR^2 ; the integral needed for x' , expressed in polar coordinates, is

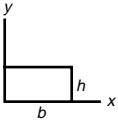

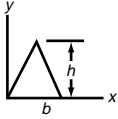

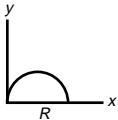

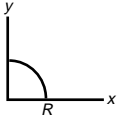

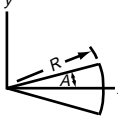

$$\int \int x \, dA = \int_{-\alpha}^{\alpha} \int_0^R (r \cos \theta) r \, dr \, d\theta = \left[\frac{R^3}{3} \sin \theta \right]_{-\alpha}^{+\alpha} = \frac{2}{3} R^3 \sin \alpha$$

and thus

$$x' = \frac{\frac{2}{3} R^3 \sin \alpha}{\alpha R^2} = \frac{2}{3} R \frac{\sin \alpha}{\alpha}$$

Centroids of some common regions are shown in Table 23.2.

TABLE 23.2 Centroids

	Area	x'	y'
Rectangle 	bh	$b/2$	$h/2$
Isosceles triangle 	$bh/2$	$b/2$	$h/3$
($y' = h/3$ for any triangle of altitude h .) Semicircle 	$\pi R^2/2$	R	$4R/3\pi$
Quarter circle 	$\pi R^2/4$	$4R/3\pi$	$4R/3\pi$
Circular sector 	$R^2 A$	$2R \sin A/3A$	0

23.6.7 Special Functions

Hyperbolic Functions

$$\sinh x = \frac{e^x - e^{-x}}{2} \qquad \operatorname{csch} x = \frac{1}{\sinh x}$$

$$\cosh x = \frac{e^x + e^{-x}}{2} \qquad \operatorname{sech} x = \frac{1}{\cosh x}$$

$$\tanh x = \frac{e^x - e^{-x}}{e^x + e^{-x}} \qquad \operatorname{ctnh} x = \frac{1}{\tanh x}$$

$$\sinh(-x) = -\sinh x \qquad \operatorname{ctnh}(-x) = -\operatorname{ctnh} x$$

$$\cosh(-x) = \cosh x \qquad \operatorname{sech}(-x) = \operatorname{sech} x$$

$$\tanh(-x) = -\tanh x \qquad \operatorname{csch}(-x) = -\operatorname{csch} x$$

$$\tanh x = \frac{\sinh x}{\cosh x} \qquad \operatorname{ctnh} x = \frac{\cosh x}{\sinh x}$$

$$\cosh^2 x - \sinh^2 x = 1 \qquad \cosh^2 x = \frac{1}{2}(\cosh 2x + 1)$$

$$\sinh^2 x = \frac{1}{2}(\cosh 2x - 1) \qquad \operatorname{ctnh}^2 x - \operatorname{csch}^2 x = 1$$

$$\operatorname{csch}^2 x - \operatorname{sech}^2 x = \operatorname{csch}^2 x \operatorname{sech}^2 x \qquad \tanh^2 x + \operatorname{sech}^2 x = 1$$

$$\sinh(x + y) = \sinh x \cosh y + \cosh x \sinh y$$

$$\cosh(x + y) = \cosh x \cosh y + \sinh x \sinh y$$

$$\sinh(x - y) = \sinh x \cosh y - \cosh x \sinh y$$

$$\cosh(x - y) = \cosh x \cosh y - \sinh x \sinh y$$

$$\tanh(x + y) = \frac{\tanh x + \tanh y}{1 + \tanh x \tanh y}$$

$$\tanh(x - y) = \frac{\tanh x - \tanh y}{1 - \tanh x \tanh y}$$

Bessel Functions

Bessel functions, also called cylindrical functions, arise in many physical problems as solutions of the differential equation

$$x^2 y'' + xy' + (x^2 - n^2)y = 0$$

which is known as Bessel's equation. Certain solutions, known as *Bessel functions of the first kind of order n* , are given by

$$J_n(x) = \sum_{k=0}^{\infty} \frac{(-1)^k}{k! \Gamma(n + k + 1)} \left(\frac{x}{2}\right)^{n+2k}$$

$$J_{-n}(x) = \sum_{k=0}^{\infty} \frac{(-1)^k}{k! \Gamma(-n + k + 1)} \left(\frac{x}{2}\right)^{-n+2k}$$

see Fig. 23.47a.

In the preceding it is noteworthy that the gamma function must be defined for the negative argument q : $\Gamma(q) = \Gamma(q + 1)/q$, provided that q is not a negative integer. When q is a negative integer, $1/\Gamma(q)$

FIGURE 23.47 Bessel Functions: (a) of the first kind, (b) of the second kind.

is defined to be zero. The functions $J_{-n}(x)$ and $J_n(x)$ are solutions of Bessel’s equation for all real n . It is seen, for $n = 1, 2, 3, \dots$, that

$$J_{-n}(x) = (-1)^n J_n(x)$$

and, therefore, these are not independent; hence, a linear combination of these is not a general solution. When, however, n is not a positive integer, a negative integer, or zero, the linear combination with arbitrary constants c_1 and c_2

$$y = c_1 J_n(x) + c_2 J_{-n}(x)$$

is the general solution of the Bessel differential equation.

The zero-order function is especially important as it arises in the solution of the heat equation (for a long cylinder):

$$J_0(x) = 1 - \frac{x^2}{2^2} + \frac{x^4}{2^2 4^2} - \frac{x^6}{2^2 4^2 6^2} + \dots$$

whereas the following relations show a connection to the trigonometric functions:

$$J_{1/2}(x) = \left[\frac{2}{\pi x} \right]^{1/2} \sin x$$

$$J_{-1/2}(x) = \left[\frac{2}{\pi x} \right]^{1/2} \cos x$$

The following recursion formula gives $J_{n+1}(x)$ for any order in terms of lower order functions:

$$\frac{2n}{x} J_n(x) = J_{n-1}(x) + J_{n+1}(x)$$

Bessel Functions of the Second Kind, $Y_n(x)$
(Also Called *Neumann Functions* or *Weber Functions*) (Fig. 23.47b)

Domain: [$x > 0$]

Recurrence relation:

$$Y_{n+1}(x) = \frac{2n}{x} Y_n(x) - Y_{n-1}(x), \quad n = 0, 1, 2, \dots$$

Symmetry: $Y_{-n}(x) = (-1)^n Y_n(x)$

Legendre Polynomials

If Laplace's equation, $\nabla^2 V = 0$, is expressed in spherical coordinates, it is

$$r^2 \sin \theta \frac{\delta^2 V}{\delta r^2} + 2r \sin \theta \frac{\delta V}{\delta r} + \sin \theta \frac{\delta^2 V}{\delta \theta^2} + \cos \theta \frac{\delta V}{\delta \theta} + \frac{1}{\sin \theta} \frac{\delta^2 V}{\delta \phi^2} = 0$$

and any of its solutions, $V(r, \theta, \phi)$, are known as *spherical harmonics*. The solution as a product

$$V(r, \theta, \phi) = R(r)\Theta(\theta)$$

which is independent of ϕ , leads to

$$\sin^2 \theta \Theta'' + \sin \theta \cos \theta \Theta' + (n(n+1) \sin^2 \theta) \Theta = 0$$

Rearrangement and substitution of $x = \cos \theta$ leads to

$$(1-x^2) \frac{d^2 \Theta}{dx^2} - 2x \frac{d\Theta}{dx} + n(n+1) \Theta = 0$$

known as *Legendre's equation*. Important special cases are those in which n is zero or a positive integer, and, for such cases, Legendre's equation is satisfied by polynomials called Legendre polynomials, $P_n(x)$. A short list of Legendre polynomials, expressed in terms of x and $\cos \theta$, is given next. These are given by the following general formula:

$$P_n(x) = \sum_{j=0}^L \frac{(-1)^j (2n-2j)!}{2^n j!(n-j)!(n-2j)!} x^{n-2j}$$

where $L = n/2$ if n is even and $L = (n-1)/2$ if n is odd

$$P_0(x) = 1$$

$$P_1(x) = x$$

$$P_2(x) = \frac{1}{2}(3x^2 - 1)$$

$$P_3(x) = \frac{1}{2}(5x^3 - 3x)$$

$$P_4(x) = \frac{1}{8}(35x^4 - 30x^2 + 3)$$

$$P_5(x) = \frac{1}{8}(63x^5 - 70x^3 + 15x)$$

$$P_0(\cos \theta) = 1$$

$$P_1(\cos \theta) = \cos \theta$$

$$P_2(\cos \theta) = \frac{1}{4}(3 \cos 2\theta + 1)$$

$$P_3(\cos \theta) = \frac{1}{8}(5 \cos 3\theta + 3 \cos \theta)$$

$$P_4(\cos \theta) = \frac{1}{64}(35 \cos 4\theta + 20 \cos 2\theta + 9)$$

Additional Legendre polynomials may be determined from the *recursion formula*

$$(n + 1)P_{n+1}(x) - (2n + 1)xP_n(x) + nP_{n-1}(x) = 0 \quad (n = 1, 2, \dots)$$

or the *Rodrigues formula*

$$P_n(x) = \frac{1}{2^n n!} \frac{d^n}{dx^n} (x^2 - 1)^n$$

Laguerre Polynomials

Laguerre polynomials, denoted $L_n(x)$, are solutions of the differential equation

$$xy'' + (1 - x)y' + ny = 0$$

and are given by

$$L_n(x) = \sum_{j=0}^n \frac{(-1)^j}{j!} C_{(n,j)} x^j \quad (n = 0, 1, 2, \dots)$$

Thus

$$L_0(x) = 1$$

$$L_1(x) = 1 - x$$

$$L_2(x) = 1 - 2x + \frac{1}{2}x^2$$

$$L_3(x) = 1 - 3x + \frac{3}{2}x^2 - \frac{1}{6}x^3$$

Additional Laguerre polynomials may be obtained from the recursion formula

$$(n + 1)L_{n+1}(x) - (2n + 1 - x)L_n(x) + nL_{n-1}(x) = 0$$

Hermite Polynomials

The Hermite polynomials, denoted $H_n(x)$, are given by

$$H_0 = 1, \quad H_n(x) = (-1)^n e^{x^2} \frac{d^n e^{-x^2}}{dx^n}, \quad (n = 1, 2, \dots)$$

and are solutions of the differential equation

$$y'' - 2xy' + 2ny = 0 \quad (n = 0, 1, 2, \dots)$$

The first few Hermite polynomials are

$$\begin{aligned} H_0 &= 1 & H_1(x) &= 2x \\ H_2(x) &= 4x^2 - 2 & H_3(x) &= 8x^3 - 12x \\ H_4(x) &= 16x^4 - 48x^2 + 12 \end{aligned}$$

Additional Hermite polynomials may be obtained from the relation

$$H_{n+1}(x) = 2xH_n(x) - H'_n(x)$$

where prime denotes differentiation with respect to x .

Orthogonality

A set of functions $\{f_n(x)\} (n = 1, 2, \dots)$ is orthogonal in an interval (a, b) with respect to a given weight function $w(x)$ if

$$\int_a^b w(x) f_m(x) f_n(x) dx = 0 \quad \text{when } m \neq n$$

The following polynomials are orthogonal on the given interval for the given $w(x)$.

Legendre polynomials:

$$P_n(x) w(x) = 1$$

$$a = -1, \quad b = 1$$

Leguerre polynomials:

$$L_n(x) w(x) = \exp(-x)$$

$$a = 0, \quad b = \infty$$

Hermite polynomials:

$$H_n(x) w(x) = \exp(-x^2)$$

$$a = -\infty, \quad b = \infty$$

The Bessel functions of order n , $J_n(\lambda_1 x)$, $J_n(\lambda_2 x)$, \dots , are orthogonal with respect to $w(x) = x$ over the interval $(0, c)$ provided that the λ_i are the positive roots of $J_n(\lambda c) = 0$

$$\int_0^c x J_n(\lambda_j x) J_n(\lambda_k x) dx = 0 \quad (j \neq k)$$

where n is fixed and $n \geq 0$.

Functions with $x^2/a^2 \pm y^2/b^2$

Elliptic Paraboloid (Fig. 23.48)

$$z = c(x^2/a^2 + y^2/b^2)$$

$$x^2/a^2 + y^2/b^2 - z/c = 0$$

Hyperbolic Paraboloid (Commonly Called Saddle) (Fig. 23.49):

$$z = c(x^2/a^2 - y^2/b^2)$$

$$x^2/a^2 - y^2/b^2 - z/c = 0$$

Elliptic Cylinder (Fig. 23.50):

$$1 = x^2/a^2 + y^2/b^2$$

$$x^2/a^2 + y^2/b^2 - 1 = 0$$

FIGURE 23.48 Elliptic paraboloid: (a) $a = 0.5, b = 1.0, c = -1.0$, viewpoint = $(5, -6, 4)$; (b) $a = 1.0, b = 1.0, c = -2.0$, viewpoint = $(5, -6, 4)$.

Elliptic Cone (Circular Cone if $a = b$) (Fig. 23.55)

$$z = c(x^2/a^2 + y^2/b^2)^{1/2}$$

$$x^2/a^2 + y^2/b^2 - z^2/c^2 = 0$$

Hyperboloid of One Sheet (Fig. 23.56)

$$z = c(x^2/a^2 + y^2/b^2 - 1)^{1/2}$$

$$x^2/a^2 + y^2/b^2 - z^2/c^2 - 1 = 0$$

Hyperboloid of Two Sheets (Fig. 23.57)

$$z = c(x^2/a^2 + y^2/b^2 + 1)^{1/2}$$

$$x^2/a^2 + y^2/b^2 - z^2/c^2 + 1 = 0$$

FIGURE 23.57 Hyperboloid of two sheets: (a) $a = 0.125, b = 0.125, c = 0.2, \pm z = c\sqrt{17}$, viewpoint = $(4, -5, 2)$; (b) $a = 0.25, b = 0.25, c = 0.2, \pm z = c\sqrt{17}$, viewpoint = $(4, -5, 2)$.

23.6.8 Basic Definitions: Linear Algebra Matrices

A *matrix* A is a rectangular array of numbers (real or complex):

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1m} \\ a_{21} & a_{22} & \cdots & a_{2m} \\ \vdots & & & \\ a_{n1} & a_{n2} & \cdots & a_{nm} \end{bmatrix}$$

The *size* of the matrix is said to be $n \times m$. The $1 \times m$ matrices $[a_{i1} \ a_{i2} \ \cdots \ a_{im}]$ are called *rows* of A , and the $n \times 1$ matrices

$$\begin{bmatrix} a_{1j} \\ a_{2j} \\ \vdots \\ a_{nj} \end{bmatrix}$$

are called *columns* of A . An $n \times m$ matrix thus consists of n rows and m columns; a_{ij} denotes the *element*, or *entry*, of A in the i th row and j th column. A matrix consisting of just one row is called a *row vector*, whereas a matrix of just one column is called a *column vector*. The elements of a vector are frequently called *components* of the vector. When the size of the matrix is clear from the context, we sometimes write $A = (a_{ij})$.

A matrix with the same number of rows as columns is a *square* matrix, and the number of rows and columns is the *order* of the matrix. The diagonal of an $n \times n$ square matrix A from a_{11} to a_{nn} is called the *main*, or *principal*, *diagonal*. The word *diagonal* with no modifier usually means the main diagonal. The *transpose* of a matrix A is the matrix that results from interchanging the rows and columns of A . It is usually denoted by A^T . A matrix A such that $A = A^T$ is said to be *symmetric*. The *conjugate transpose* of A is the matrix that results from replacing each element of A^T by its complex conjugate, and is usually denoted by A^H . A matrix such that $A = A^H$ is said to be *Hermitian*.

A square matrix $A = (a_{ij})$ is *lower triangular* if $a_{ij} = 0$ for $j > i$ and is *upper triangular* if $a_{ij} = 0$ for $j < i$. A matrix that is both upper and lower triangular is a *diagonal* matrix. The $n \times n$ *identity matrix* is the $n \times n$ diagonal matrix in which each element of the main diagonal is 1. It is traditionally denoted I_n , or simply I when the order is clear from the context.

Algebra of Matrices

The sum and difference of two matrices A and B are defined whenever A and B have the same size. In that case $C = A \pm B$ is defined by $C = (c_{ij}) = (a_{ij} \pm b_{ij})$. The product tA of a scalar t (real or complex number) and a matrix A is defined by $tA = (ta_{ij})$. If A is an $n \times m$ matrix and B is an $m \times p$ matrix, the product $C = AB$ is defined to be the $n \times p$ matrix $C = (c_{ij})$ given by $c_{ij} = \sum_{k=1}^m a_{ik}b_{kj}$. Note that the product of an $n \times m$ matrix and an $m \times p$ matrix is an $n \times p$ matrix, and the product is defined only when the number of columns of the first factor is the same as the number of rows of the second factor. Matrix multiplication is, in general, associative: $A(BC) = (AB)C$. It also distributes over addition (and subtraction):

$$A(B + C) = AB + AC \quad \text{and} \quad (A + B)C = AC + BC$$

It is, however, not in general true that $AB = BA$, even in case both products are defined. It is clear that $(A + B)^T = A^T + B^T$ and $(A + B)^H = A^H + B^H$. It is also true, but not so obvious perhaps, that $(AB)^T = B^T A^T$ and $(AB)^H = B^H A^H$.

The $n \times n$ identity matrix I has the property that $IA = AI = A$ for every $n \times n$ matrix A . If A is square, and if there is a matrix B such that $AB = BA = I$, then B is called the *inverse* of A and is denoted A^{-1} . This terminology and notation are justified by the fact that a matrix can have at most one inverse.

A matrix having an inverse is said to be *invertible*, or *nonsingular*, whereas a matrix not having an inverse is said to be *noninvertible*, or *singular*. The product of two invertible matrices is invertible and, in fact, $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$. The sum of two invertible matrices is, obviously, not necessarily invertible.

Systems of Equations

The system of n linear equations in m unknowns

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 + \cdots + a_{1m}x_m &= b_1 \\ a_{21}x_1 + a_{22}x_2 + a_{23}x_3 + \cdots + a_{2m}x_m &= b_2 \\ &\vdots \\ a_{n1}x_1 + a_{n2}x_2 + a_{n3}x_3 + \cdots + a_{nm}x_m &= b_n \end{aligned}$$

may be written $\mathbf{Ax} = \mathbf{b}$, where $\mathbf{A} = (a_{ij})$, $\mathbf{x} = (x_1 \ x_2 \ \cdots \ x_m)^T$ and $\mathbf{b} = (b_1 \ b_2 \ \cdots \ b_n)^T$. Thus, \mathbf{A} is an $n \times m$ matrix, and \mathbf{x} and \mathbf{b} are column vectors of the appropriate sizes.

The matrix \mathbf{A} is called the *coefficient matrix* of the system. Let us first suppose the coefficient matrix is square; that is, there are an equal number of equations and unknowns. If \mathbf{A} is upper triangular, it is quite easy to find all solutions of the system. The i th equation will contain only the unknowns x_i, x_{i+1}, \dots, x_n , and one simply solves the equations in reverse order: the last equation is solved for x_n ; the result is substituted into the $(n - 1)$ st equation, which is then solved for x_{n-1} ; these values of x_n and x_{n-1} are substituted in the $(n - 2)$ th equation, which is solved for x_{n-2} , and so on. This procedure is known as *back substitution*.

The strategy for solving an arbitrary system is to find an upper-triangular system equivalent with it and solve this upper-triangular system using back substitution. First, suppose the element $a_{11} \neq 0$. We may rearrange the equations to ensure this, unless, of course the first column of \mathbf{A} is all 0s. In this case proceed to the next step, to be described later. For each $i \geq 2$ let $m_{i1} = a_{i1}/a_{11}$. Now replace the i th equation by the result of multiplying the first equation by m_{i1} and subtracting the new equation from the i th equation. Thus

$$a_{i1}x_1 + a_{i2}x_2 + a_{i3}x_3 + \cdots + a_{im}x_m = b_i$$

is replaced by

$$0 \cdot x_1 + (a_{i2} + m_{i1}a_{12})x_2 + (a_{i3} + m_{i1}a_{13})x_3 + \cdots + (a_{im} + m_{i1}a_{1m})x_m = b_i + m_{i1}b_1$$

After this is done for all $i = 2, 3, \dots, n$, there results the equivalent system

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 + \cdots + a_{1n}x_n &= b_1 \\ 0 \cdot x_1 + a'_{22}x_2 + a'_{23}x_3 + \cdots + a'_{2n}x_n &= b'_2 \\ 0 \cdot x_1 + a'_{32}x_2 + a'_{33}x_3 + \cdots + a'_{3n}x_n &= b'_3 \\ &\vdots \\ 0 \cdot x_1 + a'_{n2}x_2 + a'_{n3}x_3 + \cdots + a'_{nn}x_n &= b'_n \end{aligned}$$

in which all entries in the first column below a_{11} are 0. (Note that if all entries in the first column were 0 to begin with, then $a_{11} = 0$ also.) This procedure is now repeated for the $(n - 1) \times (n - 1)$ system

$$\begin{aligned} a'_{22}x_2 + a'_{23}x_3 + \cdots + a'_{2n}x_n &= b'_2 \\ a'_{32}x_2 + a'_{33}x_3 + \cdots + a'_{3n}x_n &= b'_3 \\ &\vdots \\ a'_{n2}x_2 + a'_{n3}x_3 + \cdots + a'_{nn}x_n &= b'_n \end{aligned}$$

to obtain an equivalent system in which all entries of the coefficient matrix below a'_{22} are 0. Continuing, we obtain an upper-triangular system $U\mathbf{x} = \mathbf{c}$ equivalent with the original system. This procedure is known as *Gaussian elimination*. The numbers m_{ij} are known as the *multipliers*.

Essentially the same procedure may be used in case the coefficient matrix is not square. If the coefficient matrix is not square, we may make it square by appending either rows or columns of 0s as needed. Appending rows of 0s and appending 0s to make \mathbf{b} have the appropriate size is equivalent to appending equations $0 = 0$ to the system. Clearly the new system has precisely the same solutions as the original system. Appending columns of 0s and adjusting the size of \mathbf{x} appropriately yields a new system with additional unknowns, each appearing only with coefficient 0, thus not affecting the solutions of the original system. In either case we may assume the coefficient matrix is square, and apply the Gauss elimination procedure.

Suppose the matrix A is invertible. Then if there were no row interchanges in carrying out the above Gauss elimination procedure, we have the *LU factorization* of the matrix A :

$$A = LU$$

where U is the upper-triangular matrix produced by elimination and L is the lower-triangular matrix given by

$$L = \begin{bmatrix} 1 & 0 & \cdots & \cdots & 0 \\ m_{21} & 1 & 0 & \cdots & 0 \\ \vdots & & \ddots & & \\ m_{n1} & m_{n2} & \cdots & & 1 \end{bmatrix}$$

A *permutation* P_{ij} matrix is an $n \times n$ matrix such that $P_{ij}A$ is the matrix that results from exchanging row i and j of the matrix A . The matrix P_{ij} is the matrix that results from exchanging row i and j of the identity matrix. A product P of such matrices P_{ij} is called a *permutation* matrix. If row interchanges are required in the Gauss elimination procedure, then we have the factorization

$$PA = LU$$

where P is the permutation matrix giving the required row exchanges.

Vector Spaces

The collection of all column vectors with n real components is *Euclidean n -space*, and is denoted \mathbf{R}^n . The collection of column vectors with n complex components is denoted \mathbf{C}^n . We shall use *vector space* to mean either \mathbf{R}^n or \mathbf{C}^n . In discussing the space \mathbf{R}^n , the word *scalar* will mean a real number, and in discussing the space \mathbf{C}^n , it will mean a complex number. A subset S of a vector space is a *subspace* such that if \mathbf{u} and \mathbf{v} are vectors in S , and if c is any scalar, then $\mathbf{u} + \mathbf{v}$ and $c\mathbf{u}$ are in S . We shall sometimes use the word *space* to mean a subspace. If $B = \{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k\}$ is a collection of vectors in a vector space, then the set S consisting of all vectors $c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \cdots + c_m\mathbf{v}_m$ for all scalars c_1, c_2, \dots, c_m is a subspace, called the *span* of B . A collection $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ of vectors $c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \cdots + c_m\mathbf{v}_m$ is a *linear combination* of B . If S is a subspace and $B = \{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ is a subset of S such that S is the space of B , then B is said to *span* S .

A collection $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ of n vectors is *linearly dependent* if there exist scalars c_1, c_2, \dots, c_m , not all zero, such that $c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \cdots + c_m\mathbf{v}_m = \mathbf{0}$. A collection of vectors that is not linearly dependent is said to be *linearly independent*. The modifier *linearly* is frequently omitted, and we speak simply of dependent and independent collections. A linearly independent collection of vectors in a space S that spans S is a *basis* of S . Every basis of a space S contains the same number of vectors; this number is the *dimension* of S . The dimension of the space consisting of only the zero vector is 0. The collection $B = \{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n\}$, where $\mathbf{e}_1 = (1, 0, 0, \dots, 0)^T$, $\mathbf{e}_2 = (0, 1, 0, \dots, 0)^T$, and so forth (\mathbf{e}_i has 1 as its i th component and zero for all other components) is a basis for the spaces \mathbf{R}^n and \mathbf{C}^n . This is the *standard basis* for these spaces. The dimension of these spaces is thus n . In a space S of dimension n , no collection of fewer than n vectors can span S , and no collection of more than n vectors in S can be independent.

Rank and Nullity

The *column space* of an $n \times m$ matrix A is the subspace of R^n or C^n spanned by the columns of A . The *row space* is the subspace of R^m or C^m spanned by the rows of A . Note that for any vector $\mathbf{x} = [x_1 x_2 \cdots x_m]^T$

$$\mathbf{Ax} = x_1 \begin{bmatrix} a_{11} \\ a_{21} \\ \vdots \\ a_{n1} \end{bmatrix} + x_2 \begin{bmatrix} a_{12} \\ a_{22} \\ \vdots \\ a_{n2} \end{bmatrix} + \cdots + x_m \begin{bmatrix} a_{1m} \\ a_{2m} \\ \vdots \\ a_{nm} \end{bmatrix}$$

so that the column space is the collection of all vectors \mathbf{Ax} , and thus the system $\mathbf{Ax} = \mathbf{b}$ has a solution if and only if \mathbf{b} is a member of the column space of A .

The dimension of the column space is the *rank* of A . The row space has the same dimension as the column space. The set of all solutions of the system $\mathbf{Ax} = \mathbf{0}$ is a subspace called the *null space* of A , and the dimension of this null space is the *nullity* of A . A fundamental result in matrix theory is the fact that, for an $n \times m$ matrix A

$$\text{rank } A + \text{nullity } A = m$$

The difference of any two solutions of the linear system $\mathbf{Ax} = \mathbf{b}$ is a member of the null space of A . Thus this system has at most one solution if and only if the nullity of A is zero. If the system is square (that is, if A is $n \times n$), then there will be a solution for every right-hand side \mathbf{b} if and only if the collection of columns of A is linearly independent, which is the same as saying the rank of A is n . In this case the nullity must be zero. Thus, for any \mathbf{b} , the square system $\mathbf{Ax} = \mathbf{b}$ has exactly one solution if and only if $\text{rank } A = n$. In other words the $n \times n$ matrix A is invertible if and only if $\text{rank } A = n$.

Orthogonality and Length

The *inner product* of two vectors \mathbf{x} and \mathbf{y} is the scalar $\mathbf{x}^H \mathbf{y}$. The *length*, or *norm*, $\|\mathbf{x}\|$, of the vector \mathbf{x} is given by $\|\mathbf{x}\| = \sqrt{\mathbf{x}^H \mathbf{x}}$. A *unit vector* is a vector of norm 1. Two vectors \mathbf{x} and \mathbf{y} are *orthogonal* if $\mathbf{x}^H \mathbf{y} = 0$. A collection of vectors $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ in a space S is said to be an *orthonormal* collection if $\mathbf{v}_i^H \mathbf{v}_j = 0$ for $i \neq j$ and $\mathbf{v}_i^H \mathbf{v}_i = 1$. An orthonormal collection is necessarily linearly independent. If S is a subspace (or R^n or C^n) spanned by the orthonormal collection $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$, then the *projection* of a vector \mathbf{x} onto S is the vector

$$\text{proj}(\mathbf{x}; S) = (\mathbf{x}^H \mathbf{v}_1) \mathbf{v}_1 + (\mathbf{x}^H \mathbf{v}_2) \mathbf{v}_2 + \cdots + (\mathbf{x}^H \mathbf{v}_m) \mathbf{v}_m$$

The projection of \mathbf{x} onto S minimizes the function $f(\mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|^2$ for $\mathbf{y} \in S$. In other words the projection of \mathbf{x} onto S is the vector in S that is closest to \mathbf{x} .

If \mathbf{b} is a vector and A is an $n \times m$ matrix, then a vector \mathbf{x} minimizes $\|\mathbf{b} - \mathbf{Ax}\|^2$ if and only if it is a solution of $A^H \mathbf{Ax} = A^H \mathbf{b}$. This system of equations is called the *system of normal equations* for the least-squares problem of minimizing $\|\mathbf{b} - \mathbf{Ax}\|^2$.

If A is an $n \times m$ matrix and $\text{rank } A = k$, then there is an $n \times k$ matrix Q whose columns form an orthonormal basis for the column space of A and a $k \times m$ upper-triangular matrix R of rank k such that

$$A = QR$$

This is called the *QR factorization* of A . It now follows that \mathbf{x} minimizes $\|\mathbf{b} - \mathbf{Ax}\|^2$ if and only if it is a solution of the upper-triangular system $R\mathbf{x} = Q^H \mathbf{b}$.

If $\{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_m\}$ is a basis for a space S , the following procedure produces an orthonormal basis $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ for S :

- Set $\mathbf{v}_1 = \mathbf{w}_1 / \|\mathbf{w}_1\|$
- Let $\tilde{\mathbf{v}}_2 = \mathbf{w}_2 - \text{proj}(\mathbf{w}_2; S_1)$, where S_1 is the span of $\{\mathbf{v}_1\}$; set $\mathbf{v}_2 = \tilde{\mathbf{v}}_2 / \|\tilde{\mathbf{v}}_2\|$
- Next, let $\tilde{\mathbf{v}}_3 = \mathbf{w}_3 - \text{proj}(\mathbf{w}_3; S_2)$, where S_2 is the span of $\{\mathbf{v}_1, \mathbf{v}_2\}$; set $\mathbf{v}_3 = \tilde{\mathbf{v}}_3 / \|\tilde{\mathbf{v}}_3\|$.

And so on: $\tilde{\mathbf{v}}_i = \mathbf{w}_i - \text{proj}(\mathbf{w}_i; \mathbf{S}_{i-1})$, where \mathbf{S}_{i-1} is the span of $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{i-1}\}$ set $\mathbf{v}_i = \tilde{\mathbf{v}}_i / \|\tilde{\mathbf{v}}_i\|$. This is the *Gram–Schmidt procedure*.

If the collection of columns of a square matrix is an orthonormal collection, the matrix is called a *unitary matrix*. In case the matrix is a real matrix, it is usually called an *orthogonal matrix*. A unitary matrix \mathbf{U} is invertible, and $\mathbf{U}^{-1} = \mathbf{U}^H$. (In the real case an orthogonal matrix \mathbf{Q} is invertible, and $\mathbf{Q}^{-1} = \mathbf{Q}^T$.)

Determinants

The *determinant* of a square matrix is defined inductively. First, suppose the determinant $\det \mathbf{A}$ has been defined for all square matrices of order $< n$. Then

$$\det \mathbf{A} = a_{11}C_{11} + a_{12}C_{12} + \dots + a_{1n}C_{1n}$$

where the numbers C_{ij} are *cofactors* of the matrix \mathbf{A}

$$C_{ij} = (-1)^{i+j} \det \mathbf{M}_{ij}$$

where \mathbf{M}_{ij} is the $(n-1) \times (n-1)$ matrix obtained by deleting the i th row and j th column of \mathbf{A} . Now $\det \mathbf{A}$ is defined to be the only entry of a matrix of order 1. Thus, for a matrix of order 2, we have

$$\det \begin{bmatrix} a & b \\ c & d \end{bmatrix} = ad - bc$$

There are many interesting but not obvious properties of determinants. It is true that

$$\det \mathbf{A} = a_{i1}C_{i1} + a_{i2}C_{i2} + \dots + a_{in}C_{in}$$

for any $1 \leq i \leq n$. It is also true that $\det \mathbf{A} = \det \mathbf{A}^T$, so that we have

$$\det \mathbf{A} = a_{1j}C_{1j} + a_{2j}C_{2j} + \dots + a_{nj}C_{nj}$$

for any $1 \leq j \leq n$.

If \mathbf{A} and \mathbf{B} are matrices of the same order, then $\det \mathbf{AB} = (\det \mathbf{A})(\det \mathbf{B})$, and the determinant of any identity matrix is 1. Perhaps the most important property of the determinant is the fact that a matrix is invertible if and only if its determinant is not zero.

Eigenvalues and Eigenvectors

If \mathbf{A} is a square matrix, and $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ for a scalar λ and a nonzero \mathbf{v} , then λ is an *eigenvalue* of \mathbf{A} and \mathbf{v} is an *eigenvector* of \mathbf{A} that *corresponds* to λ . Any nonzero linear combination of eigenvectors corresponding to the same eigenvalue λ is also an eigenvector corresponding to λ . The collection of all eigenvectors corresponding to a given eigenvalue λ is thus a subspace, called an *eigenspace* of \mathbf{A} . A collection of eigenvectors corresponding to different eigenvalues is necessarily linear independent. It follows that a matrix of order n can have at most n distinct eigenvectors. In fact, the eigenvalues of \mathbf{A} are the roots of the n th degree polynomial equation

$$\det(\mathbf{A} - \lambda\mathbf{I}) = 0$$

called the *characteristic equation* of \mathbf{A} . (Eigenvalues and eigenvectors are frequently called *characteristic values* and *characteristic vectors*.)

If the n th order matrix \mathbf{A} has an independent collection of n eigenvectors, then \mathbf{A} is said to have a *full set* of eigenvectors. In this case there is a set of eigenvectors of \mathbf{A} that is a basis for \mathbf{R}^n or, in the complex case, \mathbf{C}^n . In case there are n distinct eigenvalues of \mathbf{A} , then, of course, \mathbf{A} has a full set of eigenvectors. If there are fewer than n distinct eigenvalues, then \mathbf{A} may or may not have a full set of eigenvectors. If there is a full set of eigenvectors, then

$$\mathbf{D} = \mathbf{S}^{-1} \mathbf{A} \mathbf{S} \quad \text{or} \quad \mathbf{A} = \mathbf{S} \mathbf{D} \mathbf{S}^{-1}$$

where D is a diagonal matrix the eigenvalues of A on the diagonal, and S is a matrix whose columns are the full set of eigenvectors. If A is symmetric, there are n real distinct eigenvalues of A and the corresponding eigenvectors are orthogonal. There is thus an orthonormal collection of eigenvectors that span R^n , and we have

$$A = Q D Q^T \quad \text{and} \quad D = Q^T A Q$$

where Q is a real orthogonal matrix and D is diagonal. For the complex case, if A is Hermitian, we have

$$A = U D U^H \quad \text{and} \quad D = U^H A U$$

where U is a unitary matrix and D is a *real* diagonal matrix. (A Hermitian matrix also has n distinct real eigenvalues.)

23.6.9 Basic Definitions: Vector Algebra and Calculus

A vector is a directed line segment, with two vectors being equal if they have the same length and the same direction. More precisely, a *vector* is an equivalence class of directed line segments, where two directed segments are equivalent if they have the same length and the same direction. The *length* of a vector is the common length of its directed segments, and the *angle between* vectors is the angle between any of their segments. The length of a vector \mathbf{u} is denoted $|\mathbf{u}|$. There is defined a distinguished vector having zero length, which is usually denoted $\mathbf{0}$. It is frequently useful to visualize a directed segment as an arrow; we then speak of the nose and the tail of the segment. The *sum* $\mathbf{u} + \mathbf{v}$ of two vectors \mathbf{u} and \mathbf{v} is defined by taking directed segments from \mathbf{u} and \mathbf{v} and placing the tail of the segment representing \mathbf{v} at the nose of the segment representing \mathbf{u} and defining $\mathbf{u} + \mathbf{v}$ to be the vector determined by the segment from the tail of the \mathbf{u} representative to the nose of the \mathbf{v} representative. It is easy to see that $\mathbf{u} + \mathbf{v}$ is well defined and that $\mathbf{u} + \mathbf{v} = \mathbf{v} + \mathbf{u}$. Subtraction is the inverse operation of addition. Thus the *difference* $\mathbf{u} - \mathbf{v}$ of two vectors is defined to be the vector that when added to \mathbf{v} gives \mathbf{u} . In other words, if we take a segment from \mathbf{u} and a segment from \mathbf{v} and place their tails together, the difference is the segment from the nose of \mathbf{v} to the nose of \mathbf{u} . The zero vector behaves as one might expect: $\mathbf{u} + \mathbf{0} = \mathbf{u}$, and $\mathbf{u} - \mathbf{u} = \mathbf{0}$. Addition is associative: $\mathbf{u} + (\mathbf{v} + \mathbf{w}) = (\mathbf{u} + \mathbf{v}) + \mathbf{w}$.

To distinguish them from vectors, the real numbers are called *scalars*. The product $t\mathbf{u}$ of a scalar t and a vector \mathbf{u} is defined to be the vector having length $|t| |\mathbf{u}|$ and direction the same as \mathbf{u} if $t > 0$, the opposite direction if $t < 0$. If $t = 0$, then $t\mathbf{u}$ is defined to be the zero vector. Note that $t(\mathbf{u} + \mathbf{v}) = t\mathbf{u} + t\mathbf{v}$, and $(t + s)\mathbf{u} = t\mathbf{u} + s\mathbf{u}$. From this it follows that $\mathbf{u} - \mathbf{v} = \mathbf{u} + (-1)\mathbf{v}$.

The *scalar product* $\mathbf{u} \cdot \mathbf{v}$ of two vectors is $|\mathbf{u}| |\mathbf{v}| \cos \theta$, where θ is the angle between \mathbf{u} and \mathbf{v} . The scalar product is frequently called the *dot product*. The scalar product distributes over addition

$$\mathbf{u} \cdot (\mathbf{v} + \mathbf{w}) = \mathbf{u} \cdot \mathbf{v} + \mathbf{u} \cdot \mathbf{w}$$

and it is clear that $(t\mathbf{u}) \cdot \mathbf{v} = t(\mathbf{u} \cdot \mathbf{v})$. The *vector product* $\mathbf{u} \times \mathbf{v}$ of two vectors is defined to be the vector perpendicular to both \mathbf{u} and \mathbf{v} and having length $|\mathbf{u}| |\mathbf{v}| \sin \theta$, where θ is the angle between \mathbf{u} and \mathbf{v} . The direction of $\mathbf{u} \times \mathbf{v}$ is the direction a right-hand threaded bolt advances if the vector \mathbf{u} is rotated to \mathbf{v} . The vector product is frequently called the *cross product*. The vector product is both associative and distributive, but not commutative: $\mathbf{u} \times \mathbf{v} = -\mathbf{v} \times \mathbf{u}$.

Coordinate Systems

Suppose we have a right-handed Cartesian coordinate system in space. For each vector \mathbf{u} , we associate a point in space by placing the tail of a representative of \mathbf{u} at the origin and associating with \mathbf{u} the point at the nose of the segment. Conversely, associated with each point in space is the vector determined by the directed segment from the origin to that point. There is thus a one-to-one correspondence between the points in space and all vectors. The origin corresponds to the zero vector. The coordinates of the point associated with a vector \mathbf{u} are called *coordinates* of \mathbf{u} . One frequently refers to the vector \mathbf{u} and writes

$\mathbf{u} = (x, y, z)$, which is, strictly speaking, incorrect, because the left side of this equation is a vector and the right side gives the coordinates of a point in space. What is meant is that (x, y, z) are the coordinates of the point associated with \mathbf{u} under the correspondence described. In terms of coordinates, for $\mathbf{u} = (u_1, u_2, u_3)$ and $\mathbf{v} = (v_1, v_2, v_3)$, we have

$$\begin{aligned}\mathbf{u} + \mathbf{v} &= (u_1 + v_1, u_2 + v_2, u_3 + v_3) \\ t\mathbf{u} &= (tu_1, tu_2, tu_3) \\ \mathbf{u} \cdot \mathbf{v} &= u_1v_1 + u_2v_2 + u_3v_3 \\ \mathbf{u} \times \mathbf{v} &= (u_2v_3 - v_2u_3, u_3v_1 - v_3u_1, u_1v_2 - v_1u_2)\end{aligned}$$

The *coordinate vectors* \mathbf{i} , \mathbf{j} , and \mathbf{k} are the unit vectors $\mathbf{i} = (1, 0, 0)$, $\mathbf{j} = (0, 1, 0)$, and $\mathbf{k} = (0, 0, 1)$. Any vector $\mathbf{u} = (u_1, u_2, u_3)$ is thus a linear combination of these coordinate vectors: $\mathbf{u} = u_1\mathbf{i} + u_2\mathbf{j} + u_3\mathbf{k}$. A convenient form for the vector product is the formal determinant

$$\mathbf{u} \times \mathbf{v} = \det \begin{bmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ u_1 & u_2 & u_3 \\ v_1 & v_2 & v_3 \end{bmatrix}$$

Vector Functions

A *vector function* \mathbf{F} of one variable is a rule that associates a vector $\mathbf{F}(t)$ with each real number t in some set, called the *domain* of \mathbf{F} . The expression $\lim_{t \rightarrow t_0} \mathbf{F}(t) = \mathbf{a}$ means that for any $\varepsilon > 0$, there is a $\delta > 0$ such that $|\mathbf{F}(t) - \mathbf{a}| < \varepsilon$ whenever $0 < |t - t_0| < \delta$. If $\mathbf{F}(t) = (x(t), y(t), z(t))$ and $\mathbf{a} = (a_1, a_2, a_3)$, then $\lim_{t \rightarrow t_0} \mathbf{F}(t) = \mathbf{a}$ if and only if

$$\begin{aligned}\lim_{t \rightarrow t_0} x(t) &= a_1 \\ \lim_{t \rightarrow t_0} y(t) &= a_2 \\ \lim_{t \rightarrow t_0} z(t) &= a_3\end{aligned}$$

A vector function \mathbf{F} is *continuous* at t_0 if $\lim_{t \rightarrow t_0} \mathbf{F}(t) = \mathbf{F}(t_0)$. The vector function \mathbf{F} is continuous at t_0 if and only if each of the coordinates $x(t)$, $y(t)$, and $z(t)$ is continuous at t_0 .

The function \mathbf{F} is *differentiable* at t_0 if the limit

$$\lim_{h \rightarrow 0} \frac{1}{h} (\mathbf{F}(t+h) - \mathbf{F}(t))$$

exists. This limit is called the *derivative* of \mathbf{F} at t_0 and is usually written $\mathbf{F}'(t_0)$, or $(d\mathbf{F}/dt)(t_0)$. The vector function \mathbf{F} is differentiable at t_0 if and only if each of its coordinate functions is differentiable at t_0 . Moreover, $(d\mathbf{F}/dt)(t_0) = ((dx/dt)(t_0), (dy/dt)(t_0), (dz/dt)(t_0))$. The usual rules for derivatives of real valued functions all hold for vector functions. Thus, if \mathbf{F} and \mathbf{G} are vector functions and s is a scalar function, then

$$\begin{aligned}\frac{d}{dt}(\mathbf{F} + \mathbf{G}) &= \frac{d\mathbf{F}}{dt} + \frac{d\mathbf{G}}{dt} \\ \frac{d}{dt}(s\mathbf{F}) &= s \frac{d\mathbf{F}}{dt} + \frac{ds}{dt} \mathbf{F} \\ \frac{d}{dt}(\mathbf{F} \cdot \mathbf{G}) &= \mathbf{F} \cdot \frac{d\mathbf{G}}{dt} + \frac{d\mathbf{F}}{dt} \cdot \mathbf{G} \\ \frac{d}{dt}(\mathbf{F} \times \mathbf{G}) &= \mathbf{F} \times \frac{d\mathbf{G}}{dt} + \frac{d\mathbf{F}}{dt} \times \mathbf{G}\end{aligned}$$

If \mathbf{R} is a vector function defined for t is some interval, then, as t varies, with the tail of \mathbf{R} at the origin, the nose traces out some object C in space. For nice functions \mathbf{R} , the object C is a *curve*. If $\mathbf{R}(t) = [x(t), y(t), z(t)]$, then the equations

$$\begin{aligned} x &= x(t) \\ y &= y(t) \\ z &= z(t) \end{aligned}$$

are called *parametric equations of C*. At points where \mathbf{R} is differentiable, the derivative $d\mathbf{R}/dt$ is a vector *tangent* to the curve. The unit vector $\mathbf{T} = (d\mathbf{R}/dt)/|d\mathbf{R}/dt|$ is called the *unit tangent vector*. If \mathbf{R} is differentiable and if the length of the arc of curve described by \mathbf{R} between $\mathbf{R}(a)$ and $\mathbf{R}(t)$ is given by $s(t)$, then

$$\frac{ds}{dt} = \left| \frac{d\mathbf{R}}{dt} \right|$$

Thus the length L of the arc from $\mathbf{R}(t_0)$ to $\mathbf{R}(t_1)$ is

$$L = \int_{t_0}^{t_1} \frac{ds}{dt} dt = \int_{t_0}^{t_1} \left| \frac{d\mathbf{R}}{dt} \right| dt$$

The vector $d\mathbf{T}/ds = (d\mathbf{T}/dt)/(ds/dt)$ is perpendicular to the unit tangent \mathbf{T} , and the number $\kappa = |d\mathbf{T}/ds|$ is the *curvature* of C . The unit vector $\mathbf{N} = (1/\kappa)(d\mathbf{T}/ds)$ is the *principal normal*. The vector $\mathbf{B} = \mathbf{T} \times \mathbf{N}$ is the *binormal*, and $d\mathbf{B}/ds = -\tau\mathbf{N}$. The number τ is the *torsion*. Note that C is a plane curve if and only if τ is zero for all t .

A *vector function F of two variables* is a rule that assigns a vector $\mathbf{F}(s, t)$ to each point (s, t) which is some subset of the plane, called the *domain* of \mathbf{F} . If $\mathbf{R}(s, t)$ is defined for all (s, t) in some region D of the plane, then as the point (s, t) varies over D , with its tail at the origin, the nose of $\mathbf{R}(s, t)$ traces out an object in space. For a nice function \mathbf{R} , this object is a *surface, S*. The partial derivatives $(\partial\mathbf{R}/\partial s)(s, t)$ and $(\partial\mathbf{R}/\partial t)(s, t)$ are tangent to the surface at $\mathbf{R}(s, t)$ and the vector $(\partial\mathbf{R}/\partial s) \times (\partial\mathbf{R}/\partial t)$ is thus *normal* to the surface. Of course, $(\partial\mathbf{R}/\partial t) \times (\partial\mathbf{R}/\partial s) = -(\partial\mathbf{R}/\partial s) \times (\partial\mathbf{R}/\partial t)$ is also normal to the surface and points in the direction opposite that of $(\partial\mathbf{R}/\partial s) \times (\partial\mathbf{R}/\partial t)$. By electing one of these normals, we are choosing an *orientation* of the surface. A surface can be oriented only if it has two sides, and the process of orientation consists of choosing which side is positive and which is negative.

Gradient, Curl, and Divergence

If $f(x, y, z)$ is a scalar field defined in some region D , the *gradient* of f is the vector function

$$\text{grad } f = \frac{\partial f}{\partial x} \mathbf{i} + \frac{\partial f}{\partial y} \mathbf{j} + \frac{\partial f}{\partial z} \mathbf{k}$$

If $\mathbf{F}(x, y, z) = F_1(x, y, z)\mathbf{i} + F_2(x, y, z)\mathbf{j} + F_3(x, y, z)\mathbf{k}$ is a vector field defined in some region D , then the *divergence* of \mathbf{F} is the scalar function

$$\text{div } \mathbf{F} = \frac{\partial F_1}{\partial x} + \frac{\partial F_2}{\partial y} + \frac{\partial F_3}{\partial z}$$

The curl is the vector function

$$\text{curl } \mathbf{F} = \left(\frac{\partial F_3}{\partial y} - \frac{\partial F_2}{\partial z} \right) \mathbf{i} + \left(\frac{\partial F_1}{\partial z} - \frac{\partial F_3}{\partial x} \right) \mathbf{j} + \left(\frac{\partial F_2}{\partial x} - \frac{\partial F_1}{\partial y} \right) \mathbf{k}$$

In terms of the vector operator *del*, $\nabla = \mathbf{i}(\partial/\partial x) + \mathbf{j}(\partial/\partial y) + \mathbf{k}(\partial/\partial z)$, we can write

$$\text{grad } f = \nabla f$$

$$\text{div } \mathbf{F} = \nabla \cdot \mathbf{F}$$

$$\text{curl } \mathbf{F} = \nabla \times \mathbf{F}$$

The *Laplacian operator* is $\text{div}(\text{grad}) = \nabla \cdot \nabla = \nabla^2 = (\partial^2/\partial x^2) + (\partial^2/\partial y^2) + (\partial^2/\partial z^2)$.

Integration

Suppose C is a curve from the point (x_0, y_0, z_0) to the point (x_1, y_1, z_1) and is described by the vector function $\mathbf{R}(t)$ for $t_0 \leq t \leq t_1$. If f is a scalar function (sometimes called a *scalar field*) defined on C , then the integral of f over C is

$$\int_C f(x, y, z) ds = \int_{t_0}^{t_1} f[\mathbf{R}(t)] \left| \frac{d\mathbf{R}}{dt} \right| dt$$

If \mathbf{F} is a vector function (sometimes called a *vector field*) defined on C , then the integral of \mathbf{F} over C is

$$\int_C \mathbf{F}(x, y, z) \cdot d\mathbf{R} = \int_{t_0}^{t_1} \mathbf{F}[\mathbf{R}(t)] \cdot \frac{d\mathbf{R}}{dt} dt$$

These integrals are called *line integrals*.

In case there is a scalar function f such that $\mathbf{F} = \text{grad } f$, then the line integral

$$\int_C \mathbf{F}(x, y, z) \cdot d\mathbf{R} = f(\mathbf{R}(t_1)) - f(\mathbf{R}(t_0))$$

The value of the integral thus depends only on the end points of the curve C and not on the curve C itself. The integral is said to be *path independent*. The function f is called a *potential function* for the vector field \mathbf{F} , and \mathbf{F} is said to be a *conservative field*. A vector field \mathbf{F} with domain D is conservative if and only if the integral of \mathbf{F} around every closed curve in D is zero. If the domain D is simply connected (that is, every closed curve in D can be continuously deformed in D to a point), then \mathbf{F} is conservative if and only if $\text{curl } \mathbf{F} = 0$ in D .

Suppose S is a surface described by $\mathbf{R}(s, t)$ for (s, t) in a region D of the plane. If f is a scalar function defined on D , then the integral of f over S is given by

$$\int_S f(x, y, z) dS = \int_D \int_D f(\mathbf{R}(s, t)) \left| \frac{\partial \mathbf{R}}{\partial s} \times \frac{\partial \mathbf{R}}{\partial t} \right| ds dt$$

If \mathbf{F} is a vector function defined on S , and if an orientation for S is chosen, then the integral of \mathbf{F} over S , sometimes called the *flux* of \mathbf{F} through S , is

$$\int_S \mathbf{F}(x, y, z) \cdot d\mathbf{S} = \int_D \int_D \mathbf{F}[\mathbf{R}(s, t)] \cdot \left(\frac{\partial \mathbf{R}}{\partial s} \times \frac{\partial \mathbf{R}}{\partial t} \right) ds dt$$

Integral Theorems

Suppose \mathbf{F} is a vector field with a closed domain D bounded by the surface S oriented so that the normal points out from D . Then the *divergence theorem* states that

$$\int_D \int_D \int_D \text{div } \mathbf{F} dV = \int_S \mathbf{F} \cdot d\mathbf{S}$$

If S is an orientable surface bounded by a closed curve C , the orientation of the closed curve C is chosen to be consistent with the orientation of the surface S . Then we have *Stokes's theorem*:

$$\int_S \int (\text{curl } \mathbf{F}) \cdot \mathbf{dS} = \oint_C \mathbf{F} \cdot \mathbf{ds}$$

23.6.10 The Fourier Transforms: Overview

For a piecewise continuous function $F(x)$ over a finite interval $0 \leq x \leq \pi$, the *finite Fourier cosine transform* of $F(x)$ is

$$f_c(n) = \int_0^\pi f(x) \cos nx \, dx \quad (n = 0, 1, 2, \dots) \tag{23.1}$$

If x ranges over the interval $0 \leq x \leq L$, the substitution $x' = \pi x/L$ allows the use of this definition also. The inverse transform is written

$$\bar{F}(x) = \frac{1}{\pi} f_c(0) + \frac{2}{\pi} \sum_{n=1}^\infty f_c(n) \cos nx \quad (0 < x < \pi) \tag{23.2}$$

where $\bar{F}(x) = (F(x+0) + F(x-0))/2$. We observe that $\bar{F}(x) = F(x)$ at points of continuity. The formula

$$\begin{aligned} f_c^{(2)}(n) &= \int_0^\pi F''(x) \cos nx \, dx \\ &= -n^2 f_c(n) - F'(0) + (-1)^n F'(\pi) \end{aligned} \tag{23.3}$$

makes the finite Fourier cosine transform useful in certain boundary-value problems.

Analogously, the *finite Fourier sine transform* of $F(x)$ is

$$f_s(n) = \int_0^\pi F(x) \sin nx \, dx \quad (n = 1, 2, 3, \dots) \tag{23.4}$$

and

$$\bar{F}(x) = \frac{2}{\pi} \sum_{n=1}^\infty f_s(n) \sin nx \quad (0 < x < \pi) \tag{23.5}$$

Corresponding to Eq. (23.3), we have

$$\begin{aligned} f_s^{(2)}(n) &= \int_0^\pi F''(x) \sin nx \, dx \\ &= -n^2 f_s(n) - nF(0) - n(-1)^n F(\pi) \end{aligned} \tag{23.6}$$

Fourier Transforms

If $F(x)$ is defined for $x \geq 0$ and is piecewise continuous over any finite interval, and if

$$\int_0^\infty F(x) \, dx$$

is absolutely convergent, then

$$f_c(\alpha) = \sqrt{\frac{2}{\pi}} \int_0^\infty f(x) \cos(\alpha x) \, dx \tag{23.7}$$

is the *Fourier cosine transform* of $F(x)$. Furthermore

$$\bar{F}(x) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f_c(\alpha) \cos(\alpha x) d\alpha \quad (23.8)$$

If $\lim_{x \rightarrow \infty} d^n F / dx^n = 0$, an important property of the Fourier cosine transform

$$\begin{aligned} f_c^{(2r)}(\alpha) &= \sqrt{\frac{2}{\pi}} \int_0^{\infty} \left(\frac{d^{2r} F}{dx^{2r}} \right) \cos(\alpha x) dx \\ &= -\sqrt{\frac{2}{\pi}} \sum_{n=0}^{r-1} (-1)^n a_{2r-2n-1} \alpha^{2n} + (-1)^r \alpha^{2r} f_c(\alpha) \end{aligned} \quad (23.9)$$

where $\lim_{x \rightarrow 0} d^r F / dx^r = a_r$, makes it useful in the solution of many problems.

Under the same conditions

$$f_s(\alpha) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} F(x) \sin(\alpha x) dx \quad (23.10)$$

defines the *Fourier sine transform* of $F(x)$, and

$$\bar{F}(x) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f_s(\alpha) \sin(\alpha x) d\alpha \quad (23.11)$$

Corresponding to Eq. (23.9) we have

$$\begin{aligned} f_s^{(2r)}(\alpha) &= \sqrt{\frac{2}{\pi}} \int_0^{\infty} \frac{d^{2r} F}{dx^{2r}} \sin(\alpha x) dx \\ &= -\sqrt{\frac{2}{\pi}} \sum_{n=1}^r (-1)^n \alpha^{2n-1} a_{2r-2n} + (-1)^{r-1} \alpha^{2r} f_s(\alpha) \end{aligned} \quad (23.12)$$

Similarly, if $F(x)$ is defined for $-\infty < x < \infty$, and if $\int_{-\infty}^{\infty} F(x) dx$ is absolutely convergent, then

$$f(\alpha) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} F(x) e^{i\alpha x} dx \quad (23.13)$$

is the *Fourier transform* of $F(x)$, and

$$\bar{F}(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(\alpha) e^{-i\alpha x} d\alpha \quad (23.14)$$

Also, if

$$\lim_{|x| \rightarrow \infty} \left| \frac{d^n F}{dx^n} \right| = 0 \quad (n = 1, 2, \dots, r-1)$$

then

$$f^{(r)}(\alpha) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} F^{(r)}(x) e^{i\alpha x} dx = (-i\alpha)^r f(\alpha) \quad (23.15)$$

The finite and fourier transforms for sine and cosine are given in Table 23.3 to Table 23.6. The fourier transforms for other function are given in Table 23.7.

1. $\begin{cases} 1 & (0 < x < a) \\ 0 & (x < a) \end{cases}$	$\sqrt{\frac{2}{\pi}} \frac{\sin a\alpha}{\alpha}$
2. $x^{p-1} \quad (0 < p < 1)$	$\sqrt{\frac{2}{\pi}} \frac{\Gamma(p)}{\alpha^p} \cos \frac{p\pi}{2}$
3. $\begin{cases} \cos x & (0 < x < a) \\ 0 & (x > a) \end{cases}$	$\frac{1}{\sqrt{2\pi}} \left[\frac{\sin[a(1-\alpha)]}{1-\alpha} + \frac{\sin[a(1+\alpha)]}{1+\alpha} \right]$
4. e^{-x}	$\sqrt{\frac{2}{\pi}} \left(\frac{1}{1+\alpha^2} \right)$
5. $e^{-x^2/2}$	$e^{-\alpha^2/2}$
6. $\cos \frac{x^2}{2}$	$\cos \left(\frac{\alpha^2}{2} - \frac{\pi}{4} \right)$
7. $\sin \frac{x^2}{2}$	$\cos \left(\frac{\alpha^2}{2} - \frac{\pi}{4} \right)$

TABLE 23.7 Fourier Transforms

$F(x)$	$f(\alpha)$
1. $\frac{\sin ax}{x}$	$\begin{cases} \sqrt{\frac{\pi}{2}} & \alpha < a \\ 0 & \alpha > a \end{cases}$
2. $\begin{cases} e^{iwx} & (p < x < q) \\ 0 & (x < p, x > q) \end{cases}$	$\frac{i}{\sqrt{2\pi}} \frac{e^{ip(w+\alpha)} - e^{iq(w+\alpha)}}{(w+\alpha)}$
3. $\begin{cases} e^{-cx+iwx} & (x > 0) \\ & (c > 0) \\ 0 & (x < 0) \end{cases}$	$\frac{i}{\sqrt{2\pi}(w+\alpha+ic)}$
4. $e^{-px^2} \quad R(p) > 0$	$\frac{1}{\sqrt{2p}} e^{-\alpha^2/4p}$
5. $\cos px^2$	$\frac{1}{\sqrt{2p}} \cos \left[\frac{\alpha^2}{4p} - \frac{\pi}{4} \right]$
6. $\sin px^2$	$\frac{1}{\sqrt{2p}} \cos \left[\frac{\alpha^2}{4p} + \frac{\pi}{4} \right]$
7. $ x ^{-p} \quad (0 < p < 1)$	$\sqrt{\frac{2}{\pi}} \frac{\Gamma(1-p) \sin \frac{p\pi}{2}}{ \alpha ^{(1-p)}}$
8. $\frac{e^{-a x }}{\sqrt{ x }}$	$\frac{\sqrt{\sqrt{(a^2+\alpha^2)}+a}}{\sqrt{a^2+\alpha^2}}$
9. $\frac{\cosh ax}{\cosh \pi x} \quad (-\pi < a < \pi)$	$\sqrt{\frac{2}{\pi}} \frac{\cos \frac{a}{2} \cosh \frac{\alpha}{2}}{\cosh \alpha + \cos a}$
10. $\frac{\sinh ax}{\sinh \pi x} \quad (-\pi < a < \pi)$	$\frac{1}{\sqrt{2\pi}} \frac{\sin a}{\cosh \alpha + \cos a}$
11. $\begin{cases} \frac{1}{\sqrt{a^2-x^2}} & (x < a) \\ 0 & (x > a) \end{cases}$	$\sqrt{\frac{\pi}{2}} J_0(a\alpha)$

TABLE 23.7 Fourier Transforms (*Continued*)

$F(x)$	$f(\alpha)$
12. $\frac{\sin[b\sqrt{a^2+x^2}]}{\sqrt{a^2+x^2}}$	$\begin{cases} 0 & (\alpha > b) \\ \sqrt{\frac{\pi}{2}} J_0(a\sqrt{b^2-\alpha^2}) & (\alpha < b) \end{cases}$
13. $\begin{cases} P_n(x) & (x < 1) \\ 0 & (x > 1) \end{cases}$	$\frac{i^n}{\sqrt{\alpha}} J_{n+1/2}(\alpha)$
14. $\begin{cases} \frac{\cos[b\sqrt{a^2-x^2}]}{\sqrt{a^2-x^2}} & (x < a) \\ 0 & (x > a) \end{cases}$	$\sqrt{\frac{\pi}{2}} J_0(a\sqrt{a^2+b^2})$
15. $\begin{cases} \frac{\cos h[b\sqrt{a^2-x^2}]}{\sqrt{a^2-x^2}} & (x < a) \\ 0 & (x > a) \end{cases}$	$\sqrt{\frac{\pi}{2}} J_0(a\sqrt{a^2-b^2})$

TABLE 23.8 Functions Among Transforms Tables Entries

Function	Definition	Name
$Ei(x)$	$\int_{-\infty}^x \frac{e^v}{v} dv$; or sometimes defined as $-Ei(-x) = \int_x^{\infty} \frac{e^{-v}}{v} dv$	Exponential integral function
$Si(x)$	$\int_0^x \frac{\sin v}{v} dv$	Sine integral function
$Ci(x)$	$\int_{\infty}^x \frac{\cos v}{v} dv$; or sometimes defined as negative of this integral	Cosine integral function
$erf(x)$	$\frac{2}{\sqrt{\pi}} \int_0^x e^{-v^2} dv$	Error function
$erfc(x)$	$1 - erf(x) = \frac{2}{\pi} \int_x^{\infty} e^{-v^2} dv$	Complementary function to error function
$L_n(x)$	$\frac{e^x}{n!} \frac{d^n}{dx^n} (x^n e^{-x})$, $n = 0, 1, \dots$	Laguerre polynomial of degree n

23.7 Glossary of Terms

Jerry C. Whitaker

A

Absolute delay: The amount of time a signal is delayed. The delay may be expressed in time or number of pulse events.

Absolute zero: The lowest temperature theoretically possible, -273.16°C . *Absolute zero* is equal to zero degrees Kelvin.

Absorption: The transference of some or all of the energy contained in an electromagnetic wave to the substance or medium in which it is propagating or upon which it is incident.

Absorption auroral: The loss of energy in a radio wave passing through an area affected by solar auroral activity.

Ac coupling: A method of coupling one circuit to another through a capacitor or transformer so as to transmit the varying (ac) characteristics of the signal while blocking the static (dc) characteristics.

Ac/dc coupling: Coupling between circuits that accommodates the passing of both ac and dc signals (may also be referred to as simply dc coupling).

Accelerated life test: A special form of reliability testing performed by an equipment manufacturer. The unit under test is subjected to stresses that exceed those typically experienced in normal operation. The goal of an *accelerated life test* is to improve the reliability of products shipped by forcing latent failures in components to become evident before the unit leaves the factory.

Accelerating electrode: The electrode that causes electrons emitted from an electron gun to accelerate in their journey to the screen of a cathode ray tube.

Accelerating voltage: The voltage applied to an electrode that accelerates a beam of electrons or other charged particles.

Acceptable reliability level: The maximum number of failures allowed per thousand operating hours of a given component or system.

Acceptance test: The process of testing newly purchased equipment to ensure that it is fully compliant with contractual specifications.

Access: The point at which entry is gained to a circuit or facility.

Acquisition time: In a communication system, the amount of time required to attain synchronism.

Active: Any device or circuit that introduces gain or uses a source of energy other than that inherent in the signal to perform its function.

Adapter: A fitting or electrical connector that links equipment that cannot be connected directly.

Adaptive: A device able to adjust or react to a condition or application, as an *adaptive circuit*. This term usually refers to filter circuits.

Adaptive system: A general name for a system that is capable of reconfiguring itself to meet new requirements.

Adder: A device the output of which represents the sum of its inputs.

Adjacent channel interference: Interference to communications caused by a transmitter operating on an adjacent radio channel. The sidebands of the transmitter mix with the carrier being received on the desired channel, resulting in noise.

Admittance: A measure of how well alternating current flows in a conductor. It is the reciprocal of *impedance* and is expressed in *siemens*. The real part of admittance is *conductance*; the imaginary part is *susceptance*.

AFC (automatic frequency control): A circuit that automatically keeps an oscillator on frequency by comparing the output of the oscillator with a standard frequency source or signal.

Air core: An inductor with no magnetic material in its core.

Algorithm: A prescribed finite set of well-defined rules or processes for the solution of a problem in a finite number of steps.

- Alignment:** The adjustment of circuit components so that an entire system meets minimum performance values. For example, the stages in a radio are aligned to ensure proper reception.
- Allocation:** The planned use of certain facilities and equipment to meet current, pending, and/or forecasted circuit- and carrier-system requirements.
- Alternating current (ac):** A continuously variable current, rising to a maximum in one direction, falling to zero, then reversing direction and rising to a maximum in the other direction, then falling to zero and repeating the cycle. Alternating current usually follows a sinusoidal growth and decay curve. Note that the correct usage of the term *ac* is lower case.
- Alternator:** A generator that produces alternating current electric power.
- Ambient electromagnetic environment:** The radiated or conducted electromagnetic signals and noise at a specific location and time.
- Ambient level:** The magnitude of radiated or conducted electromagnetic signals and noise at a specific test location when equipment-under-test is not powered.
- Ambient temperature:** The temperature of the surrounding medium, typically air, that comes into contact with an apparatus. Ambient temperature may also refer simply to room temperature.
- American National Standards Institute (ANSI):** A nonprofit organization that coordinates voluntary standards activities in the U.S.
- American Wire Gauge (AWG):** The standard American method of classifying wire diameter.
- Ammeter:** An instrument that measures and records the amount of current in amperes flowing in a circuit.
- Amp (A):** An abbreviation of the term *ampere*.
- Ampacity:** A measure of the current carrying capacity of a power cable. *Ampacity* is determined by the maximum continuous-performance temperature of the insulation, by the heat generated in the cable (as a result of conductor and insulation losses), and by the heat-dissipating properties of the cable and its environment.
- Ampere (amp):** The standard unit of electric current.
- Ampere per meter:** The standard unit of magnetic field strength.
- Ampere-hour:** The energy that is consumed when a current of one ampere flows for a period of one hour.
- Ampere-turns:** The product of the number of turns of a coil and the current in amperes flowing through the coil.
- Amplification:** The process that results when the output of a circuit is an enlarged reproduction of the input signal. Amplifiers may be designed to provide amplification of voltage, current, or power, or a combination of these quantities.
- Amplification factor:** In a vacuum tube, the ratio of the change in plate voltage to the change in grid voltage that causes a corresponding change in plate current. Amplification factor is expressed by the Greek letter μ (*mu*).
- Amplifier (1—general):** A device that receives an input signal and provides as an output a magnified replica of the input waveform. (2—**audio**) An amplifier designed to cover the normal audio frequency range (20 Hz to 20 kHz). (3—**balanced**) A circuit with two identical connected signal branches that operate in phase opposition, with input and output connections each balanced to ground. (4—**bridging**) An amplifying circuit featuring high input impedance to prevent loading of the source. (5—**broadband**) An amplifier capable of operating over a specified broad band of frequencies with acceptably small amplitude variations as a function of frequency. (6—**buffer**) An amplifier stage used to isolate a frequency-sensitive circuit from variations in the load presented by following stages. (7—**linear**) An amplifier in which the instantaneous output signal is a linear function of the corresponding input signal. (8—**magnetic**) An amplifier incorporating a control device dependent on magnetic saturation. A small dc signal applied to a control circuit triggers a large change in operating impedance and, hence, in the output of the circuit. (9—**microphone**) A circuit that amplifies the low level output from a microphone to make it sufficient to be used as an input signal to a power amplifier or another stage in a modulation circuit. Such a circuit is commonly known as a *preamplifier*. (10—**push-pull**) A balanced amplifier with two similar amplifying units connected in phase opposition in order to cancel undesired harmonics and minimize distortion.

(11—**tuned radio frequency**) An amplifier tuned to a particular radio frequency or band so that only selected frequencies are amplified.

Amplifier operating class (1—general): The operating point of an amplifying stage. The operating point, termed the operating *class*, determines the period during which current flows in the output.

(2—**class A**) An amplifier in which output current flows during the whole of the input current cycle.

(3—**class AB**) An amplifier in which the output current flows for more than half but less than the whole of the input cycle. (4—**class B**) An amplifier in which output current is cut off at zero input signal; a half-wave rectified output is produced. (5—**class C**) An amplifier in which output current flows for less than half the input cycle. (6—**class D**) An amplifier operating in a pulse-only mode.

Amplitude: The magnitude of a signal in voltage or current, frequently expressed in terms of *peak*, *peak-to-peak*, or *root-mean-square* (RMS). The actual amplitude of a quantity at a particular instant often varies in a sinusoidal manner.

Amplitude distortion: A distortion mechanism occurring in an amplifier or other device when the output amplitude is not a linear function of the input amplitude under specified conditions.

Amplitude equalizer: A corrective network that is designed to modify the amplitude characteristics of a circuit or system over a desired frequency range.

Amplitude-versus-frequency distortion: The distortion in a transmission system caused by the nonuniform attenuation or gain of the system with respect to frequency under specified conditions.

Analog carrier system: A carrier system whose signal amplitude, frequency, or phase is varied continuously as a function of a modulating input.

Anode (1—general): A positive pole or element. (2—**vacuum tube**) The outermost positive element in a vacuum tube, also called the *plate*. (3—**battery**) The positive element of a battery or cell.

Anodize: The formation of a thin film of oxide on a metallic surface, usually to produce an insulating layer.

Antenna (1—general): A device used to transmit or receive a radio signal. An antenna is usually designed for a specified frequency range and serves to couple electromagnetic energy from a transmission line to and/or from the free space through which it travels. Directional antennas concentrate the energy in a particular horizontal or vertical direction. (2—**aperiodic**) An antenna that is not periodic or resonant at particular frequencies, and so can be used over a wide band of frequencies. (3—**artificial**) A device that behaves, so far as the transmitter is concerned, like a proper antenna, but does not radiate any power at radio frequencies. (4—**broadband**) An antenna that operates within specified performance limits over a wide band of frequencies, without requiring retuning for each individual frequency. (5—**Cassegrain**) A double reflecting antenna, often used for ground stations in satellite systems. (6—**coaxial**) A dipole antenna made by folding back on itself a quarter wavelength of the outer conductor of a coaxial line, leaving a quarter wavelength of the inner conductor exposed. (7—**corner**) An antenna within the angle formed by two plane-reflecting surfaces. (8—**dipole**) A center-fed antenna, one half-wavelength long. (9—**directional**) An antenna designed to receive or emit radiation more efficiently in a particular direction. (10—**dummy**) An artificial antenna, designed to accept power from the transmitter but not to radiate it. (11—**ferrite**) A common AM broadcast receive antenna that uses a small coil mounted on a short rod of ferrite material. (12—**flat top**) An antenna in which all the horizontal components are in the same horizontal plane. (13—**folded dipole**) A radiating device consisting of two ordinary half-wave dipoles joined at their outer ends and fed at the center of one of the dipoles. (14—**horn reflector**) A radiator in which the feed horn extends into a parabolic reflector, and the power is radiated through a window in the horn. (15—**isotropic**) A theoretical antenna in free space that transmits or receives with the same efficiency in all directions. (16—**log-periodic**) A broadband directional antenna incorporating an array of dipoles of different lengths, the length and spacing between dipoles increasing logarithmically away from the feeder element. (17—**long wire**) An antenna made up of one or more conductors in a straight line pointing in the required direction with a total length of several wavelengths at the operating frequency. (18—**loop**) An antenna consisting of one or more turns of wire in the same or parallel planes. (19—**nested rhombic**) An assembly of two rhombic antennas, one smaller than the other, so that the complete diamond-shaped antenna fits inside the area occupied

by the larger unit. (20—**omnidirectional**) An antenna whose radiating or receiving properties are the same in all horizontal plane directions. (21—**periodic**) A resonant antenna designed for use at a particular frequency. (22—**quarter-wave**) A dipole antenna whose length is equal to one quarter of a wavelength at the operating frequency. (23—**rhombic**) A large diamond-shaped antenna, with sides of the diamond several wavelengths long. The rhombic antenna is fed at one of the corners, with directional efficiency in the direction of the diagonal. (24—**series fed**) A vertical antenna that is fed at its lower end. (25—**shunt fed**) A vertical antenna whose base is grounded, and is fed at a specified point above ground. The point at which the antenna is fed above ground determines the operating impedance. (26—**steerable**) An antenna so constructed that its major lobe may readily be changed in direction. (27—**top-loaded**) A vertical antenna capacitively loaded at its upper end, often by simple enlargement or the attachment of a disc or plate. (28—**turnstile**) An antenna with one or more tiers of horizontal dipoles, crossed at right angles to each other and with excitation of the dipoles in phase quadrature. (29—**whip**) An antenna constructed of a thin semiflexible metal rod or tube, fed at its base. (30—**Yagi**) A directional antenna constructed of a series of dipoles cut to specific lengths. *Director* elements are placed in front of the active dipole and *reflector* elements are placed behind the active element.

Antenna array: A group of several antennas coupled together to yield a required degree of directivity.

Antenna beamwidth: The angle between the *half-power* points (3 dB points) of the main lobe of the antenna pattern when referenced to the peak power point of the antenna pattern. *Antenna beamwidth* is measured in degrees and normally refers to the horizontal radiation pattern.

Antenna directivity factor: The ratio of the power flux density in the desired direction to the average value of power flux density at crests in the antenna directivity pattern in the interference section.

Antenna factor: A factor that, when applied to the voltage appearing at the terminals of measurement equipment, yields the electrical field strength at an antenna. The unit of antenna factor is volts per meter per measured volt.

Antenna gain: The ratio of the power required at the input of a theoretically perfect omnidirectional reference antenna to the power supplied to the input of the given antenna to produce the same field at the same distance. When not specified otherwise, the figure expressing the gain of an antenna refers to the gain in the direction of the radiation main lobe. In services using *scattering* modes of propagation, the full gain of an antenna may not be realizable in practice and the apparent gain may vary with time.

Antenna gain-to-noise temperature: For a satellite earth terminal receiving system, a figure of merit that equals G/T , where G is the gain in dB of the earth terminal antenna at the receive frequency, and T is the equivalent noise temperature of the receiving system in Kelvins.

Antenna matching: The process of adjusting an antenna matching circuit (or the antenna itself) so that the input impedance of the antenna is equal to the characteristic impedance of the transmission line.

Antenna monitor: A device used to measure the ratio and phase between the currents flowing in the towers of a directional AM broadcast station.

Antenna noise temperature: The temperature of a resistor having an available noise power per unit bandwidth equal to that at the antenna output at a specified frequency.

Antenna pattern: A diagram showing the efficiency of radiation in all directions from the antenna.

Antenna power rating: The maximum continuous-wave power that can be applied to an antenna without degrading its performance.

Antenna preamplifier: A small amplifier, usually mast-mounted, for amplifying weak signals to a level sufficient to compensate for down-lead losses.

Apparent power: The product of the root-mean-square values of the voltage and current in an alternating-current circuit without a correction for the phase difference between the voltage and current.

Arc: A sustained luminous discharge between two or more electrodes.

Arithmetic mean: The sum of the values of several quantities divided by the number of quantities, also referred to as the *average*.

- Armature winding:** The winding of an electrical machine, either a motor or generator, in which current is induced.
- Array (1—antenna):** An assembly of several directional antennas so placed and interconnected that directivity may be enhanced. **(2—broadside)** An antenna array the elements of which are all in the same plane, producing a major lobe perpendicular to the plane. **(3—colinear)** An antenna array the elements of which are in the same line, either horizontal or vertical. **(4—end-fire)** An antenna array the elements of which are in parallel rows, one behind the other, producing a major lobe perpendicular to the plane in which individual elements are placed. **(5—linear)** An antenna array the elements of which are arranged end-to-end. **(6—stacked)** An antenna array the elements of which are stacked, one above the other.
- Artificial line:** An assembly of resistors, inductors, and capacitors that simulates the electrical characteristics of a transmission line.
- Assembly:** A manufactured part made by combining several other parts or subassemblies.
- Assumed values:** A range of values, parameters, levels, and other elements assumed for a mathematical model, hypothetical circuit, or network, from which analysis, additional estimates, or calculations will be made. The range of values, while not measured, represents the best engineering judgment and is generally derived from values found or measured in real circuits or networks of the same generic type, and includes projected improvements.
- Atmosphere:** The gaseous envelope surrounding the earth, composed largely of oxygen, carbon dioxide, and water vapor. The atmosphere is divided into four primary layers: *troposphere*, *stratosphere*, *ionosphere*, and *exosphere*.
- Atmospheric noise:** Radio noise caused by natural atmospheric processes, such as lightning.
- Attack time:** The time interval in seconds required for a device to respond to a control stimulus.
- Attenuation:** The decrease in amplitude of an electrical signal traveling through a transmission medium caused by dielectric and conductor losses.
- Attenuation coefficient:** The rate of decrease in the amplitude of an electrical signal caused by attenuation. The *attenuation coefficient* can be expressed in decibels or nepers per unit length. It may also be referred to as the *attenuation constant*.
- Attenuation distortion:** The distortion caused by attenuation that varies over the frequency range of a signal.
- Attenuation-limited operation:** The condition prevailing when the received signal amplitude (rather than distortion) limits overall system performance.
- Attenuator:** A fixed or adjustable component that reduces the amplitude of an electrical signal without causing distortion.
- Atto:** A prefix meaning one *quintillionth*.
- Attraction:** The attractive force between two unlike magnetic poles (N/S) or electrically charged bodies (+/−).
- Attributes:** The characteristics of equipment that aid planning and circuit design.
- Automatic frequency control (AFC):** A system designed to maintain the correct operating frequency of a receiver. Any drift in tuning results in the production of a control voltage, which is used to adjust the frequency of a local oscillator so as to minimize the tuning error.
- Automatic gain control (AGC):** An electronic circuit that compares the level of an incoming signal with a previously defined standard and automatically amplifies or attenuates the signal so it arrives at its destination at the correct level.
- Autotransformer:** A transformer in which both the primary and secondary currents flow through one common part of the coil.
- Auxiliary power:** An alternate source of electric power, serving as a back-up for the primary utility company ac power.
- Availability:** A measure of the degree to which a system, subsystem, or equipment is operable and not in a stage of congestion or failure at any given point in time.

Avalanche effect: The effect obtained when the electric field across a barrier region is sufficiently strong for electrons to collide with *valence electrons*, thereby releasing more electrons and giving a cumulative multiplication effect in a semiconductor.

Average life: The mean value for a normal distribution of product or component lives, generally applied to mechanical failures resulting from “wear-out.”

B

Back emf: A voltage induced in the reverse direction when current flows through an inductance. *Back emf* is also known as *counter-emf*.

Back scattering: A form of wave scattering in which at least one component of the scattered wave is deflected opposite to the direction of propagation of the incident wave.

Background noise: The total system noise in the absence of information transmission, independent of the presence or absence of a signal.

Backscatter: The deflection or reflection of radiant energy through angles greater than 90° with respect to the original angle of travel.

Backscatter range: The maximum distance from which backscattered radiant energy can be measured.

Backup: A circuit element or facility used to replace an element that has failed.

Backup supply: A redundant power supply that takes over if the primary power supply fails.

Balance: The process of equalizing the voltage, current, or other parameter between two or more circuits or systems.

Balanced: A circuit having two sides (conductors) carrying voltages that are symmetrical about a common reference point, typically ground.

Balanced circuit: A circuit whose two sides are electrically equal in all transmission respects.

Balanced line: A transmission line consisting of two conductors in the presence of ground capable of being operated in such a way that when the voltages of the two conductors at all transverse planes are equal in magnitude and opposite in polarity with respect to ground, the currents in the two conductors are equal in magnitude and opposite in direction.

Balanced modulator: A modulator that combines the information signal and the carrier so that the output contains the two sidebands without the carrier.

Balanced three-wire system: A power distribution system using three conductors, one of which is balanced to have a potential midway between the potentials of the other two.

Balanced-to-ground: The condition when the impedance to ground on one wire of a two-wire circuit is equal to the impedance to ground on the other wire.

Balun (balanced/unbalanced): A device used to connect balanced circuits with unbalanced circuits.

Band: A range of frequencies between a specified upper and lower limit.

Band elimination filter: A filter having a single continuous attenuation band, with neither the upper nor lower cut-off frequencies being zero or infinite. A *band elimination filter* may also be referred to as a *band-stop*, *notch*, or *band reject* filter.

Bandpass filter: A filter having a single continuous transmission band with neither the upper nor the lower cut-off frequencies being zero or infinite. A bandpass filter permits only a specific band of frequencies to pass; frequencies above or below are attenuated.

Bandwidth: The range of signal frequencies that can be transmitted by a communications channel with a defined maximum loss or distortion. Bandwidth indicates the information-carrying capacity of a channel.

Bandwidth expansion ratio: The ratio of the necessary bandwidth to the baseband bandwidth.

Bandwidth-limited operation: The condition prevailing when the frequency spectrum or bandwidth, rather than the amplitude (or power) of the signal, is the limiting factor in communication capability. This condition is reached when the system distorts the shape of the waveform beyond tolerable limits.

Bank: A group of similar items connected together in a specified manner and used in conjunction with one another.

Bare: A wire conductor that is not enameled or enclosed in an insulating sheath.

- Baseband:** The band of frequencies occupied by a signal before it modulates a carrier wave to form a transmitted radio or line signal.
- Baseband channel:** A channel that carries a signal without modulation, in contrast to a *passband* channel.
- Baseband signal:** The original form of a signal, unchanged by modulation.
- Bath tub:** The shape of a typical graph of component failure rates: high during an initial period of operation, falling to an acceptable low level during the normal usage period, and then rising again as the components become time-expired.
- Battery:** A group of several cells connected together to furnish current by conversion of chemical, thermal, solar, or nuclear energy into electrical energy. A single cell is itself sometimes also called a battery.
- Bay:** A row or suite of racks on which transmission, switching, and/or processing equipment is mounted.
- Bel:** A unit of power measurement, named in honor of Alexander Graham Bell. The commonly used unit is one tenth of a Bel, or a decibel (dB). One Bel is defined as a tenfold increase in power. If an amplifier increases the power of a signal by 10 times, the power gain of the amplifier is equal to 1 Bel or 10 *decibels* (dB). If power is increased by 100 times, the power gain is 2 Bels or 20 decibels.
- Bend:** A transition component between two elements of a transmission waveguide.
- Bending radius:** The smallest bend that may be put into a cable under a stated pulling force. The bending radius is typically expressed in inches.
- Bias:** A dc voltage difference applied between two elements of an active electronic device, such as a vacuum tube, transistor, or integrated circuit. Bias currents may or may not be drawn, depending on the device and circuit type.
- Bidirectional:** An operational qualification which implies that the transmission of information occurs in both directions.
- Bifilar winding:** A type of winding in which two insulated wires are placed side by side. In some components, bifilar winding is used to produce balanced circuits.
- Bipolar:** A signal that contains both positive-going and negative-going amplitude components. A bipolar signal may also contain a zero amplitude state.
- Bleeder:** A high resistance connected in parallel with one or more filter capacitors in a high voltage dc system. If the power supply load is disconnected, the capacitors discharge through the bleeder.
- Block diagram:** An overview diagram that uses geometric figures to represent the principal divisions or sections of a circuit, and lines and arrows to show the path of a signal, or to show program functionalities. It is not a *schematic*, which provides greater detail.
- Blocking capacitor:** A capacitor included in a circuit to stop the passage of direct current.
- BNC:** An abbreviation for *bayonet Neill-Concelman*, a type of cable connector used extensively in RF applications (named for its inventor).
- Boltzmann's constant:** 1.38×10^{-23} joules.
- Bridge:** A type of network circuit used to match different circuits to each other, ensuring minimum transmission impairment.
- Bridging:** The shunting or paralleling of one circuit with another.
- Broadband:** The quality of a communications link having essentially uniform response over a given range of frequencies. A communications link is said to be *broadband* if it offers no perceptible degradation to the signal being transported.
- Buffer:** A circuit or component that isolates one electrical circuit from another.
- Burn-in:** The operation of a device, sometimes under extreme conditions, to stabilize its characteristics and identify latent component failures before bringing the device into normal service.
- Bus:** A central conductor for the primary signal path. The term bus may also refer to a signal path to which a number of inputs may be connected for feed to one or more outputs.
- Busbar:** A main dc power bus.
- Bypass capacitor:** A capacitor that provides a signal path that effectively shunts or bypasses other components.

Bypass relay: A switch used to bypass the normal electrical route of a signal or current in the event of power, signal, or equipment failure.

C

Cable: An electrically and/or optically conductive interconnecting device.

Cable loss: Signal loss caused by passing a signal through a coaxial cable. Losses are the result of resistance, capacitance, and inductance in the cable.

Cable splice: The connection of two pieces of cable by joining them mechanically and closing the joint with a weather-tight case or sleeve.

Cabling: The wiring used to interconnect electronic equipment.

Calibrate: The process of checking, and adjusting if necessary, a test instrument against one known to be set correctly.

Calibration: The process of identifying and measuring errors in instruments and/or procedures.

Capacitance: The property of a device or component that enables it to store energy in an electrostatic field and to release it later. A capacitor consists of two conductors separated by an insulating material. When the conductors have a voltage difference between them, a charge will be stored in the electrostatic field between the conductors.

Capacitor: A device that stores electrical energy. A capacitor allows the apparent flow of alternating current, while blocking the flow of direct current. The degree to which the device permits ac current flow depends on the frequency of the signal and the size of the capacitor. Capacitors are used in filters, delay-line components, couplers, frequency selectors, timing elements, voltage transient suppression, and other applications.

Carrier: A single frequency wave that, prior to transmission, is modulated by another wave containing information. A carrier may be modulated by manipulating its amplitude and/or frequency in direct relation to one or more applied signals.

Carrier frequency: The frequency of an unmodulated oscillator or transmitter. Also, the average frequency of a transmitter when a signal is frequency modulated by a symmetrical signal.

Cascade connection: A tandem arrangement of two or more similar component devices or circuits, with the output of one connected to the input of the next.

Cascaded: An arrangement of two or more circuits in which the output of one circuit is connected to the input of the next circuit.

Cathode ray tube (CRT): A vacuum tube device, usually glass, that is narrow at one end and widens at the other to create a surface onto which images can be projected. The narrow end contains the necessary circuits to generate and focus an electron beam on the luminescent screen at the other end. CRTs are used to display pictures in TV receivers, video monitors, oscilloscopes, computers, and other systems.

Cell: An elementary unit of communication, of power supply, or of equipment.

Celsius: A temperature measurement scale, expressed in degrees C, in which water freezes at 0°C and boils at 100°C. To convert to degrees Fahrenheit, multiply by 0.555 and add 32. To convert to Kelvins add 273 (approximately).

Center frequency: In frequency modulation, the resting frequency or initial frequency of the carrier before modulation.

Center tap: A connection made at the electrical center of a coil.

Channel: The smallest subdivision of a circuit that provides a single type of communication service.

Channel decoder: A device that converts an incoming modulated signal on a given channel back into the source-encoded signal.

Channel encoder: A device that takes a given signal and converts it into a form suitable for transmission over the communications channel.

Channel noise level: The ratio of the channel noise at any point in a transmission system to some arbitrary amount of circuit noise chosen as a reference. This ratio is usually expressed in *decibels above reference noise*, abbreviated *dBrn*.

- Channel reliability:** The percent of time a channel is available for use in a specific direction during a specified period.
- Channelization:** The allocation of communication circuits to channels and the forming of these channels into groups for higher order multiplexing.
- Characteristic:** The property of a circuit or component.
- Characteristic impedance:** The impedance of a transmission line, as measured at the driving point, if the line were of infinite length. In such a line, there would be no standing waves. The *characteristic impedance* may also be referred to as the *surge impedance*.
- Charge:** The process of replenishing or replacing the electrical charge in a secondary cell or storage battery.
- Charger:** A device used to recharge a battery. Types of charging include: (1) *constant voltage charge*, (2) *equalizing charge*, and (3) *trickle charge*.
- Chassis ground:** A connection to the metal frame of an electronic system that holds the components in a place. The chassis ground connection serves as the ground return or electrical common for the system.
- Circuit:** Any closed path through which an electrical current can flow. In a *parallel circuit*, components are connected between common inputs and outputs such that all paths are parallel to each other. The same voltage appears across all paths. In a *series circuit*, the same current flows through all components.
- Circuit noise level:** The ratio of the circuit noise at some given point in a transmission system to an established reference, usually expressed in decibels above the reference.
- Circuit reliability:** The percentage of time a circuit is available to the user during a specified period of scheduled availability.
- Circular mil:** The measurement unit of the cross-sectional area of a circular conductor. A *circular mil* is the area of a circle whose diameter is one mil, or 0.001 inch.
- Clear channel:** A transmission path wherein the full bandwidth is available to the user, with no portions of the channel used for control, framing, or signaling. Can also refer to a classification of AM broadcast station.
- Clipper:** A limiting circuit which ensures that a specified output level is not exceeded by restricting the output waveform to a maximum peak amplitude.
- Clipping:** The distortion of a signal caused by removing a portion of the waveform through restriction of the amplitude of the signal by a circuit or device.
- Coax:** A short-hand expression for *coaxial cable*, which is used to transport high-frequency signals.
- Coaxial cable:** A transmission line consisting of an inner conductor surrounded first by an insulating material and then by an outer conductor, either solid or braided. The mechanical dimensions of the cable determine its *characteristic impedance*.
- Coherence:** The correlation between the phases of two or more waves.
- Coherent:** The condition characterized by a fixed phase relationship among points on an electromagnetic wave.
- Coherent pulse:** The condition in which a fixed phase relationship is maintained between consecutive pulses during pulse transmission.
- Cold joint:** A soldered connection that was inadequately heated, with the result that the wire is held in place by rosin flux, not solder. A cold joint is sometimes referred to as a *dry joint*.
- Comb filter:** An electrical filter circuit that passes a series of frequencies and rejects the frequencies in between, producing a frequency response similar to the teeth of a comb.
- Common:** A point that acts as a reference for circuits, often equal in potential to the local ground.
- Common mode:** Signals identical with respect to amplitude, frequency, and phase that are applied to both terminals of a cable and/or both the input and reference of an amplifier.
- Common return:** A return path that is common to two or more circuits, and returns currents to their source or to ground.
- Common return offset:** The dc common return potential difference of a line.

- Communications system:** A collection of individual communications networks, transmission systems, relay stations, tributary stations, and terminal equipment capable of interconnection and inter-operation to form an integral whole. The individual components must serve a common purpose, be technically compatible, employ common procedures, respond to some form of control, and, in general, operate in unison.
- Commutation:** A successive switching process carried out by a commutator.
- Commutator:** A circular assembly of contacts, insulated one from another, each leading to a different portion of the circuit or machine.
- Compatibility:** The ability of diverse systems to exchange necessary information at appropriate levels of command directly and in usable form. Communications equipment items are compatible if signals can be exchanged between them without the addition of buffering or translation for the specific purpose of achieving workable interface connections, and if the equipment or systems being interconnected possess comparable performance characteristics, including the suppression of undesired radiation.
- Complex wave:** A waveform consisting of two or more sinewave components. At any instant of time, a complex wave is the algebraic sum of all its sinewave components.
- Compliance:** For mechanical systems, a property which is the reciprocal of stiffness.
- Component:** An assembly, or part thereof, that is essential to the operation of some larger circuit or system. A *component* is an immediate subdivision of the assembly to which it belongs.
- COMSAT:** The *Communications Satellite Corporation*, an organization established by an act of Congress in 1962. COMSAT launches and operates the international satellites for the INTELSAT consortium of countries.
- Concentricity:** A measure of the deviation of the center conductor position relative to its ideal location in the exact center of the dielectric cross-section of a coaxial cable.
- Conditioning:** The adjustment of a channel in order to provide the appropriate transmission characteristics needed for data or other special services.
- Conditioning equipment:** The equipment used to match transmission levels and impedances, and to provide equalization between facilities.
- Conductance:** A measure of the capability of a material to conduct electricity. It is the reciprocal of *resistance* (ohm) and is expressed in *siemens*. (Formerly expressed as *mho*.)
- Conducted emission:** An electromagnetic energy propagated along a conductor.
- Conduction:** The transfer of energy through a medium, such as the conduction of electricity by a wire, or of heat by a metallic frame.
- Conduction band:** A partially filled or empty atomic energy band in which electrons are free to move easily, allowing the material to carry an electric current.
- Conductivity:** The conductance per unit length.
- Conductor:** Any material that is capable of carrying an electric current.
- Configuration:** A relative arrangement of parts.
- Connection:** A point at which a junction of two or more conductors is made.
- Connector:** A device mounted on the end of a wire or fiber optic cable that mates to a similar device on a specific piece of equipment or another cable.
- Constant-current source:** A source with infinitely high output impedance so that output current is independent of voltage, for a specified range of output voltages.
- Constant-voltage charge:** A method of charging a secondary cell or storage battery during which the terminal voltage is kept at a constant value.
- Constant-voltage source:** A source with low, ideally zero, internal impedance, so that voltage will remain constant, independent of current supplied.
- Contact:** The points that are brought together or separated to complete or break an electrical circuit.
- Contact bounce:** The rebound of a contact, which temporarily opens the circuit after its initial *make*.
- Contact form:** The configuration of a contact assembly on a relay. Many different configurations are possible from simple *single-make* contacts to complex arrangements involving *breaks* and *makes*.

- Contact noise:** A noise resulting from current flow through an electrical contact that has a rapidly varying resistance, as when the contacts are corroded or dirty.
- Contact resistance:** The resistance at the surface when two conductors make contact.
- Continuity:** A continuous path for the flow of current in an electrical circuit.
- Continuous wave:** An electromagnetic signal in which successive oscillations of the waves are identical.
- Control:** The supervision that an operator or device exercises over a circuit or system.
- Control grid:** The grid in an electron tube that controls the flow of current from the cathode to the anode.
- Convention:** A generally acceptable symbol, sign, or practice in a given industry.
- Coordinated Universal Time (UTC):** The time scale, maintained by the BIH (Bureau International de l'Heure), that forms the basis of a coordinated dissemination of standard frequencies and time signals.
- Copper loss:** The loss resulting from the heating effect of current.
- Corona:** A bluish luminous discharge resulting from ionization of the air near a conductor carrying a voltage gradient above a certain *critical level*.
- Corrective maintenance:** The necessary tests, measurements, and adjustments required to remove or correct a fault.
- Cosmic noise:** The random noise originating outside the earth's atmosphere.
- Coulomb:** The standard unit of electric quantity or charge. One *coulomb* is equal to the quantity of electricity transported in 1 second by a current of 1 ampere.
- Coulomb's Law:** The attraction and repulsion of electric charges act on a line between them. The charges are inversely proportional to the square of the distance between them, and proportional to the product of their magnitudes. (Named for the French physicist Charles-Augustine de Coulomb, 1736–1806.)
- Counter-electromotive force:** The effective electromotive force within a system that opposes the passage of current in a specified direction.
- Couple:** The process of linking two circuits by inductance, so that energy is transferred from one circuit to another.
- Coupled mode:** The selection of either ac or dc coupling.
- Coupling:** The relationship between two components that enables the transfer of energy between them. Included are *direct coupling* through a direct electrical connection, such as a wire; *capacitive coupling* through the capacitance formed by two adjacent conductors; and *inductive coupling* in which energy is transferred through a magnetic field. Capacitive coupling is also called *electrostatic coupling*. Inductive coupling is often referred to as *electromagnetic coupling*.
- Coupling coefficient:** A measure of the electrical coupling that exists between two circuits. The *coupling coefficient* is equal to the ratio of the mutual impedance to the square root of the product of the self impedances of the coupled circuits.
- Cross coupling:** The coupling of a signal from one channel, circuit, or conductor to another, where it becomes an undesired signal.
- Crossover distortion:** A distortion that results in an amplifier when an irregularity is introduced into the signal as it crosses through a zero reference point. If an amplifier is properly designed and biased, the upper half cycle and lower half cycle of the signal coincide at the zero crossover reference.
- Crossover frequency:** The frequency at which output signals pass from one channel to the other in a *crossover network*. At the *crossover frequency* itself, the outputs to each side are equal.
- Crossover network:** A type of filter that divides an incoming signal into two or more outputs, with higher frequencies directed to one output, and lower frequencies to another.
- Crosstalk:** Undesired transmission of signals from one circuit into another circuit in the same system. Crosstalk is usually caused by unintentional capacitive (ac) coupling.
- Crosstalk coupling:** The ratio of the power in a disturbing circuit to the induced power in the disturbed circuit, observed at a particular point under specified conditions. Crosstalk coupling is typically expressed in dB.

- Crowbar:** A short-circuit or low resistance path placed across the input to a circuit, usually for protective purposes.
- CRT(cathode ray tube):** A vacuum tube device that produces light when energized by the electron beam generated inside the tube. A CRT includes an electron gun, deflection mechanism, and phosphor-covered faceplate.
- Crystal:** A solidified form of a substance that has atoms and molecules arranged in a symmetrical pattern.
- Crystal filter:** A filter that uses piezoelectric crystals to create resonant or antiresonant circuits.
- Crystal oscillator:** An oscillator using a piezoelectric crystal as the tuned circuit that controls the resonant frequency.
- Crystal-controlled oscillator:** An oscillator in which a piezoelectric-effect crystal is coupled to a tuned oscillator circuit in such a way that the crystal pulls the oscillator frequency to its own natural frequency and does not allow frequency drift.
- Current (1—general):** A general term for the transfer of electricity, or the movement of electrons or *holes*. (2—**alternating**):] An electric current that is constantly varying in amplitude and periodically reversing direction. (3—**average**):] The arithmetic mean of the instantaneous values of current, averaged over one complete half cycle. (4—**charging**) The current that flows in to charge a capacitor when it is first connected to a source of electric potential. (5—**direct**) Electric current that flows in one direction only. (6—**eddy**) A wasteful current that flows in the core of a transformer and produces heat. *Eddy currents* are largely eliminated through the use of laminated cores. (7—**effective**) The ac current that will produce the same effective heat in a resistor as is produced by dc. If the ac is sinusoidal, the *effective current* value is 0.707 times the peak ac value. (8—**fault**) The current that flows between conductors or to ground during a fault condition. (9—**ground fault**) A fault current that flows to ground. (10—**ground return**) A current that returns through the earth. (11—**lagging**) A phenomenon observed in an inductive circuit where alternating current lags behind the voltage that produces it. (12—**leading**) A phenomenon observed in a capacitive circuit where alternating current leads the voltage that produces it. (13—**magnetizing**) The current in a transformer primary winding that is just sufficient to magnetize the core and offset iron losses. (14—**neutral**) The current that flows in the neutral conductor of an unbalanced polyphase power circuit. If correctly balanced, the neutral would carry no net current. (15—**peak**) The maximum value reached by a varying current during one cycle. (16—**pick-up**) The minimum current at which a relay just begins to operate. (17—**plate**) The anode current of an electron tube. (18—**residual**) The vector sum of the currents in the phase wires of an unbalanced polyphase power circuit. (19—**space**) The total current flowing through an electron tube.
- Current amplifier:** A low output impedance amplifier capable of providing high current output.
- Current probe:** A sensor, clamped around an electrical conductor, in which an induced current is developed from the magnetic field surrounding the conductor. For measurements, the current probe is connected to a suitable test instrument.
- Current transformer:** A transformer-type of instrument in which the primary carries the current to be measured and the secondary is in series with a low current ammeter. A current transformer is used to measure high values of alternating current.
- Current-carrying capacity:** A measure of the maximum current that can be carried continuously without damage to components or devices in a circuit.
- Cut-off frequency:** The frequency above or below which the output current in a circuit is reduced to a specified level.
- Cycle:** The interval of time or space required for a periodic signal to complete one period.
- Cycles per second:** The standard unit of frequency, expressed in Hertz (one cycle per second).

D

Damped oscillation: An oscillation exhibiting a progressive diminution of amplitude with time.

Damping: The dissipation and resultant reduction of any type of energy, such as electromagnetic waves.

DB (decibel): A measure of voltage, current, or power gain equal to 0.1 Bel. Decibels are given by the equations

$$20 \log \frac{V_{out}}{V_{in}}, \quad 20 \log \frac{I_{out}}{I_{in}}, \quad \text{or} \quad 10 \log \frac{P_{out}}{P_{in}}.$$

DBk: A measure of power relative to 1 kilowatt. 0 dBk equals 1 kW.

DBm (decibels above 1 milliwatt): A logarithmic measure of power with respect to a reference power of one milliwatt.

DBmv: A measure of voltage gain relative to 1 millivolt at 75 ohms.

DBr: The power difference expressed in dB between any point and a reference point selected as the *zero relative transmission level* point. A power expressed in *dB*r does not specify the absolute power; it is a relative measurement only.

DBu: A term that reflects comparison between a measured value of voltage and a reference value of 0.775 V, expressed under conditions in which the impedance at the point of measurement (and of the reference source) are not considered.

DbV: A measure of voltage gain relative to 1 V.

DBW: A measure of power relative to 1 watt. 0 dBW equals 1 W.

Dc: An abbreviation for *direct current*. Note that the preferred usage of the term *dc* is lower case.

Dc amplifier: A circuit capable of amplifying dc and slowly varying alternating current signals.

Dc component: The portion of a signal that consists of direct current. This term may also refer to the average value of a signal.

Dc coupled: A connection configured so that both the signal (ac component) and the constant voltage on which it is riding (dc component) are passed from one stage to the next.

Dc coupling: A method of coupling one circuit to another so as to transmit the static (dc) characteristics of the signal as well as the varying (ac) characteristics. Any dc offset present on the input signal is maintained and will be present in the output.

Dc offset: The amount that the dc component of a given signal has shifted from its correct level.

Dc signal bounce: Overshoot of the proper dc voltage level resulting from multiple ac couplings in a signal path.

De-energized: A system from which sources of power have been disconnected.

Deca: A prefix meaning *ten*.

Decay: The reduction in amplitude of a signal on an exponential basis.

Decay time: The time required for a signal to fall to a certain fraction of its original value.

Decibel (dB): One tenth of a Bel. The decibel is a logarithmic measure of the ratio between two powers.

Decode: The process of recovering information from a signal into which the information has been encoded.

Decoder: A device capable of deciphering encoded signals. A decoder interprets input instructions and initiates the appropriate control operations as a result.

Decoupling: The reduction or removal of undesired coupling between two circuits or stages.

Deemphasis: The reduction of the high-frequency components of a received signal to reverse the pre-emphasis that was placed on them to overcome attenuation and noise in the transmission process.

Defect: An error made during initial planning that is normally detected and corrected during the development phase. Note that a *fault* is an error that occurs in an in-service system.

Deflection: The control placed on electron direction and motion in CRTs and other vacuum tube devices by varying the strengths of electrostatic (electrical) or electromagnetic fields.

Degradation: In susceptibility testing, any undesirable change in the operational performance of a test specimen. This term does not necessarily mean malfunction or catastrophic failure.

Degradation failure: A failure that results from a gradual change in performance characteristics of a system or part with time.

Delay: The amount of time by which a signal is delayed or an event is retarded.

Delay circuit: A circuit designed to delay a signal passing through it by a specified amount.

- Delay distortion:** The distortion resulting from the difference in phase delays at two frequencies of interest.
- Delay equalizer:** A network that adjusts the velocity of propagation of the frequency components of a complex signal to counteract the delay distortion characteristics of a transmission channel.
- Delay line:** A transmission network that increases the propagation time of a signal traveling through it.
- Delta connection:** A common method of joining together a three-phase power supply, with each phase across a different pair of the three wires used.
- Delta-connected system:** A 3-phase power distribution system where a single-phase output can be derived from each of the adjacent pairs of an equilateral triangle formed by the service drop transformer secondary windings.
- Demodulator:** Any device that recovers the original signal after it has modulated a high-frequency carrier. The output from the unit may be in baseband composite form.
- Demultiplexer (demux):** A device used to separate two or more signals that were previously combined by a compatible multiplexer and are transmitted over a single channel.
- Derating factor:** An operating safety margin provided for a component or system to ensure reliable performance. A *derating allowance* also is typically provided for operation under extreme environmental conditions, or under stringent reliability requirements.
- Desiccant:** A drying agent used for drying out cable splices or sensitive equipment.
- Design:** A layout of all the necessary equipment and facilities required to make a special circuit, piece of equipment, or system work.
- Design objective:** The desired electrical or mechanical performance characteristic for electronic circuits and equipment.
- Detection:** The rectification process that results in the modulating signal being separated from a modulated wave.
- Detectivity:** The reciprocal of *noise equivalent power*.
- Detector:** A device that converts one type of energy into another.
- Device:** A functional circuit, component, or network unit, such as a vacuum tube or transistor.
- Dewpoint:** The temperature at which moisture will condense out.
- Diagnosis:** The process of locating errors in software, or equipment faults in hardware.
- Diagnostic routine:** A software program designed to trace errors in software, locate hardware faults, or identify the cause of a breakdown.
- Dielectric:** An insulating material that separates the elements of various components, including capacitors and transmission lines. Dielectric materials include air, plastic, mica, ceramic, and Teflon. A dielectric material must be an insulator. (*Teflon* is a registered trademark of Du Pont.)
- Dielectric constant:** The ratio of the capacitance of a capacitor with a certain dielectric material to the capacitance with a vacuum as the dielectric. The *dielectric constant* is considered a measure of the capability of a dielectric material to store an electrostatic charge.
- Dielectric strength:** The potential gradient at which electrical breakdown occurs.
- Differential amplifier:** An input circuit that rejects voltages that are the same at both input terminals but amplifies any voltage difference between the inputs. Use of a differential amplifier causes any signal present on both terminals, such as common mode hum, to cancel itself.
- Differential dc:** The maximum dc voltage that can be applied between the differential inputs of an amplifier while maintaining linear operation.
- Differential gain:** The difference in output amplitude (expressed in percent or dB) of a small high frequency sinewave signal at two stated levels of a low frequency signal on which it is superimposed.
- Differential phase:** The difference in output phase of a small high frequency sinewave signal at two stated levels of a low frequency signal on which it is superimposed.
- Differential-mode interference:** An interference source that causes a change in potential of one side of a signal transmission path relative to the other side.
- Diffuse reflection:** The scattering effect that occurs when light, radio, or sound waves strike a rough surface.

- Diffusion:** The spreading or scattering of a wave, such as a radio wave.
- Diode:** A semiconductor or vacuum tube with two electrodes that passes electric current in one direction only. Diodes are used in rectifiers, gates, modulators, and detectors.
- Direct coupling:** A coupling method between stages that permits dc current to flow between the stages.
- Direct current:** An electrical signal in which the direction of current flow remains constant.
- Discharge:** The conversion of stored energy, as in a battery or capacitor, into an electric current.
- Discontinuity:** An abrupt nonuniform point of change in a transmission circuit that causes a disruption of normal operation.
- Discrete:** An individual circuit component.
- Discrete component:** A separately contained circuit element with its own external connections.
- Discriminator:** A device or circuit whose output amplitude and polarity vary according to how much the input signal varies from a standard or from another signal. A discriminator can be used to recover the modulating waveform in a frequency modulated signal.
- Dish:** An antenna system consisting of a parabolic shaped reflector with a signal feed element at the focal point. Dish antennas commonly are used for transmission and reception from microwave stations and communications satellites.
- Dispersion:** The wavelength dependence of a parameter.
- Display:** The representation of text and images on a cathode-ray tube, an array of light-emitting diodes, a liquid-crystal readout, or another similar device.
- Display device:** An output unit that provides a visual representation of data.
- Distortion:** The difference between the wave shape of an original signal and the signal after it has traversed a transmission circuit.
- Distortion-limited operation:** The condition prevailing when the shape of the signal, rather than the amplitude (or power), is the limiting factor in communication capability. This condition is reached when the system distorts the shape of the waveform beyond tolerable limits. For linear systems, *distortion-limited* operation is equivalent to *bandwidth-limited* operation.
- Disturbance:** The interference with normal conditions and communications by some external energy source.
- Disturbance current:** The unwanted current of any irregular phenomenon associated with transmission that tends to limit or interfere with the interchange of information.
- Disturbance power:** The unwanted power of any irregular phenomenon associated with transmission that tends to limit or interfere with the interchange of information.
- Disturbance voltage:** The unwanted voltage of any irregular phenomenon associated with transmission that tends to limit or interfere with the interchange of information.
- Diversity receiver:** A receiver using two antennas connected through circuitry that senses which antenna is receiving the stronger signal. Electronic gating permits the stronger source to be routed to the receiving system.
- Documentation:** A written description of a program. *Documentation* can be considered as any record that has permanence and can be read by humans or machines.
- Down-lead:** A lead-in wire from an antenna to a receiver.
- Downlink:** The portion of a communication link used for transmission of signals from a satellite or airborne platform to a surface terminal.
- Downstream:** A specified signal modification occurring after other given devices in a signal path.
- Downtime:** The time during which equipment is not capable of doing useful work because of malfunction. This does not include preventive maintenance time. In other words, *downtime* is measured from the occurrence of a malfunction to the correction of that malfunction.
- Drift:** A slow change in a nominally constant signal characteristic, such as frequency.
- Drift-space:** The area in a klystron tube in which electrons drift at their entering velocities and form electron *bunches*.
- Drive:** The input signal to a circuit, particularly to an amplifier.

- Driver:** An electronic circuit that supplies an isolated output to drive the input of another circuit.
- Drop-out value:** The value of current or voltage at which a relay will cease to be operated.
- Dropout:** The momentary loss of a signal.
- Dropping resistor:** A resistor designed to carry current that will make a required voltage available.
- Duplex separation:** The frequency spacing required in a communications system between the *forward* and *return* channels to maintain interference at an acceptably low level.
- Duplex signaling:** A configuration permitting signaling in both transmission directions simultaneously.
- Duty cycle:** The ratio of operating time to total elapsed time of a device that operates intermittently, expressed in percent.
- Dynamic:** A situation in which the operating parameters and/or requirements of a given system are continually changing.
- Dynamic range:** The maximum range or extremes in amplitude, from the lowest to the highest (noise floor to system clipping), that a system is capable of reproducing. The dynamic range is expressed in dB against a reference level.
- Dynamo:** A rotating machine, normally a dc generator.
- Dynamotor:** A rotating machine used to convert dc into ac.

E

- Earth:** A large conducting body with no electrical potential, also called *ground*.
- Earth capacitance:** The capacitance between a given circuit or component and a point at ground potential.
- Earth current:** A current that flows to earth/ground, especially one that follows from a fault in the system. *Earth current* may also refer to a current that flows in the earth, resulting from ionospheric disturbances, lightning, or faults on power lines.
- Earth fault:** A fault that occurs when a conductor is accidentally grounded/earthed, or when the resistance to earth of an insulator falls below a specified value.
- Earth ground:** A large conducting body that represents *zero level* in the scale of electrical potential. An *earth ground* is a connection made either accidentally or by design between a conductor and earth.
- Earth potential:** The potential taken to be the arbitrary zero in a scale of electric potential.
- Effective ground:** A connection to ground through a medium of sufficiently low impedance and adequate current-carrying capacity to prevent the buildup of voltages that might be hazardous to equipment or personnel.
- Effective resistance:** The increased resistance of a conductor to an alternating current resulting from the *skin effect*, relative to the direct-current resistance of the conductor. Higher frequencies tend to travel only on the outer skin of the conductor, whereas dc flows uniformly through the entire area.
- Efficiency:** The useful power output of an electrical device or circuit divided by the total power input, expressed in percent.
- Electric:** Any device or circuit that produces, operates on, transmits, or uses electricity.
- Electric charge:** An excess of either electrons or protons within a given space or material.
- Electric field strength:** The magnitude, measured in volts per meter, of the electric field in an electromagnetic wave.
- Electric flux:** The amount of electric charge, measured in coulombs, across a dielectric of specified area. *Electric flux* may also refer simply to electric lines of force.
- Electricity:** An energy force derived from the movement of negative and positive electric charges.
- Electrode:** An electrical terminal that emits, collects, or controls an electric current.
- Electrolysis:** A chemical change induced in a substance resulting from the passage of electric current through an electrolyte.
- Electrolyte:** A nonmetallic conductor of electricity in which current is carried by the physical movement of ions.
- Electromagnet:** An iron or steel core surrounded by a wire coil. The core becomes magnetized when current flows through the coil but loses its magnetism when the current flow is stopped.

- Electromagnetic compatibility:** The capability of electronic equipment or systems to operate in a specific electromagnetic environment, at designated levels of efficiency and within a defined margin of safety, without interfering with itself or other systems.
- Electromagnetic field:** The electric and magnetic fields associated with radio and light waves.
- Electromagnetic induction:** An electromotive force created with a conductor by the relative motion between the conductor and a nearby magnetic field.
- Electromagnetism:** The study of phenomena associated with varying magnetic fields, electromagnetic radiation, and moving electric charges.
- Electromotive force (EMF):** An electrical potential, measured in volts, that can produce the movement of electrical charges.
- Electron:** A stable elementary particle with a negative charge that is mainly responsible for electrical conduction. Electrons move when under the influence of an electric field. This movement constitutes an *electric current*.
- Electron beam:** A stream of emitted electrons, usually in a vacuum.
- Electron gun:** A hot cathode that produces a finely focused stream of fast electrons, which are necessary for the operation of a vacuum tube, such as a cathode ray tube. The gun is made up of a hot cathode electron source, a control grid, accelerating anodes, and (usually) focusing electrodes.
- Electron lens:** A device used for focusing an electron beam in a cathode ray tube. Such focusing can be accomplished by either magnetic forces, in which external coils are used to create the proper magnetic field within the tube, or electrostatic forces, where metallic plates within the tube are charged electrically in such a way as to control the movement of electrons in the beam.
- Electron volt:** The energy acquired by an electron in passing through a potential difference of one volt in a vacuum.
- Electronic:** A description of devices (or systems) that are dependent on the flow of electrons in electron tubes, semiconductors, and other devices, and not solely on electron flow in ordinary wires, inductors, capacitors, and similar passive components.
- Electronic Industries Association (EIA):** A trade organization, based in Washington, DC, representing the manufacturers of electronic systems and parts, including communications systems. The association develops standards for electronic components and systems.
- Electronic switch:** A transistor, semiconductor diode, or a vacuum tube used as an on/off switch in an electrical circuit. Electronic switches can be controlled manually, by other circuits, or by computers.
- Electronics:** The field of science and engineering that deals with electron devices and their utilization.
- Electroplate:** The process of coating a given material with a deposit of metal by electrolytic action.
- Electrostatic:** The condition pertaining to electric charges that are at rest.
- Electrostatic field:** The space in which there is electric stress produced by static electric charges.
- Electrostatic induction:** The process of inducing static electric charges on a body by bringing it near other bodies that carry high electrostatic charges.
- Element:** A substance that consists of atoms of the same atomic number. Elements are the basic units in all chemical changes other than those in which *atomic changes*, such as fusion and fission, are involved.
- EMI (electromagnetic interference):** Undesirable electromagnetic waves that are radiated unintentionally from an electronic circuit or device into other circuits or devices, disrupting their operation.
- Emission (1—radiation):** The radiation produced, or the production of radiation by a radio transmitting system. The emission is considered to be a *single emission* if the modulating signal and other characteristics are the same for every transmitter of the radio transmitting system and the spacing between antennas is not more than a few wavelengths. (2—**cathode**) The release of electrons from the cathode of a vacuum tube. (3—**parasitic**) A spurious radio frequency emission unintentionally generated at frequencies that are independent of the carrier frequency being amplified or modulated. (4—**secondary**) In an electron tube, emission of electrons by a plate or grid because of bombardment by *primary emission* electrons from the cathode of the tube. (5—**spurious**) An

emission outside the radio frequency band authorized for a transmitter. (**6—thermonic**) An emission from a cathode resulting from high temperature.

Emphasis: The intentional alteration of the frequency-amplitude characteristics of a signal to reduce the adverse effects of noise in a communication system.

Empirical: A conclusion not based on pure theory, but on practical and experimental work.

Emulation: The use of one system to imitate the capabilities of another system.

Enable: To prepare a circuit for operation or to allow an item to function.

Enabling signal: A signal that permits the occurrence of a specified event.

Encode: The conversion of information from one form into another to obtain characteristics required by a transmission or storage system.

Encoder: A device that processes one or more input signals into a specified form for transmission and/or storage.

Energized: The condition when a circuit is switched on, or powered up.

Energy spectral density: A frequency-domain description of the energy in each of the frequency components of a pulse.

Envelope: The boundary of the family of curves obtained by varying a parameter of a wave.

Envelope delay: The difference in absolute delay between the fastest and slowest propagating frequencies within a specified bandwidth.

Envelope delay distortion: The maximum difference or deviation of the envelope-delay characteristic between any two specified frequencies.

Envelope detection: A demodulation process that senses the shape of the modulated RF envelope. A diode detector is one type of envelope detection device.

Environmental: An equipment specification category relating to temperature and humidity.

EQ (equalization) network: A network connected to a circuit to correct or control its transmission frequency characteristics.

Equalization (EQ): The reduction of frequency distortion and/or phase distortion of a circuit through the introduction of one or more networks to compensate for the difference in attenuation, time delay, or both, at the various frequencies in the transmission band.

Equalize: The process of inserting in a line a network with complementary transmission characteristics to those of the line, so that when the loss or delay in the line and that in the equalizer are combined, the overall loss or delay is approximately equal at all frequencies.

Equalizer: A network that corrects the transmission-frequency characteristics of a circuit to allow it to transmit selected frequencies in a uniform manner.

Equatorial orbit: The plane of a satellite orbit which coincides with that of the equator of the primary body.

Equipment: A general term for electrical apparatus and hardware, switching systems, and transmission components.

Equipment failure: The condition when a hardware fault stops the successful completion of a task.

Equipment ground: A protective ground consisting of a conducting path to ground of noncurrent carrying metal parts.

Equivalent circuit: A simplified network that emulates the characteristics of the real circuit it replaces. An equivalent circuit is typically used for mathematical analysis.

Equivalent noise resistance: A quantitative representation in resistance units of the spectral density of a noise voltage generator at a specified frequency.

Error: A collective term that includes all types of inconsistencies, transmission deviations, and control failures.

Excitation: The current that energizes field coils in a generator.

Expander: A device with a nonlinear gain characteristic that acts to increase the gain more on larger input signals than it does on smaller input signals.

Extremely high frequency (EHF): The band of microwave frequencies between the limits of 30 GHz and 300 GHz (wavelengths between 1 cm and 1 mm).

Extremely low frequency: The radio signals with operating frequencies below 300 Hz (wavelengths longer than 1000 km).

F

Fail-safe operation: A type of control architecture for a system that prevents improper functioning in the event of circuit or operator failure.

Failure: A detected cessation of ability to perform a specified function or functions within previously established limits. A *failure* is beyond adjustment by the operator by means of controls normally accessible during routine operation of the system. (This requires that measurable limits be established to define “satisfactory performance”.)

Failure effect: The result of the malfunction or failure of a device or component.

Failure in time (FIT): A unit value that indicates the reliability of a component or device. One failure in time corresponds to a failure rate of 10^{-9} per hour.

Failure mode and effects analysis (FMEA): An iterative documented process performed to identify basic faults at the component level and determine their effects at higher levels of assembly.

Failure rate: The ratio of the number of actual failures to the number of times each item has been subjected to a set of specified stress conditions.

Fall time: The length of time during which a pulse decreases from 90 percent to 10 percent of its maximum amplitude.

Farad: The standard unit of capacitance equal to the value of a capacitor with a potential of one volt between its plates when the charge on one plate is one coulomb and there is an equal and opposite charge on the other plate. The farad is a large value and is more commonly expressed in *microfarads* or *picofarads*. The *farad* is named for the English chemist and physicist Michael Faraday (1791–1867).

Fast frequency shift keying (FFSK): A system of digital modulation where the digits are represented by different frequencies that are related to the baud rate, and where transitions occur at the zero crossings.

Fatigue: The reduction in strength of a metal caused by the formation of crystals resulting from repeated flexing of the part in question.

Fault: A condition that causes a device, a component, or an element to fail to perform in a required manner. Examples include a short-circuit, broken wire, or intermittent connection.

Fault to ground: A fault caused by the failure of insulation and the consequent establishment of a direct path to ground from a part of the circuit that should not normally be grounded.

Fault tree analysis (FTA): An iterative documented process of a systematic nature performed to identify basic faults, determine their causes and effects, and establish their probabilities of occurrence.

Feature: A distinctive characteristic or part of a system or piece of equipment, usually visible to end users and designed for their convenience.

Federal Communications Commission (FCC): The federal agency empowered by law to regulate all interstate radio and wireline communications services originating in the United States, including radio, television, facsimile, telegraph, data transmission, and telephone systems. The agency was established by the Communications Act of 1934.

Feedback: The return of a portion of the output of a device to the input. *Positive feedback* adds to the input; *negative feedback* subtracts from the input.

Feedback amplifier: An amplifier with the components required to feed a portion of the output back into the input to alter the characteristics of the output signal.

Feedline: A transmission line, typically coaxial cable, that connects a high frequency energy source to its load.

Femto: A prefix meaning *one quadrillionth* (10^{-15}).

Ferrite: A ceramic material made of powdered and compressed ferric oxide, plus other oxides (mainly cobalt, nickel, zinc, yttrium-iron, and manganese). These materials have low eddy current losses at high frequencies.

- Ferromagnetic material:** A material with low relative permeability and high coercive force so that it is difficult to magnetize and demagnetize. Hard ferromagnetic materials retain magnetism well, and are commonly used in permanent magnets.
- Fidelity:** The degree to which a system, or a portion of a system, accurately reproduces at its output the essential characteristics of the signal impressed upon its input.
- Field strength:** The strength of an electric, magnetic, or electromagnetic field.
- Filament:** A wire that becomes hot when current is passed through it, used either to emit light (for a light bulb) or to heat a cathode to enable it to emit electrons (for an electron tube).
- Film resistor:** A type of resistor made by depositing a thin layer of resistive material on an insulating core.
- Filter:** A network that passes desired frequencies but greatly attenuates other frequencies.
- Filtered noise:** White noise that has been passed through a filter. The power spectral density of filtered white noise has the same shape as the transfer function of the filter.
- Fitting:** A coupling or other mechanical device that joins one component with another.
- Fixed:** A system or device that is not changeable or movable.
- Flashover:** An arc or spark between two conductors.
- Flashover voltage:** The voltage between conductors at which flashover just occurs.
- Flat face tube:** The design of CRT tube with almost a flat face, giving improved legibility of text and reduced reflection of ambient light.
- Flat level:** A signal that has an equal amplitude response for all frequencies within a stated range.
- Flat loss:** A circuit, device, or channel that attenuates all frequencies of interest by the same amount, also called *flat slope*.
- Flat noise:** A noise whose power per unit of frequency is essentially independent of frequency over a specified frequency range.
- Flat response:** The performance parameter of a system in which the output signal amplitude of the system is a faithful reproduction of the input amplitude over some range of specified input frequencies.
- Floating:** A circuit or device that is not connected to any source of potential or to ground.
- Fluorescence:** The characteristic of a material to produce light when excited by an external energy source. Minimal or no heat results from the process.
- Flux:** The electric or magnetic lines of force resulting from an applied energy source.
- Flywheel effect:** The characteristic of an oscillator that enables it to sustain oscillations after removal of the control stimulus. This characteristic may be desirable, as in the case of a phase-locked loop employed in a synchronous system, or undesirable, as in the case of a voltage-controlled oscillator.
- Focusing:** A method of making beams of radiation converge on a target, such as the face of a CRT.
- Fourier analysis:** A mathematical process for transforming values between the frequency domain and the time domain. This term also refers to the decomposition of a time-domain signal into its frequency components.
- Fourier transform:** An integral that performs an actual transformation between the frequency domain and the time domain in Fourier analysis.
- Frame:** A segment of an analog or digital signal that has a repetitive characteristic, in that corresponding elements of successive *frames* represent the same things.
- Free electron:** An electron that is not attached to an atom and is, thus, mobile when an electromotive force is applied.
- Free running:** An oscillator that is not controlled by an external synchronizing signal.
- Free-running oscillator:** An oscillator that is not synchronized with an external timing source.
- Frequency:** The number of complete cycles of a periodic waveform that occur within a given length of time. Frequency is usually specified in cycles per second (*Hertz*). Frequency is the reciprocal of wavelength. The higher the frequency, the shorter the wavelength. In general, the higher the frequency of a signal, the more capacity it has to carry information, the smaller an antenna is required, and the more susceptible the signal is to absorption by the atmosphere and by physical structures. At microwave frequencies, radio signals take on a *line-of-sight* characteristic and require highly directional and focused antennas to be used successfully.

- Frequency accuracy:** The degree of conformity of a given signal to the specified value of a frequency.
- Frequency allocation:** The designation of radio-frequency bands for use by specific radio services.
- Frequency content:** The band of frequencies or specific frequency components contained in a signal.
- Frequency converter:** A circuit or device used to change a signal of one frequency into another of a different frequency.
- Frequency coordination:** The process of analyzing frequencies in use in various bands of the spectrum to achieve reliable performance for current and new services.
- Frequency counter:** An instrument or test set used to measure the frequency of a radio signal or any other alternating waveform.
- Frequency departure:** An unintentional deviation from the nominal frequency value.
- Frequency difference:** The algebraic difference between two frequencies. The two frequencies can be of identical or different nominal values.
- Frequency displacement:** The end-to-end shift in frequency that may result from independent frequency translation errors in a circuit.
- Frequency distortion:** The distortion of a multifrequency signal caused by unequal attenuation or amplification at the different frequencies of the signal. This term may also be referred to as *amplitude distortion*.
- Frequency domain:** A representation of signals as a function of frequency, rather than of time.
- Frequency modulation (FM):** The modulation of a carrier signal so that its instantaneous frequency is proportional to the instantaneous value of the modulating wave.
- Frequency multiplier:** A circuit that provides as an output an exact multiple of the input frequency.
- Frequency offset:** A frequency shift that occurs when a signal is sent over an analog transmission facility in which the modulating and demodulating frequencies are not identical. A channel with frequency offset does not preserve the waveform of a transmitted signal.
- Frequency response:** The measure of system linearity in reproducing signals across a specified bandwidth. Frequency response is expressed as a frequency range with a specified amplitude tolerance in dB.
- Frequency response characteristic:** The variation in the transmission performance (gain or loss) of a system with respect to variations in frequency.
- Frequency reuse:** A technique used to expand the capacity of a given set of frequencies or channels by separating the signals either geographically or through the use of different polarization techniques. Frequency reuse is a common element of the *frequency coordination* process.
- Frequency selectivity:** The ability of equipment to separate or differentiate between signals at different frequencies.
- Frequency shift:** The difference between the frequency of a signal applied at the input of a circuit and the frequency of that signal at the output.
- Frequency shift keying (FSK):** A commonly used method of digital modulation in which a one and a zero (the two possible states) are each transmitted as separate frequencies.
- Frequency stability:** A measure of the variations of the frequency of an oscillator from its mean frequency over a specified period of time.
- Frequency standard:** An oscillator with an output frequency sufficiently stable and accurate that it is used as a reference.
- Frequency-division multiple access (FDMA):** The provision of multiple access to a transmission facility, such as an earth satellite, by assigning each transmitter its own frequency band.
- Frequency-division multiplexing (FDM):** The process of transmitting multiple analog signals by an orderly assignment of frequency slots, that is, by dividing transmission bandwidth into several narrow bands, each of which carries a single communication and is sent simultaneously with others over a common transmission path.
- Full duplex:** A communications system capable of transmission simultaneously in two directions.
- Full-wave rectifier:** A circuit configuration in which both positive and negative half-cycles of the incoming ac signal are rectified to produce a unidirectional (dc) current through the load.

Functional block diagram: A diagram illustrating the definition of a device, system, or problem on a logical and functional basis.

Functional unit: An entity of hardware and/or software capable of accomplishing a given purpose.

Fundamental frequency: The lowest frequency component of a complex signal.

Fuse: A protective device used to limit current flow in a circuit to a specified level. The fuse consists of a metallic link that melts and opens the circuit at a specified current level.

Fuse wire: A fine-gauge wire made of an alloy that overheats and melts at the relatively low temperatures produced when the wire carries overload currents. When used in a fuse, the wire is called a fuse (or fusible) link.

G

Gain: An increase or decrease in the level of an electrical signal. Gain is measured in terms of decibels or number-of-times of magnification. Strictly speaking, *gain* refers to an increase in level. Negative numbers, however, are commonly used to denote a decrease in level.

Gain-bandwidth: The gain times the frequency of measurement when a device is biased for maximum obtainable gain.

Gain/frequency characteristic: The gain-versus-frequency characteristic of a channel over the bandwidth provided, also referred to as *frequency response*.

Gain/frequency distortion: A circuit defect in which a change in frequency causes a change in signal amplitude.

Galvanic: A device that produces direct current by chemical action.

Gang: The mechanical connection of two or more circuit devices so that they can all be adjusted simultaneously.

Gang capacitor: A variable capacitor with more than one set of moving plates linked together.

Gang tuning: The simultaneous tuning of several different circuits by turning a single shaft on which ganged capacitors are mounted.

Ganged: One or more devices that are mechanically coupled, normally through the use of a shared shaft.

Gas breakdown: The ionization of a gas between two electrodes caused by the application of a voltage that exceeds a threshold value. The ionized path has a low impedance. Certain types of circuit and line protectors rely on gas breakdown to divert hazardous currents away from protected equipment.

Gas tube: A protection device in which a sufficient voltage across two electrodes causes a gas to ionize, creating a low impedance path for the discharge of dangerous voltages.

Gas-discharge tube: A gas-filled tube designed to carry current during gas breakdown. The gas-discharge tube is commonly used as a protective device, preventing high voltages from damaging sensitive equipment.

Gauge: A measure of wire diameter. In measuring wire gauge, the lower the number, the thicker the wire.

Gaussian distribution: A statistical distribution, also called the *normal* distribution. The graph of a Gaussian distribution is a bell-shaped curve.

Gaussian noise: Noise in which the distribution of amplitude follows a Gaussian model; that is, the noise is random but distributed about a reference voltage of zero.

Gaussian pulse: A pulse that has the same form as its own Fourier transform.

Generator: A machine that converts mechanical energy into electrical energy, or one form of electrical energy into another form.

Geosynchronous: The attribute of a satellite in which the relative position of the satellite as viewed from the surface of a given planet is stationary. For earth, the geosynchronous position is 22,300 miles above the planet.

Getter: A metal used in vaporized form to remove residual gas from inside an electron tube during manufacture.

Giga: A prefix meaning one billion.

Gigahertz (GHz): A measure of frequency equal to one billion cycles per second. Signals operating above 1 gigahertz are commonly known as *microwaves*, and begin to take on the characteristics of visible light.

Glitch: A general term used to describe a wide variety of momentary signal discontinuities.

Graceful degradation: An equipment failure mode in which the system suffers reduced capability, but does not fail altogether.

Graticule: A fixed pattern of reference markings used with oscilloscope CRTs to simplify measurements. The graticule may be etched on a transparent plate covering the front of the CRT or, for greater accuracy in readings, may be electrically generated within the CRT itself.

Grid (1—general): A mesh electrode within an electron tube that controls the flow of electrons between the cathode and plate of the tube. (2—**bias**) The potential applied to a grid in an electron tube to control its center operating point. (3—**control**) The grid in an electron tube to which the input signal is usually applied. (4—**screen**) The grid in an electron tube, typically held at a steady potential, that screens the control grid from changes in anode potential. (5—**suppressor**) The grid in an electron tube near the anode (plate) that suppresses the emission of secondary electrons from the plate.

Ground: An electrical connection to earth or to a common conductor usually connected to earth.

Ground clamp: A clamp used to connect a ground wire to a ground rod or system.

Ground loop: An undesirable circulating ground current in a circuit grounded via multiple connections or at multiple points.

Ground plane: A conducting material at ground potential, physically close to other equipment, so that connections may be made readily to ground the equipment at the required points.

Ground potential: The point at zero electric potential.

Ground return: A conductor used as a path for one or more circuits back to the ground plane or central facility ground point.

Ground rod: A metal rod driven into the earth and connected into a mesh of interconnected rods so as to provide a low resistance link to ground.

Ground window: A single-point interface between the integrated ground plane of a building and an isolated ground plane.

Ground wire: A copper conductor used to extend a good low-resistance earth ground to protective devices in a facility.

Grounded: The connection of a piece of equipment to earth via a low resistance path.

Grounding: The act of connecting a device or circuit to ground or to a conductor that is grounded.

Group delay: A condition where the different frequency elements of a given signal suffer differing propagation delays through a circuit or a system. The delay at a lower frequency is different from the delay at a higher frequency, resulting in a time-related distortion of the signal at the receiving point.

Group delay time: The rate of change of the total phase shift of a waveform with angular frequency through a device or transmission facility.

Group velocity: The speed of a pulse on a transmission line.

Guard band: A narrow bandwidth between adjacent channels intended to reduce interference or crosstalk.

H

Half-wave rectifier: A circuit or device that changes only positive or negative half-cycle inputs of alternating current into direct current.

Hall effect: The phenomenon by which a voltage develops between the edges of a current-carrying metal strip whose faces are perpendicular to an external magnetic field.

Hard-wired: Electrical devices connected through physical wiring.

Harden: The process of constructing military telecommunications facilities so as to protect them from damage by enemy action, especially *electromagnetic pulse* (EMP) radiation.

Hardware: Physical equipment, such as mechanical, magnetic, electrical, or electronic devices or components.

- Harmonic:** A periodic wave having a frequency that is an integral multiple of the fundamental frequency. For example, a wave with twice the frequency of the fundamental is called the *second harmonic*.
- Harmonic analyzer:** A test set capable of identifying the frequencies of the individual signals that make up a complex wave.
- Harmonic distortion:** The production of harmonics at the output of a circuit when a periodic wave is applied to its input. The level of the distortion is usually expressed as a percentage of the level of the input.
- Hazard:** A condition that could lead to danger for operating personnel.
- Headroom:** The difference, in decibels, between the typical operating signal level and a peak overload level.
- Heat loss:** The loss of useful electrical energy resulting from conversion into unwanted heat.
- Heat sink:** A device that conducts heat away from a heat-producing component so that it stays within a safe working temperature range.
- Heater:** In an electron tube, the filament that heats the cathode to enable it to emit electrons.
- Hecto:** A prefix meaning 100.
- Henry:** The standard unit of electrical inductance, equal to the self-inductance of a circuit or the mutual inductance of two circuits when there is an induced electromotive force of one volt and a current change of one ampere per second. The symbol for inductance is *H*, named for the American physicist Joseph Henry (1797–1878).
- Hertz (Hz):** The unit of frequency that is equal to one cycle per second. Hertz is the reciprocal of the *period*, the interval after which the same portion of a periodic waveform recurs. Hertz was named for the German physicist Heinrich R. Hertz (1857–1894).
- Heterodyne:** The mixing of two signals in a nonlinear device in order to produce two additional signals at frequencies that are the sum and difference of the original frequencies.
- Heterodyne frequency:** The sum of, or the difference between, two frequencies, produced by combining the two signals together in a modulator or similar device.
- Heterodyne wavemeter:** A test set that uses the heterodyne principle to measure the frequencies of incoming signals.
- High-frequency loss:** Loss of signal amplitude at higher frequencies through a given circuit or medium. For example, high frequency loss could be caused by passing a signal through a coaxial cable.
- High Q:** An inductance or capacitance whose ratio of reactance to resistance is high.
- High tension:** A high voltage circuit.
- High-pass filter:** A network that passes signals of higher than a specified frequency but attenuates signals of all lower frequencies.
- Homochronous:** Signals whose corresponding significant instants have a constant but uncontrolled phase relationship with each other.
- Horn gap:** A lightning arrester utilizing a gap between two horns. When lightning causes a discharge between the horns, the heat produced lengthens the arc and breaks it.
- Horsepower:** The basic unit of mechanical power. One horsepower (hp) equals 550 foot-pounds per second or 746 watts.
- Hot:** A charged electrical circuit or device.
- Hot dip galvanized:** The process of galvanizing steel by dipping it into a bath of molten zinc.
- Hot standby:** System equipment that is fully powered but not in service. A *hot standby* can rapidly replace a primary system in the event of a failure.
- Hum:** Undesirable coupling of the 60 Hz power sine wave into other electrical signals and/or circuits.
- HVAC:** An abbreviation for *heating, ventilation, and air conditioning* system.
- Hybrid system:** A communication system that accommodates both digital and analog signals.
- Hydrometer:** A testing device used to measure specific gravity, particularly the specific gravity of the dilute sulphuric acid in a lead-acid storage battery, to learn the state of charge of the battery.
- Hygrometer:** An instrument that measures the relative humidity of the atmosphere.
- Hygroscopic:** The ability of a substance to absorb moisture from the air.

Hysteresis: The property of an element evidenced by the dependence of the value of the output, for a given excursion of the input, upon the history of prior excursions and direction of the input. Originally, *hysteresis* was the name for magnetic phenomena only—the lagging of flux density behind the change in value of the magnetizing flux—but now, the term is also used to describe other inelastic behavior.

Hysteresis loop: The plot of magnetizing current against magnetic flux density (or of other similarly related pairs of parameters), which appears as a loop. The area within the loop is proportional to the power loss resulting from hysteresis.

Hysteresis loss: The loss in a magnetic core resulting from hysteresis.

I

I^2R loss: The power lost as a result of the heating effect of current passing through resistance.

Idling current: The current drawn by a circuit, such as an amplifier, when no signal is present at its input.

Image frequency: A frequency on which a carrier signal, when heterodyned with the local oscillator in a superheterodyne receiver, will cause a sum or difference frequency that is the same as the intermediate frequency of the receiver. Thus, a signal on an *image frequency* will be demodulated along with the desired signal and will interfere with it.

Impact ionization: The ionization of an atom or molecule as a result of a high energy collision.

Impedance: The total passive opposition offered to the flow of an alternating current.

Impedance consists of a combination of resistance, inductive reactance, and capacitive reactance. It is the vector sum of resistance and reactance ($R + jX$) or the vector of magnitude Z at an angle θ .

Impedance characteristic: A graph of the impedance of a circuit showing how it varies with frequency.

Impedance irregularity: A discontinuity in an impedance characteristic caused, for example, by the use of different coaxial cable types.

Impedance matching: The adjustment of the impedances of adjoining circuit components to a common value so as to minimize reflected energy from the junction and to maximize energy transfer across it. Incorrect adjustment results in an *impedance mismatch*.

Impedance matching transformer: A transformer used between two circuits of different impedances with a turns ratio that provides for maximum power transfer and minimum loss by reflection.

Impulse: A short high energy surge of electrical current in a circuit or on a line.

Impulse current: A current that rises rapidly to a peak then decays to zero without oscillating.

Impulse excitation: The production of an oscillatory current in a circuit by impressing a voltage for a relatively short period compared with the duration of the current produced.

Impulse noise: A noise signal consisting of random occurrences of energy spikes, having random amplitude and bandwidth.

Impulse response: The amplitude-versus-time output of a transmission facility or device in response to an impulse.

Impulse voltage: A unidirectional voltage that rises rapidly to a peak and then falls to zero, without any appreciable oscillation.

In-phase: The property of alternating current signals of the same frequency that achieve their peak positive, peak negative, and zero amplitude values simultaneously.

Incidence angle: The angle between the perpendicular to a surface and the direction of arrival of a signal.

Increment: A small change in the value of a quantity.

Induce: To produce an electrical or magnetic effect in one conductor by changing the condition or position of another conductor.

Induced current: The current that flows in a conductor because a voltage has been induced across two points in, or connected to, the conductor.

Induced voltage: A voltage developed in a conductor when the conductor passes through magnetic lines of force.

Inductance: The property of an inductor that opposes any change in a current that flows through it. The standard unit of inductance is the *Henry*.

Induction: The electrical and magnetic interaction process by which a changing current in one circuit produces a voltage change not only in its own circuit (*self inductance*) but also in other circuits to which it is linked magnetically.

Inductive: A circuit element exhibiting inductive reactance.

Inductive kick: A voltage surge produced when a current flowing through an inductance is interrupted.

Inductive load: A load that possesses a net inductive reactance.

Inductive reactance: The reactance of a circuit resulting from the presence of inductance and the phenomenon of induction.

Inductor: A coil of wire, usually wound on a core of high permeability, that provides high inductance without necessarily exhibiting high resistance.

Inert: An inactive unit, or a unit that has no power requirements.

Infinite line: A transmission line that appears to be of infinite length. There are no reflections back from the far end because it is terminated in its characteristic impedance.

Infra low frequency (ILF): The frequency band from 300 Hz to 3000 Hz.

Inhibit: A control signal that prevents a device or circuit from operating.

Injection: The application of a signal to an electronic device.

Input: The waveform fed into a circuit, or the terminals that receive the input waveform.

Insertion gain: The gain resulting from the insertion of a transducer in a transmission system, expressed as the ratio of the power delivered to that part of the system following the transducer to the power delivered to that same part before insertion. If more than one component is involved in the input or output, the particular component used must be specified. This ratio is usually expressed in decibels. If the resulting number is negative, an *insertion loss* is indicated.

Insertion loss: The signal loss within a circuit, usually expressed in decibels as the ratio of input power to output power.

Insertion loss-vs.-frequency characteristic: The amplitude transfer characteristic of a system or component as a function of frequency. The amplitude response may be stated as actual gain, loss, amplification, or attenuation, or as a ratio of any one of these quantities at a particular frequency, with respect to that at a specified reference frequency.

Inspection lot: A collection of units of product from which a sample is drawn and inspected to determine conformance with acceptability criteria.

Instantaneous value: The value of a varying waveform at a given instant of time. The value can be in volts, amperes, or phase angle.

Institute of Electrical and Electronics Engineers (IEEE): The organization of electrical and electronics scientists and engineers formed in 1963 by the merger of the Institute of Radio Engineers (IRE) and the American Institute of Electrical Engineers (AIEE).

Instrument multiplier: A measuring device that enables a high voltage to be measured using a meter with only a low voltage range.

Instrument rating: The range within which an instrument has been designed to operate without damage.

Insulate: The process of separating one conducting body from another conductor.

Insulation: The material that surrounds and insulates an electrical wire from other wires or circuits. *Insulation* may also refer to any material that does not ionize easily and thus presents a large impedance to the flow of electrical current.

Insulator: A material or device used to separate one conducting body from another.

Intelligence signal: A signal containing information.

Intensity: The strength of a given signal under specified conditions.

Interconnect cable: A short distance cable intended for use between equipment (generally less than 3 m in length).

Interface: A device or circuit used to interconnect two pieces of electronic equipment.

Interface device: A unit that joins two interconnecting systems.

Interference emission: An emission that results in an electrical signal being propagated into and interfering with the proper operation of electrical or electronic equipment.

- Interlock:** A protection device or system designed to remove all dangerous voltages from a machine or piece of equipment when access doors or panels are opened or removed.
- Intermediate frequency:** A frequency that results from combining a signal of interest with a signal generated within a radio receiver. In superheterodyne receivers, all incoming signals are converted to a single intermediate frequency for which the amplifiers and filters of the receiver have been optimized.
- Intermittent:** A noncontinuous recurring event, often used to denote a problem that is difficult to find because of its unpredictable nature.
- Intermodulation:** The production, in a nonlinear transducer element, of frequencies corresponding to the sums and differences of the fundamentals and harmonics of two or more frequencies that are transmitted through the transducer.
- Intermodulation distortion (IMD):** The distortion that results from the mixing of two input signals in a nonlinear system. The resulting output contains new frequencies that represent the sum and difference of the input signals and the sums and differences of their harmonics. IMD is also called *intermodulation noise*.
- Intermodulation noise:** In a transmission path or device, the noise signal that is contingent upon modulation and demodulation, resulting from nonlinear characteristics in the path or device.
- Internal resistance:** The actual resistance of a source of electric power. The total electromotive force produced by a power source is not available for external use; some of the energy is used in driving current through the source itself.
- International Standards Organization (ISO):** An international body concerned with worldwide standardization for a broad range of industrial products, including telecommunications equipment. Members are represented by national standards organizations, such as ANSI (American National Standards Institute) in the United States. ISO was established in 1947 as a specialized agency of the United Nations.
- International Telecommunications Satellite Consortium (Intelsat):** A nonprofit cooperative of member nations that owns and operates a satellite system for international and, in many instances, domestic communications.
- International Telecommunications Union (ITU):** A specialized agency of the United Nations established to maintain and extend international cooperation for the maintenance, development, and efficient use of telecommunications. The union does this through standards and recommended regulations, and through technical and telecommunications studies.
- Interoperability:** The condition achieved among communications and electronics systems or equipment when information or services can be exchanged directly between them or their users, or both.
- Interpolate:** The process of estimating unknown values based on a knowledge of comparable data that falls on both sides of the point in question.
- Interrupting capacity:** The rating of a circuit breaker or fuse that specifies the maximum current the device is designed to interrupt at its rated voltage.
- Interval:** The points or numbers lying between two specified endpoints.
- Inverse voltage:** The effective value of voltage across a rectifying device, which conducts a current in one direction during one half cycle of the alternating input, during the half cycle when current is not flowing.
- Inversion:** The change in the polarity of a pulse, such as from positive to negative.
- Inverter:** A circuit or device that converts a direct current into an alternating current.
- Ionizing radiation:** The form of electromagnetic radiation that can turn an atom into an ion by knocking one or more of its electrons loose. Examples of ionizing radiation include X rays, gamma rays, and cosmic rays.
- IR drop:** A drop in voltage because of the flow of current (I) through a resistance (R), also called *resistance drop*.
- IR loss:** The conversion of electrical power to heat caused by the flow of electrical current through a resistance.

Isochronous: A signal in which the time interval separating any two significant instants is theoretically equal to a specified unit interval or to an integral multiple of the unit interval.

Isolated ground: A ground circuit that is isolated from all equipment framework and any other grounds, except for a single-point external connection.

Isolated ground plane: A set of connected frames that are grounded through a single connection to a ground reference point. That point and all parts of the frames are insulated from any other ground system in a building.

Isolated pulse: A pulse uninfluenced by other pulses in the same signal.

Isophasing amplifier: A timing device that corrects for small timing errors.

Isotropic: A quantity exhibiting the same properties in all planes and directions.

J

Jack: A receptacle or connector that makes electrical contact with the mating contacts of a plug. In combination, the plug and jack provide a ready means for making connections in electrical circuits.

Jacket: An insulating layer of material surrounding a wire in a cable.

Jitter: Small, rapid variations in a waveform resulting from fluctuations in a supply voltage or other causes.

Joule: The standard unit of work that is equal to the work done by one newton of force when the point at which the force is applied is displaced a distance of one meter in the direction of the force. The *joule* is named for the English physicist James Prescott Joule (1818–1889).

Julian date: A chronological date in which days of the year are numbered in sequence. For example, the first day is 001, the second is 002, and the last is 365 (or 366 in a leap year).

K

Kelvin (K): The standard unit of thermodynamic temperature. Zero degrees Kelvin represents *absolute zero*. Water freezes at 273 K and water boils at 373 K under standard pressure conditions.

Kilo: A prefix meaning one thousand.

Kilohertz (kHz): A unit of measure of frequency equal to 1,000 Hz.

Kilovar: A unit equal to one thousand volt-amperes.

Kilovolt (kV): A unit of measure of electrical voltage equal to 1,000 V.

Kilowatt: A unit equal to one thousand watts.

Kirchoff's Law: At any point in a circuit, there is as much current flowing into the point as there is flowing away from it.

Klystron (1—general): A family of electron tubes that function as microwave amplifiers and oscillators. Simplest in form are two-cavity klystrons in which an electron beam passes through a cavity that is excited by a microwave input, producing a velocity-modulated beam which passes through a second cavity a precise distance away that is coupled to a tuned circuit, thereby producing an amplified output of the original input signal frequency. If part of the output is fed back to the input, an oscillator can be the result. (2—**multi-cavity**) An amplifier device for UHF and microwave signals based on velocity modulation of an electron beam. The beam is directed through an input cavity, where the input RF signal polarity initializes a *bunching effect* on electrons in the beam. The bunching effect excites subsequent cavities, which increase the bunching through an energy flywheel concept. Finally, the beam passes to an output cavity that couples the amplified signal to the load (antenna system). The beam falls onto a collector element that forms the return path for the current and dissipates the heat resulting from electron beam bombardment. (3—**reflex**) A klystron with only one cavity. The action is the same as in a two-cavity klystron but the beam is reflected back into the cavity in which it was first excited, after being sent out to a reflector. The one cavity, therefore, acts both as the original exciter (or buncher) and as the collector from which the output is taken.

Knee: In a response curve, the region of maximum curvature.

Ku band: Radio frequencies in the range of 15.35 GHz to 17.25 GHz, typically used for satellite telecommunications.

L

Ladder network: A type of filter with components alternately across the line and in the line.

Lag: The difference in phase between a current and the voltage that produced it, expressed in electrical degrees.

Lagging current: A current that lags behind the alternating electromotive force that produced it. A circuit that produces a *lagging current* is one containing inductance alone, or whose effective impedance is inductive.

Lagging load: A load whose combined inductive reactance exceeds its capacitive reactance. When an alternating voltage is applied, the current lags behind the voltage.

Laminate: A material consisting of layers of the same or different materials bonded together and built up to the required thickness.

Latitude: An angular measurement of a point on the earth above or below the equator. The equator represents 0° , the north pole $+90^\circ$, and the south pole -90° .

Layout: A proposed or actual arrangement or allocation of equipment.

LC circuit: An electrical circuit with both inductance (L) and capacitance (C) that is resonant at a particular frequency.

LC ratio: The ratio of inductance to capacitance in a given circuit.

Lead: An electrical wire, usually insulated.

Leading edge: The initial portion of a pulse or wave in which voltage or current rise rapidly from zero to a final value.

Leading load: A reactive load in which the reactance of capacitance is greater than that of inductance. Current through such a load *leads* the applied voltage causing the current.

Leakage: The loss of energy resulting from the flow of electricity past an insulating material, the escape of electromagnetic radiation beyond its shielding, or the extension of magnetic lines of force beyond their intended working area.

Leakage resistance: The resistance of a path through which leakage current flows.

Level: The strength or intensity of a given signal.

Level alignment: The adjustment of transmission levels of single links and links in tandem to prevent overloading of transmission subsystems.

Life cycle: The predicted useful life of a class of equipment, operating under normal (specified) working conditions.

Life safety system: A system designed to protect life and property, such as emergency lighting, fire alarms, smoke exhaust and ventilating fans, and site security.

Life test: A test in which random samples of a product are checked to see how long they can continue to perform their functions satisfactorily. A form of *stress testing* is used, including temperature, current, voltage, and/or vibration effects, cycled at many times the rate that would apply in normal usage.

Limiter: An electronic device in which some characteristic of the output is automatically prevented from exceeding a predetermined value.

Limiter circuit: A circuit of nonlinear elements that restricts the electrical excursion of a variable in accordance with some specified criteria.

Limiting: A process by which some characteristic at the output of a device is prevented from exceeding a predetermined value.

Line loss: The total end-to-end loss in decibels in a transmission line.

Line-up: The process of adjusting transmission parameters to bring a circuit to its specified values.

Linear: A circuit, device, or channel whose output is directly proportional to its input.

Linear distortion: A distortion mechanism that is independent of signal amplitude.

Linearity: A constant relationship, over a designated range, between the input and output characteristics of a circuit or device.

Lines of force: A group of imaginary lines indicating the direction of the electric or magnetic field at all points along it.

- Lissajous pattern:** The looping patterns generated by a CRT spot when the horizontal (X) and vertical (Y) deflection signals are sinusoids. The lissajous pattern is useful for evaluating the delay or phase of two sinusoids of the same frequency.
- Live:** A device or system connected to a source of electric potential.
- Load:** The work required of an electrical or mechanical system.
- Load factor:** The ratio of the average load over a designated period of time to the peak load occurring during the same period.
- Load line:** A straight line drawn across a grouping of plate current/plate voltage characteristic curves showing the relationship between grid voltage and plate current for a particular plate load resistance of an electron tube.
- Logarithm:** The power to which a base must be raised to produce a given number. Common logarithms are to base 10.
- Logarithmic scale:** A meter scale with displacement proportional to the logarithm of the quantity represented.
- Long persistence:** The quality of a cathode ray tube that has phosphorescent compounds on its screen (in addition to fluorescent compounds) so that the image continues to glow after the original electron beam has ceased to create it by producing the usual fluorescence effect. Long persistence is often used in radar screens or where photographic evidence is needed of a display. Most such applications, however, have been superseded through the use of digital storage techniques.
- Longitude:** The angular measurement of a point on the surface of the earth in relation to the meridian of Greenwich (London). The earth is divided into 360° of longitude, beginning at the Greenwich mean. As one travels west around the globe, the longitude increases.
- Longitudinal current:** A current that travels in the same direction on both wires of a pair. The return current either flows in another pair or via a ground return path.
- Loss:** The power dissipated in a circuit, usually expressed in decibels, that performs no useful work.
- Loss deviation:** The change of actual loss in a circuit or system from a designed value.
- Loss variation:** The change in actual measured loss over time.
- Lossy:** The condition when the line loss per unit length is significantly greater than some defined normal parameter.
- Lossy cable:** A coaxial cable constructed to have high transmission loss so it can be used as an artificial load or as an attenuator.
- Lot size:** A specific quantity of similar material or a collection of similar units from a common source; in inspection work, the quantity offered for inspection and acceptance at any one time. The **lot size** may be a collection of raw material, parts, subassemblies inspected during production, or a consignment of finished products to be sent out for service.
- Low tension:** A low voltage circuit.
- Low-pass filter:** A filter network that passes all frequencies below a specified frequency with little or no loss, but that significantly attenuates higher frequencies.
- Lug:** A tag or projecting terminal onto which a wire may be connected by wrapping, soldering, or crimping.
- Lumped constant:** A resistance, inductance, or capacitance connected at a point, and not distributed uniformly throughout the length of a route or circuit.

M

- MA:** An abbreviation for *milliamperes* (0.001 A).
- Magnet:** A device that produces a magnetic field and can attract iron, and attract or repel other magnets.
- Magnetic field:** An energy field that exists around magnetic materials and current-carrying conductors. Magnetic fields combine with electric fields in light and radio waves.
- Magnetic flux:** The field produced in the area surrounding a magnet or electric current. The standard unit of flux is the *Weber*.
- Magnetic flux density:** A vector quantity measured by a standard unit called the *Tesla*. The *magnetic flux density* is the number of magnetic lines of force per unit area, at right angles to the lines.

- Magnetic leakage:** The magnetic flux that does not follow a useful path.
- Magnetic pole:** A point that appears from the outside to be the center of magnetic attraction or repulsion at or near one end of a magnet.
- Magnetic storm:** A violent local variation in the earth's magnetic field, usually the result of sunspot activity.
- Magnetism:** A property of iron and some other materials by which external magnetic fields are maintained, other magnets being thereby attracted or repelled.
- Magnetization:** The exposure of a magnetic material to a magnetizing current, field, or force.
- Magnetizing force:** The force producing magnetization.
- Magnetomotive force:** The force that tends to produce lines of force in a magnetic circuit. The *magnetomotive force* bears the same relationship to a magnetic circuit that voltage does to an electrical circuit.
- Magnetron:** A high-power, ultra high frequency electron tube oscillator that employs the interaction of a strong electric field between an anode and cathode with the field of a strong permanent magnet to cause oscillatory electron flow through multiple internal cavity resonators. The magnetron may operate in a continuous or pulsed mode.
- Maintainability:** The probability that a failure will be repaired within a specified time after the failure occurs.
- Maintenance:** Any activity intended to keep a functional unit in satisfactory working condition. The term includes the tests, measurements, replacements, adjustments, and repairs necessary to keep a device or system operating properly.
- Malfunction:** An equipment failure or a fault.
- Manometer:** A test device for measuring gas pressure.
- Margin:** The difference between the value of an operating parameter and the value that would result in unsatisfactory operation. Typical *margin* parameters include signal level, signal-to-noise ratio, distortion, crosstalk coupling, and/or undesired emission level.
- Markov model:** A statistical model of the behavior of a complex system over time in which the probabilities of the occurrence of various future states depend only on the present state of the system, and not on the path by which the present state was achieved. This term was named for the Russian mathematician Andrei Andreevich Markov (1856–1922).
- Master clock:** An accurate timing device that generates a synchronous signal to control other clocks or equipment.
- Master oscillator:** A stable oscillator that provides a standard frequency signal for other hardware and/or systems.
- Matched termination:** A termination that absorbs all the incident power and so produces no reflected waves or mismatch loss.
- Matching:** The connection of channels, circuits, or devices in a manner that results in minimal reflected energy.
- Matrix:** A logical network configured in a rectangular array of intersections of input/ output signals.
- Maxwell's equations:** Four differential equations that relate electric and magnetic fields to electromagnetic waves. The equations are a basis of electrical and electronic engineering.
- Mean:** An arithmetic average in which values are added and divided by the number of such values.
- Mean time between failures (MTBF):** For a particular interval, the total functioning life of a population of an item divided by the total number of failures within the population during the measurement interval.
- Mean time to failure (MTTF):** The measured operating time of a single piece of equipment divided by the total number of failures during the measured period of time. This measurement is normally made during that period between early life and wear-out failures.
- Mean time to repair (MTTR):** The total corrective maintenance time on a component or system divided by the total number of corrective maintenance actions during a given period of time.
- Measurement:** A procedure for determining the amount of a quantity.
- Median:** A value in a series that has as many readings or values above it as below.

Medium: An electronic pathway or mechanism for passing information from one point to another.

Mega: A prefix meaning one million.

Megahertz (MHz): A quantity equal to one million Hertz (cycles per second).

Megohm: A quantity equal to one million ohms.

Metric system: A decimal system of measurement based on the meter, the kilogram, and the second.

Micro: A prefix meaning one millionth.

Micron: A unit of length equal to one millionth of a meter (1/25,000 of an inch).

Microphonic(s): Unintended noise introduced into an electronic system by mechanical vibration of electrical components.

Microsecond: One millionth of a second (0.000001 s).

Microvolt: A quantity equal to one-millionth of a volt.

Milli: A prefix meaning one thousandth.

Milliammeter: A test instrument for measuring electrical current, often part of a *multimeter*.

Millihenry: A quantity equal to one-thousandth of a henry.

Milliwatt: A quantity equal to one thousandth of a watt.

Minimum discernible signal: The smallest input that will produce a discernible change in the output of a circuit or device.

Mixer: A circuit used to combine two or more signals to produce a third signal that is a function of the input waveforms.

Mixing ratio: The ratio of the mass of water vapor to the mass of dry air in a given volume of air. The *mixing ratio* affects radio propagation.

Mode: An electromagnetic field distribution that satisfies theoretical requirements for propagation in a waveguide or oscillation in a cavity.

Modified refractive index: The sum of the refractive index of the air at a given height above sea level, and the ratio of this height to the radius of the earth.

Modular: An equipment design in which major elements are readily separable, and which the user may replace, reducing the mean-time-to-repair.

Modulation: The process whereby the amplitude, frequency, or phase of a single-frequency wave (the *carrier*) is varied in step with the instantaneous value of, or samples of, a complex wave (the *modulating wave*).

Modulator: A device that enables the intelligence in an information-carrying modulating wave to be conveyed by a signal at a higher frequency. A *modulator* modifies a carrier wave by amplitude, phase, and/or frequency as a function of a control signal that carries intelligence. Signals are *modulated* in this way to permit more efficient and/or reliable transmission over any of several media.

Module: An assembly replaceable as an entity, often as an interchangeable plug-in item. A *module* is not normally capable of being disassembled.

Monostable: A device that is stable in one state only. An input pulse causes the device to change state, but it reverts immediately to its stable state.

Motor: A machine that converts electrical energy into mechanical energy.

Motor effect: The repulsion force exerted between adjacent conductors carrying currents in opposite directions.

Moving coil: Any device that utilizes a coil of wire in a magnetic field in such a way that the coil is made to move by varying the applied current, or itself produces a varying voltage because of its movement.

Ms: An abbreviation for *millisecond* (0.001 s).

Multimeter: A test instrument fitted with several ranges for measuring voltage, resistance, and current, and equipped with an analog meter or digital display readout. The *multimeter* is also known as a *volt-ohm-milliammeter*, or *VOM*.

Multiplex (MUX): The use of a common channel to convey two or more channels. This is done either by splitting of the common channel frequency band into narrower bands, each of which is used to

constitute a distinct channel (*frequency division multiplex*), or by allotting this common channel to multiple users in turn to constitute different intermittent channels (*time division multiplex*).

Multiplexer: A device or circuit that combines several signals onto a single signal.

Multiplexing: A technique that uses a single transmission path to carry multiple channels. In *time division multiplexing* (TDM), path time is shared. For *frequency division multiplexing* (FDM) or *wavelength division multiplexing* (WDM), signals are divided into individual channels sent along the same path but at different frequencies.

Multiplication: Signal mixing that occurs within a multiplier circuit.

Multiplier: A circuit in which one or more input signals are mixed under the direction of one or more control signals. The resulting output is a composite of the input signals, the characteristics of which are determined by the scaling specified for the circuit.

Mutual induction: The property of the magnetic flux around a conductor that induces a voltage in a nearby conductor. The voltage generated in the secondary conductor in turn induces a voltage in the primary conductor. The inductance of two conductors so coupled is referred to as *mutual inductance*.

MV: An abbreviation for *millivolt* (0.001 V).

MW: An abbreviation for *milliwatt* (0.001 W).

N

Nano: A prefix meaning one billionth.

Nanometer: 1×10^{-9} meter.

Nanosecond (ns): One billionth of a second (1×10^{-9} s).

Narrowband: A communications channel of restricted bandwidth, often resulting in degradation of the transmitted signal.

Narrowband emission: An emission having a spectrum exhibiting one or more sharp peaks that are narrow in width compared to the nominal bandwidth of the measuring instrument, and are far enough apart in frequency to be resolvable by the instrument.

National Electrical Code (NEC): A document providing rules for the installation of electric wiring and equipment in public and private buildings, published by the National Fire Protection Association. The NEC has been adopted as law by many states and municipalities in the U.S.

National Institute of Standards and Technology (NIST): A nonregulatory agency of the Department of Commerce that serves as a national reference and measurement laboratory for the physical and engineering sciences. Formerly called the *National Bureau of Standards*, the agency was renamed in 1988 and given the additional responsibility of aiding U.S. companies in adopting new technologies to increase their international competitiveness.

Negative: In a conductor or semiconductor material, an excess of electrons or a deficiency of positive charge.

Negative feedback: The return of a portion of the output signal from a circuit to the input but 180° out of phase. This type of feedback decreases signal amplitude but stabilizes the amplifier and reduces distortion and noise.

Negative impedance: An impedance characterized by a decrease in voltage drop across a device as the current through the device is increased, or a decrease in current through the device as the voltage across it is increased.

Neutral: A device or object having no electrical charge.

Neutral conductor: A conductor in a power distribution system connected to a point in the system that is designed to be at neutral potential. In a balanced system, the neutral conductor carries no current.

Neutral ground: An intentional ground applied to the neutral conductor or neutral point of a circuit, transformer, machine, apparatus, or system.

Newton: The standard unit of force. One *newton* is the force that, when applied to a body having a mass of 1 kg, gives it an acceleration of 1 m/s^2 .

Nitrogen: A gas widely used to pressurize radio frequency transmission lines. If a small puncture occurs in the cable sheath, the nitrogen keeps moisture out so that service is not adversely affected.

- Node:** The points at which the current is at minimum in a transmission system in which standing waves are present.
- Noise:** Any random disturbance or unwanted signal in a communication system that tends to obscure the clarity or usefulness of a signal in relation to its intended use.
- Noise factor (NF):** The ratio of the noise power measured at the output of a receiver to the noise power that would be present at the output if the thermal noise resulting from the resistive component of the source impedance were the only source of noise in the system.
- Noise figure:** A measure of the noise in dB generated at the input of an amplifier, compared with the noise generated by an impedance-method resistor at a specified temperature.
- Noise filter:** A network that attenuates noise frequencies.
- Noise generator:** A generator of wideband random noise.
- Noise power ratio (NPR):** The ratio, expressed in decibels, of signal power to intermodulation product power plus residual noise power, measured at the baseband level.
- Noise suppressor:** A filter or digital signal processing circuit in a receiver or transmitter that automatically reduces or eliminates noise.
- Noise temperature:** The temperature, expressed in Kelvin, at which a resistor will develop a particular noise voltage. The noise temperature of a radio receiver is the value by which the temperature of the resistive component of the source impedance should be increased—if it were the only source of noise in the system—to cause the noise power at the output of the receiver to be the same as in the real system.
- Nominal:** The most common value for a component or parameter that falls between the maximum and minimum limits of a tolerance range.
- Nominal value:** A specified or intended value independent of any uncertainty in its realization.
- Nomogram:** A chart showing three or more scales across which a straight edge may be held in order to read off a graphical solution to a three-variable equation.
- Nonconductor:** A material that does not conduct energy, such as electricity, heat, or sound.
- Noncritical technical load:** That part of the technical power load for a facility not required for minimum acceptable operation.
- Noninductive:** A device or circuit without significant inductance.
- Nonionizing radiation:** Electromagnetic radiation that does not turn an atom into an ion. Examples of nonionizing radiation include visible light and radio waves.
- Nonlinearity:** A distortion in which the output of a circuit or system does not rise or fall in direct proportion to the input.
- Nontechnical load:** The part of the total operational load of a facility used for such purposes as general lighting, air conditioning, and ventilating equipment during normal operation.
- Normal:** A line perpendicular to another line or to a surface.
- Normal-mode noise:** Unwanted signals in the form of voltages appearing in line-to-line and line-to-neutral signals.
- Normalized frequency:** The ratio between the actual frequency and its nominal value.
- Normalized frequency departure:** The frequency departure divided by the nominal frequency value.
- Normalized frequency difference:** The algebraic difference between two normalized frequencies.
- Normalized frequency drift:** The frequency drift divided by the nominal frequency value.
- Normally closed:** Switch contacts that are closed in their nonoperated state, or relay contacts that are closed when the relay is de-energized.
- Normally open:** Switch contacts that are open in their nonoperated state, or relay contacts that are open when the relay is de-energized.
- North pole:** The pole of a magnet that seeks the north magnetic pole of the earth.
- Notch filter:** A circuit designed to attenuate a specific frequency band; also known as a *band stop filter*.
- Notched noise:** A noise signal in which a narrow band of frequencies has been removed.
- Ns:** An abbreviation for *nanosecond*.
- Null:** A zero or minimum amount or position.

O

- Octave:** Any frequency band in which the highest frequency is twice the lowest frequency.
- Off-line:** A condition wherein devices or subsystems are not connected into, do not form a part of, and are not subject to the same controls as an operational system.
- Offset:** An intentional difference between the realized value and the nominal value.
- Ohm:** The unit of electric resistance through which one ampere of current will flow when there is a difference of one volt. The quantity is named for the German physicist Georg Simon Ohm (1787–1854).
- Ohm's law:** A law that sets forth the relationship between voltage (E), current (I), and resistance (R). The law states that $E = I \times R$, $I = \frac{E}{R}$, and $R = \frac{E}{I}$. *Ohm's Law* is named for the German physicist Georg Simon Ohm (1787–1854).
- Ohmic loss:** The power dissipation in a line or circuit caused by electrical resistance.
- Ohmmeter:** A test instrument used for measuring resistance, often part of a *multimeter*.
- Ohms-per-volt:** A measure of the sensitivity of a voltmeter.
- On-line:** A device or system that is energized and operational, and ready to perform useful work.
- Open:** An interruption in the flow of electrical current, as caused by a broken wire or connection.
- Open-circuit:** A defined loop or path that closes on itself and contains an infinite impedance.
- Open-circuit impedance:** The input impedance of a circuit when its output terminals are open, that is, not terminated.
- Open-circuit voltage:** The voltage measured at the terminals of a circuit when there is no load and, hence, no current flowing.
- Operating lifetime:** The period of time during which the principal parameters of a component or system remain within a prescribed range.
- Optimize:** The process of adjusting for the best output or maximum response from a circuit or system.
- Orbit:** The path, relative to a specified frame of reference, described by the center of mass of a satellite or other object in space, subjected solely to natural forces (mainly gravitational attraction).
- Order of diversity:** The number of independently fading propagation paths or frequencies, or both, used in a diversity reception system.
- Original equipment manufacturer (OEM):** A manufacturer of equipment that is used in systems assembled and sold by others.
- Oscillation:** A variation with time of the magnitude of a quantity with respect to a specified reference when the magnitude is alternately greater than and smaller than the reference.
- Oscillator:** A nonrotating device for producing alternating current, the output frequency of which is determined by the characteristics of the circuit.
- Oscilloscope:** A test instrument that uses a display, usually a cathode-ray tube, to show the instantaneous values and waveforms of a signal that varies with time or some other parameter.
- Out-of-band energy:** Energy emitted by a transmission system that falls outside the frequency spectrum of the intended transmission.
- Outage duration:** The average elapsed time between the start and the end of an outage period.
- Outage probability:** The probability that an outage state will occur within a specified time period. In the absence of specific known causes of outages, the *outage probability* is the sum of all outage durations divided by the time period of measurement.
- Outage threshold:** A defined value for a supported performance parameter that establishes the minimum operational service performance level for that parameter.
- Output impedance:** The impedance presented at the output terminals of a circuit, device, or channel.
- Output stage:** The final driving circuit in a piece of electronic equipment.
- Ovenized crystal oscillator (OXO):** A crystal oscillator enclosed within a temperature regulated heater (oven) to maintain a stable frequency despite external temperature variations.
- Overcoupling:** A degree of coupling greater than the *critical coupling* between two resonant circuits. *Overcoupling* results in a wide bandwidth circuit with two peaks in the response curve.

Overload: In a transmission system, a power greater than the amount the system was designed to carry. In a power system, an overload could cause excessive heating. In a communications system, distortion of a signal could result.

Overshoot: The first maximum excursion of a pulse beyond the 100% level. Overshoot is the portion of the pulse that exceeds its defined level temporarily before settling to the correct level. Overshoot amplitude is expressed as a percentage of the defined level.

P

Pentode: An electron tube with five electrodes, the cathode, control grid, screen grid, suppressor grid, and plate.

Photocathode: An electrode in an electron tube that will emit electrons when bombarded by photons of light.

Picture tube: A cathode-ray tube used to produce an image by variation of the intensity of a scanning beam on a phosphor screen.

Pin: A terminal on the base of a component, such as an electron tube.

Plasma (1—arc): An ionized gas in an arc-discharge tube that provides a conducting path for the discharge. (2—solar) The ionized gas at extremely high temperature found in the sun.

Plate (1—electron tube): The anode of an electron tube. (2—battery) An electrode in a storage battery. (3—capacitor) One of the surfaces in a capacitor. (4—chassis) A mounting surface to which equipment may be fastened.

Propagation time delay: The time required for a signal to travel from one point to another.

Protector: A device or circuit that prevents damage to lines or equipment by conducting dangerously high voltages or currents to ground. Protector types include spark gaps, semiconductors, varistors, and gas tubes.

Proximity effect: A nonuniform current distribution in a conductor, caused by current flow in a nearby conductor.

Pseudonoise: In a spread-spectrum system, a seemingly random series of pulses whose frequency spectrum resembles that of continuous noise.

Pseudorandom: A sequence of signals that appears to be completely random but have, in fact, been carefully drawn up and repeat after a significant time interval.

Pseudorandom noise: A noise signal that satisfies one or more of the standard tests for statistical randomness. Although it seems to lack any definite pattern, there is a sequence of pulses that repeats after a long time interval.

Pseudorandom number sequence: A sequence of numbers that satisfies one or more of the standard tests for statistical randomness. Although it seems to lack any definite pattern, there is a sequence that repeats after a long time interval.

Pulsating direct current: A current changing in value at regular or irregular intervals but which has the same direction at all times.

Pulse: One of the elements of a repetitive signal characterized by the rise and decay in time of its magnitude. A *pulse* is usually short in relation to the time span of interest.

Pulse decay time: The time required for the trailing edge of a pulse to decrease from 90 percent to 10 percent of its peak amplitude.

Pulse duration: The time interval between the points on the leading and trailing edges of a pulse at which the instantaneous value bears a specified relation to the peak pulse amplitude.

Pulse duration modulation (PDM): The modulation of a pulse carrier by varying the width of the pulses according to the instantaneous values of the voltage samples of the modulating signal (also called *pulse width modulation*).

Pulse edge: The leading or trailing edge of a pulse, defined as the 50 percent point of the pulse rise or fall time.

Pulse fall time: The interval of time required for the edge of a pulse to fall from 90 percent to 10 percent of its peak amplitude.

Pulse interval: The time between the start of one pulse and the start of the next.

Pulse length: The duration of a pulse (also called *pulse width*).

Pulse level: The voltage amplitude of a pulse.

Pulse period: The time between the start of one pulse and the start of the next.

Pulse ratio: The ratio of the length of any pulse to the total pulse period.

Pulse repetition period: The time interval from the beginning of one pulse to the beginning of the next pulse.

Pulse repetition rate: The number of times each second that pulses are transmitted.

Pulse rise time: The time required for the leading edge of a pulse to rise from 10 percent to 90 percent of its peak amplitude.

Pulse train: A series of pulses having similar characteristics.

Pulse width: The measured interval between the 50 percent amplitude points of the leading and trailing edges of a pulse.

Puncture: A breakdown of insulation or of a dielectric, such as in a cable sheath or in the insulant around a conductor.

PW: An abbreviation for picowatt, a unit of power equal to 10^{-12} W (−90 dBm).

Q

Q (quality factor): A figure of merit that defines how close a coil comes to functioning as a pure inductor. *High Q* describes an inductor with little energy loss resulting from resistance. *Q* is found by dividing the inductive reactance of a device by its resistance.

Quadrature: A state of alternating current signals separated by one quarter of a cycle (90°).

Quadrature amplitude modulation (QAM): A process that allows two different signals to modulate a single carrier frequency. The two signals of interest amplitude modulate two samples of the carrier that are of the same frequency, but differ in phase by 90° . The two resultant signals can be added and transmitted. Both signals may be recovered at a decoder when they are demodulated 90° apart.

Quadrature component: The component of a voltage or current at an angle of 90° to a reference signal, resulting from inductive or capacitive reactance.

Quadrature phase shift keying (QPSK): A type of phase shift keying using four phase states.

Quality: The absence of objectionable distortion.

Quality assurance (QA): All those activities, including surveillance, inspection, control, and documentation, aimed at ensuring that a given product will meet its performance specifications.

Quality control (QC): A function whereby management exercises control over the quality of raw material or intermediate products in order to prevent the production of defective devices or systems.

Quantum noise: Any noise attributable to the discrete nature of electromagnetic radiation. Examples include shot noise, photon noise, and recombination noise.

Quantum-limited operation: An operation wherein the minimum detectable signal is limited by quantum noise.

Quartz: A crystalline mineral that when electrically excited vibrates with a stable period. Quartz is typically used as the frequency-determining element in oscillators and filters.

Quasi-peak detector: A detector that delivers an output voltage that is some fraction of the peak value of the regularly repeated pulses applied to it. The fraction increases toward unity as the pulse repetition rate increases.

Quick-break fuse: A fuse in which the fusible link is under tension, providing for rapid operation.

Quiescent: An inactive device, signal, or system.

Quiescent current: The current that flows in a device in the absence of an applied signal.

R

Rack: An equipment rack, usually measuring 19 in (48.26 cm) wide at the front mounting rails.

Rack unit (RU): A unit of measure of vertical space in an equipment enclosure. One rack unit is equal to 1.75 in (4.45 cm).

Radiate: The process of emitting electromagnetic energy.

Radiation: The emission and propagation of electromagnetic energy in the form of waves. *Radiation* is also called *radiant energy*.

Radiation scattering: The diversion of thermal, electromagnetic, or nuclear radiation from its original path as a result of interactions or collisions with atoms, molecules, or large particles in the atmosphere or other media between the source of radiation and a point some distance away. As a result of scattering, radiation (especially gamma rays and neutrons) will be received at such a point from many directions, rather than only from the direction of the source.

Radio: The transmission of signals over a distance by means of electromagnetic waves in the approximate frequency range of 150 kHz to 300 GHz. The term may also be used to describe the equipment used to transmit or receive electromagnetic waves.

Radio detection: The detection of the presence of an object by radio location without precise determination of its position.

Radio frequency interference (RFI): The intrusion of unwanted signals or electromagnetic noise into various types of equipment resulting from radio frequency transmission equipment or other devices using radio frequencies.

Radio frequency spectrum: Those frequency bands in the electromagnetic spectrum that range from several hundred thousand cycles per second (*very low frequency*) to several billion cycles per second (*microwave frequencies*).

Radio recognition: In military communications, the determination by radio means of the “friendly” or “unfriendly” character of an aircraft or ship.

Random noise: Electromagnetic signals that originate in transient electrical disturbances and have random time and amplitude patterns. Random noise is generally undesirable; however, it may also be generated for testing purposes.

Rated output power: The power available from an amplifier or other device under specified conditions of operation.

RC constant: The time constant of a resistor-capacitor circuit. The *RC constant* is the time in seconds required for current in an RC circuit to rise to 63 percent of its final steady value or fall to 37 percent of its original steady value, obtained by multiplying the resistance value in ohms by the capacitance value in farads.

RC network: A circuit that contains resistors and capacitors, normally connected in series.

Reactance: The part of the impedance of a network resulting from inductance or capacitance. The *reactance* of a component varies with the frequency of the applied signal.

Reactive power: The power circulating in an ac circuit. It is delivered to the circuit during part of the cycle and is returned during the other half of the cycle. The *reactive power* is obtained by multiplying the voltage, current, and the sine of the phase angle between them.

Reactor: A component with inductive reactance.

Received signal level (RSL): The value of a specified bandwidth of signals at the receiver input terminals relative to an established reference.

Receiver: Any device for receiving electrical signals and converting them to audible sound, visible light, data, or some combination of these elements.

Receptacle: An electrical socket designed to receive a mating plug.

Reception: The act of receiving, listening to, or watching information-carrying signals.

Rectification: The conversion of alternating current into direct current.

Rectifier: A device for converting alternating current into direct current. A *rectifier* normally includes filters so that the output is, within specified limits, smooth and free of ac components.

Rectify: The process of converting alternating current into direct current.

- Redundancy:** A system design that provides a back-up for key circuits or components in the event of a failure. Redundancy improves the overall reliability of a system.
- Redundant:** A configuration when two complete systems are available at one time. If the online system fails, the backup will take over with no loss of service.
- Reference voltage:** A voltage used for control or comparison purposes.
- Reflectance:** The ratio of reflected power to incident power.
- Reflection:** An abrupt change, resulting from an impedance mismatch, in the direction of propagation of an electromagnetic wave. For light, at the interface of two dissimilar materials, the incident wave is returned to its medium of origin.
- Reflection coefficient:** The ratio between the amplitude of a reflected wave and the amplitude of the incident wave. For large smooth surfaces, the reflection coefficient may be near unity.
- Reflection gain:** The increase in signal strength that results when a reflected wave combines, in phase, with an incident wave.
- Reflection loss:** The apparent loss of signal strength caused by an impedance mismatch in a transmission line or circuit. The loss results from the reflection of part of the signal back toward the source from the point of the impedance discontinuity. The greater the mismatch, the greater the loss.
- Reflectometer:** A device that measures energy traveling in each direction in a waveguide, used in determining the standing wave ratio.
- Refraction:** The bending of a sound, radio, or light wave as it passes obliquely from a medium of one density to a medium of another density that varies its speed.
- Regulation:** The process of adjusting the level of some quantity, such as circuit gain, by means of an electronic system that monitors an output and feeds back a controlling signal to constantly maintain a desired level.
- Regulator:** A device that maintains its output voltage at a constant level.
- Relative envelope delay:** The difference in envelope delay at various frequencies when compared with a reference frequency that is chosen as having zero delay.
- Relative humidity:** The ratio of the quantity of water vapor in the atmosphere to the quantity that would cause saturation at the ambient temperature.
- Relative transmission level:** The ratio of the signal power in a transmission system to the signal power at some point chosen as a reference. The ratio is usually determined by applying a standard test signal at the input to the system and measuring the gain or loss at the location of interest.
- Relay:** A device by which current flowing in one circuit causes contacts to operate that control the flow of current in another circuit.
- Relay armature:** The movable part of an electromechanical relay, usually coupled to spring sets on which contacts are mounted.
- Relay bypass:** A device that, in the event of a loss of power or other failure, routes a critical signal around the equipment that has failed.
- Release time:** The time required for a pulse to drop from steady-state level to zero, also referred to as the *decay time*.
- Reliability:** The ability of a system or subsystem to perform within the prescribed parameters of quality of service. *Reliability* is often expressed as the probability that a system or subsystem will perform its intended function for a specified interval under stated conditions.
- Reliability growth:** The action taken to move a hardware item toward its reliability potential, during development or subsequent manufacturing or operation.
- Reliability predictions:** The compiled failure rates for parts, components, subassemblies, assemblies, and systems. These generic failure rates are used as basic data to predict the reliability of a given device or system.
- Remote control:** A system used to control a device from a distance.
- Remote station:** A station or terminal that is physically remote from a main station or center but can gain access through a communication channel.

Repeater: The equipment between two circuits that receives a signal degraded by normal factors during transmission and amplifies the signal to its original level for retransmission.

Repetition rate: The rate at which regularly recurring pulses are repeated.

Reply: A transmitted message that is a direct response to an original message.

Repulsion: The mechanical force that tends to separate like magnetic poles, like electric charges, or conductors carrying currents in opposite directions.

Reset: The act of restoring a device to its default or original state.

Residual flux: The magnetic flux that remains after a magnetomotive force has been removed.

Residual magnetism: The magnetism or flux that remains in a core after current ceases to flow in the coil producing the magnetomotive force.

Residual voltage: The vector sum of the voltages in all the phase wires of an unbalanced polyphase power system.

Resistance: The opposition of a material to the flow of electrical current. Resistance is equal to the voltage drop through a given material divided by the current flow through it. The standard unit of resistance is the *ohm*, named for the German physicist Georg Simon Ohm (1787–1854).

Resistance drop: The fall in potential (volts) between two points, the product of the current and resistance.

Resistance-grounded: A circuit or system grounded for safety through a resistance, which limits the value of the current flowing through the circuit in the event of a fault.

Resistive load: A load in which the voltage is in phase with the current.

Resistivity: The resistance per unit volume or per unit area.

Resistor: A device the primary function of which is to introduce a specified resistance into an electrical circuit.

Resonance: A tuned condition conducive to oscillation, when the reactance resulting from capacitance in a circuit is equal in value to the reactance resulting from inductance.

Resonant frequency: The frequency at which the inductive reactance and capacitive reactance of a circuit are equal.

Resonator: A resonant cavity.

Return: A return path for current, sometimes through ground.

Reversal: A change in magnetic polarity, in the direction of current flow.

Reverse current: A small current that flows through a diode when the voltage across it is such that normal forward current does not flow.

Reverse voltage: A voltage in the reverse direction from that normally applied.

Rheostat: A two-terminal variable resistor, usually constructed with a sliding or rotating shaft that can be used to vary the resistance value of the device.

Ripple: An ac voltage superimposed on the output of a dc power supply, usually resulting from imperfect filtering.

Rise time: The time required for a pulse to rise from 10 percent to 90 percent of its peak value.

Roll-off: A gradual attenuation of gain-frequency response at either or both ends of a transmission pass band.

Root-mean-square (RMS): The square root of the average value of the squares of all the instantaneous values of current or voltage during one half-cycle of an alternating current. For an alternating current, the RMS voltage or current is equal to the amount of direct current or voltage that would produce the same heating effect in a purely resistive circuit. For a sinewave, the root-mean-square value is equal to 0.707 times the peak value. RMS is also called the *effective value*.

Rotor: The rotating part of an electric generator or motor.

RU: An abbreviation for *rack unit*.

S

Scan: One sweep of the target area in a camera tube, or of the screen in a picture tube.

Screen grid: A grid in an electron tube that improves performance of the device by shielding the control grid from the plate.

- Self-bias:** The provision of bias in an electron tube through a voltage drop in the cathode circuit.
- Shot noise:** The noise developed in a vacuum tube or photoconductor resulting from the random number and velocity of emitted charge carriers.
- Slope:** The rate of change, with respect to frequency, of transmission line attenuation over a given frequency spectrum.
- Slope equalizer:** A device or circuit used to achieve a specified slope in a transmission line.
- Smoothing circuit:** A filter designed to reduce the amount of ripple in a circuit, usually a dc power supply.
- Snubber:** An electronic circuit used to suppress high frequency noise.
- Solar wind:** Charged particles from the sun that continuously bombard the surface of the earth.
- Solid:** A single wire conductor, as contrasted with a stranded, braided, or rope-type wire.
- Solid-state:** The use of semiconductors rather than electron tubes in a circuit or system.
- Source:** The part of a system from which signals or messages are considered to originate.
- Source terminated:** A circuit whose output is terminated for correct impedance matching with standard cable.
- Spare:** A system that is available but not presently in use.
- Spark gap:** A gap between two electrodes designed to produce a spark under given conditions.
- Specific gravity:** The ratio of the weight of a volume, liquid, or solid to the weight of the same volume of water at a specified temperature.
- Spectrum:** A continuous band of frequencies within which waves have some common characteristics.
- Spectrum analyzer:** A test instrument that presents a graphic display of signals over a selected frequency bandwidth. A cathode-ray tube is often used for the display.
- Spectrum designation of frequency:** A method of referring to a range of communication frequencies. In American practice, the designation is a two or three letter acronym for the name. The ranges are: below 300 Hz, ELF (extremely low frequency); 300 Hz–3000 Hz, ILF (infra low frequency); 3 kHz–30 kHz, VLF (very low frequency); 30 kHz–300 kHz, LF (low frequency); 300 kHz–3000 kHz, MF (medium frequency); 3 MHz–30 MHz, HF (high frequency); 30 MHz–300 MHz, VHF (very high frequency); 300 MHz–3000 MHz, UHF (ultra high frequency); 3 GHz–30 GHz, SHF (super high frequency); 30 GHz–300 GHz, EHF (extremely high frequency); 300 GHz–3000 GHz, THF (tremendously high frequency).
- Spherical antenna:** A type of satellite receiving antenna that permits more than one satellite to be accessed at any given time. A spherical antenna has a broader angle of acceptance than a parabolic antenna.
- Spike:** A high amplitude, short duration pulse superimposed on an otherwise regular waveform.
- Split-phase:** A device that derives a second phase from a single phase power supply by passing it through a capacitive or inductive reactor.
- Splitter:** A circuit or device that accepts one input signal and distributes it to several outputs.
- Splitting ratio:** The ratio of the power emerging from the output ports of a coupler.
- Sporadic:** An event occurring at random and infrequent intervals.
- Spread spectrum:** A communications technique in which the frequency components of a narrowband signal are spread over a wide band. The resulting signal resembles white noise. The technique is used to achieve signal security and privacy, and to enable the use of a common band by many users.
- Spurious signal:** Any portion of a given signal that is not part of the fundamental waveform. Spurious signals include transients, noise, and hum.
- Square wave:** A square or rectangular-shaped periodic wave that alternately assumes two fixed values for equal lengths of time, the transition being negligible in comparison with the duration of each fixed value.
- Square wave testing:** The use of a square wave containing many odd harmonics of the fundamental frequency as an input signal to a device. Visual examination of the output signal on an oscilloscope indicates the amount of distortion introduced.
- Stability:** The ability of a device or circuit to remain stable in frequency, power level, and/or other specified parameters.

- Standard:** The specific signal configuration, reference pulses, voltage levels, and other parameters that describe the input/output requirements for a particular type of equipment.
- Standard time and frequency signal:** A time-controlled radio signal broadcast at scheduled intervals on a number of different frequencies by government-operated radio stations to provide a method for calibrating instruments.
- Standing wave ratio (SWR):** The ratio of the maximum to the minimum value of a component of a wave in a transmission line or waveguide, such as the maximum voltage to the minimum voltage.
- Static charge:** An electric charge on the surface of an object, particularly a dielectric.
- Station:** One of the input or output points in a communications system.
- Stator:** The stationary part of a rotating electric machine.
- Status:** The present condition of a device.
- Statute mile:** A unit of distance equal to 1,609 km or 5,280 ft.
- Steady-state:** A condition in which circuit values remain essentially constant, occurring after all initial transients or fluctuating conditions have passed.
- Steady-state condition:** A condition occurring after all initial transient or fluctuating conditions have damped out in which currents, voltages, or fields remain essentially constant or oscillate uniformly without changes in characteristics such as amplitude, frequency, or wave shape.
- Steep wavefront:** A rapid rise in voltage of a given signal, indicating the presence of high frequency odd harmonics of a fundamental wave frequency.
- Step up (or down):** The process of increasing (or decreasing) the voltage of an electrical signal, as in a step-up (or step-down) transformer.
- Straight-line capacitance:** A capacitance employing a variable capacitor with plates so shaped that capacitance varies directly with the angle of rotation.
- Stray capacitance:** An unintended—and usually undesired—capacitance between wires and components in a circuit or system.
- Stray current:** A current through a path other than the intended one.
- Stress:** The force per unit of cross-sectional area on a given object or structure.
- Subassembly:** A functional unit of a system.
- Subcarrier (SC):** A carrier applied as modulation on another carrier, or on an intermediate subcarrier.
- Subharmonic:** A frequency equal to the fundamental frequency of a given signal divided by a whole number.
- Submodule:** A small circuit board or device that mounts on a larger module or device.
- Subrefraction:** A refraction for which the refractivity gradient is greater than standard.
- Subsystem:** A functional unit of a system.
- Superheterodyne receiver:** A radio receiver in which all signals are first converted to a common frequency for which the intermediate stages of the receiver have been optimized, both for tuning and filtering. Signals are converted by mixing them with the output of a local oscillator whose output is varied in accordance with the frequency of the received signals so as to maintain the desired *intermediate frequency*.
- Suppressor grid:** The fifth grid of a pentode electron tube, which provides screening between plate and screen grid.
- Surface leakage:** A leakage current from line to ground over the face of an insulator supporting an open wire route.
- Surface refractivity:** The refractive index, calculated from observations of pressure, temperature, and humidity at the surface of the earth.
- Surge:** A rapid rise in current or voltage, usually followed by a fall back to the normal value.
- Susceptance:** The reciprocal of reactance, and the imaginary component of admittance, expressed in siemens.
- Sweep:** The process of varying the frequency of a signal over a specified bandwidth.
- Sweep generator:** A test oscillator, the frequency of which is constantly varied over a specified bandwidth.

- Switching:** The process of making and breaking (connecting and disconnecting) two or more electrical circuits.
- Synchronization:** The process of adjusting the corresponding significant instants of signals—for example, the zero-crossings—to make them synchronous. The term *synchronization* is often abbreviated as *sync*.
- Synchronize:** The process of causing two systems to operate at the same speed.
- Synchronous:** In step or in phase, as applied to two or more devices; a system in which all events occur in a predetermined timed sequence.
- Synchronous detection:** A demodulation process in which the original signal is recovered by multiplying the modulated signal by the output of a synchronous oscillator locked to the carrier.
- Synchronous system:** A system in which the transmitter and receiver are operating in a fixed time relationship.
- System standards:** The minimum required electrical performance characteristics of a specific collection of hardware and/or software.
- Systems analysis:** An analysis of a given activity to determine precisely what must be accomplished and how it is to be done.

T

- Tetrode:** A four element electron tube consisting of a cathode, control grid, screen grid, and plate.
- Thyratron:** A gas-filled electron tube in which plate current flows when the grid voltage reaches a predetermined level. At that point, the grid has no further control over the current, which continues to flow until it is interrupted or reversed.
- Tolerance:** The permissible variation from a standard.
- Torque:** A moment of force acting on a body and tending to produce rotation about an axis.
- Total harmonic distortion (THD):** The ratio of the sum of the amplitudes of all signals harmonically related to the fundamental versus the amplitude of the fundamental signal. THD is expressed in percent.
- Trace:** The pattern on an oscilloscope screen when displaying a signal.
- Tracking:** The locking of tuned stages in a radio receiver so that all stages are changed appropriately as the receiver tuning is changed.
- Trade-off:** The process of weighing conflicting requirements and reaching a compromise decision in the design of a component or a subsystem.
- Transceiver:** Any circuit or device that receives and transmits signals.
- Transconductance:** The mutual conductance of an electron tube expressed as the change in plate current divided by the change in control grid voltage that produced it.
- Transducer:** A device that converts energy from one form to another.
- Transfer characteristics:** The intrinsic parameters of a system, subsystem, or unit of equipment which, when applied to the input of the system, subsystem, or unit of equipment, will fully describe its output.
- Transformer:** A device consisting of two or more windings wrapped around a single core or linked by a common magnetic circuit.
- Transformer ratio:** The ratio of the number of turns in the secondary winding of a transformer to the number of turns in the primary winding, also known as the *turns ratio*.
- Transient:** A sudden variance of current or voltage from a steady-state value. A transient normally results from changes in load or effects related to switching action.
- Transient disturbance:** A voltage pulse of high energy and short duration impressed upon the ac waveform. The overvoltage pulse can be one to 100 times the normal ac potential (or more) and can last up to 15 ms. Rise times measure in the nanosecond range.
- Transient response:** The time response of a system under test to a stated input stimulus.

- Transition:** A sequence of actions that occurs when a process changes from one state to another in response to an input.
- Transmission:** The transfer of electrical power, signals, or an intelligence from one location to another by wire, fiber optic, or radio means.
- Transmission facility:** A transmission medium and all the associated equipment required to transmit information.
- Transmission loss:** The ratio, in decibels, of the power of a signal at a point along a transmission path to the power of the same signal at a more distant point along the same path. This value is often used as a measure of the quality of the transmission medium for conveying signals. Changes in power level are normally expressed in decibels by calculating ten times the logarithm (base 10) of the ratio of the two powers.
- Transmission mode:** One of the field patterns in a waveguide in a plane transverse to the direction of propagation.
- Transmission system:** The set of equipment that provides single or multichannel communications facilities capable of carrying audio, video, or data signals.
- Transmitter:** The device or circuit that launches a signal into a passive medium, such as the atmosphere.
- Transparency:** The property of a communications system that enables it to carry a signal without altering or otherwise affecting the electrical characteristics of the signal.
- Tray:** The metal cabinet that holds circuit boards.
- Tremendously high frequency (THF):** The frequency band from 300 GHz to 3000GHz.
- Triangular wave:** An oscillation, the values of which rise and fall linearly, and immediately change upon reaching their peak maximum and minimum. A graphical representation of a triangular wave resembles a triangle.
- Trim:** The process of making fine adjustments to a circuit or a circuit element.
- Trimmer:** A small mechanically-adjustable component connected in parallel or series with a major component so that the net value of the two can be finely adjusted for tuning purposes.
- Triode:** A three-element electron tube, consisting of a cathode, control grid, and plate.
- Triple beat:** A third-order beat whose three beating carriers all have different frequencies, but are spaced at equal frequency separations.
- Troposphere:** The layer of the earth's atmosphere, between the surface and the stratosphere, in which about 80 percent of the total mass of atmospheric air is concentrated and in which temperature normally decreases with altitude.
- Trouble:** A failure or fault affecting the service provided by a system.
- Troubleshoot:** The process of investigating, localizing, and (if possible) correcting a fault.
- Tube (1—electron):** An evacuated or gas-filled tube enclosed in a glass or metal case in which the electrodes are maintained at different voltages, giving rise to a controlled flow of electrons from the cathode to the anode. (2—**cathode ray, CRT**) An electron beam tube used for the display of changing electrical phenomena, generally similar to a television picture tube. (3—**cold-cathode**) An electron tube whose cathode emits electrons without the need of a heating filament. (4—**gas**) A gas-filled electron tube in which the gas plays an essential role in operation of the device. (5—**mercury-vapor**) A tube filled with mercury vapor at low pressure, used as a rectifying device. (6—**metal**) An electron tube enclosed in a metal case. (7—**traveling wave, TWT**) A wide band microwave amplifier in which a stream of electrons interacts with a guided electromagnetic wave moving substantially in synchronism with the electron stream, resulting in a net transfer of energy from the electron stream to the wave. (8—**velocity-modulated**) An electron tube in which the velocity of the electron stream is continually changing, as in a klystron.
- Tune:** The process of adjusting the frequency of a device or circuit, such as for resonance or for maximum response to an input signal.
- Tuned trap:** A series resonant network bridged across a circuit that eliminates ("traps") the frequency of the resonant network.

Tuner: The radio frequency and intermediate frequency parts of a radio receiver that produce a low level output signal.

Tuning: The process of adjusting a given frequency; in particular, to adjust for resonance or for maximum response to a particular incoming signal.

Turns ratio: In a transformer, the ratio of the number of turns on the secondary to the number of turns on the primary.

Tweaking: The process of adjusting an electronic circuit to optimize its performance.

Twin-line: A feeder cable with two parallel, insulated conductors.

Two-phase: A source of alternating current circuit with two sinusoidal voltages that are 90° apart.

U

Ultra high frequency (UHF): The frequency range from 300 MHz to 3000 MHz.

Ultraviolet radiation: Electromagnetic radiation in a frequency range between visible light and high-frequency X-rays.

Unattended: A device or system designed to operate without a human attendant.

Unattended operation: A system that permits a station to receive and transmit messages without the presence of an attendant or operator.

Unavailability: A measure of the degree to which a system, subsystem, or piece of equipment is not operable and not in a committable state at the start of a mission, when the mission is called for at a random point in time.

Unbalanced circuit: A two-wire circuit with legs that differ from one another in resistance, capacity to earth or to other conductors, leakage, or inductance.

Unbalanced line: A transmission line in which the magnitudes of the voltages on the two conductors are not equal with respect to ground. A coaxial cable is an example of an unbalanced line.

Unbalanced modulator: A modulator whose output includes the carrier signal.

Unbalanced output: An output with one leg at ground potential.

Unbalanced wire circuit: A circuit whose two sides are inherently electrically unlike.

Uncertainty: An expression of the magnitude of a possible deviation of a measured value from the true value. Frequently, it is possible to distinguish two components: the *systematic uncertainty* and the *random uncertainty*. The random uncertainty is expressed by the standard deviation or by a multiple of the standard deviation. The systematic uncertainty is generally estimated on the basis of the parameter characteristics.

Undamped wave: A signal with constant amplitude.

Underbunching: A condition in a traveling wave tube wherein the tube is not operating at its optimum bunching rate.

Underwriters Laboratories, Inc.: A laboratory established by the National Board of Fire Underwriters which tests equipment, materials, and systems that may affect insurance risks, with special attention to fire dangers and other hazards to life.

Ungrounded: A circuit or line not connected to ground.

Unicoupler: A device used to couple a balanced circuit to an unbalanced circuit.

Unidirectional: A signal or current flowing in one direction only.

Uniform transmission line: A transmission line with electrical characteristics that are identical, per unit length, over its entire length.

Unit: An assembly of equipment and associated wiring that together forms a complete system or independent subsystem.

Unity coupling: In a theoretically perfect transformer, complete electromagnetic coupling between the primary and secondary windings with no loss of power.

Unity gain: An amplifier or active circuit in which the output amplitude is the same as the input amplitude.

Unity power factor: A power factor of 1.0, which means that the load is—in effect—a pure resistance, with ac voltage and current completely in phase.

Unterminated: A device or system that is not terminated.

Up-converter: A frequency translation device in which the frequency of the output signal is greater than that of the input signal. Such devices are commonly found in microwave radio and satellite systems.

Uplink: A transmission system for sending radio signals from the ground to a satellite or aircraft.

Upstream: A device or system placed ahead of other devices or systems in a signal path.

Useful life: The period during which a low, constant failure rate can be expected for a given device or system. The *useful life* is the portion of a product life cycle between break-in and wear out.

User: A person, organization, or group that employs the services of a system for the transfer of information or other purposes.

V

VA: An abbreviation for *volt-amperes*, volts times amperes.

Vacuum relay: A relay the contacts of which are enclosed in an evacuated space, usually to provide reliable long-term operation.

Vacuum switch: A switch the contacts of which are enclosed in an evacuated container so that spark formation is discouraged.

Vacuum tube: An electron tube. The most common vacuum tubes include the diode, triode, tetrode, and pentode.

Validity check: A test designed to ensure that the quality of transmission is maintained over a given system.

Varactor: A semiconductor that behaves like a capacitor under the influence of an external control voltage.

Varactor diode: A semiconductor device with capacitance as a function of the applied voltage. A varactor diode, also called a *variable reactance diode* or simply a *varactor*, is often used to tune the operating frequency of a radio circuit.

Variable frequency oscillator (VFO): An oscillator the frequency of which can be set to any required value in a given range of frequencies.

Variable impedance: A capacitor, inductor, or resistor that is adjustable in value.

Variable-gain amplifier: An amplifier the gain of which can be controlled by an external signal source.

Variable-reluctance: A transducer in which the input (usually a mechanical movement) varies the magnetic reluctance of a device.

Variation monitor: A device used for sensing a deviation in voltage, current, or frequency, which is capable of providing an alarm and/or initiating transfer to another power source when programmed limits of voltage, frequency, current, or time are exceeded.

Varicap: A diode used as a variable capacitor.

VCXO (voltage controlled crystal oscillator): A device the output frequency of which is determined by an input control voltage.

Vector: A quantity having both magnitude and direction.

Vector diagram: A diagram using vectors to indicate the relationship between voltage and current in a circuit.

Vector sum: The sum of two vectors which, when they are at right angles to each other, equal the length of the hypotenuse of the right triangle so formed. In the general case, the vector sum of the two vectors equals the diagonal of the parallelogram formed on the two vectors.

Velocity of light: The speed of propagation of electromagnetic waves in a vacuum, equal to 299,792,458 m/s, or approximately 186,000 mi/s. For rough calculations, the figure of 300,000 km/s is used.

Velocity of propagation: The velocity of signal transmission. In free space, electromagnetic waves travel at the speed of light. In a cable, the velocity is substantially lower.

Vernier: A device that enables precision reading of a measuring set or gauge, or the setting of a dial with precision.

Very low frequency (VLF): A radio frequency in the band 3 kHz to 30 kHz.

Vestigial sideband: A form of transmission in which one sideband is significantly attenuated. The carrier and the other sideband are transmitted without attenuation.

- Vibration testing:** A testing procedure whereby subsystems are mounted on a test base that vibrates, thereby revealing any faults resulting from badly soldered joints or other poor mechanical design features.
- Volt:** The standard unit of electromotive force, equal to the potential difference between two points on a conductor that is carrying a constant current of one ampere when the power dissipated between the two points is equal to one watt. One *volt* is equivalent to the potential difference across a resistance of one ohm when one ampere is flowing through it. The volt is named for the Italian physicist Alessandro Volta (1745–1827).
- Volt-ampere (VA):** The apparent power in an ac circuit (volts times amperes).
- Volt-ohm-milliammeter (VOM):** A general purpose multirange test meter used to measure voltage, resistance, and current.
- Voltage:** The potential difference between two points.
- Voltage drop:** A decrease in electrical potential resulting from current flow through a resistance.
- Voltage gradient:** The continuous drop in electrical potential, per unit length, along a uniform conductor or thickness of a uniform dielectric.
- Voltage level:** The ratio of the voltage at a given point to the voltage at an arbitrary reference point.
- Voltage reference circuit:** A stable voltage reference source.
- Voltage regulation:** The deviation from a nominal voltage, expressed as a percentage of the nominal voltage.
- Voltage regulator:** A circuit used for controlling and maintaining a voltage at a constant level.
- Voltage stabilizer:** A device that produces a constant or substantially constant output voltage despite variations in input voltage or output load current.
- Voltage to ground:** The voltage between any given portion of a piece of equipment and the ground potential.
- Voltmeter:** An instrument used to measure differences in electrical potential.
- Vox:** A voice-operated relay circuit that permits the equivalent of push-to-talk operation of a transmitter by the operator.
- VSAT (very small aperture terminal):** A satellite Ku-band earth station intended for fixed or portable use. The antenna diameter of a VSAT is on the order of 1.5 m or less.

W

- Watt:** The unit of power equal to the work done at one joule per second, or the rate of work measured as a current of one ampere under an electric potential of one volt. Designated by the symbol *W*, the watt is named after the Scottish inventor James Watt (1736–1819).
- Watt meter:** A meter indicating in watts the rate of consumption of electrical energy.
- Watt-hour:** The work performed by one watt over a one hour period.
- Wave:** A disturbance that is a function of time or space, or both, and is propagated in a medium or through space.
- Wave number:** The reciprocal of wavelength; the number of wave lengths per unit distance in the direction of propagation of a wave.
- Waveband:** A band of wavelengths defined for some given purpose.
- Waveform:** The characteristic shape of a periodic wave, determined by the frequencies present and their amplitudes and relative phases.
- Wavefront:** A continuous surface that is a locus of points having the same phase at a given instant. A *wavefront* is a surface at right angles to rays that proceed from the wave source. The surface passes through those parts of the wave that are in the same phase and travel in the same direction. For parallel rays the wavefront is a plane; for rays that radiate from a point, the wavefront is spherical.
- Waveguide:** Generally, a rectangular or circular pipe that constrains the propagation of an acoustic or electromagnetic wave along a path between two locations. The dimensions of a waveguide determine the frequencies for optimum transmission.

- Wavelength:** For a sinusoidal wave, the distance between points of corresponding phase of two consecutive cycles.
- Weber:** The unit of magnetic flux equal to the flux that, when linked to a circuit of one turn, produces an electromotive force of one volt as the flux is reduced at a uniform rate to zero in one second. The *weber* is named for the German physicist Wilhelm Eduard Weber (1804–1891).
- Weighted:** The condition when a correction factor is applied to a measurement.
- Weighting:** The adjustment of a measured value to account for conditions that would otherwise be different or appropriate during a measurement.
- Weighting network:** A circuit, used with a test instrument, that has a specified amplitude-versus-frequency characteristic.
- Wideband:** The passing or processing of a wide range of frequencies. The meaning varies with the context.
- Wien bridge:** An ac bridge used to measure capacitance or inductance.
- Winding:** A coil of wire used to form an inductor.
- Wire:** A single metallic conductor, usually solid-drawn and circular in cross section.
- Working range:** The permitted range of values of an analog signal over which transmitting or other processing equipment can operate.
- Working voltage:** The rated voltage that may safely be applied continuously to a given circuit or device.

X

- X-band:** A microwave frequency band from 5.2 GHz to 10.9 GHz.
- X-cut:** A method of cutting a quartz plate for an oscillator, with the x-axis of the crystal perpendicular to the faces of the plate.
- X ray:** An electromagnetic radiation of approximately 100 nm to 0.1 nm, capable of penetrating non-metallic materials.

Y

- Y-cut:** A method of cutting a quartz plate for an oscillator, with the y-axis of the crystal perpendicular to the faces of the plate.
- Yield strength:** The magnitude of mechanical stress at which a material will begin to deform. Beyond the *yield strength* point, extension is no longer proportional to stress and rupture is possible.
- Yoke:** A material that interconnects magnetic cores. *Yoke* can also refer to the deflection windings of a CRT.
- Yttrium-iron garnet (YIG):** A crystalline material used in microwave devices.

23.8 Abbreviations and Acronyms

Jerry C. Whitaker

A

a	atto (10^{-18})
Å	angstrom
A	ampere
AAR	automatic alternate routing
AARTS	automatic audio remote test set
ac	alternating current

This chapter is adapted from: General Services Administration, Information Technology Service, *National Communications System: Glossary of Telecommunication Terms*, Technology and Standards Division, Federal Standard 1037C, General Services Administration, Washington, D.C., August, 7, 1996.

ACA	automatic circuit assurance
ACC	automatic callback calling
ACD	automatic call distributor
ac-dc	alternating current-direct current
ACK	acknowledge character
ACTS	Advanced Communications Technology Satellite
ACU	automatic calling unit
A-D	analog-to-digital
ADC	analog-to-digital converter; analog-to-digital conversion
ADCCP	Advanced Data Communication Control Procedures
ADH	automatic data handling
ADP	automatic data processing
ADPCM	adaptive differential pulse-code modulation
ADPE	automatic data processing equipment
ADU	automatic dialing unit
ADX	automatic data exchange
AECS	Aeronautical Emergency Communications System [Plan]
AF	audio frequency
AFC	area frequency coordinator; automatic frequency control
AFRS	Armed Forces Radio Service
AGC	automatic gain control
AGE	aerospace ground equipment
AI	artificial intelligence
AIG	address indicator group; address indicating group
AIM	amplitude intensity modulation
AIN	advanced intelligent network
AIOD	automatic identified outward dialing
AIS	automated information system
AJ	anti-jamming
ALC	automatic level control; automatic load control
ALE	automatic link establishment
ALU	arithmetic and logic unit
AM	amplitude modulation
AMA	automatic message accounting
AMC	administrative management complex
AME	amplitude modulation equivalent; automatic message exchange
AMI	alternate mark inversion [signal]
AM/PM/VSB	amplitude modulation/phase modulation/vestigial sideband
AMPS	automatic message processing system
AMPSSO	automated message processing system security officer
AMSC	American Mobile Satellite Corporation
AMTS	automated maritime telecommunications system
ANI	automatic number identification
ANL	automatic noise limiter
ANMCC	Alternate National Military Command Center
ANS	American National Standard
ANSI	American National Standards Institute
AP	anomalous propagation
APC	adaptive predictive coding
API	application program interface
APK	amplitude phase-shift keying

APL	average picture level
ARP	address resolution protocol
ARPA	Advanced Research Projects Agency [now DARPA]
ARPANET	Advanced Research Projects Agency Network
ARQ	automatic repeat-request
ARS	automatic route selection
ARSR	air route surveillance radar
ARU	audio response unit
ASCII	American Standard Code for Information Interchange
ASIC	application-specific integrated circuits
ASP	Aggregated Switch Procurement; adjunct service point
ASR	automatic send and receive; airport surveillance radar
AT	access tandem
ATACS	Army Tactical Communications System
ATB	all trunks busy
ATCRBS	air traffic control radar beacon system
ATDM	asynchronous time-division multiplexing
ATE	automatic test equipment
ATM	asynchronous transfer mode
ATV	advanced television
au	astronomical unit
AUI	attachment unit interface
AUTODIN	Automatic Digital Network
AUTOVON	Automatic Voice Network
AVD	alternate voice/data
AWG	American wire gauge
AWGN	additive white Gaussian noise
AZ	azimuth

B

b	bit
B	bel; byte
balun	balanced to unbalanced
basecom	base communications
BASIC	beginners' all-purpose symbolic instruction code
BCC	block check character
BCD	binary coded decimal; binary-coded decimal notation
BCI	bit-count integrity
Bd	baud
B8ZS	bipolar with eight-zero substitution
bell	BEL character
BER	bit error ratio
BERT	bit error ratio tester
BETRS	basic exchange telecommunications radio service
BEX	broadband exchange
BIH	International Time Bureau
B-ISDN	broadband ISDN
bi-sync	binary synchronous [communication]
bit	binary digit
BIT	built-in test

BITE	built-in test equipment
BIU	bus interface unit
BNF	Backus Naur form
BOC	Bell Operating Company
bpi	bits per inch; bytes per inch
BPSK	binary phase-shift keying
b/s	bits per second
b/in	bits per inch
BPSK	binary phase-shift keying
BR	bit rate
BRI	basic rate interface
BSA	basic serving arrangement
BSE	basic service element
BSI	British Standards Institution
B6ZS	bipolar with six-zero substitution
B3ZS	bipolar with three-zero substitution
BTN	billing telephone number
BW	bandwidth

C

c	centi (10^{-2})
CACS	centralized alarm control system
CAM	computer-aided manufacturing
CAMA	centralized automatic message accounting
CAN	cancel character
CAP	competitive access provider; customer administration panel
CARS	cable television relay service [station]
CAS	centralized attendant services
CASE	computer-aided software engineering; computer aided system engineering; computer-assisted software engineering
CATV	cable TV; cable television; community antenna television
CBX	computer branch exchange
C ²	command and control
C ³	command, control, and communications
C ³ CM	C ³ countermeasures
C ³ I	command, control, communications and intelligence
CCA	carrier-controlled approach
CCD	charge-coupled device
CCH	connections per circuit hour
CCIF	International Telephone Consultative Committee
CCIR	International Radio Consultative Committee
CCIS	common-channel interoffice signaling
CCIT	International Telegraph Consultative Committee
CCITT	International Telegraph and Telephone Consultative Committee
CCL	continuous communications link
CCS	hundred call-seconds
CCSA	common control switching arrangement
CCTV	closed-circuit television
CCW	cable cutoff wavelength
cd	candela

CD	collision detection; compact disk
CDF	combined distribution frame; cumulative distribution function
CDMA	code-division multiple access
CDPSK	coherent differential phase-shift keying
CDR	call detail recording
CD ROM	compact disk read-only memory
CDT	control data terminal
CDU	central display unit
C-E	communications-electronics
CEI	comparably efficient interconnection
CELP	code-excited linear prediction
CEP	circular error probable
CFE	contractor-furnished equipment
cgs	centimeter-gram-second
ChR	channel reliability
CIAS	circuit inventory and analysis system
CIC	content indicator code
CIF	common intermediate format
CIFAX	ciphred facsimile
GiR	circuit reliability
C/kT	carrier-to-receiver noise density
CLASS	custom local area signaling service
cm	centimeter
CMI	coded mark inversion
CMIP	Common Management Information Protocol
CMIS	common management information service
CMOS	complementary metal oxide substrate
CMRR	common-mode rejection ratio
CNR	carrier-to-noise ratio; combat-net radio
CNS	complementary network service
C.O.	central office
COAM	customer owned and maintained equipment
COBOL	common business oriented language
codec	coder-decoder
COG	centralized ordering group
COMINT	communications intelligence
COMJAM	communications jamming
compandor	compressor-expander
COMPUSEC	computer security
COMSAT	Communications Satellite Corporation
COMSEC	communications security
CONEX	connectivity exchange
CONUS	Continental United States
COP	Committee of Principals
COR	Council of Representatives
COT	customer office terminal
CPAS	cellular priority access services
CPE	customer premises equipment
cpi	characters per inch
cpm	counts per minute
cps	characters per second

CPU	central processing unit; communications processor unit
CR	channel reliability; circuit reliability
CRC	cyclic redundancy check
CRITICOM	Critical Intelligence Communications
CROM	control read-only memory
CRT	cathode ray tube
c/s	cycles per second
CSA	Canadian Standards Association
CSC	circuit-switching center; common signaling channel
CSMA	carrier sense multiple access
CSMA/CA	carrier sense multiple access with collision avoidance
CSMA/CD	carrier sense multiple access with collision detection
CSU	channel service unit; circuit switching unit; customer service unit
CTS	clear to send
CTX	Centrex® [service]; clear to transmit
CVD	chemical vapor deposition
CVSD	continuously variable slope delta [modulation]
cw	carrier wave; composite wave; continuous wave
CX	composite signaling
cxr	carrier

D

d	deci (10^{-1})
da	deka (10)
D-A	digital-to-analog; digital-to-analog converter
D/L	downlink
DACS	digital access and cross-connect system
DAMA	demand assignment multiple access
DARPA	Defense Advanced Research Projects Agency
dB	decibel
dBa	decibels adjusted
dBa0	noise power measured at zero transmission level point
dBc	dB relative to carrier power
dBm	dB referred to 1 milliwatt
dBm(psoph)	noise power in dBm measured by a set with psophometric weighting
DBMS	database management system
dBmV	dB referred to 1 millivolt across 75 ohms
dBm0	noise power in dBm referred to or measured at 0TLP
dBm0p	noise power in dBm0 measured by a psophometric or noise measuring set having psophometric weighting
dBr	power difference in dB between any point and a reference point
dBrn	dB above reference noise
dBrnC	noise power in dBrn measured by a set with C-message weighting
dBrnC0	noise power in dBrnC referred to or measured at 0TLP
dBrn($f_1 - f_2$)	flat noise power in dBrn
dBrn(144)	noise power in dBrn measured by a set with 144-line weighting
dBv	dB relative to 1 V (volt) peak-to-peak
dBW	dB referred to 1 W (watt)
dBx	dB above reference coupling
dc	direct current

DCA	Defense Communications Agency
DCE	data circuit-terminating equipment
DCL	direct communications link
DCPSK	differentially coherent phase-shift keying
DCS	Defense Communications System
DCTN	Defense Commercial Telecommunications Network
DCWV	direct-current working volts
DDD	direct distance dialing
DDN	Defense Data Network
DDS	digital data service
DEL	delete character
demarc	demarcation point
demux	demultiplex; demultiplexer; demultiplexing
dequeue	double-ended queue
DES	Data Encryption Standard
detem	detector/emitter
DFSK	double-frequency shift keying
DIA	Defense Intelligence Agency
DID	direct inward dialing
DIN	Deutsches Institut für Normung
DIP	dual in-line package
DISA	Defense Information Systems Agency
DISC	disconnect command
DISN	Defense Information System Network
DISNET	Defense Integrated Secure Network
DLA	Defense Logistic Agency
DLC	digital loop carrier
DLE	data link escape character
DM	delta modulation
DMA	Defense Mapping Agency; direct memory access
DME	distance measuring equipment
DMS	Defense Message System
DNA	Defense Nuclear Agency
DNIC	data network identification code
DNPA	data numbering plan area
DNS	Domain Name System
DO	design objective
DoC	Department of Commerce
DOD	Department of Defense; direct outward dialing
DODD	Department of Defense Directive
DODISS	Department of Defense Index of Specifications and Standards
DOD-STD	Department of Defense Standard
DOS	Department of State
DPCM	differential pulse-code modulation
DPSK	differential phase-shift keying
DQDB	distributed-queue dual-bus [network]
DRAM	dynamic random access memory
DRSI	destination station routing indicator
DS	digital signal; direct support
DS0	digital signal 0
DS1	digital signal 1

DS1C	digital signal 1C
DS2	digital signal 2
DS3	digital signal 3
DS4	digital signal 4
DSA	dial service assistance
DSB	double sideband (transmission); Defense Science Board
DSB-RC	double-sideband reduced carrier transmission
DSB-SC	double-sideband suppressed-carrier transmission
DSC	digital selective calling
DSCS	Defense Satellite Communications System
DSE	data switching exchange
DSI	digital speech interpolation
DSL	digital subscriber line
DSN	Defense Switched Network
DSR	data signaling rate
DSS	direct station selection
DSSCS	Defense Special Service Communications System
DSTE	data subscriber terminal equipment
DSU	data service unit
DTE	data terminal equipment
DTG	date-time group
DTMF	dual-tone multifrequency (signaling)
DTN	data transmission network
DTS	Diplomatic Telecommunications Service
DTU	data transfer unit; data tape unit; digital transmission unit; direct to user
DVL	direct voice link
DX signaling	direct current signaling; duplex signaling

E

E	exa (10^{18})
E-MAIL	electronic mail
EAS	extended area service
EBCDIC	extended binary coded decimal interchange code
E_b/N_0	signal energy per bit per hertz of thermal noise
EBO	embedded base organization
EBS	Emergency Broadcast System
EBX	electronic branch exchange
EC	Earth coverage; Earth curvature
ECC	electronically controlled coupling; enhance call completion
ECCM	electronic counter-countermeasures
ECM	electronic countermeasures
EDC	error detection and correction
EDI	electronic data interchange
EDTV	extended-definition television
EHF	extremely high frequency
EIA	Electronic Industries Association
eirp	effective isotropically radiated power; equivalent isotropically radiated power
EIS	Emergency Information System
el	elevation
ELF	extremely low frequency

ELINT	electronics intelligence; electromagnetic intelligence
ELSEC	electronics security
ELT	emergency locator transmitter
EMC	electromagnetic compatibility
EMCON	emission control
EMD	equilibrium mode distribution
EME	electromagnetic environment
emf	electromotive force
EMI	electromagnetic interference; electromagnetic interference control
EMP	electromagnetic pulse
EMR	electromagnetic radiation
EMR hazards	electromagnetic radiation hazards
e.m.r.p.	effective monopole radiated power; equivalent monopole radiated power
EMS	electronic message system
EMSEC	emanations security
emu	electromagnetic unit
EMV	electromagnetic vulnerability
EMW	electromagnetic warfare; electromagnetic wave
ENQ	enquiry character
EO	end office
E.O.	Executive Order
EOD	end of data
EOF	end of file
EOL	end of line
EOM	end of message
EOP	end of program; end output
EOS	end-of-selection character
EOT	end-of-transmission character; end of tape
EOW	engineering orderwire
EPROM	erasable programmable read-only memory
EPSCS	enhanced private switched communications system
ERL	echo return loss
ERLINK	emergency response link
ERP, e.r.p.	effective radiated power
ES	end system; expert system
ESC	escape character; enhanced satellite capability
ESF	extended superframe
ESM	electronic warfare support measures
ESP	enhanced service provider
ESS	electronic switching system
ETB	end-of-transmission-block character
ETX	end-of-text character
EW	electronic warfare
EXCSA	Exchange Carriers Standards Association

F

f	femto (10^{-15})
<i>f</i>	frequency
FAA	Federal Aviation Administration
FAQ file	Frequently Asked Questions file

FAX	facsimile
FC	functional component
FCC	Federal Communications Commission
FCS	frame check sequence
FDDI	fiber distributed data interface
FDDI-2	fiber distributed data interface-2
FDHM	full duration at half maximum
FDM	frequency-division multiplexing
FDMA	frequency-division multiple access
FDX	full duplex
FEC	forward error correction
FECC	Federal Emergency Communications Coordinators
FED-STD	Federal Standard
FEMA	Federal Emergency Management Agency
FEP	front-end processor
FET	field effect transistor
FIFO	first-in first-out
FIP	Federal Information Processing
FIPS	Federal Information Processing Standards
FIR	finite impulse response
FIRMR	Federal Information Resources Management Regulations
FISINT	foreign instrumentation signals intelligence
flops	floating-point operations per second
FM	frequency modulation
FO	fiber optics
FOC	final operational capability; full operational capability
FOT	frequency of optimum traffic; frequency of optimum transmission
FPIS	forward propagation ionospheric scatter
fps	foot-pound-second
FPS	frames per second; focus projection and scanning
FRP	Federal Response Plan
FSDPSK	filtered symmetric differential phase-shift keying
FSK	frequency-shift keying
FSS	fully separate subsidiary
FT	fiber optic T-carrier
FTAM	file transfer, access, and management
FTF	Federal Telecommunications Fund
ft/min	feet per minute
FTP	file transfer protocol
ft/s	feet per second
FTS	Federal Telecommunications System
FTS2000	Federal Telecommunications System 2000
FTSC	Federal Telecommunications Standards Committee
FWHM	full width at half maximum
FX	fixed service; foreign exchange service
FYDP	Five Year Defense Plan

G

g	profile parameter
G	giga (10^9)

GBH	group busy hour
GCT	Greenwich Civil Time
GDF	group distribution frame
GETS	Government Emergency Telecommunications Service
GFE	Government-furnished equipment
GGCL	government-to-government communications link
GHz	gigahertz
GII	Global Information Infrastructure
GMT	Greenwich Mean Time
GOS	grade of service
GOSIP	Government Open Systems Interconnection Profile
GSA	General Services Administration
GSTN	general switched telephone network
G/T	antenna gain-to-noise-temperature
GTP	Government Telecommunications Program
GTS	Government Telecommunications System
GUI	graphical user interface

H

h	hecto (10^2); hour; Planck's constant
HCS	hard clad silica (fiber)
HDLC	high-level data link control
HDTV	high-definition television
HDX	half-duplex (operation)
HE ¹¹ mode	the fundamental hybrid mode (of an optical fiber)
HEMP	high-altitude electromagnetic pulse
HERF	hazards of electromagnetic radiation to fuel
HERO	hazards of electromagnetic radiation to ordnance
HERP	hazards of electromagnetic radiation to personnel
HF	high frequency
HFDf	high-frequency distribution frame
HLL	high-level language
HPC	high probability of completion
HV	high voltage
Hz	hertz

I

IA	International Alphabet
I&C	installation and checkout
IC	integrated circuit
ICI	incoming call identification
ICNI	Integrated Communications, Navigation, and Identification
ICW	interrupted continuous wave
IDDD	International Direct Distance Dialing
IDF	intermediate distribution frame
IDN	integrated digital network
IDTV	improved-definition television
IEC	International Electrotechnical Commission
IEEE	Institute of Electrical and Electronics Engineers

IES	Industry Executive Subcommittee
IF	intermediate frequency
I/F	interface
IFF	identification, friend or foe
IFRB	International Frequency Registration Board
IFS	ionospheric forward scatter
IIR	infinite impulse response
IITF	Information Infrastructure Task Force
ILD	injection laser diode
ILS	instrument landing system
IM	intensity modulation; intermodulation
I&M	installation and maintenance
IMD	intermodulation distortion
IMP	interface message processor
IN	intelligent network
INFOSEC	information systems security
INS	inertial navigation system
INTELSAT	International Telecommunications Satellite Consortium
INWATS	Inward Wide-Area Telephone Service
I/O	input/output (device)
IOC	integrated optical circuit; initial operational capability; input-output controller
IP	Internet protocol; intelligent peripheral
IPA	intermediate power amplifier
IPC	information processing center
IPM	impulses per minute; interference prediction model; internal polarization modulation; interruptions per minute
in/s	inches per second
ips	interruptions per second
IPX	Internet Packet Exchange
IQF	intrinsic quality factor
IR	infrared
IRAC	Interdepartment Radio Advisory Committee
IRC	international record carrier; Interagency Radio Committee
ISB	independent-sideband (transmission)
ISDN	Integrated Services Digital Network
ISM	industrial, scientific, and medical (applications)
ISO	International Organization for Standardization
ITA	International Telegraph Alphabet
ITA-5	International Telegraph Alphabet Number 5
ITC	International Teletraffic Congress
ITS	Institute for Telecommunication Sciences
ITSO	International Telecommunications Satellite Organization
ITU	International Telecommunication Union
IVDT	integrated voice data terminal
IXC	interexchange carrier

J

JANAP	Joint Army-Navy-Air Force Publication(s)
JCS	Joint Chiefs of Staff
JPL	Jet Propulsion Laboratory

JSC	Joint Steering Committee; Joint Spectrum Center
JTC ³ A	Joint Tactical Command, Control and Communications Agency
JTIDS	Joint Tactical Information Distribution System
JTRB	Joint Telecommunications Resources Board
JTSSG	Joint Telecommunications Standards Steering Group
JWID	Joint Warrior Interoperability Demonstration

K

k	kilo (10^3); Boltzmann's constant
K	coefficient of absorption; kelvin
KDC	key distribution center
KDR	keyboard data recorder
KDT	keyboard display terminal
kg	kilogram
kg·m·s	kilogram-meter-second
kHz	kilohertz
km	kilometer
k Ω , k	kilohm
KSR	keyboard send/receive device
kT	noise power density
KTS	key telephone system
KTU	key telephone unit

L

LAN	local area network
LAP-B	Data Link Layer protocol (CCITT Recommendation X.25 [1989])
LAP-D	link access procedure D
laser	light amplification by stimulated emission of radiation
LASINT	laser intelligence
LATA	local access and transport area
LBO	line buildout
LC	limited capability
LCD	liquid crystal display
LD	long distance
LDM	limited distance modem
LEC	local exchange carrier
LED	light-emitting diode
LF	low frequency
LFB	look-ahead-for-busy (information)
LIFO	last-in first-out
LLC	logical link control (sublayer)
l/m	lines per minute
LMF	language media format
LMR	land mobile radio
LNA	launch numerical aperture
LOF	lowest operating frequency
loran	long-range aid to navigation system; long-range radio navigation; long-range radio aid to navigation system
LOS	line of sight, loss of signal

LP	linearly polarized (mode); linear programming; linking protection; log-periodic (antenna); log-periodic (array)
LPA	linear power amplifier
LPC	linear predictive coding
LPD	low probability of detection
LPI	low probability of interception
lpi	lines per inch
lpm	lines per minute
LP ₀₁	the fundamental mode (of an optical fiber)
LQA	link quality analysis
LRC	longitudinal redundancy check
LSB	lower sideband, least significant bit
LSI	large scale integrated (circuit); large scale integration; line status indication
LTC	line traffic coordinator
LUF	lowest usable high frequency
LULT	line-unit-line termination
LUNT	line-unit-network termination
LV	low voltage
M	
m	meter
M	mega (10 ⁶)
MAC	medium access control [sublayer]
MACOM	major command
MAN	metropolitan area network
MAP	manufacturers' automation protocol
maser	microwave amplification by the stimulated emission of radiation
MAU	medium access unit
MCC	maintenance control circuit
MCEB	Military Communications-Electronics Board
MCM	multicarrier modulation
MCS	Master Control System
MCW	modulated continuous wave
MCXO	microcomputer compensated crystal oscillator
MDF	main distribution frame
MDT	mean downtime
MEECN	Minimum Essential Emergency Communications Network
MERCAST	merchant-ship broadcast system
MF	medium frequency; multifrequency (signaling)
MFD	mode field diameter
MFJ	Modification of Final Judgment
MFSK	multiple frequency-shift keying
MHF	medium high frequency
MHS	message handling service; message handling system
MHz	megahertz
mi	mile
MIC	medium interface connector; microphone; microwave integrated circuit; minimum ignition current; monolithic integrated circuit; mutual interface chart
MILNET	military network
MIL-STD	Military Standard
min	minute

MIP	medium interface point
MIPS, mips	million instructions per second
MIS	management information system
MKS	meter-kilogram-second
MLPP	multilevel precedence and preemption
MMW	millimeter wave
modem	modulator-demodulator
mol	mole
ms	millisecond (10^{-3} second)
MSB	most significant bit
MSK	minimum-shift keying
MTBF	mean time between failures
MTBM	mean time between maintenance
MTBO	mean time between outages
MTBPM	mean time between preventive maintenance
MTF	modulation transfer function
MTSO	mobile telephone switching office
MTSR	mean time to service restoration
MTTR	mean time to repair
μ	micro (10^{-6})
μs	microsecond
MUF	maximum usable frequency
MUX	multiplex; multiplexer
MUXing	multiplexing
mw	microwave
MWI	message waiting indicator
MWV	maximum working voltage

N

n	nano (10^{-9}); refractive index
N_0	sea level refractivity; spectral noise density
NA	numerical aperture
NACSEM	National Communications Security Emanation Memorandum
NACSIM	National Communications Security Information Memorandum
NAK	negative-acknowledge character
NASA	National Aeronautics and Space Administration
NATA	North American Telecommunications Association
NATO	North Atlantic Treaty Organization
NAVSTAR	Navigational Satellite Timing and Ranging
NBFM	narrowband frequency modulation
NBH	network busy hour
NBRVF	narrowband radio voice frequency
NBS	National Bureau of Standards
NBSV	narrowband secure voice
NCA	National Command Authorities
NCC	National Coordinating Center for Telecommunications
NCS	National Communications System; net control station
NCSC	National Communications Security Committee
NDCS	network data control system
NDER	National Defense Executive Reserve

NEACP	National Emergency Airborne Command Post
NEC	National Electric Code®
NEP	noise equivalent power
NES	noise equivalent signal
NF	noise figure
NFS	Network File System
NIC	network interface card
NICS	NATO Integrated Communications System
NID	network interface device; network inward dialing; network information database
NII	National Information Infrastructure
NIOD	network inward/outward dialing
NIST	National Institute of Standards and Technology
NIU	network interface unit
NLP	National Level Program
nm	nanometer
NMCS	National Military Command System
nmi	nautical mile
NOD	network outward dialing
Np	neper
NPA	numbering plan area
NPR	noise power ratio
NRI	net radio interface
NRM	network resource manager
NRRC	Nuclear Risk Reduction Center
NRZ	non-return-to-zero
NRZI	non-return-to-zero inverted
NRZ-M	non-return-to-zero mark
NRZ-S	non-return-to-zero space
NRZ1	non-return-to-zero, change on ones
NRZ-1	non-return-to-zero mark
ns	nanosecond
NSA	National Security Agency
NSC	National Security Council
NS/EP	National Security or Emergency Preparedness telecommunications
NSTAC	National Security Telecommunications Advisory Committee
NTCN	National Telecommunications Coordinating Network
NTDS	Naval Tactical Data System
NT1	Network termination 1
NT2	Network termination 2
NTI	network terminating interface
NTIA	National Telecommunications and Information Administration
NTMS	National Telecommunications Management Structure
NTN	network terminal number
NTSC	National Television Standards Committee; National Television Standards Committee (standard)
NUL	null character
NVIS	near vertical incidence skywave

O

O&M	operations and maintenance
OC	operations center

OCC	other common carrier
OCR	optical character reader; optical character recognition
OCU	orderwire control unit
OCVCXO	oven controlled-voltage controlled crystal oscillator
OCXO	oven controlled crystal oscillator
OD	optical density; outside diameter
OFC	optical fiber, conductive
OFCP	optical fiber, conductive, plenum
OFCR	optical fiber, conductive, riser
OFN	optical fiber, nonconductive
OFNP	optical fiber, nonconductive, plenum
OFNR	optical fiber, nonconductive, riser
OMB	Office of Management and Budget
ONA	open network architecture
opm	operations per minute
OPMODEL	operations model
OPSEC	operations security
OPX	off-premises extension
OR	off-route service; off-route aeronautical mobile service
OSHA	Occupational Safety and Health Administration
OSI	open switching interval; Open Systems Interconnection
OSI-RM	Open Systems Interconnection—Reference Model
OSRI	originating stations routing indicator
OSSN	originating stations serial number
OTAM	over-the-air management of automated HF network nodes
OTAR	over-the-air rekeying
OTDR	optical time domain reflectometer; optical time domain reflectometry
OW	orderwire [circuit]

P

p	pico (10^{-12})
P	peta (10^{15})
PABX	private automatic branch exchange
PAD	packet assembler/disassembler
PAL	phase alternation by line
PAL-M	phase alternation by line—modified
PAM	pulse-amplitude modulation
PAMA	pulse-address multiple access
p/a r	peak-to-average ratio
PAR	performance analysis and review
PARAMP	parametric amplifier
par meter	peak-to-average ratio meter
PAX	private automatic exchange
PBER	pseudo-bit-error-ratio
PBX	private branch exchange
PC	carrier power (of a radio transmitter); personal computer
PCB	power circuit breaker; printed circuit board
PCM	pulse-code modulation; plug compatible module; process control module
PCS	Personal Communications Services; personal communications system; plastic-clad silica (fiber)

PCSR	parallel channels signaling rate
PD	photodetector
PDM	pulse delta modulation; pulse-duration modulation
PDN	public data network
PDS	protected distribution system; power distribution system; program data source
PDT	programmable data terminal
PDU	protocol data unit
PE	phase-encoded (recording)
PEP	peak envelope power (of a radio transmitter)
pF	picofarad
PF	power factor
PFM	pulse-frequency modulation
PI	protection interval
PIC	plastic insulated cable
ping	packet Internet groper
PIV	peak inverse voltage
PLA	programmable logic array
PL/I	programming language 1
PLL	phase-locked loop
PLN	private line network
PLR	pulse link repeater
PLS	physical signaling sublayer
pm	phase modulation
PM	mean power; polarization-maintaining (optical fiber); preventive maintenance; pulse modulation
PMB	pilot-make-busy (circuit)
PMO	program management office
POI	point of interface
POP	point of presence
POSIX	portable operating system interface for computer environments
POTS	plain old telephone service
PP	polarization-preserving (optical fiber)
P-P	peak-to-peak (value)
P/P	point-to-point
PPM	pulse-position modulation
pps	pulses per second
PR	pulse rate
PRF	pulse-repetition frequency
PRI	primary rate interface
PRM	pulse-rate modulation
PROM	programmable read-only memory
PRR	pulse repetition rate
PRSL	primary area switch locator
PS	permanent signal
psi	pounds (force) per square inch
PSK	phase-shift keying
PSN	public switched network
p-static	precipitation static
PSTN	public switched telephone network
PTF	patch and test facility
PTM	pulse-time modulation

PTT	postal, telephone, and telegraph; push-to-talk (operation)
PTTC	paper tape transmission code
PTTI	precise time and time interval
PU	power unit
PUC	public utility commission; public utilities commission
PVC	permanent virtual circuit; polyvinyl chloride (insulation)
pW	picowatt
PWM	pulse-width modulation
PX	private exchange

Q

QA	quality assurance
QAM	quadrature amplitude modulation
QC	quality control
QCIF	quarter common intermediate format
QMR	qualitative material requirement
QOS	quality of service
QPSK	quadrature phase-shift keying
QRC	quick reaction capability

R

racon	radar beacon
rad	radian; radiation absorbed dose
radar	radio detection and ranging
RADHAZ	electromagnetic radiation hazards
RADINT	radar intelligence
RAM	random access memory; reliability, availability, and maintainability
R&D	research and development
RATT	radio teletypewriter system
RBOC	Regional Bell Operating Company
RbXO	rubidium-crystal oscillator
RC	reflection coefficient; resource controller
RCC	radio common carrier
RCVR	receiver
RDF	radio-direction finding
REA	Rural Electrification Administration
REN	ringer equivalency number
RF	radio frequency; range finder
RFI	radio frequency interference
RFP	request for proposal
RFQ	request for quotation
RGB	red-green-blue
RH	relative humidity
RHR	radio horizon range
RI	routing indicator
RISC	reduced instruction set chip
RJ	registered jack
RJE	remote job entry
rms	root-mean-square (deviation)
RO	read only; receive only

ROA	recognized operating agency
ROC	required operational capability
ROM	read-only memory
ROSE	remote operations service element protocol
rpm	revolutions per minute
RPM	rate per minute
RPOA	recognized private operating agency
rps	revolutions per second
RQ	repeat-request
RR	repetition rate
RSL	received signal level
rss	root-sum-square
R/T	real time
RTA	remote trunk arrangement
RTS	request to send
RTTY	radio teletypewriter
RTU	remote terminal unit
RTX	request to transmit
RVA	reactive volt-ampere
RVWG	Reliability and Vulnerability Working Group
RWI	radio and wire integration
RX	receive; receiver
RZ	return-to-zero

S

s	second
SCC	specialized common carrier
SCE	service creation environment
SCF	service control facility
SCP	service control point
SCPC	single channel per carrier
SCR	semiconductor-controlled rectifier; silicon-controlled rectifier
SCSR	single channel signaling rate
SDLC	synchronous data link control
SDM	space-division multiplexing
SDN	software-defined network
SECDEF	Secretary of Defense
SECORD	secure voice cord board
SECTEL	secure telephone
SETAMS	systems engineering, technical assistance, and management services
SEVAS	Secure Voice Access System
S-F	store-and-forward
SF	single-frequency (signaling)
SGDF	supergroup distribution frame
S/H	sample and hold
SHA	sidereal hour angle
SHARES	Shared Resources (SHARES) HF Radio Program
SHF	super high frequency
SI	International System of Units
SID	sudden ionospheric disturbance

SIGINT	signals intelligence
SINAD	signal-plus-noise-plus-distortion to noise-plus-distortion ratio
SLD	superluminescent diode
SLI	service logic interpreter
SLP	service logic program
SMDR	station message-detail recording
SMSA	standard metropolitan statistical area
SNR	signal-to-noise ratio
SOH	start-of-heading character
SOM	start of message
sonar	sound navigation and ranging
SONET	synchronous optical network
SOP	standard operating procedure
SOR	start of record
SOW	statement of work
(S + N)/N	signal-plus-noise-to-noise ratio
sr	steradian
S/R	send and receive
SSB	single-sideband (transmission)
SSB-SC	single-sideband suppressed carrier (transmission)
SSN	station serial number
SSP	service switching point
SSUPS	solid-state uninterruptible power system
STALO	stabilized local oscillator
STD	subscriber trunk dialing
STFS	standard time and frequency signal (service); standard time and frequency service
STL	standard telegraph level; studio-to-transmitter link
STP	standard temperature and pressure; signal transfer point
STU	secure telephone unit
STX	start-of-text character
SUB	substitute character
SWR	standing wave ratio
SX	simplex signaling
SXS	step-by-step switching system
SYN	synchronous idle character
SYSGEN	system generation

T

T	tera (10^{12})
TADIL	tactical data information link
TADIL-A	tactical data information link-A
TADIL-B	tactical data information link-B
TADS	teletypewriter automatic dispatch system
TADSS	Tactical Automatic Digital Switching System
TAI	International Atomic Time
TASI	time-assignment speech interpolation
TAT	trans-Atlantic telecommunication (cable)
TC	toll center
TCB	trusted computing base
TCC	telecommunications center

TCCF	Tactical Communications Control Facility
TCF	technical control facility
TCP	transmission control protocol
TCS	trusted computer system
TCU	teletypewriter control unit
TCVXO	temperature compensated-voltage controlled crystal oscillator
TCXO	temperature controlled crystal oscillator
TD	time delay; transmitter distributor
TDD	Telecommunications Device for the Deaf
TDM	time-division multiplexing
TDMA	time-division multiple access
TE	transverse electric [mode]
TED	trunk encryption device
TEK	traffic encryption key
TEM	transverse electric and magnetic [mode]
TEMPEST	compromising emanations
TEMS	telecommunications management system
TGM	trunk group multiplexer
THD	total harmonic distortion
THF	tremendously high frequency
THz	terahertz
TIA	Telecommunications Industry Association
TIE	time interval error
TIFF	tag image file format
TIP	terminal interface processor
T _k	response timer
TLP	transmission level point
TM	transverse magnetic [mode]
TP	toll point
TRANSEC	transmission security
TRC	transverse redundancy check
TRF	tuned radio frequency
TRI-TAC	tri-services tactical [equipment]
TSK	transmission security key
TSP	Telecommunications Service Priority [system]
TSPS	traffic service position system
TSR	telecommunications service request; terminate and stay resident
TTL	transistor-transistor logic
TTTN	tandem tie trunk network
TTY	teletypewriter
TTY/TDD	Telecommunications Device for the Deaf
TV	television
TW	traveling wave
TWT	traveling wave tube
TWTA	traveling wave tube amplifier
TWX [®]	teletypewriter exchange service
TX	transmit; transmitter

U

UDP	User Datagram Protocol
UHF	ultra high frequency

U/L	uplink
ULF	ultra low frequency
UPS	uninterruptible power supply
UPT	Universal Personal Telecommunications service
USB	upper sideband
USDA	U.S. Department of Agriculture
USFJ	U.S. Forces, Japan
USFK	U.S. Forces, Korea
USNO	U.S. Naval observatory
USTA	U.S. Telephone Association
UT	Universal Time
UTC	Coordinated Universal Time
uv	ultraviolet
V	
V	volt
VA	volt-ampere
VAN	value-added network
VAR	value added reseller
VARISTAR	variable resistor
vars	volt-amperes reactive
VC	virtual circuit
VCO	voltage-controlled oscillator
VCXO	voltage-controlled crystal oscillator
V/D	voice/data
Vdc	volts direct current
VDU	video display unit; visual display unit
VF	voice frequency
VFCT	voice frequency carrier telegraph
VFDF	voice frequency distribution frame
VFO	variable-frequency oscillator
VFTG	voice-frequency telegraph
VHF	very high frequency
VLF	very low frequency
V/m	volts per meter
VNL	via net loss
VNLF	via net loss factor
vocoder	voice-coder
vodas	voice-operated device anti-sing
vogad	voice-operated gain-adjusting device
volcas	voice-operated loss control and echo/signaling suppression
vox	voice-operated relay circuit; voice operated transmit
VRC	vertical redundancy check
VSAT	very small aperture terminal
VSF	vestigial sideband [transmission]
VSM	vestigial sideband modulation
VSWR	voltage standing wave ratio
VT	virtual terminal
VTU	video teleconferencing unit
vu	volume unit

W

WADS	wide area data service
WAIS	Wide Area Information Servers
WAN	wide area network
WARC	World Administrative Radio Conference
WATS	Wide Area Telecommunications Service; Wide Area Telephone Service
WAWS	Washington Area Wideband System
WDM	wavelength-division multiplexing
WHSR	White House Situation Room
WIN	WWMCCS Intercomputer Network
WITS	Washington Integrated Telecommunications System
WORM	write once, read many times
wpm	words per minute
wps	words per second
wv	working voltage
WVDC	working voltage direct current
WWDSA	worldwide digital system architecture
WWMCCS	Worldwide Military Command and Control System
WWW	World Wide Web

X

XMIT	transmit
XMSN	transmission
XMTD	transmitted
XMTR	transmitter
XO	crystal oscillator
XOFF	transmitter off
XON	transmitter on
XT	crosstalk
XTAL	crystal

Z

Z	Zulu time
ZD	zero defects
Z_o	characteristic impedance
0TLP	zero transmission level point
