Component failures, such as pin to pin leakage, can also be caused by contaminating films that are on the seal and embedment glass of the package. One such failure mode reported for SRAMs was caused by lead sulfide from antistatic ABS/PVC (acrylonitrile-butadiene-styrene/polyvinyl chloride) plastic trays used to store parts during assembly and postseal operations. The lead sulfide exhibited itself as a shiny film over the seal and embedment glass and resulted in more than 20 μA (at 5 V) leakage. PVC plastic that uses Thioglycolate (or Dibutyltin bis or Iso Octylthioglycolate, heat stabilizers), a common additive, can cause sulfur-based contamination (and corrosion) on parts with lead-based embedment glass. Because of this, PVC manufacturers are pursuing alternate stabilizer materials, and products that can have performance degradations are often stored and processed using metal trays.

7.10.6 Lead Finish

Reducing lead in the environment is an environmental health and safety issue that is of prime importance today. While a typical microprocessor has approximately 0.2 g of lead and a computer motherboard has 2 to 3 g of lead, and the whole USA electronic interconnection market uses less than 2% of the world's lead production, to address environmental concerns, there are various environmental directives limiting the use of lead and other hazardous substances. These directives, formulated by the European Union in a Directive of the European parliament and of the Council of the European Union are:

- End of Life Vehicles (ELV) Directive 2000/53/EC in force since October 21, 2000, requires that products be free of heavy metals such as mercury, cadmium, hexavalent chromium and lead. It requires a recycling system be established by vehicle manufacturers for vehicles made after July 1, 2002 and for all vehicles regardless of date of manufacture by July 1, 2007. Lead can still be used as an alloying additive in copper and in solderable applications.
- The WEEE Directive, Waste Electrical and Electronic Equipment (WEEE) Directive 2002/96/EC, expands the recycling requirements of the ELV Directive to include a broad range of electronic and electrical appliances and equipment. WEEE went into effect on February 13, 2003. It is to be scheduled to become European national law by August 13, 2004, and be applicable to consumer use products by August 13, 2005. Article 2(3) however states "Equipment which is connected with the protection of the essential interests of the security of Member States, arms, munitions and war material shall be excluded from this Directive. This does not, however, apply to products which are not intended for specifically military purposes."
- RoHS Directive, The Restriction of Hazardous Substances in Electrical and Electronic Equipment, this Directive 2002/95/EC establishes standards and limits for the hazardous material content in electronic and electrical equipment. The Directive went into effect on February 13, 2003. It is scheduled to become European national law by August 13, 2004 for be in force for products by July 1, 2006. Banned or restricted substances include lead, mercury, cadmium, hexavalent chromium, certain brominated flame retardants (PBBs), and polybrominated diphenyl ethers (PBDEs).

The recommended lead-free solder formulation is Sn-Ag-Cu for board assembly but there are other formulations such as Nickel-Palladium (NiPd), or Nickel-Palladium with Gold flash (NiPdAu). Passive components, to be compatible with a lower temperature Lead process (which is 215°C for 50/50 Tin/Lead formulations and 230°C for 40/60 formulations) and the higher lead-free process of up to 260°C, use pure matte Tin for their contacts. The use of lead in solder is partially based on several potential reliability issues. Pure Tin component leads have been shown to result in inter-metallic migration in the termination of the electronic component and the growth of tin whiskers which could cause short circuits (which is why there is an exemption for military use (only) components).

The National Electronics Manufacturing Initiative (NEMI) has addressed the problem of "tin whiskers" in lead-free assemblies. A tin whisker is defined by them as

A spontaneous columnar or cylindrical filament, which rarely branches, of monocrystalline tin emanating from the surface of a plating finish. Furthermore, tin whiskers may have the following characteristics:

- an aspect ratio (length/width) greater than 2
- can be kinked, bent, twisted
- generally have consistent cross-sectional shape
- may have striations or rings around it

Their recommended test method is

- temperature cycling (-55°C to $+85^{\circ}\text{C}$, approximately 3 cycles/hour)
- temperature humidity tests at $60^{\circ}\text{C}/93\%$ RH
- ambient storage (air-conditioned facility)

(Note: Tin will undergo a phase transformation, becoming a powdery form (called Tin Pest) if Tin plated parts are stored for more than 1 week at temperatures below 13°C).

7.10.7 Screening and Rescreening Tests

In the 1970s, the Navy instituted a policy requiring devices be rescreened on receipt (by the contractor or an independent test laboratory) because there was evidence that Joint Army Navy (JAN) qualified devices (including JANTX, JANTXV discrete component) were not of a quality level to be used in military hardware (DoD directive 4245.7-M Transition from Development to Production, which was signed in 1984 and saw wide implementation by the end of 1986).

Rescreening tests often imposed included the following:

Destructive physical analysis (DPA) examination tests, where two pieces of each lot of parts (as a minimum) were cut open and examined to determine the workmanship of the parts. If the workmanship was judged to be poor, the whole lot of parts were rejected (a lot of parts is defined as parts from one manufacturer from one assembly line and one date code).

Particle impact noise detection (PIND) tests, where each hybrid part or IC with a cavity where the die was unglassivated (insulated with a glass coating, Fig. 7.160 shows an IC with cracks in this coating), was vibrated and transducers, mounted on the part would detect if there were any particles rattling around. Parts with loose pieces in them were rejected from the shipment.

Go-no go electrical tests, and static and dynamic tests were required to be performed at low, ambient (25°C) and high temperatures.

Hermeticity testing was required to test the integrity of the package seal.

To review the reasons for component rescreening we need to examine test data for the time period involved. In 1981 it was reported that the Naval Weapons Support Center (NWSC) in Crane, Indiana, found part defect rates of 15% for ICs and 17% for discrete semiconductors. In a January 1983 report, one independent test laboratory found reject rates of 16.7% for linear ICs, 8.4% for digital ICs, and 9.2% for CMOS ICs. By October 1984, this same laboratory found defect rates of 5.5% for linear ICs, 3.7% for digital ICs, 8.2% for transistors, and 3.8% for optoelectronics. In 1983, the Defense Electronic Center found semiconductor defect rates of 8% for nonmilitary specification parts, with a less than 1% defect rate for military specification devices. In 1986, a military contractor estimated rescreening failures of 0.9% for ICs and 1.5% for transistors. In 1989, a manufacturer of a special purpose computer workstation for the U.S. Navy reported the following rescreening results: IC/semiconductors tested: 8312 (127 types of parts); total rejects PIND/DPA: 25 (16 PIND failures on hybrid components, 6 electrical failures, 3 mechanical failures—broken leads); reject rate: 0.30%.

Breaking down the hybrid failures, of 99 military qualified oscillators tested, 6 were rejected for a rejection rate of 6.1%; 53 nonmilitary qualified oscillators were tested of which 10 were rejected, for a rejection rate of 18.8%.

The Semiconductor Industry of America conducted a quality statistics program to monitor and report on industry data on various quality control indices and parameters of microcircuits from 1985 to the early

FIGURE 7.160 An IC with cracks in the die glass coating.

1990s. In 1991, the analysis of the data showed that for every 10,000 parts shipped, there is on average only one part with electrical defects, or a 100 **parts per million (PPM)** defect rate. The data were reported using JEDEC standard 16, Assessment of Microcircuit Outgoing Quality Levels in Parts Per Million and represents data on JAN qualified parts, DESC drawing parts, MIL-STD-883C screened devices, and devices procured to source control drawings (SCDs). Over 150 million devices were sampled with the reporting companies supplying about 80% of all military microcircuits.

The breakdown of defects based upon part type are linear parts: 100 PPM, bipolar digital 50 PPM (10 PPM in the first quarter of 1991), MOS digital: <100 PPM, and MOS memory: 160 PPM (with defects falling an average 30 PPM/quarter). If all the data are combined, the data indicate that for every 25,000 parts shipped, there averages only 1 part with electrical defects. The study also shows that there is a steady and continual decline in the level of electrically defective parts. This analysis shows a significant improvement in part quality since the 1970s, when component rescreening was instituted, and rescreening is probably not necessary except for very high-reliability applications (such as space applications).

Semiconductor, Integrated Circuit, and Hybrid Device Screening Tests

Table 7.9 is a summary of the various screening tests that can be used to detect semiconductor failure mechanisms. Failure mechanisms independent of application environment (oxide or diffusion defects) can be accelerated by operating the device, i.e., performance of a **burn-in** test.

Failure mechanisms dependent on the application environment (bond or metallization defects) can be accelerated by temperature or mechanical stresses (vibration).

Time and environment dependent failure mechanisms (metal migration, corrosion, intermetallic compound formulations caused by dissimilar use) can be accelerated by device operation (i.e., elevated temperature burn-in testing).

7.10.8 Electrostatic Discharge Effects

ICs are susceptible to damage from electrostatic discharge. Static electricity does not have to be large enough to cause a visible spark for an IC to be damaged. Figure 7.161 is an ESD failure in a D/A converter circuit. Figure 1.162 shows a passivation fault extending under the metallization.

FIGURE 7.161 An ESD failure in a D/A converter circuit.

FIGURE 7.162 Passivation fault extending under the metallization.

To prevent ESD damage, various materials are used. Topical antistats, such as those that may be used to coat some plastic IC dip shipping tubes, include detergent substances, which wet the surface being treated. These coatings depend on their moisture content and work most effectively at high humidities. However, these coatings do wear out and treated surfaces must be checked periodically with a static detector. Treated IC dip tubes should be retreated after use as the IC leads can scrape away the coating as they slide out of the tube.

Pink poly bags are also used to contain components or assemblies. These bags also lose their effectiveness, because they rely on absorbed moisture within the material, and must be checked periodically.

Nickel coated bags may have conductivity discontinuities due to the thin coating cracking after repeated bag handling. These bags should be periodically tested and examined for physical damage.

Defining Terms

Alpha particle: A product given off by the decay of radioactive material (usually emitted by traces of radioactivity in IC ceramic packaging materials). This particle has a positive charge equal to twice that of an electron and is emitted at a very high velocity. Alpha particles can cause temporary memory upsets in DRAMs, which is known as *soft error rate*.

Bond pad: Areas of metallization on the IC die that permit the connection of fine wires or circuit elements to the die. (See also wire bond.)

Burn-in: Component testing where infant mortality failures (defective or weak parts) are screened out by testing at elevated voltages and temperatures for a specified length of time.

Ceramic: An inorganic, nonmetallic clay or glasslike material whose final characteristics are produced by subjection to high temperatures.

DC test: Tests that measure a static parameter, for example, leakage current.

Defense Electric Supply Center (DESC) part: Used to denote a Standard Military drawing part that has been approved by the DESC, in Columbus (formerly in Dayton), Ohio.

Die: A single IC, also known as a chip.

Die information exchange (DIE): A specification created by chip makers and software vendors to provide basic die information in a standard format.

DIE bonding: The attachment of an IC chip (or DIE) to a substrate or a header.

DIE separation: Refers to the separation of the actual microcircuit chip from the inside of the package.

Destructive physical analysis (DPA): Devices are opened and analyzed for process integrity and workmanship.

Electrostatic discharge (ESD): The instantaneous transfer of charges accumulated on a nonconductor to a conductor, into ground.

Failure in time (FIT): A rating equal to the number of failures in one billion (10^9) h.

Frit: A relatively low softening point material of glass composition.

Function test: A check for correct device operation generally by truth table verification.

Hermetic: Sealed so that the object is gas tight (usually to a rate of less than 1×10^{-6} cc/s of helium.)

Joint Army Navy (JAN): When used when referring to microcircuits indicated a part fully qualified to the requirements of MIL-M-38510 for ICs (now replaced by MIL-M-38535) and MIL-S-19500 for semiconductors. JAN class B microcircuit level of the standard military drawing (SMD) program is the preferred level for design in new weapons systems.

JANTX: A prefix denoting that the military specification device has received extra screening and testing, such as an 100% 168-h burn-in.

JANTXV: A JANTX part with an added precapsulation visual requirement.

Joint Electron Device Engineering Council (JEDEC): A part of the EIA.

Lead: A conductive path, usually self-supporting, the portion of an electrical component that connects it to outside circuitry.

Lead frame: The metallic portion of the device package that makes electrical connections from the die to other circuitry.

- Mask:** The stencil of circuit elements through which light is shown to expose that circuit pattern onto a photoresist coating on the chip (die). The exposed areas are stripped away leaving a pattern.
- Metallization:** The deposited thin metallic coating layer on a microcircuit or semiconductor.
- Passivation:** The process in which an insulating dielectric layer is formed over the surface of the die. Passivation is normally achieved by thermal oxidation of the silicon and a thin layer of silicon dioxide is obtained in this manner (a combination of PECVD oxide and PECVD nitride deposited at lower temperature (below 450°C)). Other passivation dielectric coatings may also be applied (used), such as silicon glass (silicon oxynitride).
- Particle impact noise detection testing (PIND):** A test where cavity devices are vibrated and monitored for the presence of loose particles inside the device package via the noise the material makes. These loose particles may be conductive (such as gold flake particles from gold eutectic die attachment operations) and could result in short circuits. This is not required on a 100% basis for military class B devices. It is required for all class S, or devices generally required for spacecraft application use.
- Popcorning:** A plastic package crack or delamination that is caused by the phase change and expansion of internally condensed moisture in the package during reflow soldering, which results in stress the plastic package can not withstand.
- Parts per million (PPM):** The number of failures in one million parts. A statistical estimation of the number of defective devices, usually calculated at a 90% confidence level.
- Schmooplot:** An X–Y plot giving the pass/fail region for a specific test while varying the parameters in the X and Y coordinates.
- Soft error:** An error, or upset in the output of a part (usually applies to memory devices for a single bit output error), which does not reoccur (i.e., the device performs to specifications when tested after the failure occurred).
- Substrate:** The supporting material upon which the microcircuit (IC) is fabricated, or in hybrids the part to which the IC (and other components, etc.) is attached.
- Tin whisker:** A hairlike single crystal growth formed on the metallization surface.
- Wire bond:** A wire connection between the semiconductor die bond pad and the leadframe or terminal.

8.1 Integrated Circuits

Tom Chen

8.1.1 Introduction

Transistors and their fabrication into *very large scale integrated (VLSI)* circuits are the invention that has made modern computing possible. Since its inception, integrated circuits have been advancing rapidly from a few transistors on a small silicon die in the early 1960s to 4 millions of transistors integrated on to a single large silicon substrate. The dominant type of transistor used in today's integrated circuits is the metal-oxide-semiconductor (MOS) type transistor. The rapid technological advances in integrated circuit (IC) technology accelerated during and after the 1980s, and one of the most influential factors for such a rapid advance is the technology scaling, that is, the reduction in MOS transistor feature sizes. The MOS feature size is typically measured by the MOS transistor channel length. The smaller the transistors, the more dense the integrated circuits in terms of the number of transistors packed on to a unit area of silicon substrate, and the faster the transistor can switch. Not only can we pack more transistors onto a unit silicon area, the chip size has also increase. As the transistor gets smaller and silicon chip size gets bigger, the transistor's driving capability decreases and the interconnect parasitics (interconnect capacitance and resistance) increases. Consequently, the entire VLSI system has to be designed very carefully to meet the speed demands of the future. Common design issues include optimal gate design and transistor sizing, minimization of clock skew and proper timing budgeting, and realistic modeling of interconnect parasitics.

8.1.2 High-Speed Design Techniques

A modern VLSI device typically consists of several *megacells*, such as memory blocks and data-path arithmetic blocks, and a lot of basic MOS logic gates, such as inverters and NAND/NOR gates. **Complementary MOS (CMOS)** is one of the most widely used logic families, mainly because of its low-power consumption and high-noise margin. Other logic families include NMOS and PMOS logic. Because of its popularity, only the CMOS logic will be discussed. Many approaches to high-speed design discussed here are equally applicable to other logic families.

Optimizing a VLSI device for high-speed operation can be carried out at the system level, as well as at the circuit and logic level. To achieve the maximum operating speed at the circuit and logic levels for a given technology, it is essential to properly set the size of each transistor in a logic gate to optimally drive the output load. If the output load is very large, a string of drivers with geometrically increasing sizes is needed. The size of transistors in a logic gate is also determined by the impact of the transistors as a load to be driven by their preceding gates.

Optimization of Gate Level Design

To optimize the gate level design, let us look at the performance of a single CMOS inverter as shown in Fig. 8.1. Delay of a gate is typically defined as the time difference between input transition and output transition at 50% of supply voltage. The inverter gate delay can be analytically expressed as

$$T_d = C_l(A_n/\beta_n + A_p/\beta_p)/2$$

where C_l is the load capacitance of the inverter; β_n and β_p are the forward current gains of n -type and p -type transistors, respectively, and are proportional to the transistor's channel width and inversely proportional to the transistor's channel length; A_n and A_p are process related parameters for a given supply voltage and they are determined by

$$A_n = [2n/(1-n) + \ln((2(1-n) - V_0)/V_0)][V_{dd}(1-n)]$$

$$A_p = [-2p/(1+p) + \ln((2(1+p) - V_0)/V_0)][V_{dd}(1+p)]$$

FIGURE 8.1 Gate delay in a single inverter.

where $n = V_{thn}/V_{dd}$ and $p = V_{thp}/V_{dd}$. V_{thn} and V_{thp} are gate threshold voltages for n -channel and p -channel transistors, respectively. This expression does not take the input signal slope into account. Otherwise, the expression would become more complicated. For more complex CMOS gates, an equivalent inverter structure is constructed to reflect the effective strength of their p -tree and n -tree in order to apply the inverter delay model.

In practice, CMOS gate delay is treated in a simple fashion. The delay of a logic gate can be divided into two parts: the intrinsic delay D_{ins} , and the load-related delay D_{load} . The gate intrinsic delay is determined by the internal characteristics of the gate including the implementing technology, the gate structure, and the transistor sizes. The load-related delay is a function of the total load capacitance at the gate's output. The total gate delay can be expressed as

$$T_d = D_{ins} + C_l^* S$$

where C_l is the total load capacitance and S is the factor for gate's driving strength. $C_l^* S$ represents the gate's load-related delay. In most CMOS circuits using leading-edge submicron technologies, the total delay of a gate can be dominated by the load-related delay. For an inverter in a modern submicron CMOS technology of around $0.5\text{-}\mu\text{m}$ feature size, D_{ins} can range from 0.08 to 0.12 ns and S can range from 0.00065 to 0.00085 ns/fF depending on specifics in the technology and the minimum transistor feature size. For other more complex gates such as NAND and NOR gates, D_{ins} and S generally increase.

To optimize a VLSI circuit for its maximum operating speed, **critical paths** must be identified. A critical path in a circuit is a signal path with the longest time delay from a primary input to a primary output. The time delay on the critical path in a circuit determines the maximum operating speed of the circuit. The time delay of a critical path can be minimized by altering the size of the transistors on the critical path. Using the lumped resistor-capacitor (RC) delay model, the problem of transistor sizing can be formulated to an optimization problem with a convex relationship between the path delay and the sizes of the transistors on the path. This optimization problem is simple to solve. The solutions often have 20–30% deviation, however, compared to the SPICE simulation results. Realistic modeling of gate delay taking some second-order variables, such as input signal slope, into consideration has shown that the relationship between the path delay and the sizes of the transistors on the path is not convex. Such detailed analysis led to more sophisticated transistor sizing algorithms. One of these algorithms suggested using genetic methods to search for an optimal solution and has shown some promising results.

Clocks and Clock Schemes in High-Speed Circuit Design

Most of the modern electronic systems are **synchronous systems**. The clock is a central pace setter in a synchronous system to step the desired system operations through various stages of the computation. Latches are often used to facilitate catching the output data at the end of each clock cycle. Figure 8.2 shows the typical synchronous circuit with random logic clusters as computational blocks and latches as pace setting devices. When there exist feedbacks, as shown in Fig. 8.2, the circuit is referred to as *sequential circuit*.

A latch is also called a *register* or a *flip-flop*. The way a latch catches data depends on how it is triggered by the clock signal. Generally, there are level-triggered and edge-triggered latches, the former can be further subdivided according to the triggering polarity as positive or negative level or edge-triggered latches. The performance of a digital circuit is often determined by the maximum clock frequency the circuit can run. For a synchronous digital circuit to function properly, the longest delay through any combinational clusters must be less than the clock cycle period. Therefore, the following needs to be done for high-speed design:

- Partition the entire system so that the delays of all of the combinational clusters are as balanced as possible.
- Design the circuit of the combinational clusters so that the delay of critical paths in the circuit is minimized and less than the desired clock cycle period.
- Use a robust clock scheme to ensure that the entire system is free of race conditions and has minimal tolerable clock skew.

The first item listed is beyond the scope of this section. The second item was discussed in the preceding subsection.

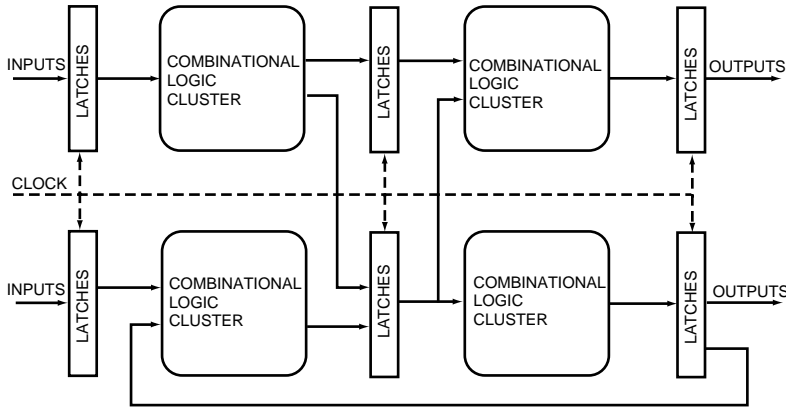

FIGURE 8.2 A typical synchronous circuit with combinational logic clusters and latches.

Race conditions typically occur with the use of level triggered latches. Figure 8.3 shows a typical synchronous system based on level triggered latches. Because of delays on the clock distribution network, such as buffers and capacitive parasitics on the interconnect, the timing difference caused by such a distribution delay is often referred to as **clock skew** which is modeled by a delay element in Fig. 8.3. For the system to operate properly, at the positive edge each latch is supposed to capture its input data from the previous clock cycle. If the clock skew is severe shown as skewed clock clk' , however, it could be possible that the delay from $Q1$ to $D2$ becomes short enough that $D1$ is not only caught by the clk , but also caught by clk' . The solution to such a race condition caused by severe clock skew is as follows:

- Change the latch elements from level triggered to edge triggered or pseudoedge triggered latches such as latches using two-phase, nonoverlapping clocks.
- Resynthesize the system to balance to the critical path delay of different combinational clusters.
- Reduce the clock skew.

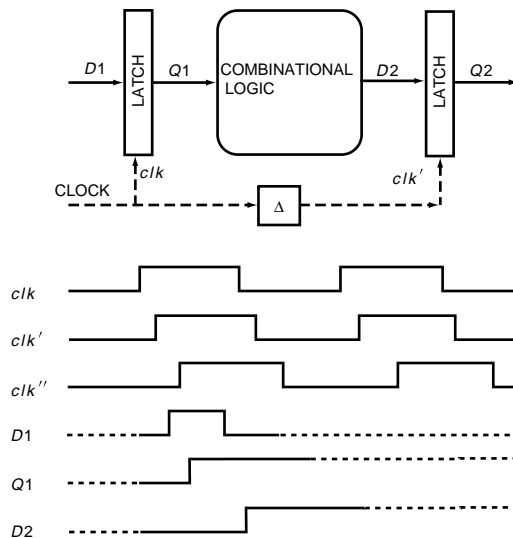

FIGURE 8.3 An example of race condition caused by a severe clock skew in the system.

Clock skew can also cause other types of circuit malfunction if it is not attended properly. In dynamic logic, severe clock skew may result in different functional blocks being in different stages of precharging or evaluating. Severe clock skew eats away a significant amount of precious cycle time in VLSI systems. Therefore, reducing clock skew is an important problem in high-speed circuit design.

As discussed earlier, clock skew is mainly caused by the imbalance of the clock distribution network. Such an imbalance can be the result of distance differences from the nearest clock driver, different functional blocks driven by different clock drivers with different driving strengths, temperature difference on the same die, device characteristic differences on the same die due to process variation, etc. Two general approaches are often taken to minimize the clock skew. The first approach deals with the way the clock signal is distributed. The geometric shape of the clock distribution network is a very important attribute. Depending on the type of system operation, several popular distribution network topologies are illustrated in Fig. 8.4. Among these topologies, **H-tree** presents least amount of clock skew and, therefore, is widely used in high-performance systems.

The second approach deals with employing additional on-chip circuits to force the clock signals of two different functional blocks to be aligned, or to force the on-chip clock signal to be aligned with the global clock signal at the system level. The widely used circuits for this purpose include **phase-locked loop (PLL)** and **delay-locked loop (DLL)**. Figure 8.5 shows a simple phase-locked loop. A simple PLL consists of four components: a digital phase detector, a charge pump, a low-pass filter, and a voltage controlled oscillator (VCO). The phase detector accepts reference clock, CLK_ref, and a skewed clock, CLK_out, and compares the phase difference of the two clocks to charge or discharge the charge pump. The low-pass filter is used to convert the phase difference between the reference frequency and the skewed frequency to a voltage level. This voltage is then fed into the VCO to reduce the difference of the reference and skewed clocks until they are locked to each other.

One of the most important design parameters for PLL is the output jitter. The output jitter is demonstrated by the random deviation of the output clock's phase from the reference clock signal. Significant peak-to-peak jitter will effectively reduce the clock period. The main contributor of the output jitter is the noise on the input of the VCO. Additional jitter can be induced by the noise on power supply rails that are common to high-speed VLSI circuits. Furthermore, acquisition time of PLL, in the several microsecond range, is often longer than desirable. This is mainly attributed to the response time of the VCO. In a typical scenario where clock skew is caused by the imbalance of the distribution network, the skewed clock often has the correct frequency. What needs to be corrected is the relative phase of the clock signals. Therefore, there is no need to have a VCO. Rather, a simple delay logic can be used to modify the clock signal's phase. This type of simplified phase correct circuit is referred to as a delay-locked loop. By replacing the VCO with a simple programmable delay line, DLL is simpler, yet exhibits less jitter than its PLL counterpart.

Asynchronous Circuits and Systems

Clock distribution within large VLSI chips is becoming more and more of a problem for high-speed digital systems. Such a problem may be surmountable using state-of-the-art computer aided design (CAD) tools and on-chip PLL/DLL circuits. Asynchronous circuits have, nevertheless, gained a great deal of attention lately. An asynchronous circuit does not require an external clock to get it through the computation. Instead, it works on the principle of handshaking between functional blocks. Therefore, execution of a computational operation is totally dependent on the readiness of all of the input variables of the functional block. The biggest advantage of asynchronous circuits over synchronous circuits is that the correct behavior of asynchronous circuits is independent of the speed of their components or signal interconnect delays.

In a typical asynchronous circuit, functional blocks will have two more signals, *request* and *complete*, apart from their input and output signals as shown in Fig. 8.6. These two binary signals are necessary and sufficient for handshaking purposes. Even though asynchronous circuits are speed independent, the order of computation is still maintained by connecting the complete signal from one block to the request signal to another block. When the request signal is active for a functional block, indicating the computation of the preceding functional block is completed, the current functional block starts computation evaluation using its valid inputs from the preceding functional block. Once the evaluation is completed, the current

FIGURE 8.4 Various clock distribution structures.

FIGURE 8.5 A simple phase-locked loop structure.

FIGURE 8.6 The single request and complete are two extra signals for a typical asynchronous circuit.

functional block sets the complete signal to active to activate other functional blocks for computation. Figure 8.7 shows a schematic of such a communication protocol where block A and block B are connected in a pipeline.

To ensure that asynchronous circuits function correctly regardless of individual block speed, the *request* signal of a functional block should only be activated if the functional block has already completed the current computation. Otherwise, the current computation would be overwritten by incoming computation requests. To prevent this situation from happening, an interconnection block is required with an *acknowledge* signal from the current functional block to the preceding functional block. An active acknowledge signal indicates to the preceding function block that the current block is ready to accept new data from it. This two-way communication protocol with request and acknowledge is illustrated in Fig. 8.7. The interconnect circuit is unique to asynchronous circuits. It is often referred to as a **C-element**. Figure 8.8 shows a design of the C-element.

In recent years, much effort has been spent on applying the asynchronous circuits to real-world applications. Several totally asynchronous designs of microprocessors have demonstrated their commercial feasibility. Several issues that still need to be addressed with regard to asynchronous circuits include acceptable amounts of silicon overhead, power efficiency, and performance as compared to their synchronous counterparts.

Interconnect Parasitics and Their Impact on High-Speed Design

On-chip interconnects present parasitic capacitance and resistance as loads to active circuits. Such parasitic loads had little impact on earlier ICs because the intrinsic gate delay dominated the total gate delay.

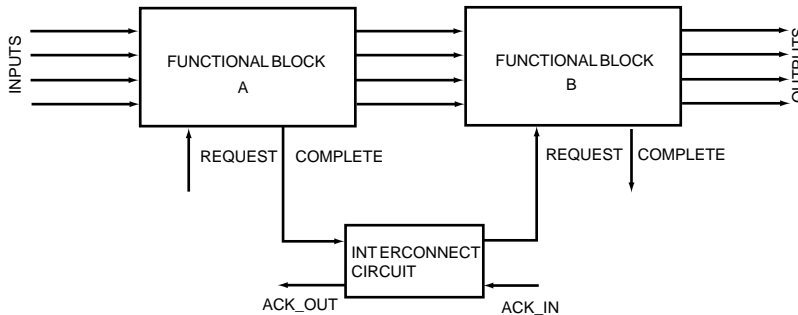

FIGURE 8.7 The schematic of a communication protocol in asynchronous systems.

FIGURE 8.8 A schematic design of the C-element.

With aggressive scaling in the VLSI process, the gate intrinsic delay decreases dramatically. The interconnect parasitics does not scale proportionally, however, and the wire resistance tends to increase, resulting in the delay caused by the interconnect load parasitics gradually becoming a dominant factor in the total gate delay. The problem is further exacerbated by the fact that when the operating speed reaches several hundred megahertz, the traditional lumped RC model is no longer accurate. It has been suggested that such a lumped RC model should be modified to include a grounded resistor and an inductor. The RLC interconnect model includes nonequilibrium initial conditions and its response waveform may be nonmonotonic. Such a model may be more accurate because the existence of the inductance reduces the rate of increase in current and, therefore, increases the signal transition time. When the operating speed increases further such that the rise time of a signal is much less than the signal transmission time from point A to point B, a transmission line model should be used. On-chip interconnect, thus, is typically modeled as a microstrip. The characteristics of a transmission line are determined by its relative dielectric constant and magnetic permeability. Table 8.1 shows the signal transmission velocity in some common materials used in VLSI. As a rule of thumb, the transmission line phenomena become significant when

$$t_r < 2.5 * t_f$$

where t_r is the rise time of a signal and t_f is the signal transmission time, which is the interconnect length divided by the signal traveling velocity in the given material. The interconnect can be treated as a lumped RC network when

$$t_r > 5 * t_f$$

TABLE 8.1 Transmission Line Velocity in Some Common Materials

	Velocity, cm/ns
Polymide	16–19
SiO ₂	15
Epoxy glass (PCB)	13
Aluminium	10

The signal rise time depends on the driver design and the transmission line's characteristic impedance Z_0 . In MOS ICs, the load device at the receiving end of the transmission line can always be treated as an open circuit. Therefore, driver design is a very important aspect of high-speed circuit design. The ideal case is to have the driver's output impedance match the transmission line's characteristic impedance. Driving an unterminated transmission line (the MOS IC case) with its output impedance lower than the line's characteristic impedance, however, can increase driver's settling time due to excess ringing and, therefore, is definitely to be avoided. Excess ringing at the receiving end could also cause the load to switch undesirably. Assuming MOS transistor's threshold is 0.6–0.8 V, to ensure that no undesirable switching takes place, the output impedance of the drive should be at least a third of the characteristic impedance of the transmission line. When the output impedance is higher than the line's characteristic impedance, multiple wave trips of the signal may be required to switch the load. To ensure that only one wave trip is needed to switch the load, the output impedance of the driver should be within 60% of the characteristic impedance of the transmission line.

For a lossy transmission line due to parasitic resistance of on-chip interconnects, an exponential attenuating transfer function can be applied to the signal transfer at any point on the transmission line. The rate of the attenuation is proportional to the unit resistance of the interconnect. When operating frequency increases beyond a certain level, the on-chip transmission media exhibits the *skin effect* in which the time-varying currents concentrate near the skin of the conductor. Therefore, the unit resistance of the transmission media increases dramatically.

Defining Terms

Application-specific integrated circuit (ASIC): Device designed specifically for a particular application.

Application-specific standard product (ASSP): Device designed specifically for one area of applications, such as graphics and video processing.

Asynchronous system: A system in which the progress of a computation is driven by the readiness of all the necessary input variables for the computation through a handshaking protocol. Therefore, no central clock is needed.

C-element: A circuit used in an asynchronous as an interconnect circuit. The function of this circuit is to facilitate the handshaking communication protocol between two functional blocks.

Clock skew: A phase difference between two clock signals at different part of a chip/system due to imbalance of the distribution media and the distribution network.

Complementary metal-oxide silicon (CMOS): It is a very popular integrated circuit type in use today.

Critical path: A signal path from a primary input pin to a primary output pin with the longest delay time in a logic block.

Delay-locked loop (DLL): It is similar to PLL except that it has better jitter suppression capability.

Digital signal processor (DSP): A processing device specialized in popular math routines used by signal processing algorithms.

Field programmable gate array (FPGA): A popular device which can be tailored to a particular application by loading a customizing program on to the chip.

H-tree: A popular clock distribution tree topologically that resembles the H shape. It introduces the least amount of clock skew compared to other distribution topologies.

Phase-locked loop (PLL): A circuit that can detect the phase difference of two signals and reduce the difference in the presence of the phase difference.

Programmable logic devices (PLD): A class of IC products which are easy to customize for a particular application.

SPICE: A popular circuit level simulation program to perform detailed analysis of circuit behavior.

Synchronous system: A system in which a computation is divided into unit periods defined by a central clock signal. Signal transfer within the system typically occurred at the transition edge of the clock signal.

8.2 Integrated Circuit Design

Samuel O. Agbo and Eugene D. Fabricius

8.2.1 Introduction

Integrated circuits (ICs) are classified according to their levels of complexity: small-scale integration (SSI), medium-scale integration (MSI), large-scale integration (LSI) and very large-scale integration (VLSI). They are also classified according to the technology employed for their fabrication (bipolar, N metal oxide semiconductor (NMOS), complementary metal oxide semiconductor (CMOS), etc.). The design of integrated circuits needs to be addressed at the SSI, MSI, LSI, and VLSI levels. Digital SSI and MSI typically consist of gates and combinations of gates. Design of digital SSI and MSI is presented in [Sec. 8.2.3](#), and consists largely of the design of standard gates. These standard gates are designed to have large noise margins, large fan out, and large load current capability, in order to maximize their versatility.

In principle, the basic gates are sufficient for the design of any digital integrated circuit, no matter how complex. In practice, modifications are necessary in the basic gates and MSI circuits like flip-flops, registers, adders, etc., when such circuits are to be employed in LSI or VLSI design. For example, circuits to be interconnected on the same chip can be designed with lower noise margins, reduced load driving capability, and smaller logic swing. The resulting benefits are lower power consumption, greater circuit density, and improved reliability. On the other hand, several methodologies have emerged in LSI and VLSI

design that are not based on interconnections or modification of SSI and MSI circuits. Both approaches to LSI and VLSI design are presented in the following sections.

8.2.2 An Overview of the IC Design Process

The effort required for the design of an integrated circuit depends on the complexity of the circuit. The requirement may range from several days effort for a single designer to several months work for a team of designers. **Custom design** of complex integrated circuits is the most demanding. By contrast, **semicustom design** of LSI and VLSI that utilize preexisting designs, such as standard cells and gate arrays, requires less design effort.

IC design is performed at many different levels and Fig. 8.9 is a nonunique depiction of these levels. Level 1 presents the design in terms of subsystems (standard cells, gate arrays, custom subcircuits, etc.) and their interconnections. Design of the system **layout** begins with the floor plan of level 3. It does not involve the layout of individual transistors and devices, but is concerned with the geometric arrangement and interconnection of the subsystems. Level 4 involves the circuit design of the subsystems. Levels 2 and 5 involve system and subcircuit simulations, respectively, which may lead to modifications in levels 1 and/or 4.

Discussion here will focus primarily on the system design of level 1 and the subsystem circuit design of level 4. Lumped under the fabrication process of level 7 are many tasks, such as **mask** generation, process simulation, wafer fabrication, testing, etc. Broadly speaking, floor plan generation is a part of layout. For large ICs, layout design is often relevant to system and circuit design.

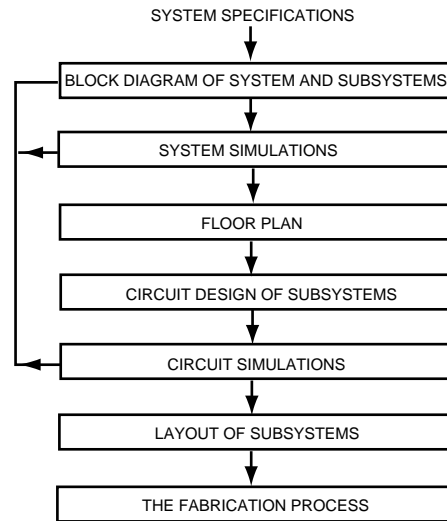

FIGURE 8.9 Different levels in IC design.

8.2.3 General Considerations in IC Design

Layout or actual arrangement of components on an IC is a design process involving design tradeoffs. Circuit design often influences layout and vice versa, especially in LSI and VLSI. Thus, it is helpful to outline some general considerations in IC design:

- *Circuit components:* Chip area is crucial in IC design. The usual IC components are transistors, resistors, and capacitors. Inductors are uneconomical in area requirements and are hardly ever used in ICs except in certain microwave applications. Transistors require small chip areas and are heavily utilized in ICs. Resistor area requirements increase with resistor values. IC resistors generally range between 50 Ω and 100 k Ω . Capacitors are area intensive and tend to be limited to 100 pF.
- *Isolation regions:* Usually, different components would be placed in different isolation regions. The number of isolation regions, however, should be minimized in the interest of chip area economy by placing more than one component in an isolation region whenever possible. For example, several resistors could share one isolation region.
- *Design rules:* Geometric design rules that specify minimum dimensions for features and separation between features must be followed for a given IC process.
- *Power dissipation:* Chip layout should allow for adequate power dissipation and avoid overheating or development of hot spots on the chip. In low-power circuits such as CMOS ICs, device size is determined by lithographic constraints. In circuits with appreciable power dissipation, device size is determined by thermal constraints and may be much larger than lithographic constraints would allow.

Device size determination from power-density considerations is illustrated with the aid of Fig. 8.10. The device resides close to the surface of the substrate. Thus, heat flow is approximately one-dimensional, from the device to the substrate, although it is actually a three-dimensional flow. Assuming an infinite heat sink of ambient temperature T_A , substrate thickness ΔX , thermal conductivity α , device of surface area A , and temperature $T_A + \Delta T$, the rate of heat flow toward the heat sink, dQ/dt , is given by

$$\frac{dQ}{dt} = \alpha A \left(\frac{\Delta T}{\Delta X} \right) \quad (8.1)$$

The power density or power dissipation per unit area of the device is

$$\frac{P}{A} = \alpha \left(\frac{\Delta T}{\Delta X} \right) \quad (8.2)$$

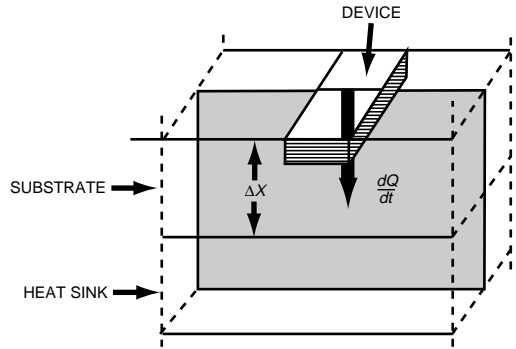

FIGURE 8.10 Heat flow in an IC device.

Device Scaling

The trend in IC design, especially VLSI, is progressively toward smaller sizes. Scaling techniques permit the design of circuits that can be shrunk as technological developments allow progressively smaller sizes. Two basic approaches to scaling are full scaling and constant voltage scaling.

- *Full scaling*: All device dimensions, both surface and vertical, and all voltages are reduced by the same scaling factor S .
- *Constant voltage (CV) scaling*: All device dimensions, both surface and vertical, are reduced by the same scaling factor S , but voltages are not scaled. Voltages are maintained at levels compatible with transistor-transistor logic (TTL) supply voltages and logic levels.

Scaling of device dimensions has implications for other device parameters. Full scaling tends to maintain constant electric field strength and, hence, parameters that are no worse off, as device dimensions are reduced, but does not ensure TTL voltage compatibility. Table 8.2 compares effect on device parameters

TABLE 8.2 Effect of Full Scaling and Constant Voltage Scaling on IC Device Parameters

Parameter	Full Scaling	CV Scaling
Channel length, L	$1/S$	$1/S$
Channel width, W	$1/S$	$1/S$
Oxide thickness, t_{OX}	$1/S$	$1/S$
Supply voltage, V_{DD}	$1/S$	1
Threshold voltage, V_{TD}	$1/S$	1
Oxide capacitances, C_{OX}, C_{SW}, C_{FOX}	S	S
Gate capacitance, $C_g = C_{OX}WL$	$1/S$	$1/S$
Transconductances, K_N, K_P	S	S
Current, I_D	$1/S$	$1/S$
Power dissipation per dense, P	$1/S^2$	S
Power dissipation per unit area, P/A	1	S^3
Packing density	S^2	S^2
Propagation delay, t_p	$1/S$	$1/S^2$
Power-delay product, Pt_p	$1/S^3$	$1/S$

of the two scaling approaches. A compromise that is often adopted is to use full scaling for all internal circuits and maintain TTL voltage compatibility at the chip input/output (I/O) pins.

Although many scaling relationships are common to MOS field effect transistors (MOSFETs) and bipolar ICs (Keyes, 1975), the scaling relationships of Table 8.2 more strictly applies to MOSFETs. Bipolar doping levels, unlike MOSFETs, are not limited by oxide breakdown. Thus, in principle, miniaturization can be carried further in bipolar processing technology. However, bipolar scaling is more complex. One reason is that the junction voltages required to turn on a bipolar junction transistor (BJT) does not scale down with dimensions.

Geometric Design Rules

Design rules specify minimum device dimensions, minimum separation between features and maximum misalignment of features on an IC. Such rules tend to be process and equipment dependent. For example, a design rule for a 2- μm process may not be appropriate for a 0.5- μm process. Design rules should protect against fatal errors such as short circuits due to excessive misalignment of features, or open circuits due to too narrow a metal or polysilicon conductive path.

Generalized design rules that are portable between processes and scalable to facilitate adaptation to shrinking minimum geometries as processes evolve are desirable. Other advantages of generalized design rules include increased design efficiency due to fewer levels and fewer rules, automatic translation to final layout, layout-rule and electrical-rule checking, simulation, verification, etc. The Mead-Conway approach (1980) to generalized design rules is to define a scalable and process-dependent parameter, lambda (λ), as the maximum misalignment of a feature from its intended position on a wafer or half the maximum misalignment of two features on different mask layers. Table 8.3 shows a version of the Mead-Conway scalable design rules for NMOS (Fabricius, 1990).

CMOS ICs utilize both NMOS and PMOS devices. Starting with a p -substrate, the NMOS would be fabricated on the p -substrate and the PMOS in an n -well, and vice versa. With the addition of an n -well, p -well or twin tub process, CMOS fabrication is similar to that for NMOS, although more complex. Table 8.4 (Fabricius, 1990) shows the Mead-Conway scalable CMOS design rules. The dimensions are given in multiples of λ and the rules are specified by the MOS Implementation System (MOSIS) of the

FIGURE 8.11 Layout design for NMOS inverter with depletion load and a CMOS inverter: (a) NMOS inverter, (b) CMOS inverter, (c) NMOS inverter layout, (d) CMOS inverter layout.

University of Southern California Information Sciences Institute. Further clarification of the rules may be obtained from MOSIS manuals (USCISI, 1984, 1988).

Figure 8.11 illustrates the layout of an NMOS inverter with depletion load and a CMOS inverter, employing the NMOS and CMOS scalable design rules just discussed. Figure 8.11(a) and Figure 8.11(b) show the circuit diagrams for the NMOS and CMOS, respectively, with the aspect ratios Z defined as the ratio of the length to the width of a transistor gate. Figure 8.11(c) and Figure 8.11(d) give the layouts for the NMOS and CMOS, respectively.

A simplified design rule for a bipolar npn comparable to those previously discussed for NMOS and CMOS is presented in Table 8.5. As before, the minimum size of a feature in the layout is denoted by lambda (λ). The following six masks are required for the fabrication: n^+ buried-layer diffusion, p^+ isolation diffusion, p base region diffusion, n^+ emitter and collector diffusions, contact windows, and metalization.

8.2.4 Design of Small-Scale and Medium-Scale Integrated Circuits

Gates are the basic building blocks in digital integrated circuits. Small-scale integrated circuits are essentially gate circuits, and medium-scale integrated circuits are circuits employing several gates. Gates, in turn, are based on inverters and can be realized from inverter circuits with some modifications, especially those modifications that allow for multiple inputs. This section will start with a discussion of inverters and gates.

NMOS Inverters

A resistive load NMOS inverter, its output characteristics, and its voltage transfer characteristic are shown in Fig. 8.12. The loadline is also shown on the output characteristics. Resistive load inverters are not widely

TABLE 8.5 Simplified Design Rules for *npn* Transistor

Mask Level	Feature	Size (times λ)
Isolation mask	width of isolation wall	1

Metallization	width	1.5
	metal to metal spacing	1

used in ICs because resistors require long strips and, hence, large areas on the chip. A solution to this problem is to use active loads, since transistors are economical in chip area.

Figure 8.13 shows three NMOS inverters with three types of NMOS active loads: saturated enhancement load, linear enhancement load, and depletion load. One basis for comparison between these inverters is the geometric ratio K_R , which is defined as Z_{pu}/Z_{pd} . Z denotes the ratio of length to width of a transistor channel. The subscript pu refers to the pull-up or load device, whereas the subscript pd refers to the pull-down or driving transistor.

FIGURE 8.12 NMOS resistive load inverter: (a) resistive load NMOS inverter, (b) output characteristics, (c) transfer characteristic.

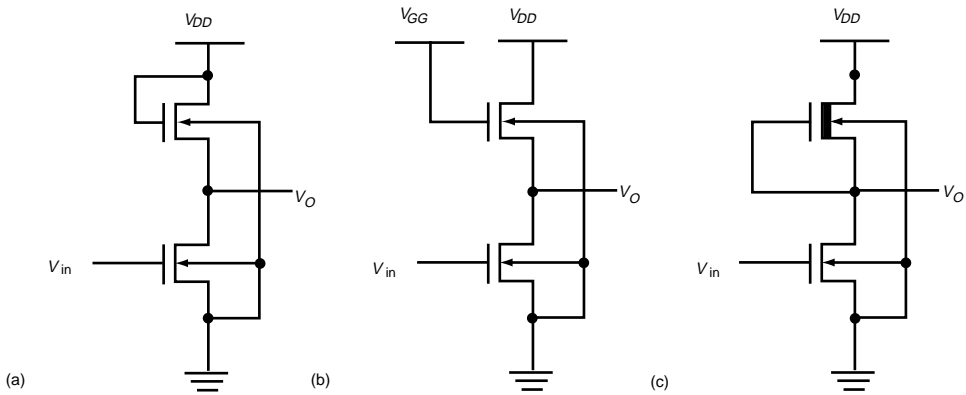

FIGURE 8.13 NMOS inverters with different types of active loads: (a) saturated enhancement load, (b) linear enhancement load, (c) depletion load.

The saturated enhancement load inverter overcomes much of the area disadvantage of the resistive load inverter. When carrying the same current and having the same pull-down transistor as the resistive inverter, however, K_R is large for the saturated enhancement load inverter, indicating load transistor area minimization is still possible. This configuration yields a smaller logic swing relative to the resistive load inverter, however, because the load transistor stops conducting when its $V_{GS} = V_{DS}$ decreases to V_T . Thus, for this inverter, $V_{OH} = V_{DD} - V_T$.

In Fig. 8.13(b), because V_{GG} is greater than $V_{DD} + V_T$, V_{DS} is always smaller than $V_{GS} - V_T$; thus, the load always operates in the linear region. This results in a linear enhancement load NMOS inverter. The high value of V_{GG} also ensures that V_{GS} is always greater than V_T , so that the load remains on and V_{OH} pulls up to V_{DD} . The linear enhancement load configuration, however, requires a load transistor of larger area relative to the saturated enhancement load inverter, and requires additional chip area for the V_{GG} contact.

In the depletion NMOS load inverter of Fig. 8.13(c), $V_{GS} = 0$, thus the load device is always on and V_{OH} pulls all the way to V_{DD} . This configuration overcomes the area disadvantage without incurring a voltage swing penalty. It is, therefore, the preferred alternative. The performance of the NMOS inverters with the four different types of loads are graphically compared in Fig. 8.14(a) and Fig. 8.14(b). Both the loadlines

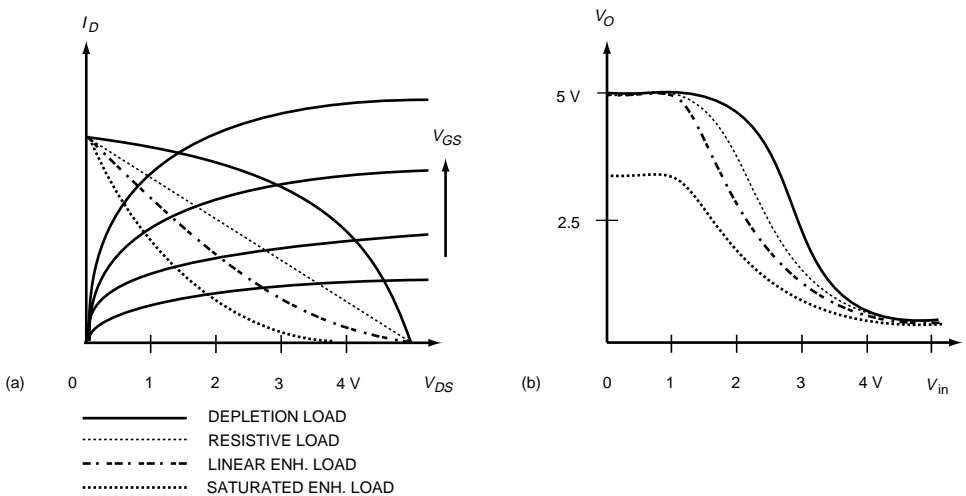

FIGURE 8.14 Performance of NMOS inverters with different types of loads: (a) output characteristics and load lines, (b) voltage transfer characteristics.

and the voltage transfer characteristics were obtained from SPICE simulation. Figure 8.14(a) shows the loadlines superimposed on the output characteristics of the pull-down transistor, which is the same for the four inverters. R_L is 100 k Ω and each inverter has $V_{DD} = 5$ V, $V_{OL} = 0.2$ V and $I_{D \max} = 48 \mu\text{A}$. Note that V_{OH} falls short of V_{DD} for the saturated enhancement load inverter but not for the others. Figure 8.14(b) shows the voltage transfer characteristics (VTC) for the four inverters. V_{OH} is again shown to be less than V_{DD} for the saturated enhancement load. Note, also, that the depletion load VTC more closely approaches the ideal inverter VTC than any of the others.

The loadlines of Fig. 8.13(a) are easy to generate. Consider, for example the depletion NMOS load. V_{GS} is fixed at 0 V, so that its output characteristic consists of only the curve for $V_{GS} = 0$. I_D is always the same for the load and driving transistor, but their V_{DS} add up to V_{DD} . Thus, when V_{DS} is high for one transistor, it is low for the other. The loadline is obtained by shifting the origin for V_{DS} for the load characteristic to V_{DD} , reflecting it about the vertical axis through V_{DD} and superimposing it on the $V-I$ characteristics for the driving inverter.

The voltage transfer characteristics are best generated by computer simulation. Useful insights, however, can be gained from an analysis yielding the critical voltages V_{OH} , V_{OL} , V_{IH} , V_{IL} , and V_O for any specified V_{in} . The NMOS currents hold the key to such an analysis. Threshold voltages are different for enhancement and depletion NMOS transistors, but the drain current equations are the same. The drain current is given in the linear region and the saturated region, respectively, by

$$I_D = K_n [2(V_{GS} - V_T)V_{DS} - V_{DS}^2]; \quad V_{DS} \leq V_{GS} - V_T \tag{8.3}$$

$$I_D = K_n (V_{GS} - V_T)^2; \quad V_{DS} \geq V_{GS} - V_T \tag{8.4}$$

where

- V_T = threshold voltage
- $K_n = \frac{\mu_n C_{ox}}{2} \left(\frac{w}{L}\right) = \text{transconductance}$
- μ_n = electron channel mobility
- C_{ox} = gate capacitance per unit area

Similar definitions apply to PMOS transistors.

Consider the VTC of Fig. 8.15(a) for a depletion load NMOS inverter. For the region $0 < V_{in} < V_T$ the driving transistor is off, so $V_{OH} = V_{DD}$. At A, V_{in} is small; thus, for the driving transistor, $V_{DS} = V_O > V_{in} - V_T = V_{GS} - V_T$. For the load $V_{DS} = V_{DD} - V_O$ is small. Hence, the driver is saturated and load

FIGURE 8.15 Regions of the VTC and VTCs for different geometric ratios for the depletion load NMOS inverters: (a) depletion load NMOS inverter VTC and its regions, (b) VTCs for different geometric ratios.

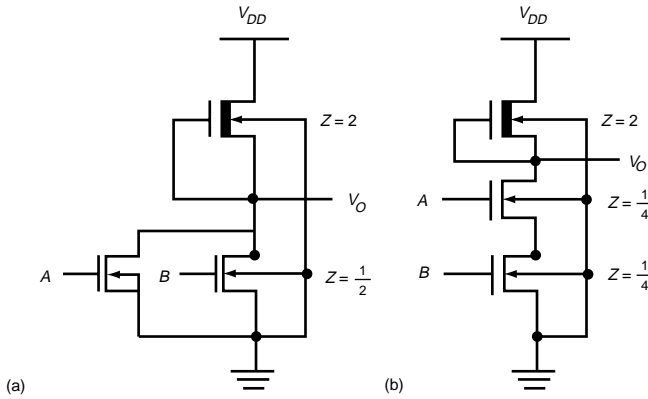

FIGURE 8.16 NMOS gates: (a) NMOS NOR gate, (b) NMOS NAND gate.

is linear. Similar considerations lead to the conclusions as to the region in which each device operates, as noted in the figure. To find V_{IL} and V_{IH} , the drain currents for the appropriate region of operation for points A and C, respectively, are equated, for both transistors. Differentiating the resulting equations with respect to V_{in} and applying the condition that $dV_O/dV_{in} = -1$ yields the required critical voltages. Equating drain currents for saturated load and linear driver at $V_{in} = V_{DD}$ and solving yields V_{OL} . The output voltage V_O may be found at any value of V_{in} by equating the drain currents for the two transistors, appropriate for that region of V_{in} , and solving for V_O at the given V_{in} .

NMOS Gates

Only NOR and NAND need be considered because these are more economical in chip area than OR and AND, and any logic system can be implemented entirely with either NOR or NAND. By connecting driving transistors in parallel to provide the multiple inputs, the NMOS inverter is easily converted to a NOR gate as shown in Fig. 8.16(a). By connecting driving transistors in series as in Fig. 8.16(b), an NAND gate is obtained.

The NMOS, NOR, and NAND gates are essentially modifications of the depletion load NMOS inverter of Fig. 8.13(c). They all have the same depletion load, and their performance should be similar. For the same value of V_{DD} , each has $V_{OH} = V_{DD}$, and they should have the same V_{OL} and the same drain current when $V_O = V_{OL}$. In Fig. 8.13(c), the depletion load inverter has $Z_{pu} = 2$, $Z_{pd} = \frac{1}{2}$ and $K_R = 4$. Thus, Z_{pu} is 2 for the NOR and the NAND gate. With only one driving transistor on in the NOR gate, the drain current should be sufficient to ensure that $V_O = V_{OL}$. Thus, for each of the driving transistors, $Z_I = \frac{1}{2}$, as for the depletion load inverter. For the NAND gate, the equivalent series combination of Z_{pd} (proportional to drain-source resistance) should also be $\frac{1}{2}$ to allow the same value of V_O , leading to $Z_I = \frac{1}{4}$ for each driving transistor in the NAND gate. Thus, K_R is 4 for the inverter, 4 for the NOR gate, and 8 for the NAND. As the number of inputs increases, K_R increases for the NAND but not for the NOR. It is clear that NMOS NAND gates are wasteful of chip area relative to NMOS NOR. Hence, NOR gates are preferred (and the NOR is the standard gate) in NMOS.

CMOS Inverters

As shown in Fig. 8.17(a), the CMOS inverter consists of an enhancement NMOS as the driving transistor, and a complementary enhancement PMOS load transistor. The driving transistor is off when V_{in} is low, and the load transistor is off when V_{in} is high. Thus, one of the two series transistors is always off (equivalently, drain current and power dissipation are zero) except during switching, when both transistors are momentarily on. The resulting low-power dissipation is an important CMOS advantage and makes it an attractive alternative in VLSI design.

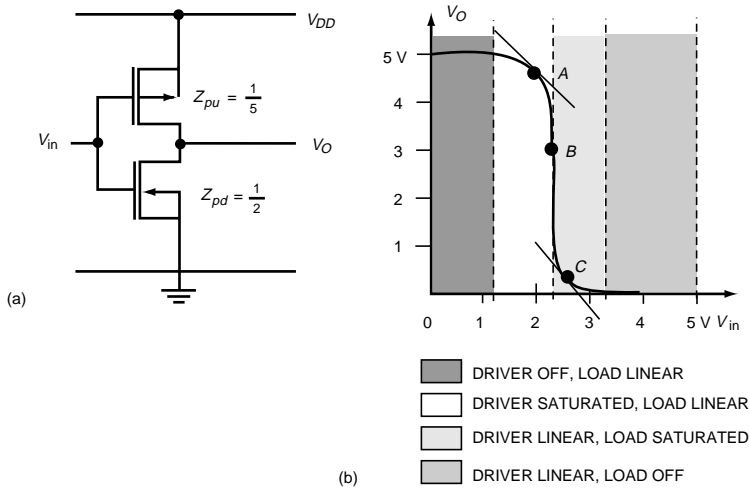

FIGURE 8.17 The CMOS inverter and its voltage transfer characteristics: (a) CMOS inverter, (b) CMOS transfer characteristic and its regions.

NMOS circuits are ratioed in the sense that the pull up never turns off, and V_{OL} is determined by the inverter ratio. CMOS is ratioless in this sense, since V_{OL} is always the negative rail. If one desires equal sourcing and sinking currents, however, the pull-up device must be wider than the pull-down device by the ratio of the electron-to-hole mobilities, typically about 2.5 to 1. This also gives a symmetrical voltage transfer curve, with the voltage at which $V_{in} = V_O$ having a value of $V_{DD}/2$. This voltage is referred to as the inverter voltage V_{inv} .

The voltage transfer for the CMOS inverter is shown in Fig. 8.17(b). Note that the voltage transfer characteristic approaches that of the ideal logic inverter. These characteristics are best obtained with computer circuit simulation programs. As with the depletion load NMOS inverter, useful insights may be gained by performing an analytical solution. The analysis proceeds as previously described for the depletion load NMOS inverter. Note that the VTC of Fig. 8.17(b) has been divided into regions as in Fig. 8.15(a). In each region, the appropriate expressions for the load and driving transistor drain currents are equated so that V_O can be computed for any given V_{in} . To find V_{IL} and V_{IH} , the condition that $dV_O/dV_{in} = -1$ at such critical voltages is applied to the drain current equation. Note that the drain current equations for the PMOS are the same as for NMOS (Eqs. 8.3 and 8.4), except for reverse voltage polarities for the PMOS.

CMOS Gates

CMOS gates are based on simple modifications to the CMOS inverter. Figure 8.18(a) and Figure 8.18(b) show that the CMOS NOR and NAND gates are essentially CMOS inverters in which the load and driving transistor are replaced by series or parallel combinations (as appropriate) of PMOS and NMOS transistors, respectively.

Suppose the NOR gate of Fig. 8.18(a) is to have the same V_{DD} and V_{inv} as the CMOS inverter of Fig. 8.17(a), then the equivalent Z_{pu} and Z_{pd} for the NOR gate should equal those for the inverter. Since only one of the parallel pull-down transistors needs be on in the NOR to ensure $V_O = 0$ V, $Z_I = Z_{pd} = \frac{1}{2}$, as for the inverter. For the series load, however, $Z_L = \frac{1}{10}$ to give equivalent $Z_{pu} = \frac{1}{5}$. If the NAND gate of Fig. 8.18(b) is to have the same V_{inv} as the said inverter, similar arguments lead to $Z_I = \frac{1}{4}$ and $Z_L = \frac{1}{5}$ for the NAND. Thus, $K_R = 0.4$ for the inverter, 0.2 for the NOR, and 0.8 (closer to unity) for NAND. Hence, NAND is the standard gate in CMOS. Another way of putting this is that for the given Z values, if the channel length L is constant, then the widths of the loads for the inverter, NOR, and NAND are in the ratio 1:2:1. Thus, the NOR requires more chip area, and this larger area requirement increases with the number of inputs.

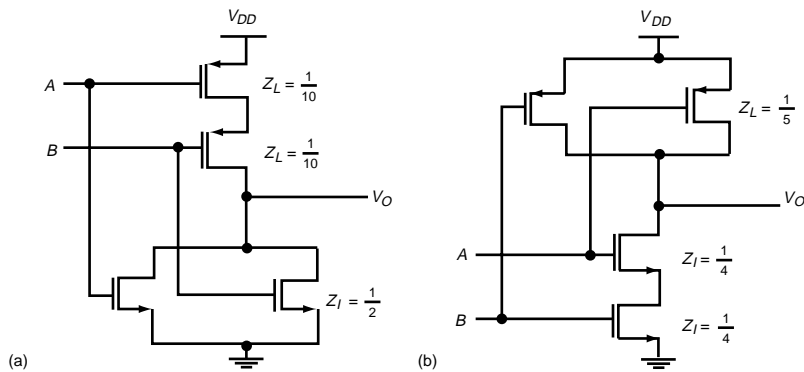

FIGURE 8.18 CMOS gates: (a) CMOS NOR gate, (b) CMOS NAND gate.

Bipolar Gates

The major bipolar digital logic families are TTL, emitter-coupled logic (ECL), and integrated injection logic (I²L). Within each logic family, there are subclassifications, for example, the Schottky transistor logic (STL), and the integrated Schottky logic (ISL), which developed from the basic I²L. Bipolar gates have faster switching speeds but greater power dissipation than CMOS gates. The most popular bipolar gate in SSI is the low-power Schottky TTL, which has moderate power dissipation and propagation delay. The fastest switching bipolar family is the ECL, but it has relatively high-power dissipation. The highest packing density is achieved with I²L and its relatives with low-power dissipation and moderate switching speeds. A better comparison of logic families should be based on the power-delay product, which takes into account both power dissipation and propagation delay.

Medium-Scale Integrated Circuits

MSI circuits have between 10 and 100 transistors per chip. They are built from inverters and basic logic gates with hardly any modifications. They require minimal design effort beyond putting together and interconnecting logic gates. Examples of MSI circuits are flip-flops, counters, registers, adders, multiplexers, demultiplexers, etc.

8.2.5 LSI and VLSI Circuit Design

Semicustom design is a heavily utilized technique in LSI and VLSI design. In this technique, largely predesigned subcircuits or cells are interconnected to form the desired, larger circuit. Such subcircuits are usually highly regular in nature, so that the technique leads to highly regular circuits and layouts.

Multiphase Clocking

Multiphase clocking is an important technique that can be used to reduce device count in LSI and VLSI circuits. To illustrate the savings that can be realized with the technique, device count is compared for a conventional design of a 4-b shift register employing D flip-flops based on CMOS NAND gates and a 4-b shift register employing two-phase clocks and CMOS technology.

Both designs are shown in Fig. 8.19. Figure 8.19(a) shows the conventional design for the shift register, which employs a single phase clock signal, whereas Fig. 8.19(b) shows the circuit realization of each D flip-flop with CMOS NAND gates (Taub and Schilling, 1977). The device count for each in this design is obtained as follows:

- 5 two-input CMOS NAND gates, 4 transistors each: 20 transistors
- 1 three-input CMOS NAND gate: 6 transistors
- Number of transistors per D flip-flop: 26
- Total number of transistors for the 4-b register: 104

FIGURE 8.19 Conventional (static) and dynamic 4-b shift register: (a) conventional static shift register, (b) D flip-flop, (c) dynamic shift register, (d) two-phase clock pulses.

The second design, which employs two-phase clocking, is shown in 8.19(c), whereas the nonoverlapping clock signals are shown in Fig. 8.19(d). Note that each flip-flop now consists of two CMOS transmission gates and two CMOS inverters. Thus, there are 8 transmission gates and 8 inverters in the 4-b shift register. Device count for this design is as follows:

- Number of transistors for 8 transmission gates: 16
- Number of transistors for 8 CMOS inverters: 16
- Total number of transistors for the 4-b register: 32

In the preceding example, employing two-phase clocking helped to reduce device count to less than one-third of the requirement in the conventional static design. This gain, however, is partly offset by the need for more complex clocking and the fact that the shift register is now dynamic. To avoid loss of data due to leakage through off transistors, the clock must run above a minimum frequency. The times required to charge and discharge capacitive loads determine the upper clock frequency.

8.2.6 Increasing Packing Density and Reducing Power Dissipation in MOS Circuits

CMOS gates have much lower power dissipation than NMOS gates. This is a great advantage in LSI and VLSI design. Standard CMOS gates, however, require two transistors per input and, therefore, have higher device count than NMOS gates that require one driving transistor per input, plus one depletion load transistor, irrespective of the number of inputs (Mavor, Jack, and Denyer, 1983). This NMOS feature is put to advantage in applications such as semiconductor memories and programmable logic arrays, which will be discussed later. In addition to requiring a higher device count, it is necessary to isolate the PMOS and NMOS transistors in the CMOS and to employ metal interconnection between their drains, which are of opposite conductivity. Consequently, gate count per chip for NMOS is about half that of CMOS, using the same design rules.

Figure 8.20 shows a CMOS domino logic circuit in which clocking is employed in an unconventional CMOS circuit to provide both high density and low-power dissipation. When T is low, Q_1 is off, so there is no path to ground irrespective of the logic levels at the inputs A, B, C, D and E . Q_2 is on, so that the

FIGURE 8.20 CMOS domino AND-OR logic.

parasitic capacitance C_1 charges to V_{DD} . When T is high, Q_2 is off and Q_1 is on. Thus if both A and B , or both C and D , or all of A, B, C , and D are high, a path exists from C_1 to ground, and it discharges. Otherwise, C_1 remains high (but for slow leakage), and the valid logic $(A B) + (C + D)$ appears at the output F . Note that this circuit has only two load PMOS transistors, and only one driving transistor is required for each additional input. Thus, device count is minimized by using complex instead of simple logic functions. Each transistor, except those in the output inverter, may be minimum size, since they are required only to charge or discharge C_1 . Power dissipation is low as for standard CMOS, because no steady-state current flows.

8.2.7 Gate Arrays

Gate arrays are a category of semicustom integrated circuits typically containing 100 to several thousand gate cells arranged in rows and columns on a chip. The gate cell may be a NAND, NOR, or other gate. Often, each gate cell is a set of components that could be interconnected to form the desired gate or gates. Identical gate cell pattern is employed, irrespective of chip function. Consequently, gate arrays can be largely processed in advance (Reinhard, 1987). Less effort is required for design with gate arrays since only the masks needed for interconnection are required to customize a chip for a particular application.

Figure 8.21 illustrates a gate array in various levels of detail and possible interconnections within a cell. The floor plan of Fig. 8.21(a) shows that there are 10 columns of cells with 10 cells per column, for a total of 100 cells in the chip. The cell layout of Fig. 8.21(b) shows that there are 4 NMOS and 4 PMOS transistors per cell. Thus there are a total of 800 transistors in the chip. The transistor channels are under the polysilicon and inside the diffusion areas. Figure 8.21(c) shows the cell layout with interconnection to form an NAND gate, whereas Fig. 8.21(d) shows the circuit equivalent of a cell.

Because of their simplicity, a significant amount of wiring is required for interconnections in gate arrays. Good computer software is essential for designing interconnections. In practice, wiring channels tend to fill up, so that it is difficult to utilize more than 70% of the cells on a chip (Alexander, 1985). The standard cell approach discussed next reduces this problem, to some extent, by permitting use of more complex logic functions or cells.

FIGURE 8.21 Gate array at various levels of detail: (a) cell structure, (b) transistor structure, (c) NAND gate interconnection, (d) equivalent circuit.

8.2.8 Standard Cells

In the **standard cell** approach, the IC designer selects from a library of predefined logic circuits or cells to build the desired circuit. In addition to the basic gates, the **cell library** usually includes more complex logic circuits such as exclusive-OR, AND-OR-INVERT, flip-flops, adders, read only memory (ROM), etc.

The standard cell approach to design is well suited to automated layout. The process consists of selecting cells from the library in accordance with the desired circuit functions, the relative placement of the cells, and their interconnections. The floor plan for a chip designed by this method is similar to the floor plan for a gate array chip as shown in Fig. 8.21(a). Note, however, that the designer has control over the number and width of wiring channels in this case. Layout for a cell is always the same each time the cell is used, but the cells used and their relative placement is unique to a chip. Thus, every mask level is unique in this approach, and fabrication is more involved and more costly than in the gate array approach (Hodges and Jackson, 1988).

8.2.9 Programmable Logic Devices

Programmable logic devices (PLDs) are a class of circuits widely used in LSI and VLSI design to implement two-level, sum-of-products, boolean functions. Multilevel logic can be realized with Weinberger arrays or gate matrices (Fabricius, 1990; Weinberger, 1967). Included among PLDs are programmable logic arrays (PLAs), programmable array logic (PAL), and ROM. The AND-OR structure of the PLA, which can be used to implement any two-level function, is the core of all PLDs. The AND-OR function is often implemented with NOR-NOR or NAND-NAND logic.

PLDs have the advantage of leading to highly regular layout structure. The PLD consists of an AND plane followed by an OR plane. The logic function is determined by the presence or absence of contacts or

FIGURE 8.22 Types of programmable logic devices: (a) programmable logic array, (b) programmable read only memory, (c) programmable array logic.

connections at row and column intersections in a single conducting layer. Programming or establishment of appropriate contacts may be accomplished during fabrication. Alternatively, the PLDs may be user programmable by means of fuse links.

Figure 8.22 shows the three types of PLDs. Hollow diamonds at row/column intersections in an AND or OR plane indicates that the plane is programmable. Presence of solid diamonds in some row/column intersections indicate that the logic for that plane is already defined and fixed. The PLD is a PLA if both the AND and OR planes are programmable, a PAL if only the AND plane is programmable, and a ROM if only the OR plane (the decoder in this case) is programmable. Because PLAs are programmable in both planes, they permit more versatile logic realizations than PALs. Also, the PAL can be considered a special case of the PLA. Thus, only the PLA is discussed further.

Programmable Logic Array

PLAs provide an alternative to implementation of combinational logic that results in highly regular layout structures. Consider, for example, a PLA implementation of the following sum of product expressions:

$$Y_1 = \bar{I}_0\bar{I}_1 + I_0\bar{I}_2 \tag{8.5}$$

$$Y_2 = \bar{I}_0I_1I_2 + I_0\bar{I}_2 \tag{8.6}$$

$$Y_3 = \bar{I}_0\bar{I}_1\bar{I}_2 + \bar{I}_0I_1I_2 \tag{8.7}$$

The PLA has three inputs and three outputs. In terms of the AND and OR planes, the outputs of the AND plane are

$$P_1 = \bar{I}_0\bar{I}_2 \tag{8.8}$$

$$P_2 = \bar{I}_0\bar{I}_1\bar{I}_2 \tag{8.9}$$

$$P_3 = \bar{I}_0I_1I_2 \tag{8.10}$$

$$P_4 = I_0\bar{I}_2 \tag{8.11}$$

The overall output is the output of the OR plane and can be written in terms of the AND plane outputs as

$$Y_1 = P_1 + P_4 \tag{8.12}$$

$$Y_2 = P_3 + P_4 \tag{8.13}$$

$$Y_3 = P_2 + P_3 \tag{8.14}$$

Figure 8.23 shows the logic circuit consisting of the AND and the OR planes. Note that each product line in the AND plane is an NMOS NOR gate with one depletion load; the gate of each driving transistor

FIGURE 8.23 An NMOS PLA.

is controlled by an input line. Likewise, each output line in the OR plane is an NMOS NOR gate with driving transistors whose gates are controlled by the product lines. Thus, the PLA employs a NOR–NOR implementation.

The personality matrix for a PLA (Lighthart, Aarts, and Beenker, 1986) gives a good description of the PLA and how it is to be programmed. The personality matrix Q of the PLA of Fig. 8.23 is given by Eq. (8.15).

$$Q = \begin{bmatrix} 0 & 0 & x & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 1 & 1 \\ 1 & x & 0 & 1 & 1 & 0 \end{bmatrix} \tag{8.15}$$

The first three columns comprise the AND plane of the matrix, whereas the last three columns comprise the OR plane of the three-input, three-output PLA. In the AND plane, element $q_{ij} = 0$ if a transistor is to link the product line P_i to the input line I_j ; $q_{ij} = 1$ if a transistor is to link P_i to \bar{I}_j , and q_{ij} is a *don't care* if neither input is to be connected to P_i . In the OR plane, $q_{ij} = 1$ if product line P_i is connected to output Y_j and 0 otherwise.

Figure 8.24 shows the stick diagram layout of the PLA circuit of Fig. 8.23, and illustrates how the regular structure of the PLA facilitates its layout. The input lines to each plane are polysilicon, the output lines from each plane are metal, and the sources of driving transistors are connected to ground by diffused lines. The connecting transistors are formed by grounded, crossing diffusion lines.

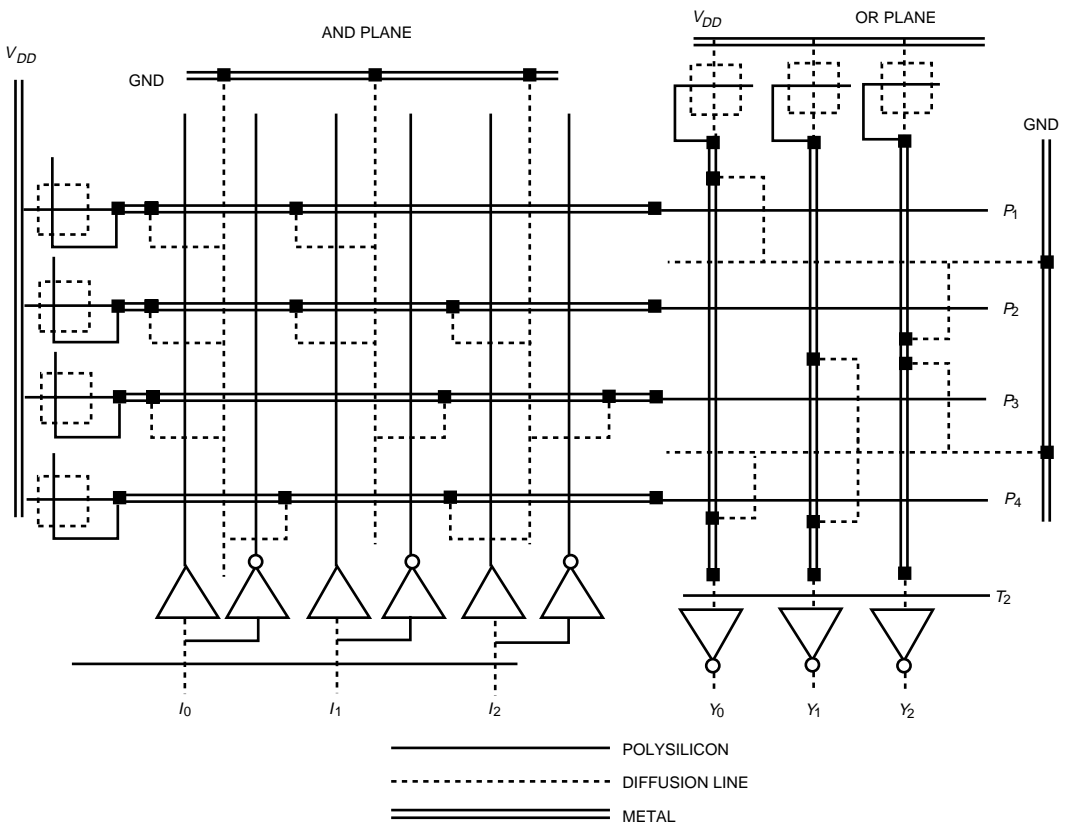

FIGURE 8.24 Stick diagram layout of the PLA shown in Fig. 8.23.

FIGURE 8.25 Lumped circuit model of a long polysilicon line.

8.2.10 Reducing Propagation Delays

Large capacitive loads are encountered in many ways in large integrated circuits. Bonding pads are required for interfacing the chip with other circuits, whereas probe pads are often required for testing. Both present large capacitive loads to their drivers. Interconnections within the chip are by means of metal or polysilicon lines. When long, such lines present long capacitive loads to their drivers. Although regular array structures, such as those of gate arrays, standard cells, and PLAs, are very convenient for semicustom design of LSI and VLSI, they have an inherent drawback with regard to propagation delay. Their row and column lines contact many devices and, hence, are very capacitive. The total delay of a long line may be reduced by inserting buffers along the line to restore the signal. Superbuffers are used for interfacing between small gates internal to the chip and large pad drivers and for driving highly capacitive lines.

Resistance-Capacitance (RC) Delay Lines

A long polysilicon line can be modeled as a lumped RC transmission line as shown in Fig. 8.25. Let Δx represent the length of a section of resistance R and capacitance C , and Δt be the time required for the signal to propagate along the section. Let $\Delta V = (V_{n-1} - V_n)\Delta x$, where V_n is the voltage at node n . The difference equation governing signal propagation along the line is (Fabricius, 1990)

$$RC \frac{\Delta V}{\Delta t} = \frac{\Delta^2 V}{\Delta x^2} \quad (8.16)$$

As the number of sections becomes very large, the difference equation can be approximated with the differential equation

$$RC \frac{dV}{dt} = \frac{d^2 V}{dx^2} \quad (8.17)$$

For a delay line with N sections, matched load $C_L = C$, resistance R and capacitance C per unit length, and overall length L in micrometer, Horowitz (1983) showed that the propagation delay is

$$t_d = \frac{0.7N(n+1)L^2 RC}{2N^2} \quad (8.18)$$

Note that the propagation delay is proportional to the square of the length of the line. As N tends to infinity, the propagation delay becomes

$$t_d = \frac{0.7RCL^2}{2} \quad (8.19)$$

To reduce the total delay restoring inverters can be inserted along a long line. Consider as an example, a 5-mm-long polysilicon line with $r = 20 \Omega/\mu\text{m}$ and $C = 0.2 \text{ fF}/\mu\text{m}$. It is desired to find the respective propagation delays, if the number of inverters inserted in the line varies from zero to four. The delay of each inverter is proportional to the length of the segment it drives and is given by $t_i = 0.4 \text{ ns}$ when it is

TABLE 8.6 Improvement in Propagation Delay with Increase in Number of Line Buffered

No. of Inverters K	Total Delay t_d , ns	% of Unbuffered Line Delay
0 (unbuffered)	35.0	100
1	18.5	52.86
2	13.0	37.14
3	10.25	29.29
4	8.6	24.57

driving a 1-mm-long segment. In each case, the inverters used are spaced uniformly along the line. Let

$$\begin{aligned} K &= \text{number of inverters used} \\ K + 1 &= \text{number of sections} \\ \ell &= \text{length per section, } \frac{5\text{mm}}{k+1} \\ t_d &= \text{total delay} \end{aligned}$$

then

$$t_d = \left[(k + 1) \left(\frac{0.7RC\ell^2}{2} \right) + 0.4\ell K \right] \text{ ns} \quad (8.20)$$

From Eq. (8.20), the propagation delays can be calculated. The delay for each number of inverters as a percentage of the unbuffered line delay is also computed. The results are tabulated in Table 8.6.

The results in the table show that the propagation delay decreases as the number of inverters is increased. The improvement in propagation delay, however, is less dramatic for each additional inverter than the one preceding it. The designer would stop increasing the number of inverters when the incremental gain no longer justifies an additional inverter. If the number of inverters is even, there is no inversion of the overall signal.

Superbuffers

Propagation delays can be reduced without excessive power consumption by using superbuffers. These are inverting or noninverting circuits that can source and sink larger currents and drive large capacitive loads faster than standard inverters. Unlike ratioed NMOS inverters in which the pull-up current drive capability is much less than the pull-down capability, superbuffers have symmetric drive capabilities. A superbuffer consists of a push-pull or totem pole output inverter driven by a conventional inverter. In an inverting superbuffer, the gates of both pull-down transistors in the driving and the totem pole inverters are driven by the input signal whereas the gate of the pull-up transistor in the output totem pole inverter is driven by the complement of the input signal.

An inverting and a noninverting NMOS superbuffer is shown in Fig. 8.26. By designing for an inverter ratio (K_R) of 4, and driving the totem pole pull-up with twice the gate voltage of a standard depletion mode pull-up, the NMOS superbuffer can be rendered essentially ratioless. In standard NMOS inverters, the pull-up transistor has the slower switching speed. Consider the inverting superbuffer of Fig. 8.26(a). When the input voltage goes low, the output voltage of the standard inverter and the gate voltage of Q_4 goes high rapidly since the only load it sees is the small gate capacitance of Q_4 . Thus, the totem pole output switches rapidly. Similar considerations shows that the noninverting super buffer also results in fast switching speeds.

The improvement in drive current capability of the NMOS superbuffer, relative to the standard (depletion load) NMOS inverter, can be estimated by comparing the average, output pull-up currents (Fabricius, 1990). The depletion load in the standard NMOS inverter is in saturation for $V_O < 2\text{ V}$ and in linear region for $V_O > 2\text{ V}$. For the pull-up device, $V_{DS} = 5\text{ V} - V_O$. Thus, the pull-up transistor is in saturation when it has $3\text{ V} < V_{DS} < 5\text{ V}$ and is in the linear region when $0\text{ V} < V_{DS} < 3\text{ V}$. The average current

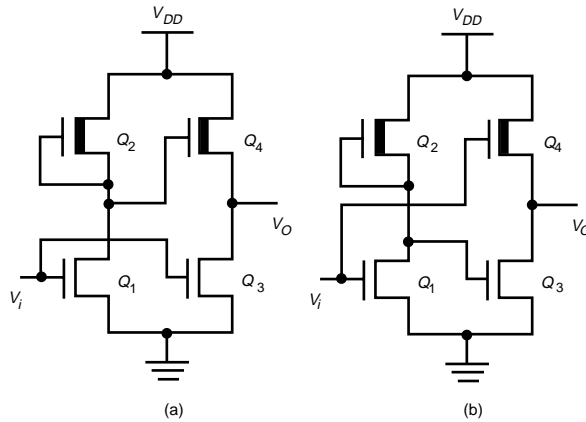

FIGURE 8.26 NMOS superbuffers: (a) inverting superbuffer, (b) noninverting superbuffer.

will be estimated by evaluating $I_D(\text{sat})$ at $V_{DS} = 5\text{ V}$ and $I_{D(\text{lin})}$ at $V_{DS} = 2.5\text{ V}$. Let $V_{TD} = -3\text{ V}$ for the depletion mode transistor. Then for the standard NMOS inverter

$$I_{D(\text{sat})} = K_{\text{pu}}(V_{GS} - V_{TD})^2 = K_{\text{pu}}(0 + 3)^2 = 9K_{\text{pu}} \tag{8.21}$$

$$I_{D(\text{lin})} = K_{\text{pu}}(2(V_{GS} - V_{TD})V_{DS} - V_{DS}^2) = K_{\text{pu}}(2(0 + 3)2.5 - 2.5^2) = 8.76K_{\text{pu}} \tag{8.22}$$

Thus the average pull-up current for the standard NMOS inverter is approximately $8.88K_{\text{pu}}$. For the totem pole output of the NMOS superbuffer, the average pull-up current is also estimated from drain currents at $V_{DS} = 5\text{ V}$ and 2.5 V . Note that in this case, the pull-up transistor has $V_G = V_{DD} = 5\text{ V}$ when it is on. Thus, $V_{GS} = V_{DS} = 5\text{ V}$ so that it always operates in the linear region. The currents are

$$I_D(5\text{ V}) = K_{\text{pu}}[2(5 + 3)5 - 5^2] = 55K_{\text{pu}} \tag{8.23}$$

$$I_D(2.5\text{ V}) = K_{\text{pu}}(2(2.5 + 3)2.5 - 2.5^2) = 10.62K_{\text{pu}} \tag{8.24}$$

The average pull-up current for the totem pole output is $38.12K_{\text{pu}}$. The average totem pole pull-up current is approximately 4.3 times the average NMOS pull-up current. Consequently, the superbuffer is roughly ratioless if designed for an inverter ratio of 4.

8.2.11 Output Buffers

Internal gates on a VLSI chip have load capacitances of about 50 fF or less and typical propagation delays of less than 1 ns. However, the chip output pins have to drive large capacitive loads of about 50 pF or more (Hodges and Jackson, 1988). For MOSFETs, the propagation delay is directly proportional to load capacitance. Thus, using a typical gate on the chip to drive an output pin would result in too long a propagation delay. Output buffers utilize a cascade of inverters of progressively larger drive capability to reduce the propagation delay.

An N -stage output buffer is illustrated in Fig. 8.27. Higher drive capability results from employing transistors of increasing channel width. As the transistor width increases from stage to stage by a factor of f , so does the current drive capability and the input capacitance. If C_G is the input or gate capacitance of the first inverter in the buffer, then the second inverter has an input capacitance of fC_G and the N th inverter has an input capacitance of $f^{N-1}C_G$ and a load capacitance of $f^N C_G$, which is equal to C_L , the load capacitance at the output pin. The inverter on the left in the figure is a typical inverter on the chip with an input or gate capacitance of C_G and a propagation delay of τ . The first inverter in the buffer has an input capacitance of fC_G , but it has a current driving capability f times larger than the on chip inverter.

FIGURE 8.27 An N -stage output buffer chain.

Thus, it has a propagation delay of $f\tau$. The second inverter in the buffer has an input capacitance of f^2C_G and an accumulated delay of $2f\tau$ at its output. The N th inverter has an input capacitance of $f^N C_G$, which is equal to the load capacitance at the output pin, and an accumulated propagation delay of $Nf\tau$, which is the overall delay of the buffer.

Let

$$\text{load capacitance} = Y C_G = f^N C_G$$

$$\text{total delay} = t_B = Nf\tau$$

Then

$$N = \frac{1nY}{1nf} \tag{8.25}$$

and

$$t_B = \frac{1nY}{1nf} f\tau \tag{8.26}$$

By equating to zero the first derivative of t_B with respect to f , it is found that t_B is minimum at $f = e = 2.72$, the base of the natural logarithms. This is not a sharp minimum (Moshen and Mead, 1979), and values of f between 2 and 5 do not greatly increase the time delay.

Consider an example in which $C_G = 50$ fF and $\tau = 0.5$ ns for a typical gate driving an identical gate on the chip. Suppose this typical gate is to drive an output pin with load capacitance $C_L = 55$ pF, instead of an identical gate. If an output buffer is used

$$Y = \frac{C_L}{C_G} = \frac{55 \text{ pF}}{50 \text{ fF}} = 1100$$

$$N = 1nY = 7$$

$$t_B = 7e\tau = 9.5 \text{ ns}$$

If the typical chip gate is directly connected to the output pin, the propagation delay is $Y\tau = 550$ ns, which is extremely large compared with the 9.5 ns delay obtained when the buffer is used. This example illustrates the effectiveness of the buffer.

Defining Terms

Cell library: A collection of simple logic elements that have been designed in accordance with a specific set of design rules and fabrication processes. Interconnections of such logic elements are often used in semicustom design of more complex IC chips.

- Custom design:** A design method that aims at providing a unique implementation of the function needed for a specific application in a way that minimizes chip area and possibly other performance features.
- Design rules:** A prescription for preparing the photomasks used in IC fabrication so that optimum yield is obtained in as small a geometry as possible without compromising circuit reliability. They specify minimum device dimensions, minimum separation between features, and maximum misalignment of features on an IC chip.
- Layout:** An important step in IC chip design that specifies the position and dimension of features and components on the different layers of masks.
- Masks:** A set of photographic plates used to define regions for diffusion, metalization, etc., on layers of the IC wafer. Each mask consists of a unique pattern: the image of the corresponding layer.
- Standard cell:** A predefined logic circuit in a cell library designed in accordance with a specific set of design rules and fabrication processes. Standard cells are typically employed in semicustom design of more complex circuits.
- Semicustom design:** A design method in which largely predesigned subcircuits or cells are interconnected to form the desired more complex circuit or part of it.

8.3 Digital Logic Families

Robert J. Feigate, Jr.

8.3.1 Introduction

Digital devices are constrained to two stable operating regions (usually voltage ranges) separated by a transition region through which the operating point may pass but not remain (see Fig. 8.28). Prolonged operation in the transition region does not cause harm to the devices, it simply means that the resulting outputs are unspecified. For the inverter shown in the figure, the output voltage is guaranteed to be greater than V_{OH} as long as the input voltage is below the specified V_{IH} . Note that the circuit is designed so that the input high voltage is lower than the output high voltage (vice versa for logic low voltages). This difference, called **noise margin**, permits interfering signals to corrupt the logic voltage within limits without producing erroneous operation. Logical conditions and binary numbers can be represented physically by associating one of the stable voltage ranges with one logic state or binary value and identifying the other stable voltage with the opposite state or value. By extension, then, it is possible to design electronic circuits that physically perform logical or arithmetic operations. As detailed examination of logic design is beyond the scope of this chapter, the reader is referred to any of the large number of digital logic textbooks.¹

FIGURE 8.28 Logic voltage levels.

Digital logic components were the earliest commercially produced integrated circuits. *Resistor-transistor logic* (RTL) and a speedier variant *resistor-capacitor-transistor logic* (RCTL) were introduced in the early 1960s by Fairchild Semiconductor. *Diode-transistor logic* (DTL) was introduced a few years later by Signetics Corporation. Although these families are often discussed in electronics texts as ancestors of later logic families, they have been obsolete for many years and are of historical interest only.

A primary performance characteristic of different logic families is their *speed-power product*, that is, the average propagation delay of a basic gate multiplied by the average power dissipated by the gate. Table 8.7

TABLE 8.7 Speed-Product Comparison for Popular Discrete Logic Families^a

Logic Family	Power Dissipation/Gate			pJ
	Static at 100 kHz, mW	Typical Delay, mW	Product at 100 kHz, ns	
Metal-gate CMOS	0.001	0.1	75	7.5
Silicon-gate CMOS	0.0000025	.17	10	1.7
Standard TTL	10	10	10	100
Low Power Schottky TTL	2	2	8	16
Schottky TTL	19	19	4.5	85.5
Adv. Schottky TTL	8.5	8.5	1	8.5
ALS TTL	1	1	2.5	2.5
10 K ECL	24	24	0.2	4.8

^aLoad capacitance is 50 pF, load resistance 500 Ω, except ECL is driving 50-Ω transmission.

¹Two excellent recent logic design texts are *Modern Digital Design*, by Richard Sandige, McGraw-Hill, New York, 1990 and *Contemporary Logic Design*, by Randy Katz, Benjamin Cummings, Redwood City, CA, 1994.

lists the speed-power product for several popular logic families. Note that propagation delays specified in manufacturer handbooks may be measured under different loading conditions, which must be taken into account in computing speed-power product.

8.3.2 Transistor-Transistor Logic

First introduced in the 1960s, transistor-transistor logic (TTL) was the technology of choice for discrete logic designs into the 1990s, when complementary metal oxide semi-conductor (CMOS) equivalents gained ascendancy. Because TTL has an enormous base of previous designs, is available in a rich variety of small-scale and medium-scale building blocks, is electrically rugged, offers relatively high-operating speed, and has well-known characteristics, transistor-transistor logic continues to be an important technology for some time. Texas Instruments Corporation's 54/7400 TTL series became a *de facto* standard, with its device numbers and pinouts used by other TTL (and CMOS) manufacturers.

There are actually several families of TTL devices having circuit and semiconductor process variations that produce different speed-power characteristics. Individual parts are designated by a scheme combining numbers and letters to identify the exact device and the TTL family. Parts having 54 as the first digits have their performance specified over the military temperature range from -55 to $+125^{\circ}\text{C}$, whereas 74-series parts are specified from 0 to $+70^{\circ}\text{C}$. Letters identifying the family come next, followed by a number identifying the part's function. For example, 7486 identifies a package containing four, 2-input exclusive-OR gates from the standard TTL family, whereas 74ALS86 indicates the same function in the low-power Schottky family. Additional codes for package type and, possibly, circuit revisions may also be appended. Generally speaking, devices from different TTL families can be intermixed, although attention must be paid to **fanout** (discussed subsequently) and noise performance.

The basic building block of standard TTL is the NAND gate shown in Fig. 8.29. If either input *A* or *B* is connected to a logic-low voltage, multiple-emitter transistor Q1 is saturated, holding the base of transistor Q2 low and keeping it cut off. Consequently, Q4 is starved of base current and is also off, while Q3 receives base drive current through resistor R2 and is turned on, pulling the output voltage up toward V_{cc} . Typical high output voltage for standard TTL circuits is 3.4 V. On the other hand, if both of the inputs are high, Q1 moves into the reverse-active region and current flows out of its collector into the base of Q2.

FIGURE 8.29 Two input standard TTL NAND gate.

FIGURE 8.30 Propagation delay times.

Q2 turns on, raising Q4’s base voltage until it is driven into saturation. At the same time, the Ohm’s law voltage drop across R2 from Q2’s collector current lowers the base voltage of Q3 below the value needed to keep D1 and Q3’s base-emitter junction forward biased. Q3 cuts off, with the net result that the output is drawn low, toward ground. In normal operation, then, transistors Q2, Q3, and Q4 must move between saturation and cutoff. Saturated transistors experience an accumulation in minority carriers in their base regions, and the time required for the transistor to leave saturation depends on how quickly excess carriers can be removed from the base. Standard TTL processes introduce gold as an impurity to create *trapping sites* in the base that speed the annihilation of minority electrons. Later TTL families incorporate circuit refinements and processing enhancements designed to reduce excess carrier concentrations and speed removal of accumulated base electrons.

Because the internal switching dynamics differ and because the pull-up and pull-down transistors have different current drive capabilities, TTL parts show a longer propagation time when driving the output from low to high than from high to low (see Fig. 8.30). Although the average propagation delay $((t_{phl} + t_{plh})/2)$ is often used in speed comparisons, conservative designers use the slower propagation delay in computing circuit performance. NAND gate delays for standard TTL are typically 10 ns, with guaranteed maximum t_{phl} of 15 ns and t_{plh} of 22 ns.

When a TTL gate is producing a low output, the output voltage is the collector-to-emitter voltage of pull-down transistor Q4. If the collector current flowing in from the circuits being driven increases, the output voltage rises. The output current, therefore, must be limited to ensure that output voltage remains in the specified logic low range (less than V_{OL}). This places a maximum on the number of inputs that can be driven low by a given output stage; in other words, any TTL output has a maximum low-level fanout. Similarly, there is a maximum fanout for high logic levels. Since circuits must operate properly at either logic level, the smaller of the two establishes the maximum overall fanout. That is

$$\text{fanout} = \text{minimum}(-I_{OH,\text{max}}/I_{IH,\text{max}}, -I_{OL,\text{max}}/I_{IL,\text{max}})$$

where

- $I_{OH,\text{max}}$ = specified maximum output current for $V_{OH,\text{min}}$
- $I_{OL,\text{max}}$ = specified maximum output current for $V_{OL,\text{max}}$
- $I_{IH,\text{max}}$ = specified maximum input current, high level
- $I_{IL,\text{max}}$ = specified maximum input current, low level

The minus sign in the fanout computations arises because both input and output current reference directions are defined into the device. Most parts in the standard TTL family have a fanout of 10 when driving other standard TTL circuits. Buffer circuits with increased output current capability are available for applications such as clock signals that must drive an unusually large number of inputs. TTL families other than standard TTL have different input and output current specifications; fanout computations should be performed whenever parts from different families are mixed.

One of the transistors in the conventional *totem pole* TTL output stage is always turned on, pulling the output pin toward either a logic high or low. Consequently, two or more outputs cannot be connected to the same node; if one output were attempting to drive a low logic voltage and the other a high, a low-resistance path is created from between V_{cc} and ground. Excessive currents may damage the output transistors and, even if damage does not occur, the output voltage settles in the forbidden transition region between V_{OH}

FIGURE 8.31 Wired-AND gate using open collector outputs and a pullup resistor.

and V_{OL} . Some TTL parts are available in versions with open-collector outputs, truncated output stages having only a pull down transistor (see Fig. 8.31). Two or more open-collector outputs can be connected to V_{cc} through a pull-up resistor, creating a wired-AND phantom logic gate. If any output transistor is turned on, the common point is pulled low. It only assumes a high voltage if all output transistors are turned off. The pull-up resistor must be large enough to ensure that the I_{OL} specification is not exceeded when a single gate is driving the output low, but small enough to guarantee that input leakage currents will not pull the output below V_{OH} when all driving gates are off. Since increasing the pull-up resistor value increases the resistance-capacitance (RC) time constant of the wired-AND gate and slows the effective propagation delay, the pull-up resistor is usually selected near its minimum value. The applicable design equations are

$$(V_{cc} - V_{OL,max}) / (I_{OL,max} + nI_{IL,max}) < R_{pu} < (V_{cc} - V_{OH,min}) / (mI_{OH,max} + nI_{IH,max})$$

where m is the number of open collector gates connected to R_{pu} and n is the number of driven inputs. Reference direction for all currents is into the device pin.

Some TTL parts have three-state outputs: totem pole outputs that have the added feature that both output transistors can be turned off under the control of an output enable signal. When the output enable is in its active state, the part's output functions conventionally, but when the enable is inactive, both transistors are off, effectively disconnecting the output pin from the internal circuitry. Several three-state outputs can be connected to a common bus, and only one output is enabled at a time to selectively place its logic level on the bus.

Over the long history of TTL, a number of variants have been produced to achieve faster speeds, lower power consumption, or both. For example, the 54/74L family of parts incorporated redesigned internal circuitry using higher resistance values to lower the supply current, reducing power consumption to a little as 1/10 that of standard TTL. Speed was reduced as well, with delay times as much as three times longer. Conversely, the 54/74H family offered higher speeds than standard TTL, at the expense of increased power consumption. Both of these TTL families are obsolete, their places taken by various forms of Schottky TTL.

As noted earlier, TTL output transistors are driven well into saturation. Rather than using gold doping to hasten decay of minority carriers, Schottky transistors limit the forward bias of the collector-base junction and, hence, excess base minority carrier accumulation by paralleling the junction with a Schottky (gold-semiconductor) diode, as shown in Fig. 8.32. As the NPN transistor starts to saturate, the Schottky diode becomes forward biased. This clamps the collector-base junction to about 0.3 V, keeping the transistor out of hard saturation. Schottky TTL (S) is about three times faster than standard TTL, while consuming about 1.5 times as much power.

Lower power Schottky TTL (LS) combined an improved input circuit design with Schottky transistors to reduce power consumption to a fifth of standard TTL, while maintaining equal or faster speed.

The redesigned input circuitry of LS logic changes the input logic thresholds, resulting in slightly reduced noise margin.

Still another TTL family is *Fairchild Advanced Schottky TTL* (FAST). The F parts combine circuit improvements with processing techniques that reduce junction capacitances and increase transistor speeds. The result is a fivefold increase in speed compared to standard TTL, with lowered power consumption.

As their names imply, advanced Schottky (AS) and advanced low-power Schottky (ALS) use improved fabrication processes to improve transistor switching speeds. Parts from these families are two

to three times faster than their S and LS equivalents, while consuming half the power. Although the standard TTL, Schottky (S), and low-power Schottky (LS) families remain in volume production, the newer advanced Schottky families (AS, ALS, F) offer better speed-power products and are favored for new designs.

In making speed comparisons between different logic families, one should keep in mind that manufacturer's published specifications use different load circuits for different TTL families. For example, propagation delays of standard TTL are measured using a load circuit of a 15-pF capacitor paralleled by a 400- Ω resistor, whereas FAST uses 50 pF and 500 Ω . Since effective propagation delay increases approximately linearly with the capacitance of the load circuit, direct comparisons of raw manufacturer data is meaningless. Manufacturer's databooks include correction curves showing how propagation delay changes with changes in load capacitance.

As outputs change from one logic state to another, sharp transients occur on the power supply current. Decoupling capacitors are connected between the V_{cc} and ground leads of TTL logic packages to provide filtering, minimizing transient currents along the power supply lines and reducing noise generation. Guidelines for distribution of decoupling capacitors are found in manufacturer handbooks and texts on digital system design, for example, Barnes (1987).

Circuit boards using advanced TTL with very short **risetimes** (FAST and AS) require physical designs that reduce waveform distortion due to transmission line effects. A brief discussion of such considerations is given in the following section on emitter-coupled logic.

8.3.3 CMOS Logic

In 1962, Frank Wanlass of Fairchild Semiconductor noted that enhancement nMOS and pMOS transistors could be stacked totem pole fashion to form an extraordinarily simple inverter stage (see Fig. 8.33). If the input voltage is near V_{dd} , the nMOS pull-down transistor channel will be enhanced, whereas the pMOS transistor remains turned off. The voltage divider effect of a low nMOS channel resistance and very high pMOS channel resistance produces a low output voltage. On the other hand, if the input voltage is near ground, the nMOS transistor will be turned off, while the pMOS channel is enhanced to pull the output voltage high. Logic gates can be easily created by adding parallel pull-down transistors and series pull-up transistors. When a CMOS gate is in either of its static states, the only current flowing is the very small leakage current through the off transistor plus any current needed by the driven inputs. Since the inputs to CMOS gates are essentially capacitances, input currents can be very small (on the order of 100 pA). Thus, the static power supply current and power dissipation of CMOS gates is far smaller than that of TTL gates. Since the early versions of discrete CMOS logic were much slower than TTL, CMOS was usually relegated to applications where power conservation was more important than performance.

In TTL logic, the high and low output logic levels and the input switching threshold (point at which a particular gate input interprets the voltage as a one rather than a zero) are established largely by forward bias voltages of PN junctions. Since these voltages do not scale with the power supply voltage, TTL operates properly over a rather restricted range ($5.0\text{ V} \pm 10\%$). In an all CMOS system, however, output voltage is

FIGURE 8.32 Schottky transistor construction and symbol.

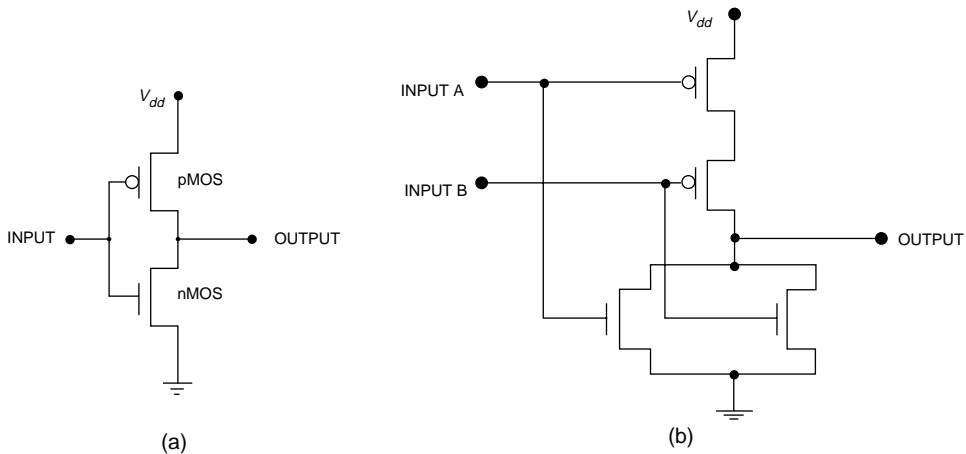

FIGURE 8.33 Elementary CMOS logic circuit: (a) complementary MOS inverter stage, (b) two-input CMOS NOR gate.

determined by the voltage divider effect. Since the off-resistance of the inactive transistor's channel is far larger than the resistance of the active channel, CMOS logic high and low levels both are close to the power supply values (V_{dd} and ground) and scale with power supply voltage. The output transistors are designed to have matching channel resistances when turned on. Thus, as long as the supply voltage remains well above the transistor threshold voltage (about 0.7 V for modern CMOS), the input switching voltage also scales with supply voltage and is about one-half of V_{dd} . Unlike TTL, CMOS parts can operate over a very wide range of supply voltages (3–15 V) although lower voltages reduce noise immunity and speed. In the mid-1990s, integrated circuit manufacturers introduced new generations of CMOS parts optimized for operation in the 3-V range, intended for use in portable applications powered by two dry cell batteries.

Requiring only four transistors, the basic CMOS gate requires much less area than an LS TTL gate with its 11 diodes and bipolar transistors and 6 diffused resistors. This fact, coupled with its much higher static power consumption, disqualifies TTL as a viable technology for very large-scale integrated circuits. In the mid-1980s, CMOS quickly obsoleted the earlier nMOS integrated circuits and has become almost the exclusive technology of choice for complex digital integrated circuits.

Older discrete CMOS integrated circuits (RCA's 4000-series is the standard, with several manufacturers producing compatible devices) use aluminum as the gate material. The metal gate is deposited after creation of the drain and source regions. To guarantee that the gate overlies the entire channel even at maximum interlayer alignment tolerances, there is a substantial overlap of the gate and drain and source. Comparatively large parasitic capacitances result, slowing transistor (hence, gate) speed. In the mid-1980s several manufacturers introduced advanced discrete CMOS logic based on the self-aligning polysilicon gate processes developed for large-scale integrated circuits (ICs). Discrete silicon gate parts are often functional emulations of TTL devices, and have similar numbering schemes (e.g., 74HCxxx). Since silicon gate CMOS is much faster than metal gate CMOS (8 ns typical gate propagation delay vs 125 ns.) while offering similar static power consumption (1 mW per gate vs. 0.6 mW), silicon gate CMOS is the technology of choice for new discrete logic designs. There are two distinct groups of modern CMOS parts: HC high-speed CMOS and AC or C advanced CMOS.

Even though parts from the 74HC and similar families may emulate TTL functions and have matching pin assignments, they cannot be intermingled with TTL parts. As mentioned, CMOS output voltages are much closer to the power supply voltages than TTL outputs. Gates are designed with this characteristic in mind and do not produce solid output voltages when driven by typical TTL high logic levels. Specialized advanced CMOS parts are produced with modified input stages specifically for interfacing with TTL circuits (for example, the HCT family). These parts exhibit slightly higher power consumption than normal silicon-gate CMOS.

The gate electrodes of CMOS transistors are separated from the channel by a layer of silicon dioxide that may be only a few hundred angstroms thick. Such a thin dielectric layer can be damaged by a potential difference of only 40–100 V. Without precautions, the normal electrostatic potentials that build up on the human body can destroy CMOS devices. Although damage from electrostatic discharge (ESD) can be minimized through proper handling procedures (Matisof, 1986), CMOS parts include ESD protection circuitry on all inputs (see Fig. 8.34). The input diodes serve to limit gate voltages to one diode drop above V_{dd} or below ground, whereas the resistor serves both to limit input current and to slow the rise time of very fast pulses.

FIGURE 8.34 A typical CMOS input protection circuit.

As shown in Fig. 8.35, CMOS inverters and gates inherently have cross-connected parasitic bipolar transistors that form a silicon controlled rectifier (SCR). Suppose that external circuitry connected to the output pin pulls the pin low, below ground level. As this voltage approaches -0.5 V, the base-emitter junction of the parasitic NPN transistor will start to forward bias and the transistor will turn on. The resulting collector current is primarily determined by whatever external circuitry is pulling the output low. That current flows through R_{well} and lowers the base voltage of the parasitic PNP transistor. A large enough current will forward bias the PNP base emitter junction, causing PNP collector current to flow through R_{sub} and helping to maintain the forward bias of the NPN transistor. The SCR then enters a regenerative condition and will quickly assume a stable state in which both transistors remain on even after the initial driving stimulus is removed. In this **latchup** condition, substantial current flows from V_{dd} to ground. Normal operation of the CMOS gate is disrupted and permanent damage is likely. For latchup to occur, the product of the NPN and PNP transistor current gains must be greater than one, the output pin must be driven either below -0.5 V or above $V_{dd} + 0.5$ V by a source that supplies enough current to trigger regenerative operation, and V_{dd} must supply a sustaining current large enough to keep the SCR turned on. Although the potential for latchup cannot be avoided, CMOS manufacturers design input and output circuits that are latchup resistant, using configurations that reduce the gain of the parasitic transistors and that lower the substrate and p -well resistances. Nevertheless, CMOS users must ensure that input and output pins are not driven outside normal operating ranges. Limiting power supply current below the holding current level is another means of preventing latchup damage.

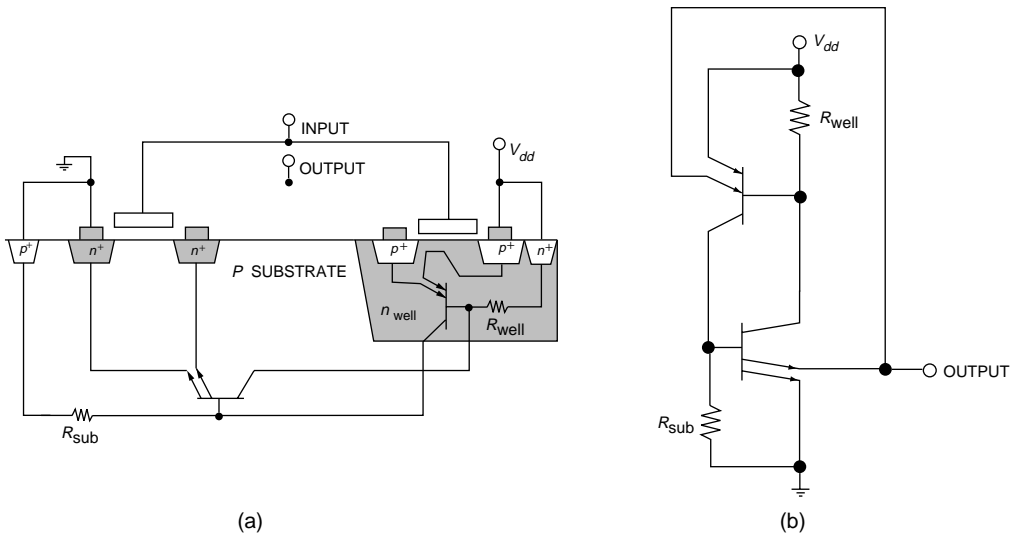

FIGURE 8.35 CMOS parasitic SCR: (a) cross-section showing parasitic bipolar transistors, (b) equivalent circuit.

FIGURE 8.36 Equivalent circuit for a CMOS output driving n CMOS inputs.

Fanout of CMOS outputs driving TTL inputs is limited by static current drive requirements and is calculated as for transistor-transistor logic. In all-CMOS systems, the static input current is just the leakage current flowing through the input ESD protection diodes, a current on the order of 100 pA. Consequently, static fanout of CMOS driving CMOS is so large as to be meaningless. Instead, fanout is limited by speed deterioration as the number of driven gates increases (Texas Instruments, 1984). If all driven inputs are assumed identical, an all-CMOS system can be represented by the approximate equivalent circuit of Fig. 8.36. The parallel input resistance R_{in} is on the order of 60 M Ω and can be neglected in later computations. The pull-up resistor R_{pu} can be approximately calculated from manufacturer data as $(V_{dd} - V_{OH})/I_{OH}$ ($\sim 50 \Omega$). The output will charge exponentially from low to high with a time constant of $nR_{pu}C_{in}$, where n is the actual fanout. Since the low output voltage is nearly zero, time required to reach a logic high is given by

$$t = nR_{pu}C_{in} \ln(1 - V_{IH,min}/V_{OH}).$$

Thus, once the maximum allowable risetime (that is, the maximum effective propagation delay) has been specified for an all-CMOS system, the dynamic fanout n can be computed. Although static power consumption of CMOS logic is quite small, outputs that are changing logic states will dissipate power each time they charge and discharge the capacitance loading the output. In addition, both the pull-up and pull-down transistors of the output will be simultaneously partially conducting for a short period on each switching cycle, creating a transient supply current beyond that needed for capacitance charging. Thus, the total power consumption of a CMOS gate is given by the relation

$$P_{total} = P_{static} + C_{load} V_{dd}^2 f$$

where

P_{total} = total power dissipated

P_{static} = static power dissipation

C_{load} = total equivalent load capacitance, $C_{pd} + C_{ext}$

C_{pd} = *power dissipation capacitance*, a manufacturer specification representing the equivalent internal capacitance (the effect of transient switching current is included)

C_{ext} = total parallel equivalent load capacitance

V_{dd} = power supply voltage

f = output operating frequency

HCT and ACT parts include an additional static power dissipation term proportional to the number of TTL inputs being driven ($n\Delta I_{dd}V_{dd}$, where ΔI_{dd} is specified by the manufacturer). CMOS average power consumption is proportional to the frequency of operation, whereas power consumption of TTL circuits is almost independent of operating frequency until about 1 MHz, when dynamic power dissipation becomes significant (see Fig. 8.37). Direct comparison of CMOS and TTL power consumption for a digital system is difficult, since not all outputs are changing at the same frequency. Moreover, the relative

advantages of CMOS become greater with increasing part complexity; CMOS and TTL power curves for a modestly complicated decoder circuit crossover at a frequency 10 times that of simple gates. Finally, TTL manufacturers do not publish C_{pd} specifications for their parts.

Like TTL parts, CMOS logic requires use of decoupling capacitors to reduce noise due to transient current spikes on power supply lines. Although such decoupling capacitors reduce electromagnetic coupling of noise into parallel signal leads, they do not eliminate an additional noise consideration that arises in both advanced CMOS and advanced

Schottky due to voltages induced on the power supply leads from transient current spikes. Consider the multiple inverter IC package of Fig. 8.38, in which five outputs are switching from low to high simultaneously, while the remaining output stays low. In accord with Faraday's law, the switching current spike will induce transient voltage across L , which represents parasitic inductances from internal package leads and external ground supply traces. That same voltage also lifts the unchanging output above the ground reference. A sufficiently large voltage spike may make signal A exceed the input switching threshold and cause erroneous operation of following logic elements. Careful physical design of the power supply and ground leads can reduce external inductance and limit power supply sag and ground bounce. Other useful techniques include use of synchronous clocking and segregation of high drive signals, such as clock lines, into separate buffer packages, separated from reset and other asynchronous buffers.

As has been suggested several times, effective propagation delay of a logic circuit is directly proportional to the capacitive loading of its output. Systems built from small- and medium-scale logic have many

FIGURE 8.37 Power dissipation vs. operating frequency for TTL and CMOS logic devices.

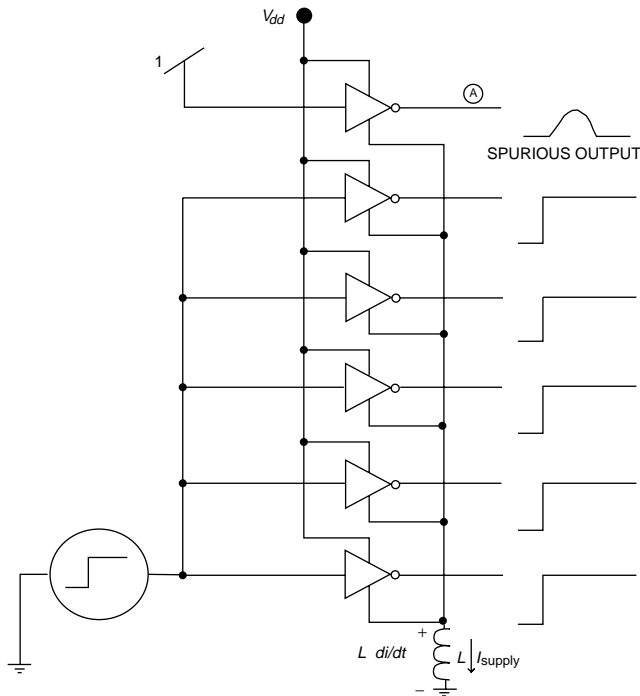

FIGURE 8.38 Output bounce due to ground lead inductance.

integrated circuit outputs with substantial load capacitance from interconnecting printed circuit traces. This is the primary impetus for using larger scale circuits: on-chip interconnections present far smaller capacitance and result in faster operation. Thus, a system built using a highly integrated circuit fabricated in a slower technology may be faster overall than the same system realized using faster small-scale logic.

Bipolar-CMOS (BiCMOS) logic is a hybrid technology for very large-scale integrated circuits that incorporates both bipolar and MOS transistors on the same chip. It is intended to offer the most of the circuit density and static power savings of CMOS while providing the electrical ruggedness and superior current drive capability of bipolar logic. BiCMOS also holds the opportunity for fabricated mixed systems using bipolar transistors for linear portions and CMOS for logic. It is a difficult task to produce high-quality bipolar transistors on the same chip as MOS devices, meaning that BiCMOS circuits are more expensive and may have suboptimal performance.

8.3.4 Emitter-Coupled Logic

Emitter coupled logic (ECL) is the fastest variety of discrete logic. It is also one of the oldest, dating back to Motorola's MECL I circuits in 1962. Improved MECL III circuits were introduced in the late 1960s. Today, the 10 and 100 K ECL families remain in use where very high speed is required. Unlike either TTL or CMOS, emitter-coupled logic uses a differential amplifier configuration as its basic topology (see Fig. 8.39). If all inputs to the gate are at a voltage lower than the reference voltage, the corresponding input transistors are cutoff and the entire bias current flows through Q1. The output is pulled up to V_{cc} through resistor R_a . If any input voltage rises above the reference, the corresponding transistor turns on, switching the current from Q1 to the input transistor and lowering the output voltage to $V_{cc} - I_{bias}R_a$. If the collector resistors and bias current are properly chosen, the transistors never enter saturation, and switching time is quite fast. Typical propagation delay for MECL 10 K gates is only 2.0 ns. To reduce the output impedance and improve current drive capability, actual ECL parts include emitter follower outputs (Fig. 8.39(b)). They also include integral voltage references with temperature coefficients matching those of the differential amplifier.

Note that ECL circuits are normally operated with the collectors connected to ground and the emitter current source to a negative supply voltage. From the standpoint of supply voltage fluctuations, the circuit operates as a common base amplifier, attenuating supply variations at the output. The power supply current in both TTL and CMOS circuits exhibits sharp spikes during switching; in ECL gates, the bias current remains constant and simply shifts from one transistor to another. Lower logic voltage swings also reduce noise generation. Although the noise margin for ECL logic is less than TTL and CMOS, ECL circuits generate less noise.

Emitter-coupled logic offers both short propagation delay and fast risetimes. When interconnecting paths introduce a time delay longer than about one-half the risetime, the interconnection's transmission line behavior must be taken into account. Reflections from unterminated lines can distort the waveform with ringing. The need to wait until reflections have damped to an acceptable value increases the effective propagation delay. The maximum open line length depends on the fanout of the driving output, the characteristic impedance of the transmission line, and the velocity of propagation of the line. Motorola databooks indicate that MECL III parts, with an actual fanout of 8 connected with fine-pitch printed circuit traces (100- Ω microstrip), can tolerate an unterminated line length of only 0.1 in. In high-speed ECL designs, physical interconnections must be made using properly terminated transmission lines (see Fig. 8.40). For an extended treatment of transmission lines in digital systems, see manufacturer's publications (Blood, 1988) or Rosenstark (1994). The necessity for using transmission lines with virtually all ECL III designs resulted in the introduction in 1971 of the MECL 10 K family of parts, with 2-ns propagation delays and 3.5-ns risetimes. The slowed risetimes meant that much longer unterminated lines could be used (Motorola cites 2.6 in. for the configuration mentioned earlier). Thus, many designs could be implemented in 10 K ECL without transmission line interconnections. This relative ease of use and a wider variety of parts has made 10 K ECL and its variants the dominant ECL family. It should be noted that, although transmission line interconnections were

FIGURE 8.39 Emitter coupled logic (ECL) gates: (a) simplified schematic of ECL NOR gate, (b) commercial ECL gate.

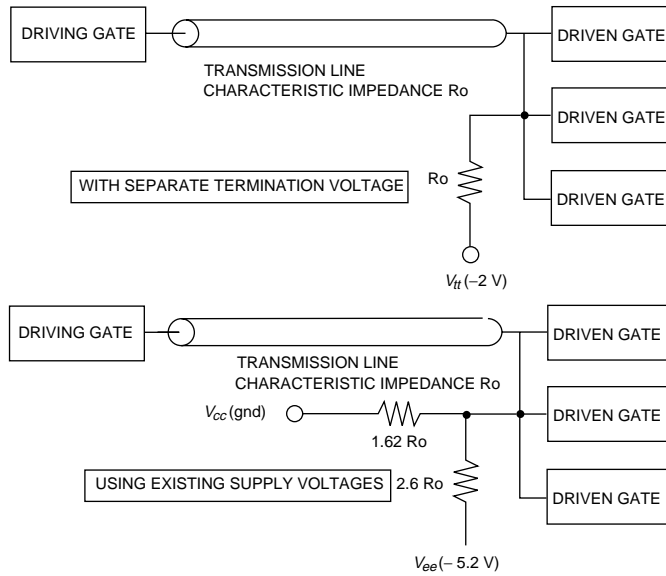

FIGURE 8.40 Parallel-terminated ECL interconnections.

traditionally associated with ECL, advanced CMOS and advanced Schottky TTL have rapid risetimes and are being used in very high-speed systems. Transmission line effects must be considered in the physical design of any high-performance system, regardless of the logic family being used.

Although ECL is often regarded as a power-hungry technology compared to TTL and CMOS, this is not necessarily true at very high-operating frequencies. At high frequencies, the power consumption for both of the latter families increases approximately linearly with frequency, whereas ECL consumption remains constant. Above about 250 MHz, CMOS power consumption exceeds that of ECL.

Gallium Arsenide

It was known even before the advent of the transistor that gallium arsenide constituted a semiconducting compound having significantly higher electron mobility than silicon. Holes, however, are substantially slower in GaAs than in silicon. As a consequence, unipolar GaAs transistors using electrons for charge transport are faster than their silicon equivalents and can be used to create logic circuits with very short propagation delays. Since gallium arsenide does not have a native oxide, it is difficult to fabricate high-quality MOS field effect transistors (MOSFETs). The preferred GaAs logic transistor is the *metal-semiconductor field-effect transistor* (MESFET) which is essentially a junction field effect transistor in which the gate is formed by a metal-semiconductor (Schottky) junction instead of a p-n diode. Figure 8.41 shows a NOR gate formed using two enhancement MESFETs as pull-down transistors with a depletion MESFET active load for the pull-up. At room temperatures, the underlying

FIGURE 8.41 A GaAs enhancement/ depletion-mode MESFET NOR gate.

GaAs substrate has a very high resistivity (is semi-insulating), providing sufficient transistor-to-transistor isolation without the need for reverse-biased isolation junctions.

Gallium arsenide logic exhibits both short delay and fast risetimes. As noted in the ECL discussion, fast logic signals exhibit ringing if transmission line interconnections are not used. The waveform distortion due to ringing extends the effective propagation delay and can negate the speed advantage of the basic logic circuit. Furthermore, complex fabrication processes and limited volumes make gallium arsenide logic from 10 to 20 times more expensive than silicon. The dual requirements to control costs and to preserve GaAs speed advantage by limiting the number of off-chip interfaces make the technology better suited to large-scale rather small- and medium-scale logic. GaAs digital circuits are available from several vendors in the form of custom integrated circuits or gate arrays. Gate arrays are semifinished large-scale integrated circuits that have large numbers of unconnected gates. The customer specifies the final metallization patterns that interconnect the gates to create the desired logic circuits. As of this writing, vendors were offering application-specific GaAs integrated circuits with more than 20,000 gates and worst-case internal gate delays on the order of 0.07 ns.

8.3.5 Programmable Logic

Although traditional discrete logic remains an important means of implementing digital systems, various forms of programmable logic have become increasingly popular. Broadly speaking, programmable logic denotes large- and very large-scale integrated circuits containing arrays of generalized logic blocks with user-configurable interconnections. In programming the device, the user modifies it to define the functions of each logic block and the interconnections between logic blocks. Depending on the complexity of the programmable logic being used, a single programmable package may replace dozens of conventional small- and medium-scale integrated circuits. Because most interconnections are on the programmable logic chip itself, programmable logic designs offer both speed and reliability gains over conventional logic. Effectively all programmable logic design is done using electronic design automation (EDA) tools that automatically generate device programming information from a description of the function to be performed. The functional description can be supplied in terms of a logic diagram, logic equations, or a hardware description language. EDA tools also perform such tasks as logic synthesis, simplification, device selection, functional simulation, and timing/speed analysis. The combination of electronic design automation and device programmability makes it possible to design and physically implement digital subsystems very quickly compared to conventional logic.

Although the definitions are somewhat imprecise, programmable logic is divided into two broad categories: programmable logic devices (PLDs) and field programmable gate arrays (FPGAs). The PLD category itself is often subdivided into complex PLDs (CPLDs) with numerous internal logic blocks and simpler PLDs. Although the general architecture of small PLDs is fairly standardized, that of FPGAs and CPLDs continues to evolve and differs considerably from one manufacturer to another. Programmable logic devices cover a very wide range, indeed, from simple PALs containing a few gates to field programmable gate arrays providing thousands of usable gate equivalents.

Programmable Array Logic

Programmable array logic (PAL) was first introduced by Monolithic Memories, Inc. In their simplest form, PALs consist of a large array of logic AND gates fed by both the true (uninverted) and complemented (inverted) senses of the input signals. Any AND gate may be fed by either sense of any input. The outputs of the AND gates are hardwired to OR gates that drive the PAL outputs (see Fig. 8.42). By programming the AND inputs, the PAL user can implement any logic function provided that the number of product terms does not exceed the **fanin** to the OR gate. Modern PALs incorporate several logic macrocells that include a programmable inverter following the AND/OR combinatorial logic, along with a programmable flip-flop that can be used when registered outputs are needed. Additional AND gates are used to clock and reset the flip-flop. Macrocells usually also have a programmable three-state buffer driving the block output and programmable switches that can be used to feed macrocell outputs back into the AND-OR array to develop combinatorial logic with many product terms or to implement state machines.

FIGURE 8.42 A simplified small PAL device.

PLDs are fabricated using either bipolar or CMOS technologies. Although CMOS parts have become quite fast, bipolar PALs offer higher speed (<5 ns input to output combinatorial delay) at the expense of higher power consumption. Different manufacturers accomplish interconnect and logic options programming in different ways. In some instances, the circuit is physically modified by blowing fuses or antifuses (an antifuse is an open circuit until fused, then it becomes a low-resistance circuit). CMOS programmable devices often use interconnections based on erasable programmable read only memory (EPROM) cells. EPROM-based parts can be programmed, then erased and reprogrammed. Although reprogrammability can be useful during the development phase, it is less important in production, and EPROM-based PLDs are also sold in cheaper, one-time programmable versions. Although not a major market factor, electrically reprogrammable PLDs are also available. When used in digital systems, PLDs require fanout computation, just as discrete TTL or CMOS logic. In addition, fast PLDs require the same consideration of transmission line effects.

Although it is possible to hand-develop programming tables for very simple PALs, virtually all design is now done using EDA tools supplied by PLD vendors and third parties. Although computer methods automate the design process to a considerable extent, they usually permit some user control over resource assignments. The user needs to have a thorough knowledge of a specific device's architecture and programming options to optimize the resulting design.

Programmable Logic Arrays

Field programmable logic arrays (FPLAs) resemble PALs with the additional feature that the connections from the AND intermediate outputs to the OR inputs are also programmable, rather than hardwired (Fig. 8.42). Like simpler PALs, FPLAs are produced in registered versions that have flip-flops between the OR gate and the output pin. Even though they are more complex devices, FPLAs were actually introduced before programmable array logic. Programmable AND/OR interconnections make them more flexible than PALs, since product terms (AND gate outputs) can drive more than one OR input and any number of

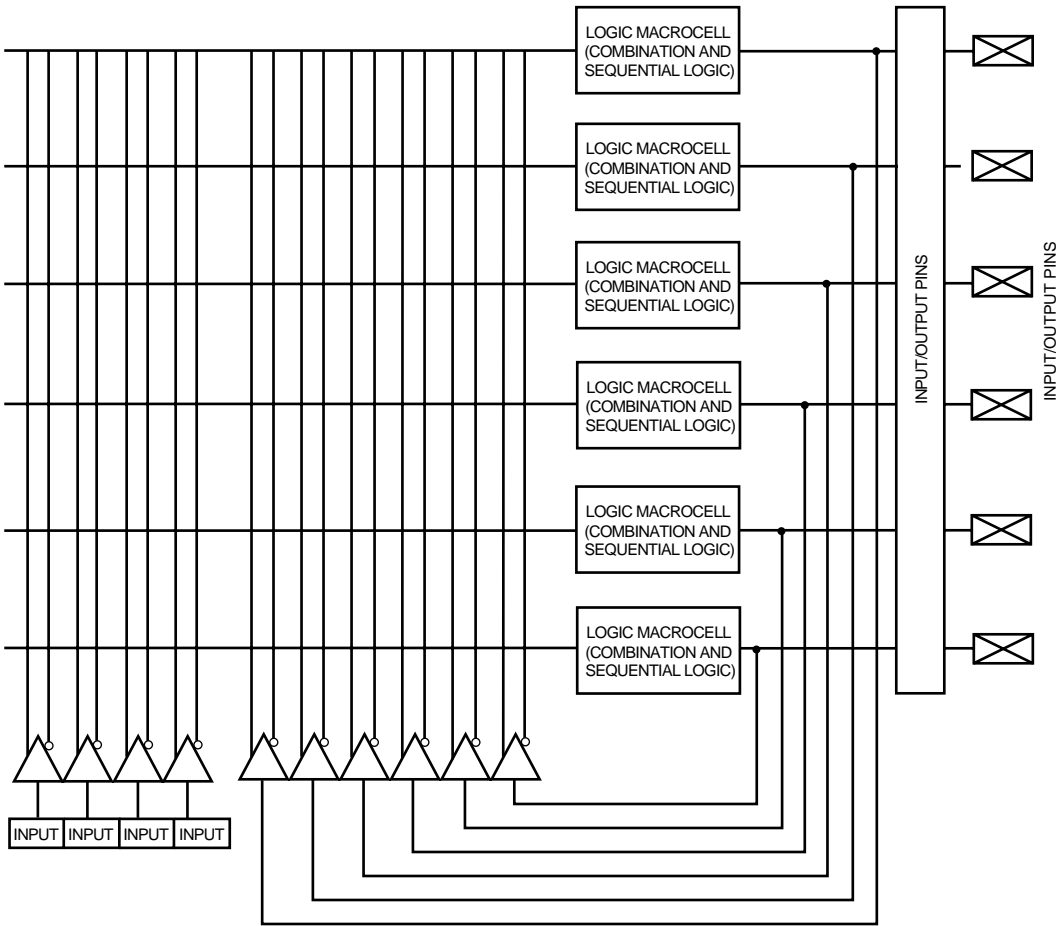

FIGURE 8.43 A simplified complex programmable logic device structure.

product terms can be used to develop a particular output function. The additional layer of programmable interconnects consumes chip area, however, increasing cost. The extra level of interconnections also makes programming more complicated. The most important drawback to FPLAs, however, is lower speed. The programmable interconnections add significant series resistance, slowing signal propagation between the AND and OR gates and making FPLAs sluggish compared to PALs. Since programmable array logic is faster, simpler to program, and flexible enough for most uses, PALs are much more popular than field programmable logic arrays. Most FPLAs marketed today have registered outputs (that is, a flip-flop is placed between the OR gate and the macrocell output) that are fed back into to the AND/OR array. Termed *field programmable logic sequencers*, these parts are intended for implementing small state machines.

Field Programmable Gate Arrays and Complex PLDs

There is no universally accepted dividing line between complex PLDs and FPGAs. Not only do architectures differ from manufacturer to manufacturer, the method of interconnect programming also differs. The term *complex programmable logic device* (CPLD) generally denotes devices organized as large arrays of PAL macrocells, with fixed delay feedback of macrocells outputs into the AND–OR array (Fig. 8.43). CLPD time delays are more predictable than those of FPGAs, which can make them simpler to design with. A more important distinction between CPLDs and FPGAs is the ratio of combinatorial logic to sequential logic in their logic cells. The PAL-like structure of CPLDs means that the flip-flop in each logic macrocell

is fed by the logical sum of several logical products. The products can include a large number of input and feedback signals. Thus, CPLDs are well suited to applications such as state machines that have logic functions including many variables. FPGAs, on the other hand, tend toward cells that include a flip-flop driven by a logic function of only three or so variables and are better suited to situations requiring many registers fed by relatively simple functions.

Field programmable gate arrays and complex programmable logic devices concentrate far more logic per package than traditional discrete logic and smaller PLDs, making computer aided design essential. The overall procedure is as follows.

1. Describe system functionality to the EDA system, using schematics, boolean equations, truth tables, or high level programming languages. Subparts of the overall system may be described separately, using whatever description is most suitable to that part, and then combined. As systems become more complex, high level languages have become increasingly useful. Subsequent steps in the design process are largely automated functions of the EDA software.
2. Translate the functional description into equivalent logic cells and their interconnections.
3. Optimize the result of step 2 to produce a result well suited to the implementation architecture. The goal of the optimization and the strategies involved depend strongly on the target architecture. For instance, EDA tools for FPGAs with limited interconnections seek to reduce the number of block interconnects.
4. Fit the optimized design to the target architecture. Fitting includes selection of an appropriate part, placing of logic (mapping of functional blocks to specific physical cells), and routing of cell interconnections.
5. Produce tables containing information required for device programming and back annotate interconnection netlists. Back annotation provides information about interconnection paths and fanout that is necessary to produce accurate timing estimates during simulation.
6. Perform functional and performance verification through simulation. Simulation is critical, because of the high ratio of internal logic to input–output ports in FPGA/CPLD designs. Logic errors due to timing problems or bugs in the compilation and fitting steps can be extremely difficult to locate and correct based purely on performance testing of a programmed device. Simulation, on the other hand, produces invaluable information about internal behavior.

Defining Terms

Fanin: The number of independent inputs to a given logic gate.

Fanout: (1) The maximum number of similar inputs that a logic device output can drive while still meeting output logic voltage specifications. (2) The actual number of inputs connected to a particular output.

Latchup: A faulty operating condition of CMOS circuits in which its parasitic SCRs produce a low resistance path between power supply rails.

Noise margin: The difference between an output logic high (low) voltage produced by a properly functioning output and the input logic high (low) voltage required by a driven input; noise margin provides immunity to a level of signal distortion less than the margin.

Risetime: The time required for a logic signal to transition from one static level to another; usually, risetime is measured from 10 to 90% of the final value.

Further Information

For the practitioner, the following technical journals are excellent sources dealing with current trends in both discrete logic and programmable devices.

Electronic Design, published 30 times a year by Penton Publishing, Inc. of Cleveland, OH, covers a very broad range of design-related topics. It is free to qualified subscribers.

EDN, published by Cahners Publishing Company, Newton, MA, appears 38 times annually. It also deals with the entire range of electronics design topics and is free to qualified subscribers.

Computer Design, Pennwell Publishing, Nashua, NH, appears monthly. It focuses more specifically on digital design topics than the foregoing. Like them, it is free to qualified subscribers.

Integrated System Design, a monthly periodical of the Verecom Group, Los Altos, CA, is a valuable source of current information about programmable logic and the associated design tools.

For the researcher, the *IEEE Journal of Solid State Circuits* is perhaps the best single source of information about advances in digital logic. The IEEE sponsors a number of conferences annually that deal in one way or another with digital logic families and programmable logic.

Manufacturer's databooks and application notes provide much current information about logic, especially with regard to applications information. They usually assume some background knowledge, however, and can be difficult to use as a first introduction. Recommended textbooks to provide that background include the following.

8.4 Memory Devices

Shih-Lien Lu

8.4.1 Introduction

Memory is an essential part of any computation system. It is used to store both the computation instructions and the data. Logically, memory can be viewed as a collection of sequential locations, each with a unique address as its label and capable of storing information. Accessing memory is accomplished by supplying the address of the desired data to the device.

Memory devices can be categorized according to their functionality and fall into two major categories, **read-only-memory (ROM)**, and write-and-read memory or random-access memory (RAM). There is also another subcategory of ROM: mostly read but sometimes write memory or flash ROM memory. Within the RAM category there are two types of memory devices differentiated by storage characteristics, **static RAM (SRAM)** and **dynamic RAM (DRAM)** respectively. DRAM devices need to be refreshed periodically to prevent the corruption of their contents due to charge leakage. SRAM devices, on the other hand, do not need to be refreshed.

Both SRAM and DRAM are volatile memory devices, which means that their contents are lost if the power supply is removed from these devices. Nonvolatile memory, the opposite of volatile memory, retains its contents even when the supply power is turned off. All current ROM devices, including mostly read sometimes write devices are nonvolatile memories. Except for a very few special memories, these devices are all interfaced in a similar way. When an address is presented to a memory device, and sometimes after a control signal is strobed, the information stored at the specified address is retrieved after a certain delay. This process is called a **memory read**. This delay, defined as the time taken from address valid to data ready, is called **memory read access time**. Similarly, data can be stored into the memory device by performing a **memory write**. When writing, data and an address are presented to the memory device with the activation of a write control signal. There are also other control signals used to interface. For example, most of the memory devices in packaged chip format has a chip select (or chip enable) pin. Only when this pin is asserted, the particular memory device gets active. Once an address is supplied to the chip, internal address decoding logic is used to pinpoint the particular content for output. Because of the nature of the circuit structure used in implementing the decoding logic, a memory device usually needs to recover before a subsequent read or write can be performed. Therefore, the time between subsequent address issues is called **cycle time**. Cycle time is usually twice as long as the access time. There are other timing requirements for memory devices. These timing parameters play a very important role in interfacing the memory devices with computation processors. In many situations, a memory device's timing parameters affect the performance of the computation system greatly.

Some special memory structures do not follow the general accessing scheme of using an address. Two of the most frequently used are content addressable memory (CAM), and first-in-first-out (FIFO) memory. Another type of memory device, which accepts multiple addresses and produces several results at different ports, is called multiport memory. There is also a type of memory that can be written in parallel, but is read serially. It is referred to as video RAM or VDRAM since they are used primarily in graphic display applications. We will discuss these in more detail later.

8.4.2 Memory Organization

There are several aspects to memory organization. We will take a top down approach in discussing them.

Memory Hierarchy

The speed of memory devices has been lagging behind the speed of processors. As processors become faster and more capable, larger memory spaces are required to keep up with the every increasing software complexity written for these machines. Figure 8.44(a) illustrates the well-known Moore's law, depicting the exponential growth in central processing unit (CPU) and memory capacity. Although CPUs' speed continues to grow with the advancement of technology and design technique (in particular pipelining), due to the nature of increasing memory size, more time is needed to decode wider and wider addresses and to sense the information stored in the ever-shrinking storage element. The speed gap between CPU and memory devices continues to grow wider. Figure 8.44(b) illustrates this phenomenon.

The strategy used to remedy this problem is called **memory hierarchy**. Memory hierarchy works because of the locality property of memory references due to the sequentially fetched program instructions and the conjugation of related data. In a hierarchical memory system there are many levels of memory hierarchies. A small amount of very fast memory is usually allocated and brought right next to the central processing unit to help match up the speed of the CPU and memory. As the distance becomes greater between the

FIGURE 8.44 (a) Processor and memory development trend, (b) speed difference between RAM and CPU.

CPU and memory, the performance requirement for the memory is relaxed. At the same time, the size of the memory grows larger to accommodate the overall memory size requirement. Some of the memory hierarchies are *registers*, *cache*, *main memory*, and *disk*. Figure 8.45 illustrates the general memory hierarchy employed in a traditional system. When a memory reference is made, the processor accesses the memory at the top of the hierarchy. If the desired data is in the higher hierarchy, a “bit” is encountered and information is obtained quickly. Otherwise a *miss* is encountered. The requested information must be brought up from a lower level in the hierarchy. Usually memory space is divided into blocks so that it can be transferred between levels in groups. At the cache level a chunk is called a *cache block* or a *cache line*. At the main memory level a chunk is referred to as a *memory page*. A miss in the cache is called a *cache miss* and a miss in the main memory is called a *page fault*. When a miss occurs, the whole block of memory containing the requested missing information is brought in from the lower hierarchy as mentioned before. If the current memory hierarchy level is full when a miss occurs, some existing blocks or pages must be removed and sometimes written back to a lower level to allow the new one(s) to be brought in. There are several different *replacement algorithms*. One of the most commonly used is the *least recently used (LRU)* replacement algorithm.

FIGURE 8.45 Traditional memory hierarchy.

In modern computing systems, there may be several sublevels of cache within the hierarchy of cache. The general principle of memory hierarchy is that the farther away from the CPU it is, the larger its size, slower its speed, and the cheaper its price per memory unit becomes. Because the memory space addressable by

the CPU is normally larger than necessary for a particular software program at a given time, disks are used to provide an economical supplement to main memory. This technique is called *virtual memory*. Besides disks there are tapes, optical drives, and other backup devices, which we normally call *backup storage*. They are used mainly to store information that is no longer in use, to protect against main memory and disk failures, or to transfer data between machines.

System Level Memory Organization

On the system level, we must organize the memory to accomplish different tasks and to satisfy the need of the program. In a computation system, addresses are supplied by the CPU to access the data or instruction. With a given address width a fixed number of memory locations may be accessed. This is referred to as the *memory address space*. Some processing systems have the ability to access another separate space called *input/output (I/O) address space*. Others use part of the memory space for I/O purposes. This style of performing I/O functions is called *memory-mapped I/O*. The memory address space defines the maximum size of the directly addressable memory that a computation system can access using memory type instructions. For example, a processor with address width of 16-b can access up to 64 K different locations (memory entries), whereas a 32-b address width can access up to 4 Gig different locations. However, sometimes we can use indirection to increase the address space. The method used by 80X86 processors provides an excellent example of how this is done. The address used by the user or programmer in specifying a data item stored in the memory system is called a *logical address*. The address space accessed by the logical address is named *logical address space*. However, this logical address may not necessarily be used directly to index the physical memory. We called the memory space accessed by physical address the *physical address space*. When the logical space is larger than the physical space, then memory hierarchy is required to accommodate the difference of space sizes and store them in a lower hierarchy. In most of the current computing systems, a hard-disk is used as this lower hierarchy memory. This is termed *virtual memory system*. This mapping of logical address to physical address could be either linear or nonlinear. The actual address calculation to accomplish the mapping process is done by the CPU and the memory management unit (MMU). Thus far, we have not specified the exact size of a memory entry. A commonly used memory entry size is one byte. For historical reasons, memory is organized in bytes. A byte is usually the smallest unit of information transferred with each memory access. Wider memory entries are becoming more popular as the CPU continues to grow in speed and complexity. There are many modern systems that have a data width wider than a byte. A common size is a double word (32 b). in current desktop. As a result, memory in bytes is organized in sections of multibytes. However, due to need for backward compatibility, these wide datapath systems are also organized to be byte addressable. The maximum width of the memory transfer is usually called *memory word length*, and the size of the memory in bytes is called *memory capacity*. Since there are different memory device sizes, the memory system can be populated with different sized memory devices.

Memory Device Organization

Physically, within a memory device, cells are arranged in a two-dimensional array with each of the cell capable of storing 1 b of information. This matrix of cells is accessed by specifying the desired row and column addresses. The individual row enable line is generated using an address decoder while the column is selected through a multiplexer. There is usually a sense amplifier between the column bit line and the multiplexer input to detect the content of the memory cell it is accessing. Figure 8.46 illustrates this general memory cell array described with r bit of row address and c bit of column address. With the total number of $r + c$ address bits, this memory structure contains 2^{r+c} number of bits. As the size of memory array increases, the row enable lines, as well as the column bit lines, become longer. To reduce the capacitive load of a long row enable line, the row decoders, sense amplifiers, and column multiplexers are often placed in the middle of divided matrices of cells, as illustrated in Fig. 8.47. By designing the multiplexer differently we are able to construct memory with different output width, for example, $\times 1$, $\times 8$, $\times 16$, etc. In fact, memory designers go to great efforts to design the column multiplexers so that most of the fabrication masks may be shared for memory devices that have the same capacity but with different configurations.

FIGURE 8.46 Generic memory structure.

8.4.3 Memory Device Types

As mentioned before, according to the functionality and characteristics of memory, we may divide memory devices into two major categories: ROM and RAM. We will describe these different type of devices in the following sections.

Read-Only Memory

In many systems, it is desirable to have the system level software (for example, basic input/output system [BIOS]) stored in a read-only format, because these types of programs are seldom changed. Many embedded systems also use read-only memory to store their software routines because these programs also are never changed during their lifetime, in general. Information stored in the read-only memory is permanent. It is retained even if the power supply is turned off. The memory can be read out reliably

FIGURE 8.47 Divided memory structure.

by a simple current sensing circuit without worrying about destroying the stored data. Figure 8.48 shows the general structure of a read-only memory (ROM). The effective switch position at the intersection of the word-line/bit-line determines the stored value. This switch could be implemented using different technologies resulting in different types of ROMs.

Masked Read-Only Memory (ROM)

The most basic type of this read-only-memory is called masked ROM, or simply ROM. It is programmed at manufacturing time using fabrication processing masks. ROM can be produced using different technologies, bipolar, complementary metal oxide semiconductor (CMOS), n-channel metal oxide semiconductor (nMOS), p-channel metal oxide semiconductor (pMOS), etc. Once they are programmed there are no means to change their contents. Moreover, the programming process is performed at the factory.

Programmable Read-Only Memory (PROM)

Some read-only memory is one-time programmable, but it is programmable by the user at the user's own site. This is called programmable read-only memory (PROM). It is also often referred to as write once memory (WOM). PROMs are based mostly on bipolar technology, since this technology supports it very well. Each of the single transistors in a cell has a fuse connected to its emitter. This transistor and fuse make up the memory cell. When a fuse is blown, no connection can be established when the cell is selected using the row line. Thereby a zero is stored. Otherwise, with the fuse intact, a logic one is represented. The programming is done through a programmer called a PROM programmer or PROM burner. Figure 8.49 illustrates the structure of a bipolar PROM cell and its cross section when fabricated.

FIGURE 8.48 General structure of a ROM (an 8 × 4 ROM).

FIGURE 8.49 Bipolar PROM: (a) bipolar PROM cell, (b) cross section of a bipolar PROM cell.

FIGURE 8.50 Cross section of a floating gate EPROM cell.

Erasable Programmable Read-Only Memory (EPROM)

It is sometimes inconvenient to program the ROM only once. Thus, the erasable PROM is designed. This type of erasable PROM is called EPROM. The programming of a cell is achieved by avalanche injection of high-energy electrons from the substrate through the oxide. This is accomplished by applying a high drain voltage, causing the electrons to gain enough energy to jump over the 3.2-eV barrier between the substrate and silicon dioxide thus collecting charge at the floating gate. Once the applied voltage is removed, this charge is trapped on the floating gate. Erasing is done using an ultraviolet (UV) light eraser. Incoming UV light increases the energy of electrons trapped on the floating gate. Once the energy is increased above the 3.2-eV barrier, the electrons leave the floating gate and move toward the substrate and the selected gate. Therefore, these EPROM chips all have windows on their packages where erasing UV light can reach inside the packages to erase the content of cells. The erase time is usually in minutes. The presence of a charge on the floating gate will cause the MOS transistor to have a high threshold voltage. Thus, even with a positive select gate voltage applied at the second level of polysilicon the MOS remains to be turned off. The absence of a charge on the floating gate causes the MOS to have a lower threshold voltage. When the gate is selected the transistor will turn on and give the opposite data bit. Figure 8.50 illustrates the cross section of a EPROM cell with floating gate. EPROM technologies that migrate toward smaller geometries make floating-gate discharge (erase) via UV light exposure increasingly difficult. One problem is that the width of metal bit lines cannot reduce proportionally with advancing process technologies. EPROM metal width requirements limit bit-lines spacing, thus reducing the amount of high-energy photons that reach charged cells. Therefore, EPROM products built on submicron technologies will face longer and longer UV exposure time.

Electrical Erasable Read-Only Memory (EEPROM)

Reprogrammability is a very desirable property. However, it is very inconvenient to use a separate light-source eraser for altering the contents of the memory. Furthermore, even a few minutes of erase time is intolerable. For this reason, an erasable PROM was designed called electrical erasable PROM (EEPROM). EEPROM permits new applications where erasing is done without removing the device from the system it resides in. There are a few basic technologies used in the processing of EEPROMs or electrical reprogrammable ROMs. All of them uses the Fowler-Nordheim tunneling effect to some extent. In this tunneling effect, cold electrons jump through the energy barrier at a silicon-silicon dioxide interface and into the oxide conduction band. This can only happen when the oxide thickness is of 100 Å or less, depending on the technology. This tunneling effect is reversible, allowing the reprogrammable ROMs to be used over and over again. One of the first electrical erasable PROMs is the electrical alterable ROM (EAROM) which is based on metal-nitrite-oxide silicon (MNOS) technology. The other is EEPROM, which is based on silicon floating gate technology used in fabricating EPROMs. The floating gate type of EEPROM is favored because of its reliability and density. The major difference between EPROM and EEPROM is in the way they discharge the charge stored in the floating gate. EEPROM must discharge floating gates electrically as opposed to using an UV light source in an EPROM device where electrons absorb photons from the UV

FIGURE 8.51 (a) Triple poly EEPROM cell layout and structure, (b) flotex EEPROM cell structure (source programming), (c) EEPROM with drain programming, (d) another source programming EEPROM.

radiation and gain enough energy to jump the silicon/silicon-dioxide energy barrier in the reverse direction as they return to the substrate. The solution for the EEPROM is to pass low-energy electrons through the thin oxide through high field (10^7 V/cm²). This is known as the Fowler-Nordheim tunneling, where electrons can pass a short distance through the forbidden gap of the insulator and enter the conduction band when the field applied is high enough. There are three common types of flash EEPROM cells. One uses the erase gate (three levels of polysilicon), the second and third use source and drain, respectively, to erase. Figures 8.51(a)–8.51(d) illustrate the cross sections of different EEPROMs. To realize a small EEPROM memory cell, the NAND structure was proposed in 1987. In this structure, cells are arranged in series. By using different patterns, an individual cell can be detected whether it is programmed or not. From the user's point of view, EEPROMs differs from RAM only in their write time and number of writes allowed before failure occurs. Early EEPROMs were hard to use because they have no latches for data and address to hold values during the long write operations. They also require a higher programming voltage, other than the operating voltage. Newer EEPROMs use charge pumps to generate the high programming voltage on the chip so the user does not need to provide a separate programming voltage.

Flash-EEPROM

This type of erasable PROM lacks the circuitry to erase individual locations. When you erase them, they are erased completely. By doing so, many transistors may be saved, and larger memory capacities are possible. Note that sometimes you do not need to erase before writing. You can also write to an erased, but unwritten

location, which results in an average write time comparable to an EEPROM. Another important thing to know is that writing zeros into a location charges each of the flash EEPROM's memory cells to the same electrical potential so that subsequent erasure drains an equal amount of free charge (electrons) from each cell. Failure to equalize the charge in each cell prior to erasure can result in the overerasure of some cells by dislodging bound electrons in the floating gate and driving them out. When a floating gate is depleted in this way, the corresponding transistor can never be turned off again, thus destroying the flash EEPROM.

Random Access Memory (RAM)

RAM stands for random-access memory. It is really read-write memory because ROM is also random access in the sense that given a random address the corresponding entry is read. RAM can be categorized by content duration. A static RAM's contents is always retained, as long as power is applied. A DRAM, on the other hand, needs to be refreshed every few milliseconds. Most RAMs by themselves are volatile, which means that without the power supply their content will be lost. All of the ROMs mentioned in the previous section are nonvolatile. RAM can be made nonvolatile by using a backup battery.

Static Random Access Memory (SRAM)

Figure 8.52 shows various SRAM memory cells (6T, 5T, 4T). The six transistor (6T) SRAM cell is commonly used SRAM. The crossed coupled inverters in a SRAM cell retain the information indefinitely, as long as the power supply is on since one of the pull-up transistors supplies current to compensate for the leakage current. During a read, bit and bitbar line are precharged while the word enable line is held low. Depending on the content of the cell, one of the lines is discharged slightly causing the precharged voltage to drop when the word enable line is strobed. This difference in voltage between the bit and bitbar lines is sensed by the sense amplifier, which produces the read result. During a write process, one of the bit/bitbar lines is discharged, and by strobing the word enable line the desired data is forced into the cell before the word line goes away.

Figure 8.53 gives the circuit of a complete SRAM circuit design with only one column and one row shown. One of the key design parameters of a SRAM cell is to determine the size of transistors used in the memory cell. We first need to determine the criteria used in sizing transistors in a CMOS 6-transistor/cell SRAM.

FIGURE 8.52 Different SRAM cells: (a) six-transistor SRAM cell with depletion transistor load, (b) four-transistor SRAM cell with polyresistor load, (c) CMOS six-transistor SRAM cell, (d) five-transistor SRAM cell.

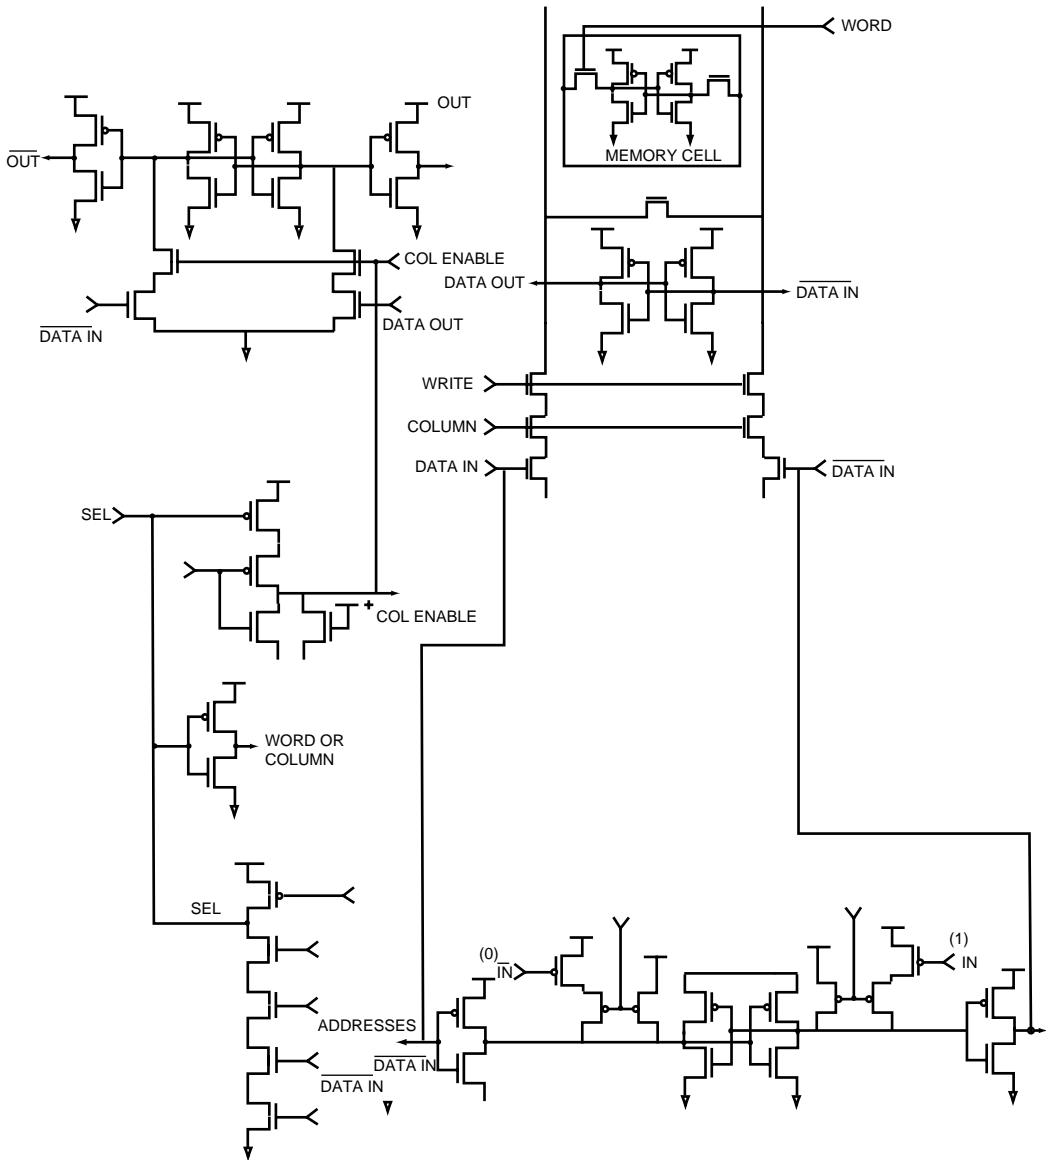

FIGURE 8.53 A complete circuit of an SRAM memory.

There are three transistor sizes to choose in a 6-transistor CMOS SRAM cell due to symmetry. They are the pMOS pull-up size, the nMOS pull-down size, and the nMOS access transistor (also called the pass-transistor gate) size. There are two identical copies of each transistor, giving a total of six. Since the sole purpose of the pMOS pull-up is to supply enough current in overcoming junction current leakage, we should decide this size first. This is also the reason why some SRAMs completely remove the two pMOS transistors and replace them with two 10-GΩ polysilicon resistors giving the 4T cell shown in Fig. 8.52. Since one of the goals is to make your cell layout as small as possible, pMOS pull-up is chosen to be minimum both in its length and width. Only when there is room available (i.e., if it does not increase the cell layout area), the length of pMOS pull-up is increased. By increasing the length of pMOS pull-up transistors, the capacitance on the crossed-coupled inverters output nodes is increased. This helps in protecting against certain soft errors. It also makes the cell slightly easier to write.

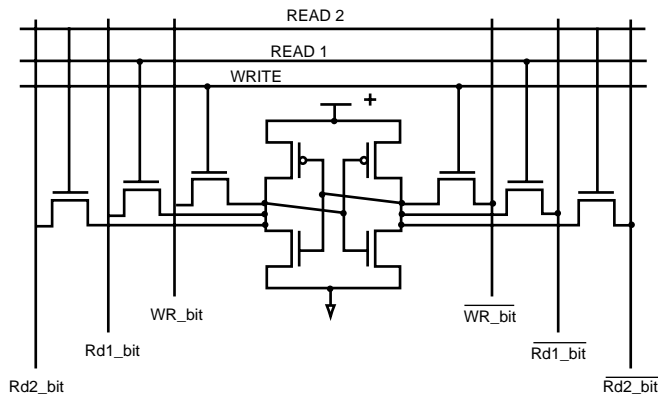

FIGURE 8.54 Multiported CMOS SRAM cell (shown with 2-read and 1-write).

The next step is to choose the nMOS access transistor size. This is a rather complicated process. To begin we need to determine the length of this transistor. It is difficult to choose because, on one hand, we want it also to be minimum in order to reduce the cell layout size. However, on the other hand, a column of n SRAM bits (rows) has to have n of access transistors connected to the bit or bitbar line. If each of the cells leaks just a small amount of current, the leakage is multiplied by n . Thus, the bit or bitbar line, which one might think should be sitting at the bit-line pull-up (or precharge) voltage, is actually pulled down by this leakage. Thus, the bit or bitbar line high level is lower than the intended voltage. When this happens, the voltage difference between the bit and bitbar lines, which is seen by the sense amplifier during a read, is smaller than expected, perhaps catastrophically so. Thus, if the transistors used are not particularly leaky or n is small, a minimum sized nMOS is sufficient. Otherwise, a larger sized transistor should be used. Beside considering leakage, there are three other factors that may affect the transistor sizes of the two nMOSs. They are: (1) cell stability, (2) speed, and (3) layout area. The first factor, cell stability, is a DC phenomenon. It is a measure of the cell's ability to retain its data when reading and to change its data when writing. A read is done by creating a voltage difference between the bit and bitbar lines (which are normally precharged) for the sense amplifier to differentiate. A write is done by pulling one of the bit or bitbar lines down completely. Thus, one must design the size to satisfy the cell stability while achieving the maximum read and write speed and maintaining the minimum layout area.

Much work has been done in writing computer-aided design (CAD) tools that automatically size transistors for arrays of SRAM cells, and then do the polygon layout. Generally, these are known as SRAM macrogenerators or RAM compilers. These generated SRAM blocks are used as drop ins in many application specific intergrated circuits (ASICs). Standard SRAM chips are also available in many different organizations. Common ones are arranged in 4 b, bytes, and double words (32 b) in width.

There is also a special type of SRAM cell used in computers to implement registers. These are called multiple port memories. In general, the contents can be read by many different requests at the same time. Figure 8.54 shows a dual-read port single-write port SRAM cell. When laying out SRAM cells, adjacent cells usually are mirrored to allow sharing of supply or ground lines. Figure 8.55 illustrates the layout of four adjacent SRAM cells using a generic digital process design rules. This block of four cells can be repeated in a two-dimensional array format to form the memory core.

Direct Random Access Memory (DRAM)

The main disadvantage of SRAM is in its size since it takes six transistors (or at least four transistors and two resistors) to construct a single memory cell. Thus, the DRAM is used to improve the capacity. There are different DRAM cell designs. There is the four-transistor DRAM cell, three-transistor DRAM cell, and the one-transistor DRAM cell. Figures 8.56 shows the corresponding circuits for these cells. Data writing is accomplished in a three-transistor cell by keeping the RD line low (see Fig. 8.56(b)) while strobing the WR line with the desired data to be written is kept on the bus. If a 1 is desired to be stored, the gate of T2 is charged turning

FIGURE 8.55 Layout example of four abutted 6-t SRAM cells.

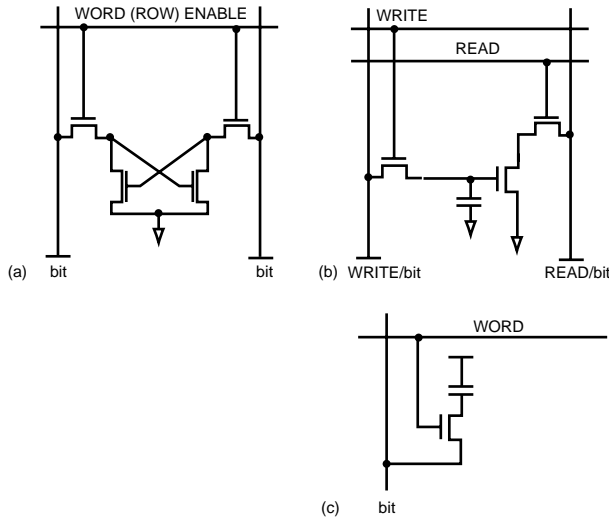

FIGURE 8.56 Different DRAM cells: (a) four-transistor DRAM cell, (b) three-transistor DRAM cell, (c) one-transistor DRAM cell.

on T2. This charge remains on the gate of T2 for a while before the leakage current discharges it to a point where it cannot be used to turn on T2. When the charge is still there, a read can be performed by precharging the bus and strobing the RD line. If a 1 is stored, then both T2 and T3 are on during a read, causing the charge on the bus to be discharged. The lowering of voltage can be picked up by the sense amplifier. If a zero is stored, then there is no direct path from the bus to ground, thus the charge on the bus remains. To further reduce the area of a memory cell, a single transistor cell is often used. Figure 8.56(c) shows the single transistor cell with a capacitor. Usually, two columns of cells are mirror images of each other to reduce the layout area. The sense amplifier is shared, as shown in Fig. 8.57. In this one-transistor DRAM cell, there is a capacitor used to store the charge, which determines the content of the memory. The amount of the charge in the capacitor also determines the overall performance of the memory. A continuing goal is to downscale the physical area of this capacitor to achieve higher and higher density. Usually, as one reduces the area of the capacitor, the capacitance also decreases. One approach is to increase the surface area of the storage electrode without increasing the layout area by employing stacked capacitor structures, such as finned or cylindrical structures. Certain techniques can be used to utilize a cylindrical capacitor structure with hemispherical grains. Figure 8.58 illustrates the cross section of a

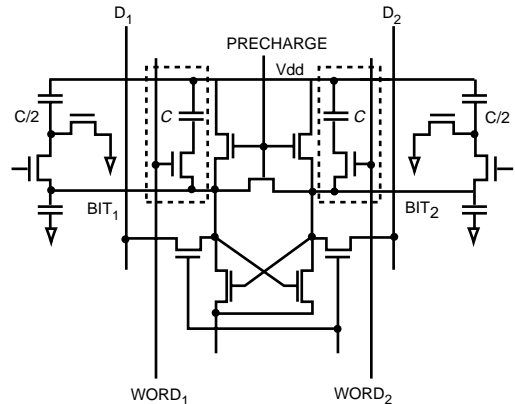

FIGURE 8.57 DRAM sense amplifier with 2 bit lines and 2 cells.

FIGURE 8.58 Cross section view of trench DRAM cells.

FIGURE 8.59 Physical layout of trench DRAM cells.

one-transistor DRAM cell with the cylindrical capacitor structure. Since the capacitor is charged by a source follower of the pass transistor, these capacitors can be charged maximally to a threshold voltage drop from the supply voltage. This reduces the total charge stored and affects performance, noise margin, and density. Frequently, to avoid this problem, the word lines are driven above the supply voltage when the data are written. Figure 8.59 shows typical layout of one-transistor DRAM cells.

The writing is done by putting either a 0 or 1 (the desired data to store) on the read/writing line. Then the row select line is strobed. A zero or one is stored in the capacitor as charge. A read is performed with precharging the read/write line then strobing the row select. If a zero is stored due to charge sharing, the voltage on the read/write line decreases. Otherwise, the voltage remains. A sense amplifier is placed at the end to pick up if there is a voltage change or not. DRAM differs from SRAM in another aspect. As the density of DRAM increases, the amount of charge stored in a cell reduces. It becomes more subject to noise. One type of noise is caused by radiation called alpha particles. These particles are helium nuclei that are present in the environment naturally or emitted from the package that houses the DRAM die. If an alpha particle hits a storage cell, it may change the state of the memory. Since alpha particles can be reduced, but not eliminated, some DRAMs institute error detection and correction techniques to increase their reliability. Another difference between DRAMs and SRAMs is in the number of address pins needed for a given size RAM. SRAM chips require all address bits to be given at the same time. DRAMs, however, utilize time-multiplex address lines. Only half of the address bits are given at a given time. They are divided by rows and columns. An extra control signal is thus required. This is the reason why DRAM chips have two address strobe signals: row address strobe (RAS) and column address strobe (CAS).

Special Memory Structures

The trend in memory devices is toward larger, faster and better-performance products. There is a complementary trend toward the development of special purpose memory devices. Several types of special purpose RAMs are offered for particular applications such as content addressable memory for cache memory, line buffers (FIFOs) for office automation machines, frame buffers for TV and broadcast equipment, and graphics buffers for computers.

Content Addressable Memory (CAM)

A special type of memory called content addressable memory (CAM) or associative memory is used in many applications such as cache memory and associative processor. A CAM stores a data item consisting

of a tag and a value. Instead of giving an address, a data pattern is given to the tag section of the CAM. This data pattern is matched with the content of the tag section. If an item in the tag section of the CAM matches the supplied data pattern, the CAM outputs the value associated with the matched tag. Figure 8.60 illustrates the basic structure of a CAM. CAM cells must be both readable and writable just like the RAM cell. Figure 8.61 shows a circuit diagram for a basic CAM cell with a match output signal. This output signal may be used as an input for some logic to determine the matching process.

FIGURE 8.60 Functional view of a CAM.

First-In-First-Out/Queue (FIFO/Queue)

A FIFO/queue is used to hold data while waiting. It serves as the buffering region for two systems, which may have different rates of consuming and producing data. FIFO can be implemented using shift registers or RAMs with pointers.

Video RAM: Frame Buffer

There is a rapid growth in computer graphic applications. The technology that is most successful is termed raster scanning. In a raster scanning display system, an image is constructed with series of horizontal lines. Each of these lines are connected pixels of the picture image. Each pixel is represented with bits controlling the intensity. Usually there are three planes corresponding to each of the primary colors: red, green, and blue. These three planes of bit maps are called frame buffer or image memory. Frame buffer architecture affects the performance of a raster scanning graphic system greatly. Since these frame buffers needs to be read out serially to display the image line by line, a special type of DRAM memory called video memory is used. Usually these memory are dual ported with a parallel random access port for writing and a serial port for reading.

8.4.4 Interfacing Memory Devices

Besides capacity and type of devices, other characteristics of memory devices include its speed and the method of access. We mentioned in the Introduction memory access time. It is defined as the time between the address available to the divide and the data available at the pin for access. Sometimes the access time

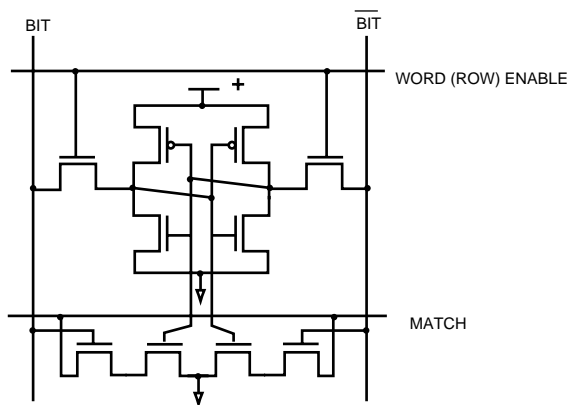

FIGURE 8.61 Static CMOS CAM cell.

FIGURE 8.62 SRAM read cycle: (a) simple read cycle of SRAM (\overline{OE} , \overline{CE} are all asserted and \overline{WE} is low), (b) SRAM read cycle.

is measured from a particular control signal. For example, the time between the read control line ready to data ready is called the read command access time. The memory cycle time is the minimum time between two consecutive accesses. The memory write command time is measured from the write control ready to data stored in the memory. The memory latency time is the interval between the CPU issuing an address to data available for processing. The memory bandwidth is the maximum amount of memory capacity being transferred in a given time. Access is done with address, read/write control lines, and data lines. SRAM and ROMs are accessed similarly during read. Figure 8.62 shows the timing diagram of two SRAM read cycles. In both methods read cycle time is defined as the time period between consecutive read addresses. In the first method, SRAM acts as an asynchronous circuit. Given an address, the output of the SRAM changes and become valid after a certain delay, which is the read access time. The second method uses two control signals, chip select and output enable, to initiate the read process. The main difference is in the data output valid time. With the second method data output is only valid after the output enable signal is asserted, which allows several devices to be connected to the data bus. Writing SRAM and electrically reprogrammable ROM is slightly different. Since there are many different programmable ROMs and their writing processes depend on the technology used, we will not discuss the writing of ROMs here. Figure 8.63 shows the timing diagram of writing typical SRAM chips. Figure 8.63(a) shows the write cycle using the write enable signal as the control signal, whereas Fig. 8.63(b) shows the write cycle using chip enable signals. Accessing DRAM is very different from SRAM and ROMs. We will discuss the different access modes of DRAMs in the following section.

Accessing DRAMs

DRAM is very different from SRAM in that its row and column address are time multiplexed. This is done to reduce the pins of the chip package. Because of time multiplexing there are two address strobe lines for DRAM address, RAS and CAS. There are many ways to access the DRAM. We list the five most common ways.

FIGURE 8.63 SRAM write cycles: (a) write enable controlled (b) chip enable controlled.

Normal Read/Write

When reading, a row address is given first, followed by the row address strobe signal RAS. RAS is used to latch the row address on chip. After RAS, a column address is given followed by the column address strobe CAS. After certain delay (read access time) valid data appear on the data lines. Memory write is done similarly to memory read with only the read/write control signal reversed. There are three cycles available to write a DRAM. They are early write, read-modify-write, and late write cycles. Figure 8.64 shows only the early write cycle of a DRAM chip. Other write cycles can be found in most of the DRAM databooks.

Fast Page Mode (FPM) or Page Mode

In page mode (or fast page mode), a read is done by lowering the RAS when the row address is ready. Then, repeatedly give the column address and CAS whenever a new one is ready without cycling the RAS line. In this way a whole row of the two-dimensional array (matrix) can be accessed with only one RAS and the same row address. Figure 8.65 illustrates the read timing cycle of a page mode DRAM chip.

Static Column

Static column is almost the same as page mode except the CAS signal is not cycled when a new column address is given—thus the static column name.

FIGURE 8.64 DRAM read and write cycles: (a) read, (b) write.

FIGURE 8.65 Page mode read cycle.

FIGURE 8.66 EDO-page mode read cycle.

Extended Data Output (EDO) Mode

In page mode, CAS must stay low until valid data reach the output. Once the CAS assertion is removed, data are disabled and the output pins go to open circuit. With EDO DRAM, an extra latch following the sense amplifier allows the CAS line to return to high much sooner, permitting the memory to start precharging earlier to prepare for the next access. Moreover, data are not disabled after CAS goes high. With burst EDO DRAM, not only does the CAS line return to high, it can also be toggled to step through the sequence in burst counter mode, providing even faster data transfer between memory and the host. Figure 8.66 shows a read cycle of an EDO page mode DRAM chip. EDO mode is also called hyper page mode (HPM) by some manufacturers.

Nibble Mode

In nibble mode after one CAS with a given column three more accesses are performed automatically without giving another column address (the address is assumed to be incremented from the given address).

Refreshing the DRAM

Row Address Strobe- (RAS-) Only Refresh

This type of refresh is done row by row. As a row is selected by providing the row address and strobing RAS, all memory cells in the row are refreshed in parallel. It will take as many cycles as the number of rows in the memory to refresh the entire device. For example, an $1\text{M} \times 1$ DRAM, which is built with 1024 rows and columns will take 1024 cycles to refresh the device. To reduce the number of refresh cycles, memory arrays are sometimes arranged to have less rows and more columns. The address, however, is nevertheless multiplexed as two evenly divided words (in the case of $1\text{M} \times 1$ DRAM the address word width is 10 b each for rows and columns). The higher order bits of address lines are used internally as column address lines and they are ignored during the refresh cycle. No CAS signal is necessary to perform the RAS-only refresh. Since the DRAM output buffer is enabled only when CAS is asserted, the data bus is not affected during the RAS-only refresh cycles.

Hidden Refresh

During a normal read cycle, RAS and CAS are strobed after the respective row and column addresses are supplied. Instead of restoring the CAS signal to high after the read, several RASs may be asserted with the corresponding refresh row address. This refresh style is called the hidden refresh cycles. Again, since the CAS is strobed and not restored, the output data are not affected by the refresh cycles. The number of refresh cycles performed is limited by the maximum time that CAS signal may be held asserted.

Column Address Strobe (CAS) Before RAS Refresh (Self-Refresh)

To simplify and speed up the refresh process, an on-chip refresh counter may be used to generate the refresh address to the array. In such a case, a separate control pin is needed to signal to the DRAM to initiate the refresh cycles. However, since in normal operation RAS is always asserted before CAS for read and write, the opposite condition can be used to signal the start of a refresh cycle. Thus, in modern self-refresh DRAMs, if the control signal CAS is asserted before the RAS, it signals the start of refresh cycles. We call this CAS-before-RAS refresh, and it is the most commonly used refresh mode in 1-Mb DRAMs. One discrepancy needs to be noted. In this refresh cycle the \overline{WE} pin is a *don't care* for the 1-Mb chips. However, the 4 Mb specifies the CAS_Before_RAS refresh mode with \overline{WE} pin held at high voltage. A CAS-before-RAS cycle with \overline{WE} low puts the 4 Meg into the JEDEC-specified test mode (WCBR). In contrast, the 1 Meg test mode is entered by applying a high to the test pin.

All of the mentioned three refresh cycles can be implemented on the device in two ways. One method utilizes a distributed method, the second uses a wait and burst method. Devices using the first method refresh the row at a regular rate utilizing the CBR refresh counter to turn on rows one at a time. In this type of system, when it is not being refreshed, the DRAM can be accessed, and the access can begin as soon as the self-refresh is done. The first CBR pulse should occur within the time of the external refresh rate prior to active use of the DRAM to ensure maximum data integrity and must be executed within three external refresh rate periods. Since CBR refresh is commonly implemented as the standard refresh, this ability to access the DRAM right after exciting the self-refresh is a desirable advantage over the second method. The second method is to use an internal burst refresh scheme. Instead of turning on rows at regular interval, a sensing circuit is used to detect the voltage of the storage cells to see if they need to be refreshed. The refresh is done with a series of refresh cycles one after another until all rows are completed. During the refresh other access to the DRAM is not allowed.

8.4.5 Error Detection and Correction

Most DRAMs require a read parity bit for two reasons. First, alpha particle strikes disturb cells by ionizing radiation, resulting in lost data. Second, when reading DRAM, the cell's storage mechanism capacitively shares its charge with the bit-line through an enable (select) transistor. This creates a small voltage differential to be sensed during read access. This small voltage difference can be influenced by other close by bit-line voltages and other noises. To have even more reliable memory, error correction code may be used. One of the error correction methods is called the Hamming code, which is capable of correcting any 1-b error.

Defining Terms

Dynamic random access memory (DRAM): This memory is dynamic because it needs to be refreshed periodically. It is random access because it can be read and written.

Memory access time: The time between a valid address supplied to a memory device and data becoming ready at output of the device.

Memory cycle time: The time between subsequent address issues to a memory device.

Memory hierarchy: Organize memory in levels to make the speed of memory comparable to the processor.

Memory read: The process of retrieving information from memory.

Memory write: The process of storing information into memory.

ROM: Acronym for read-only memory.

Static random-access memory (SRAM): This memory is static because it needs not to be refreshed. It is random access because it can be read and written.

Further Information

More information on basic issues concerning memory organization and memory hierarchy can be found in Pohm and Agrawal (1983). Prince and Due-Gundersen (1983) provides a good background on the different memory devices. Newer memory technology can be found in memory device databooks such as Mukherjee et al. (1985) and the NEC databook. *IEEE Journal on Solid-State Circuits* publishes an annual special issue on the International Solid-State Circuits Conference. This conference reports the current state-of-the-art development on most memory devices such as DRAM, SRAM, EEPROM, and flash ROM. Issues related to memory technology can be found in the *IEEE Transactions on Electron Devices*. Both journals have an annual index, which is published at the end of each year (December issue).

8.5 Microprocessors

James G. Cottle

8.5.1 Introduction

In the simplest sense, a *microprocessor* may be thought of as a central processing unit (CPU) on a chip. Technical advances of microprocessors evolve quickly and are driven by progress in ultra large-scale integrated/very large-scale integrated (ULSI/VLSI) physics and technology; fabrication advances, including reduction in feature size; and improvements in architecture.

Developers of microprocessor-based systems are interested in cost, performance, power consumption, and ease of programmability. The latter of these is, perhaps, the most important element in bringing a product to market quickly. A key item in the ease of programmability is availability of program development tools because it is these that save a great deal of time in small system implementation and make life a lot easier for the developer. It is not unusual to find small electronic systems driven by microcontrollers and

microprocessors that are far more complex than need be for the project at hand simply because the ease of development on these platforms offsets considerations of cost and power consumption. Development tools are, therefore, a tangible asset to the efficient implementation of systems, utilizing microprocessors.

Often, a more general purpose microprocessor has a companion *microcontroller* within the same family. The subject of microcontrollers is a subset of the broader area of *embedded systems*. A microcontroller contains the basic architecture of the parent microprocessor with additional on-chip special purpose hardware to facilitate easy small system implementation. Examples of special purpose hardware include analog to digital (A/D) and digital to analog (D/A) converters, timers, small amounts of on-chip memory, serial and parallel interfaces, and other input output specific hardware. These devices are most cost efficient for development of the small electronic control system, since all externally needed hardware is already designed onto the chip. Component count external to the microcontroller is therefore kept to a minimum. In addition, the advanced development tools of the parent microprocessor are often available for programming. Therefore, a potential product may be brought to market much faster than if the developer used a more general purpose microprocessor, which often requires a substantial amount of external support hardware.

8.5.2 Architecture Basics

In the early days of mainframe computers, only a few instructions (e.g., addition, load accumulator, store to memory) were available to the programmer and the CPU had to be patched, or its configuration changed, for various applications. Invention of microprogramming, by Maurice Wilkes in 1949, unbound the instruction set. Microprogramming made possible more complex tasks by manipulating the resources of the CPU (its registers, arithmetic logic unit, and internal buses) in a well-defined, but programmable, way. In this type of CPU the microprogram, or *control store*, contained the realization of the semantics of native machine instructions on a particular set of CPU internal resources. Microprogramming is still in strong use today. Within the microprogram resides the routines used to implement more complex instructions and addressing modes. It is this scheme that is still widely used and a key element of the complex instruction set computer (CISC) microprocessor.

Evolution from the original large mainframe computers with hard-wired logical paths and schemes for instruction manipulation toward more flexible and complex instruction sets and addressing modes was a natural one. It was driven by advances in semiconductor fabrication technology, memory design, and device physics. Advances in semiconductor fabrication technology have made it possible to place the CPU on a monolithic integrated circuit along with additional hardware. With the advent of programmable read-only memory, the microprogram was not even bound to the whims of the original designer. It could be reprogrammed at a later date if the manipulation of resources for a particular task needed to be modified or streamlined. In the simplest view, microprocessors became more and more complex with larger instruction sets and many addressing modes. All of these advances were welcomed by compiler writers, and the instruction set complexity was a natural evolution of advances in component reliability and density.

Complex Instruction Set Computer (CISC) and Reduced Instruction Set Computer (RISC) Processors

The strength of the microprocessor is in its ability to perform simple logical tasks at a high rate of speed. In *Complex instruction set computer* (CISC) microprocessors, small register sets, memory to memory operations, large instruction sets (with variable instruction lengths), and the use of microcode are typical. The basic simplified philosophy of the CISC microprocessor is that added hardware can result in an overall increase in speed. The penultimate CISC processor would have each high-level language statement mapped to a single native CPU instruction. Microcode simplifies the complexity somewhat but necessitates the use of multiple machine cycles to execute a single CISC instruction. After the instruction is decoded on a CISC machine, the actual implementation may require 10 or 12 machine cycles depending on the instruction and addressing mode used. The original trend in microprocessor development was toward increased complexity of the instruction set. Although there may be hundreds of native machine instructions, only a handful are actually used. Ironically, the CISC instruction set complexity evolves at a sacrifice in speed because its

harder to increase the clock speed of a complex chip. Recently, recognition of this along with demands for increased clock speeds have yielded favor toward the reduced instruction set (RISC) microprocessor.

This trend reversal followed studies in the early 1970s that showed that although the CISC machines had plenty of instructions, only relatively few of these were actually being used by programmers. In fact, 85% of all programming consists of simple assignment instructions) (i.e., A=B).

RISC machines have very few instructions and few machine cycles to implement them. What they do have is a lot of registers and a lot of parallelism. The ideal RISC machine attempts to accomplish a complete instruction in a single machine cycle. If this were the case, a 100-MHz microprocessor would execute 100 million instructions per second. There are typically many registers for moving data to accomplish the goal of reduced machine cycles. There is, therefore, a high degree of parallelism in a RISC processor. On the other hand, CISC machines have relatively few registers, depending on multiple machine cycle manipulation of data by the microprogram. In a CISC machine, the microprogram handles a lot of complexity in interpreting the native machine instruction. It is not uncommon for an advanced microprocessor of this type to have over 100 native machine instructions and a slew of addressing modes.

The two basic philosophies, CISC and RISC, are ideal concepts. Both philosophies have their merits. In practice, microprocessors typically incorporate both philosophical schemes to enhance performance and speed. A general summary of RISC vs CISC is as follows. CISC machines depend on complexity of programming in the microprogram, thereby simplifying the compiler. Complexity in the RISC machine is realized by the compiler itself.

Logical Similarity

Microprocessors may often be highly specialized for a particular application. The external logical appearance of all microprocessors, however, is the same. Although the package itself will differ, it contains connection pins for the various control signals coming from or going to the microprocessor. These are connected to the system power supply, external logic, and hardware to make up a complete computing system. External memory, math-processors, clock generators, and interrupt controllers are examples of such hardware and all must have an interface to the generic microprocessor. A diagram of a typical microprocessor pinout and the common grouping of these control signals is shown in Fig. 8.67 and microprocessor

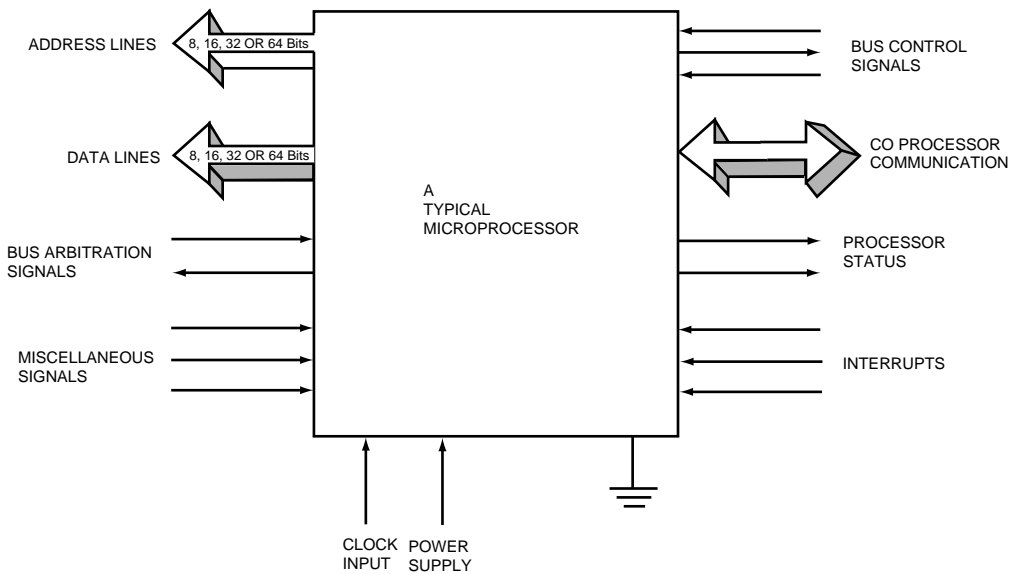

FIGURE 8.67 The pins connecting all microprocessors to external hardware are logically the same. They contain pins for addressing, data bus arbitration and control, coprocessor signals and interrupts, and those pins needed to connect to the power supply and clock generating chips.

FIGURE 8.68 Microprocessor chip pinouts for the Intel 8086 (left) and the 8088 (right).

printout for Intel[®] 8086 and 8088 processors are shown Fig. 8.68. Externally, there are signals, which may be grouped as addressing, data, bus arbitration and control, coprocessor signals, interrupts, status, and miscellaneous connections. In some cases, multiple pins are used for connections such as the case for the address and data buses.

Just as the logical connections of the microprocessor are the same from family to family, so are the basic instructions. For instance, all microprocessors have an add instruction, a subtract instruction, and a memory read instruction. Although logically, these instructions all are the same, the particular microprocessor realizes the semantics of the instruction (e.g., ADD) in a very unique way. This implementation of the ADD depends on the internal resources of the CPU such as how many registers are available, how many internal buses there are, and whether the data and address information may be separated on travel along the same internal paths.

To understand how a microprogram realizes the semantics of a native machine language instruction in a CISC machine, refer to Fig. 8.69. The figure illustrates a very simple CISC machine with a single bus, which is used to transfer both memory and data information on the inside of the microprocessor. Only one instruction may be operated on at a time with this scheme, and it is far simpler than most microprocessors available today, but it illustrates the process of instruction implementation. The process begins by a procedure (a routine in control store called the instruction fetch) that fetches the next contiguous instruction in memory and places its contents in the instruction register for interpretation. The program counter register contains the address of this instruction, and its contents are placed in the memory address register so that execution of a read command to the memory will cause, some time later, the contents of the next instruction to appear in the memory data register. These contents are then moved along the bus to the instruction register to be decoded. Meanwhile, the program counter is appropriately incremented and contains the address of the next instruction to be fetched. The contents of the instruction register for the current instruction contain the opcode and certain address information regarding the operands associated with the coded operation. For example, if the fetched instruction were an add, the instruction register would contain the coded bits indicating an add, and the information relevant to obtaining the operands for the addition. The number of bits for the machine is constant (such as 8-, 16-, or 32-b instructions) but the number of bits dedicated to the opcode and operand fields may vary to accommodate instructions with single or multiple operands, different addressing modes, and so forth. The opcode is almost always a coded address referring to a position in the microprogram of the microprocessor. For the case of the add

FIGURE 8.69 The basic single bus computer. This CISC machine is characterized by multiple registers linked by a bus, which carries both address and data information to and from the various registers (see text). Control lines gating the input and output of each register are governed by the information contained in the control store.

instruction, the opcode indicates a place in microprogram memory that contains the logic code needed to implement the add. Several machine cycles are necessary for the add instruction, including those steps needed to fetch the instruction itself. The number of these steps depends on the particular microprocessor. That is, all machines have an add instruction. The microprogram contains the realization of the add on the specific microprocessor's architecture with its individual set of hardware resources.

Specific steps (micro-operations), which direct the microprocessor to fetch the next instruction from memory, are included with every native instruction. The instruction fetch procedure is an integral part of every native instruction and represents the minimum number of machine cycles that a microprocessor must go through to implement even the simplest instruction. Even a halt instruction, therefore, requires several machine cycles to implement.

The advantages of the CISC scheme are clear. With a large number of instructions available, the programmer of a compiler or high-level language interpreter has a relatively easy task and a lot of tools at hand.

These include addressing mode schemes to facilitate relative addressing, indirect addressing, and modes such as autoincrementing or decrementing. In addition, there are typically instructions for memory to memory data transfers. Ease of programming, however, does not come without a price. The disadvantages of the CISC scheme are, therefore, relatively clear. Implementation of a particular instruction is bound to the microprogram, may take too many machine cycles, and may be relatively slow. The CISC architectural scheme also requires a lot of real estate on the semiconductor chip. Therefore, size and speed (which are really one and the same) are sacrificed for programming simplicity.

The von Neumann architecture was once the basis of most all CISC machines. This scheme is characterized by a common bus for data and address flow linking a small number of registers. The number of registers in the von Neumann machine varies depending on design, but typically consists of about 10 registers including those for general program data and addresses as well as special purposes such as instruction storage, memory addressing, and latching registers for the arithmetic logic unit (ALU). The basic architecture of the von-Neumann machine is illustrated in [Figure 8.68](#). Recent advances, however, have led to a departure of CISC machines from the basic single bus system.

Short Chronology of Microprocessor Development

The first single chip CPU was the Intel 4004 developed for calculators. It processed data in 4 bits, and its instructions were 8 bits long. Program and data were separate. The 4004 had 46 instructions, a 4 level stack, 12-b program counter, and 16, 4-b registers. Later in 1972, the 4004's successor, the 8008, was introduced, which was followed by the 8080 in 1974. The 8080 had a 16-b address bus and an 8-b data bus, seven, 8-b registers, a 16-b stack pointer to memory, and a 16-b program counter. It also had 256 input/output (I/O) ports so that I/O devices did not take up memory space and could be addressed more directly. The design was updated in 1976 (the 8085) to only require a +5 V supply.

Zilog in July 1976 introduced the Z-80, which was intended to be an improved 8080. It also used 8-b data and 16-b address, could execute all of the opcodes of the 8080 and added 80 more instructions. The register set was doubled and consisted of two banks, which could be switched. Two index registers (IX and IY) allowed for more complex memory instructions. Probably the most successful feature of the Z-80 was its memory interface. Until its introduction, dynamic random-access memory (RAM) had to be refreshed with rather complex external circuitry, which made small computing systems more complex and expensive. The Z-80 was the first chip to incorporate this refreshing capability on-chip, which increased its popularity among system developers. The Z-8 was an embedded processor similar to the Z-80 with on-chip RAM and read-only memory (ROM). It was available in clock speeds to 20 MHz and was used in a variety of small microprocessor-based control systems.

The next processor of note in the chronology was the 6800 in 1975. Although introduced by Motorola, MOS Technologies gained popularity through introducing its 650x series, principally, the 6502, which was used in early desktop computers (Commodores, Apples, and Ataris). The 6502 had very few registers and was principally an 8-b processor with a 16-b address bus. The Apple II, one of the first computers introduced to the mainstream consumer market, incorporated the 6502. Subsequent improvements in the Apple line of micros were downward compatible with the 6502 processor. The extension to the 6502 came in 1977 when Motorola introduced the 6809 with two 8-b accumulators, which could combine mathematics operations in a single 16-b combination. It had 59 instructions. Members of the 6800 family live on in embedded microcontrollers such as the 68HC05 and 68HC11. These microcontrollers are still popular for small control systems. The 68HC11 was extended to 16-b and named the 68HC16. Radiation hardened versions of the 68HC11 have been used in communications satellites.

Advanced micro devices (AMD) introduced a 4-b bit-sliced microprocessor, the Am2901. Bit-sliced processors were modular in that they could be assembled to form larger word sizes. The Am2901 had a 4-b ALU; 16, 4-b registers; and the hardware to connect carry/borrow signals between adjacent modules. In 1979, AMD developed the first floating point coprocessor for microprocessors. The AMD 9511 arithmetic circuit was used in some CP/M, Z-80-based systems and some systems based on the S-100 bus.

Around 1976, competition was heating up for the 16-b microprocessor market. The Texas Instruments (TI) TM9900 was one of the first truly 16-b microprocessors and was designed as a single chip version of

the TI 990 minicomputer. The TM9900 had two 16-b registers, good interrupt handling capability, and a decent instruction set for compiler developers. An embedded version (the TMS 9940) was also produced by TI. In 1976, the stage was being set for IBM's choice of a microprocessor for its IBM-PC line of personal computers. Several 16-b microprocessors around at the time had much more powerful features and more straightforward open memory architectures (such as Motorola's 68000). It is rumoured that IBM's own engineers wanted to use the 68000 but at the time IBM had already negotiated the rights to the Intel 8086. Apparently, the choice of the 8-b 8088 was a cost decision because the 8088 could have used the lower cost support chips associated with the 8085, whereas 68000 components were more expensive and not readily available.

Around 1976, Zilog introduced the Z-8000 (shortly after the 8086 by Intel). It was a 16-b microprocessor that had the capability of addressing up to 23-b of address data. The Z-8000 had 16, 16-b registers. The first 8 could be used as 16, 8-b registers, or all 16 could be used as 8, 32-b registers. This offered great flexibility in programming and for arithmetic calculations. Its instruction set included a 32-b multiply and divide instruction. It, also, like the Z-80 had memory refresh circuitry built into the chip. Probably most important, however, in the CPU chronology, is that the Z-8000 was the first microprocessor to incorporate two different modes of operation. One mode was strictly reserved for use by the operating system. The other mode was a general purpose user mode. The use of this scheme improved stability, in that the user could not crash the system as easily, and opened up the possibility of porting the chip towards multitasking, multiuser operating systems such as UNIX.

The Intel Family of Microprocessors

Intel was the first to develop a CPU on a chip in 1971 with the 4004 microprocessor. This chip, along with the 8008, was commissioned for calculators and terminal control. Intel did not expect the demand for these units to be high and several years later, developed a more general purpose microprocessor, the 8080, and a similar chip with more onboard hardware, the 8085. These were the industry's first truly general CPU's available to be integrated into microcomputing systems. The first 16-b chip, the 8086, was developed by Intel in 1978 and was the first industry entry into the realm of the 16-b processors. A companion mathematic coprocessor, the 8087, was developed for calculations requiring higher precision than the 16-b registers the 8086 would offer. Shortly after developing the 8086 and the 16-b address/8-b data version the 8088, IBM chose the 8088 for its IBM PC microcomputers. This decision was a tremendous boon to Intel and its microprocessor efforts. In some ways, it has also made the 80×86 family a victim of its early success, as all subsequent improvements and moves to larger data and address bus CPUs have had to contend with downward compatibility.

The 80186 and 80188 microprocessors were, in general, improvements to the 8086 and 8088 and incorporated more on-chip hardware for input and output support. They were never widely used, however, most likely due to the masking effect of the 8088's success in the IBM PC. The 80186 is architecturally identical to the 8086 but also contains a clock generator, a programmable controlled interrupt, three 16-b programmable timers, two programmable DMA controllers, a chip select unit, programmable control registers, a bus interface unit, and a 6-byte prefetch queue. The 80188 scheme is the same, with the exception that it only has an 8-b external data bus and a 4-byte prefetch queue.

None of the processors of the Intel family up to the beginning of the 1980s had the ability to address more than 1 megabyte of memory. The 80286, a 68-pin microprocessor, was developed to cater to the needs of systems and programs that were evolving, in a large part, due to the success of the 8088. The 80286 increased the available address space of the Intel microprocessor family to 16 megabytes of memory. Also, beginning with the 80286, the data and address lines external to the chip were not shared. In earlier chips, the address pins were multiplexed with the data lines. The internal architecture to accomplish this was a bit cumbersome, however, was kept so as to include downward compatibility with the earlier CPUs. Despite the scheme's unwieldiness, the 80286 was a huge success.

In a decade, the evolution of the microprocessor had advanced from its earliest beginnings (with a 4-b CPU) to a true 16-b microprocessor. Many everyday computing tasks were off loaded from mainframes to desktop machines. In 1985 Intel developed a true 32-b processor on a chip, the 80386. It was downward

compatible with all object codes back to the 8008 and continued to lock Intel into the rather awkward memory model developed in the 80286. At Motorola, the 68000 in some ways had a far more simple and straightforward open address space and was a serious contender for heavy computing applications being ported to desktop machines from their larger, mainframe cousins. It is for this reason that even today the 68000 is found systems requiring compatibility with UNIX operating systems. The 80386 was, nevertheless, highly successful. The 80386SX was a version of the 80386 developed with an identical package to the 80286 and meant as an upgrade for existing 80286 systems. It did so by upgrading the address bus to 32 b but maintained the 16-b data bus of the 80286. A companion mathematic coprocessor (a floating point math unit (FPU)), the 80387, was developed for use with the 80386.

The 80386's success prompted other semiconductor companies (notably AMD and Cyrix) to piggyback on its success by offering clones of the processors and thus alternative sources for its end users and system developers. With Intel's addition of its 80486 in 1989, including full **pipelines**, on-chip **caching** and an integrated rather than separate floating point processor, competition for the chips, popularity was fierce. In late 1993, Intel could no longer protect the next subsequent name in the series (the 80586). It trademarked the Pentium name to its 80586 processor. Because of its popularity, the 80×86 line is the most widely cloned.

The Motorola Family of Microprocessors

Alongside of Intel's development of the 8080, Motorola developed the 6800, 8-b microprocessor. In the early 1970s, the 6800 was used in many embedded industrial control systems. It was not until 1979 however, that Motorola introduced its 16-b entry into the industry, the 68000. The 68000 was designed to be far more advanced than the 8086 microprocessor by Intel in several ways. All internal registers were 32-b wide, and it had the benefit of being able to address all 16 megabytes of external memory without the segmentation schemes utilized in the Intel series. This nonsegmented approach meant that the 68000 had no segment registers, and each of its instructions could address the complete complement of external memory.

The 68000 was the first 16-b microprocessor to incorporate 32-b internal registers. This asset allowed its selection by designers who set out to port sophisticated operating systems to desktop computers. In some ways, the 68000 was ahead of its time. If IBM had chosen the 68000 series as the core chip for its personal computers, the present state-of-the-art of the desktop machine would be radically different. The 68000 was chosen by Apple for its MacIntosh computers. Other computer manufacturers, including Amiga and Atari chose it for its flexibility and its large internal registers.

In 1982, Motorola marketed another chip, the 68008, which was a stripped down version of the 68000 for low-end, low-cost products. The 68008 only had the capability to address 4 megabytes of memory, and its data bus was only 8-b wide. It was never very popular and certainly did not compete well with the 8088 by Intel (which was chosen for the IBM PC computers).

Advanced operating systems were ideal for the 68000 except that the chip had no capability for supporting virtual memory. For this reason, Motorola developed the 68010, which had the capability to continue an instruction after it had been suspended by a bus error. The 68012 was identical to the 68000 except that it had the capability to address 2 gigabytes of memory with its 30 address bus pins.

One of the most successful microprocessors introduced by Motorola was the 68020. It was introduced in 1984 and was the industry's first true 32-b microprocessor. Along with the 32-b registers standard to the 68000 series, it has the capability of addressing 4 gigabytes of memory and a true 32-b wide data bus. It is still widely used.

The 68020 contains an internal 256 byte cache memory. This is an instruction cache, holding up to 64 instructions of the long-word type. Direct access to this cache is not allowed. It serves only as an advance *prefetch queue* to enable the 68020 to execute tight loops of instructions with any further instruction fetches. Since an instruction fetch takes time to process, the presence of the 256-byte instruction cache in the 68020 is a significant speed enhancement.

The cache treatment was expanded in the 68030 to include a 256-byte data cache. In addition, the 68030 includes an onboard paged memory management unit (PMMU) to control access to virtual memory. This is the primary difference in the 68030 and the 68020. The PMMU is available as an extra chip (the 68851)

for the 68020 but included on the same chip with the 68030. The 68030 also includes an improved bus interface scheme. Externally, the connections of the 68020 and the 68030 are very nearly the same. The 68030 is available in two speeds, the MC68030RC16 at 16 MHz and the MC68030RC20 with a 20-MHz clock.

The 68000 featured a supervisor and user mode. It was designed for expansion and could fetch the next instruction during an instruction's execution. (This represents 2-stage pipelining.) The 68040 had 6-stages of pipelining. The advances in the 680×0 series continued toward the 68060 in late 1994, which was a **superscalar** microprocessor similar to the Intel Pentium. It truly represents a merging of the two CISC and RISC philosophies of architecture. The 68060 10-stage pipeline translates 680×0 instructions into a decoded RISC-like form and uses a resource renaming scheme to reorder the execution of the instructions. The 68060 includes power saving features that can be shutdown and operates off of a 3.3-V power supply (again similar to the Intel Pentium processors).

RISC Processor Development

The major development efforts for RISC processors were led by the University of California at Berkeley and the Stanford University designs. Sun Microsystems developed the Berkeley version of the RISC processor [scalable processor architecture (SPARC)] for their high-speed workstations. This, however, was not the first RISC processor. It was preceded by the MIPS R2000 (based on the Stanford University design), the Hewlett Packard PA-RISC CPU, and the AMD 29000.

The AMD 29000 is a RISC design, which follows the lead of the Berkeley scheme. It has a large set of registers spilt into local and global sets. The 64 global registers reduced instruction set processors were developed following the recognition that many of the CISC complex instructions were not being used.

Defining Terms

Cache: Small amount of *fast* memory, physically close to CPU, used as storage of a block of data needed immediately by the processor. Caches exist in a memory hierarchy. There is a small but very fast L1 (level one) cache; if that misses, then the access is passed on to the bigger but slower L2 (level two) cache, and if that misses, the access goes to the main memory (or L3 cache, if it exists).

Pipelining: A microarchitecture technique that divides the execution of an instruction into sequential steps. Pipelined CPUs have multiple instructions executing at the same time but at different stages in the machine. Or, the act of sending out an address before the data is actually needed.

Superscalar: Capable of executing multiple instructions in a given clock cycle. For example, the Pentium processor has two execution pipes (U and V) so it is superscalar level 2. The Pentium Pro processor can dispatch and retire three instructions per clock so it is superscalar level 3.

Further Information

In the fast changing world of the microprocessor, obsolescence is a fact of life. In fact, the marketing data shows that, with each introduction of a new generation, the time spent ramping up a new technology and ramping down the old gets shorter. There is more need for accuracy in design and development to avoid errors such as Intel experienced with their Pentium Processor with their floating point mathematic computations in 1994. For the small system developer or user of microprocessors, there is an important need to keep abreast of newer, more enhanced chips with better capabilities. Luckily, there is an excellent way to keep up to date.

The CPU Information Center at the University of California, Berkeley maintains an excellent, up to date compilation of microprocessors and microcontrollers, their architectures, and specifications on the World Wide Web (WWW). The site includes chip size and pinout information, tabular comparisons of microprocessor performance and architecture (such as that shown in the tables in this chapter), and references. It is updated regularly and serves as an excellent source for the small systems developer. Some of the information contained in this chapter was obtained and used with permission from that Web site. See <http://www.infopad.berkeley.edu> for an excellent, up to date summary.

8.6 D/A and A/D Converters

Susan A. Garrod

8.6.1 Introduction

Digital-to-analog (D/A) conversion is the process of converting digital codes into a continuous range of analog signals. *Analog-to-digital (A/D) conversion* is the complementary process of converting a continuous range of analog signals into digital codes. Such conversion processes are necessary to interface real-world systems, which typically monitor continuously varying analog signals, with digital systems that process, store, interpret, and manipulate the analog values.

D/A and A/D applications have evolved from predominately military-driven applications to consumer-oriented applications. Up to the mid-1980s, the military applications determined the design of many D/A and A/D devices. The military applications required very high performance coupled with hermetic packaging, radiation hardening, shock and vibration testing, and military specification and record keeping. Cost was of little concern, and “low power” applications required approximately 2.8 W. The major applications up the mid-1980s included military radar warning and guidance systems, digital oscilloscopes, medical imaging, infrared systems, and professional video.

The applications requiring D/A and A/D circuits today have different performance criteria from those of earlier years. In particular, low power and high speed applications are driving the development of D/A and A/D circuits, as the devices are used extensively in battery-operated consumer products.

8.6.2 D/A and A/D Circuits

D/A and A/D conversion circuits are available as integrated circuits (ICs) from many manufacturers. A huge array of ICs exists, consisting of not only the D/A or A/D conversion circuits, but also closely related circuits such as sample-and-hold amplifiers, analog multiplexers, voltage-to-frequency and frequency-to-voltage converters, voltage references, calibrators, operation amplifiers, isolation amplifiers, instrumentation amplifiers, active filters, DC-to-DC converters, analog interfaces to digital signal processing systems, and data acquisition subsystems. Data books from the IC manufacturers contain an enormous amount of information about these devices and their applications to assist the design engineer.

The ICs discussed in this chapter will be strictly the D/A and A/D conversion circuits. The ICs usually perform either D/A or A/D conversion. There are serial interface ICs, however, typically for digital signal processing applications, that perform both A/D and D/A processes.

D/A and A/D Converter Performance Criteria

The major factors that determine the quality of performance of D/A and A/D converters are *resolution*, *sampling rate*, *speed*, and *linearity*.

The *resolution* of a D/A circuit is the smallest change in the output analog signal. In an A/D system, the resolution is the smallest change in voltage that can be detected by the system and can produce a change in the digital code. The resolution determines the total number of digital codes, or *quantization levels*, that is recognized or produced by the circuit.

The *resolution* of a D/A or A/D IC is usually specified in terms of the bits in the digital code or in terms of the least significant bit (LSB) of the system. An n -bit code allows for 2^n quantization levels, or $2^n - 1$ steps between quantization levels. As the number of bits increases, the step size between quantization levels decreases, therefore increasing the accuracy of the system when a conversion is made between an analog and digital signal. The system resolution can be specified also as the voltage step size between quantization levels. For A/D circuits, the resolution is the smallest input voltage that is detected by the system.

The *speed* of a D/A or A/D converter is determined by the time it takes to perform the conversion process. For D/A converters, the speed is specified as the *settling time*. For A/D converters, the speed is specified as the *conversion time*. The settling time for D/A converters varies with supply voltage and transition in the digital code; thus, it is specified in the data sheet with the appropriate conditions stated.

A/D converters have a maximum *sampling rate* that limits the speed at which they can perform continuous conversions. The sampling rate is the number of times per second that the analog signal can be sampled and converted into a digital code. For proper A/D conversion, the minimum sampling rate must be at least two times the highest frequency of the analog signal being sampled to satisfy the Nyquist sampling criterion. The conversion speed and other timing factors must be taken into consideration to determine the maximum sampling rate of an A/D converter. **Nyquist A/D converters** use a sampling rate that is slightly more than twice the highest frequency in the analog signal. **Oversampling A/D converters** use sampling rates of N times rate, where N typically ranges from 2 to 64.

Both D/A and A/D converters require a voltage reference in order to achieve absolute conversion accuracy. Some conversion ICs have internal voltage references, whereas others accept external voltage references. For high-performance systems, an external precision reference is needed to ensure long-term stability, load regulation, and control over temperature fluctuations. External precision voltage reference ICs can be found in manufacturer's data books.

Measurement accuracy is specified by the converter's *linearity*. *Integral linearity* is a measure of linearity over the entire conversion range. It is often defined as the deviation from a straight line drawn between the endpoints and through zero (or the offset value) of the conversion range. Integral linearity is also referred to as *relative accuracy*. The *offset* value is the reference level required to establish the zero or midpoint of the conversion range. *Differential linearity* is the linearity between code transitions. Differential linearity is a measure of the *monotonicity* of the converter. A converter is said to be monotonic if increasing input values result in increasing output values.

The accuracy and linearity values of a converter are specified in the data sheet in units of the LSB of the code. The linearity can vary with temperature, and so the values are often specified at +25°C as well as over the entire temperature range of the device.

D/A Conversion Processes

Digital codes are typically converted to analog voltages by assigning a voltage weight to each bit in the digital code and then summing the voltage weights of the entire code. A general D/A converter consists of a network of precision resistors, input switches, and level shifters to activate the switches to convert a digital code to an analog current or voltage. D/A ICs that produce an analog current output usually have a faster settling time and better linearity than those that produce a voltage output. When the output current is available, the designer can convert this to a voltage through the selection of an appropriate output amplifier to achieve the necessary response speed for the given application.

D/A converters commonly have a fixed or variable reference level. The reference level determines the switching threshold of the precision switches that form a controlled impedance network, which in turn controls the value of the output signal. **Fixed reference D/A converters** produce an output signal that is proportional to the digital input. **Multiplying D/A converters** produce an output signal that is proportional to the product of a varying reference level times a digital code.

D/A converters can produce bipolar, positive, or negative polarity signals. A four-quadrant multiplying D/A converter allows both the reference signal and the value of the binary code to have a positive or negative polarity. The four-quadrant multiplying D/A converter produces bipolar output signals.

D/A Converter ICs

Most D/A converters are designed for general-purpose control applications. Some D/A converters, however, are designed for special applications, such as video or graphic outputs, high-definition video displays, ultra high-speed signal processing, digital video tape recording, digital attenuators, or high-speed function generators.

D/A converter ICs often include special features that enable them to be interfaced easily to microprocessors or other systems. Microprocessor control inputs, input latches, buffers, input registers, and compatibility to standard logic families are features that are readily available in D/A ICs. In addition, the ICs usually have laser-trimmed precision resistors to eliminate the need for user trimming to achieve full-scale performance.

A/D Conversion Processes

Analog signals can be converted to digital codes by many methods, including integration, **successive approximation**, parallel (flash) conversion, **delta modulation**, **pulse code modulation**, and **sigma-delta conversion**. Two common A/D conversion processes are successive approximation A/D conversion and parallel or **flash A/D** conversion. Very high-resolution digital audio or video systems require specialized A/D techniques that often incorporate one of these general techniques as well as specialized A/D conversion processes. Examples of specialized A/D conversion techniques are pulse code modulation (PCM), and sigma-delta conversion. PCM is a common voice encoding scheme used not only by the audio industry in digital audio recordings but also by the telecommunications industry for voice encoding and multiplexing. Sigma-delta conversion is an oversampling A/D conversion where signals are sampled at very high frequencies. It has very high resolution and low distortion.

Successive approximation A/D conversion is a technique that is commonly used in medium- to high-speed data acquisition applications. It is one of the fastest A/D conversion techniques that requires a minimum amount of circuitry. The conversion times for successive approximation A/D conversion typically range from 10 to 300 μs for 8-b systems.

The successive approximation A/D converter can approximate the analog signal to form an n -bit digital code in n steps. The successive approximation register (SAR) individually compares an analog input voltage to the midpoint of one of n ranges to determine the value of 1 b. This process is repeated a total of n times,

FIGURE 8.70 Successive approximation A/D converter block diagram. (Source: Garrod, S. and Borns, R. 1991. *Digital Logic: Analysis, Application, and Design*, p. 919. Copyright ©1991 by Saunders College Publishing, Philadelphia, PA. Reprinted by permission of the publisher.)

using n ranges, to determine the n bits in the code. The comparison is accomplished as follows. The SAR determines if the analog input is above or below the midpoint and sets the bit of the digital code accordingly. The SAR assigns the bits beginning with the most significant bit. The bit is set to a 1 if the analog input is greater than the midpoint voltage, or it is set to a 0 if it is less than the midpoint voltage. The SAR then moves to the next bit and sets it to a 1 or a 0 based on the results of comparing the analog input with the midpoint of the next allowed range. Because the SAR must perform one approximation for each bit in the digital code, an n -bit code requires n approximations.

A successive approximation A/D converter consists of four functional blocks, as shown in Fig. 8.70: the SAR, the analog comparator, a D/A converter, and a clock.

Parallel or flash A/D conversion is used in high-speed applications such as video signal processing, medical imaging, and radar detection systems. A flash A/D converter simultaneously compares the input analog voltage to $2^n - 1$ threshold voltages to produce an n -bit digital code representing the analog voltage. Typical flash A/D converters with 8-b resolution operate at 20–100 MHz.

The functional blocks of a flash A/D converter are shown in Fig. 8.71. The circuitry consists of a precision resistor ladder network, $2^n - 1$ analog comparators, and a digital priority encoder. The resistor network establishes threshold voltages for each allowed quantization level. The analog comparators indicate whether or not the input analog voltage is above or below the threshold at each level. The output of the analog comparators is input to the digital priority encoder. The priority encoder produces the final digital output code that is stored in an output latch.

An 8-b flash A/D converter requires 255 comparators. The cost of high-resolution A/D comparators escalates as the circuit complexity increases and as the number of analog converters rises by $2^n - 1$. As a low-cost alternative, some manufacturers produce modified flash A/D converters that perform the A/D conversion in two steps to reduce the amount of circuitry required. These modified flash A/D converters are also referred to as *half-flash* A/D converters, since they perform only half of the conversion simultaneously.

A/D Converter ICs

A/D converter ICs can be classified as general-purpose, high-speed, flash, and sampling A/D converters. The *general-purpose A/D converters* are typically low speed and low cost, with conversion times ranging

FIGURE 8.71 Flash A/D converter block diagram. (Source: Garrod, S. and Borns, R. *Digital Logic: Analysis, Application, and Design*, p. 928. Copyright ©1991 by Saunders College Publishing, Philadelphia, PA. Reprinted by permission of the publisher.)

from 2 μ s to 33 ms. A/D conversion techniques used by these devices typically include successive approximation, tracking, and integrating. The general-purpose A/D converters often have control signals for simplified microprocessor interfacing. These ICs are appropriate for many process control, industrial, and instrumentation applications, as well as for environmental monitoring such as seismology, oceanography, meteorology, and pollution monitoring.

High-speed A/D converters have conversion times typically ranging from 400 ns to 3 μ s. The higher speed performance of these devices is achieved by using the successive approximation technique, modified flash techniques, and statistically derived A/D conversion techniques. Applications appropriate for these A/D ICs include fast Fourier transform (FFT) analysis, radar digitization, medical instrumentation, and multiplexed data acquisition. Some ICs have been manufactured with an extremely high degree of linearity, to be appropriate for specialized applications in digital spectrum analysis, vibration analysis, geological research, sonar digitizing, and medical imaging.

Flash A/D converters have conversion times ranging typically from 10 to 50 ns. Flash A/D conversion techniques enable these ICs to be used in many specialized high-speed data acquisition applications such as TV video digitizing (encoding), radar analysis, transient analysis, high-speed digital oscilloscopes, medical ultrasound imaging, high-energy physics, and robotic vision applications.

Sampling A/D converters have a sample-and-hold amplifier circuit built into the IC. This eliminates the need for an external sample-and-hold circuit. The throughput of these A/D converter ICs ranges typically from 35 kHz to 100 MHz. The speed of the system is dependent on the A/D technique used by the sampling A/D converter.

A/D converter ICs produce digital codes in a serial or parallel format, and some ICs offer the designer both formats. The digital outputs are compatible with standard logic families to facilitate interfacing to other digital systems. In addition, some A/D converter ICs have a built-in analog multiplexer and therefore can accept more than one analog input signal.

Pulse code modulation (PCM) ICs are high-precision A/D converters. The PCM IC is often referred to as a PCM *codec* with both encoder and decoder functions. The encoder portion of the codec performs the

A/D conversion, and the decoder portion of the codec performs the D/A conversion. The digital code is usually formatted as a serial data stream for ease of interfacing to digital transmission and multiplexing systems.

PCM is a technique where an analog signal is sampled, quantized, and then encoded as a digital word. The PCM IC can include successive approximation techniques or other techniques to accomplish the PCM encoding. In addition, the PCM codec may employ nonlinear data compression techniques, such as companding, if it is necessary to minimize the number of bits in the output digital code. Companding is a logarithmic technique used to compress a code to fewer bits before transmission. The inverse logarithmic function is then used to expand the code to its original number of bits before converting it to the analog signal. Companding is typically used in telecommunications transmission systems to minimize data transmission rates without degrading the resolution of low-amplitude signals. Two standardized companding techniques are used extensively: A-law and μ -law. The A-law companding is used in Europe, whereas the μ -law is used predominantly in the United States and Japan. Linear PCM conversion is used in high-fidelity audio systems to preserve the integrity of the audio signal throughout the entire analog range.

Digital signal processing (DSP) techniques provide another type of A/D conversion ICs. Specialized A/D conversion such as *adaptive differential pulse code modulation* (ADPCM), sigma–delta modulation, *speech subband encoding*, *adaptive predictive speech encoding*, and *speech recognition* can be accomplished through the use of DSP systems. Some DSP systems require analog front ends that employ traditional PCM codec ICs or DSP interface ICs. These ICs can interface to a digital signal processor for advanced A/D applications. Some manufacturers have incorporated DSP techniques on board the single-chip A/D IC, as in the case of the DSP56ACD16 sigma–delta modulation IC by Motorola.

Integrating A/D converters are used for conversions that must take place over a long period of time, such as digital voltmeter applications or sensor applications such as thermocouples. The integrating A/D converter produces a digital code that represents the average of the signal over time. Noise is reduced by means of the signal averaging, or integration. Dual-slope integration is accomplished by a counter that advances while an input voltage charges a capacitor in a specified time interval, T . This is compared to another count sequence that advances while a reference voltage is discharging across the same capacitor in a time interval, Δt . The ratio of the charging count value to the discharging count value is proportional to the ratio of the input voltage to the reference voltage. Hence, the integrating converter provides a digital code that is a measure of the input voltage averaged over time. The conversion accuracy is independent of the capacitor and the clock frequency since they affect both the charging and discharging operations. The charging period, T , is selected to be the period of the fundamental frequency to be rejected. The maximum conversion rate is slightly less than $1/(2T)$ conversions per second. While this limits the conversion rate to be too slow for high-speed data acquisition applications, it is appropriate for long-duration applications of slowly varying input signals.

Grounding and Bypassing on D/A and A/D ICs

D/A and A/D converter ICs require correct grounding and capacitive bypassing in order to operate according to performance specifications. The digital signals can severely impair analog signals. To combat the electromagnetic interference induced by the digital signals, the analog and digital grounds should be kept separate and should have only one common point on the circuit board. If possible, this common point should be the connection to the power supply.

Bypass capacitors are required at the power connections to the IC, the reference signal inputs, and the analog inputs to minimize noise that is induced by the digital signals. Each manufacturer specifies the recommended bypass capacitor locations and values in the data sheet. The manufacturers' recommendations should be followed to ensure proper performance.

Selection Criteria for D/A and A/D Converter ICs

Hundreds of D/A and A/D converter ICs are available, with prices ranging from a few dollars to several hundred dollars each. The selection of the appropriate type of converter is based on the application

requirements of the system, the performance requirements, and cost. The following issues should be considered in order to select the appropriate converter.

1. What are the input and output requirements of the system? Specify all signal current and voltage ranges, logic levels, input and output impedances, digital codes, data rates, and data formats.
2. What level of accuracy is required? Determine the resolution needed throughout the analog voltage range, the dynamic response, the degree of linearity, and the number of bits encoding.
3. What speed is required? Determine the maximum analog input frequency for sampling in an A/D system, the number of bits for encoding each analog signal, and the rate of change of input digital codes in a D/A system.
4. What is the operating environment of the system? Obtain information on the temperature range and power supply to select a converter that is accurate over the operating range.

Final selection of D/A and A/D converter ICs should be made by consulting manufacturers to obtain their technical specifications of the devices.

Defining Terms

Comanding: A process designed to minimize the transmission bit rate of a signal by compressing it prior to transmission and expanding it upon reception. It is a rudimentary “data compression” technique that requires minimal processing.

Delta modulation: An A/D conversion process where the digital output code represents the change, or slope, of the analog input signal, rather than the absolute value of the analog input signal. A 1 indicates a rising slope of the input signal. A 0 indicates a falling slope of the input signal. The sampling rate is dependent on the derivative of the signal, since a rapidly changing signal would require a rapid sampling rate for acceptable performance.

Fixed reference D/A converter: The analog output is proportional to a fixed (nonvarying) reference signal.

Flash A/D: The fastest A/D conversion process available to date, also referred to as parallel A/D conversion. The analog signal is simultaneously evaluated by $2^n - 1$ comparators to produce an n -bit digital code in one step. Because of the large number of comparators required, the circuitry for flash A/D converters can be very expensive. This technique is commonly used in digital video systems.

Integrating A/D: The analog input signal is integrated over time to produce a digital signal that represents the area under the curve, or the integral.

Multiplying D/A: A D/A conversion process where the output signal is the product of a digital code multiplied times an analog input reference signal. This allows the analog reference signal to be scaled by a digital code.

Nyquist A/D converters: A/D converters that sample analog signals that have a maximum frequency that is less than the Nyquist frequency. The Nyquist frequency is defined as one-half of the sampling frequency. If a signal has frequencies above the Nyquist frequency, a distortion called *aliasing* occurs. To prevent aliasing, an *antialiasing filter* with a flat passband and very sharp rolloff is required.

Oversampling converters: A/D converters that sample frequencies at a rate much higher than the Nyquist frequency. Typical oversampling rates are 32 and 64 times the sampling rate that would be required with the Nyquist converters.

Pulse code modulation (PCM): An A/D conversion process requiring three steps: the analog signal is sampled, quantized, and encoded into a fixed length digital code. This technique is used in many digital voice and audio systems. The reverse process reconstructs an analog signal from the PCM code. The operation is very similar to other A/D techniques, but specific PCM circuits are optimized for the particular voice or audio application.

Sigma-delta A/D conversion: An *oversampling* A/D conversion process where the analog signal is sampled at rates much higher (typically 64 times) than the sampling rates that would be required with a Nyquist converter. Sigma-delta modulators integrate the analog signal before performing the delta modulation. The integral of the analog signal is encoded rather than the change in the analog signal,

as is the case for traditional delta modulation. A digital sample rate reduction filter (also called a digital decimation filter) is used to provide an output sampling rate at twice the Nyquist frequency of the signal. The overall result of oversampling and digital sample rate reduction is greater resolution and less distortion compared to a Nyquist converter process.

Successive approximation: An A/D conversion process that systematically evaluates the analog signal in n steps to produce an n -bit digital code. The analog signal is successively compared to determine the digital code, beginning with the determination of the most significant bit of the code.

Further Information

Analog Devices, Inc. has edited or published several technical handbooks to assist design engineers with their data acquisition system requirements. These references should be consulted for extensive technical information and depth. The publications include *Analog-Digital Conversion Handbook*, by the engineering staff of Analog Devices, published by Prentice-Hall, Englewood Cliffs, NJ, 1986; *Nonlinear Circuits Handbook*, *Transducer Interfacing Handbook*, and *Synchro and Resolver Conversion*, all published by Analog Devices Inc., Norwood, MA.

Engineering trade journals and design publications often have articles describing recent A/D and D/A circuits and their applications. These publications include *EDN Magazine*, *EE Times*, and *IEEE Spectrum*. Research-related topics are covered in *IEEE Transactions on Circuits and Systems* and also *IEEE Transactions on Instrumentation and Measurement*.

8.7 Application-Specific Integrated Circuits

Constantine N. Anagnostopoulos and Paul P.K. Lee

8.7.1 Introduction

Application specific integrated circuits (ASICs), also called custom ICs, are chips specially designed to (1) perform a function that cannot be done using standard components, (2) improve the performance of a circuit, or (3) reduce the volume, weight, and power requirement and increase the reliability

of a given system by integrating a large number of functions on a single chip or a small number of chips.

ASICs can be classified into the following three categories: (1) full custom, (2) semicustom, and (3) programmable logic devices (PLDs).

The first step of the process toward realizing a custom IC chip is to define the function the chip must perform. This is accomplished during system partitioning, at which time the system engineers and IC designers make some initial decisions as to which circuit functions will be implemented using standard, off the shelf, components and which will require custom ICs. After several iterations the functions that each custom chip has to perform are determined.

There usually are many different ways by which a given function may be implemented. For example, the function may be performed in either the analog or the digital domain. If a digital approach is selected, different execution strategies may be chosen. For example, a delay function may be implemented either by a shift register or by a random access memory. Thus, in the second step of the process, the system engineers and IC designers decide how the functions each of the chips has to perform will be executed. How a function is executed by a given chip constitutes the behavioral description of that chip.

Next, a design approach needs to be developed for each of the custom chips. Depending on the implementation method selected, either a full custom, a semicustom, or a user programmable device approach is chosen.

One important consideration in the design choice is cost and turn around time (Fey and Paraskevopoulos, 1985). Typically, a full custom approach takes the longest to design, and the cost per chip is very high unless the chip volume is also high, normally more than a few hundred thousands chips per year. The shortest design approach is using programmable devices but the cost per chip is the highest. This approach is best for prototype and limited production systems.

8.7.2 Full Custom ASICs

In a typical full custom IC design, every device and circuit element on the chip is designed for that particular chip. Of course, common sense dictates that device and circuit elements proven to work well in previous designs are reused in subsequent ones whenever possible.

A full custom approach is selected to minimize the chip size or to implement a function that is not available or would not be optimum with semicustom or standard ICs. Minimizing chip size increases the fabrication yield and the number of chips per wafer. Both of these factors tend to reduce the cost per chip.

Fabrication yield is given by

$$Y = [(1 - e^{-AD})/AD]^2$$

where A is the chip or die area and D is the average number of defects per square centimeter per wafer. The number of die per wafer is given by

$$N = [\pi(R - A^{1/2})^2]/A$$

where R is the wafer radius and A is, again, the area of the die.

Additional costs incurred involve testing of the die while still on the wafer and packaging a number of the good ones and testing them again. Then good die must be subjected to reliability testing to find out the expected lifetime of the chip at normal operating conditions (Hu, 1992).

Fabrication of full custom ASICs is done at silicon foundries. Some of the foundries are captive, that is, they fabricate devices only for the system divisions of their own company. Others make available some of their lines to outside customers. There also are foundries that exclusively serve external customers. Foundries often provide design services as well. If users are interested in doing their own design, however, then the foundry provides a set of design rules for each of the processes they have available. The design rules describe in broad terms the fabrication technology, whether CMOS, bipolar, BiCMOS, or GaAs and

then specify in detail the minimum dimensions that can be defined on the wafer for the various layers, the SPICE [Vladimirescu et al. 1981] parameters of each of the active devices, the range of values for the passive devices and other rules and limitations.

Designing a full custom chip is a complex task and can only be done by expert IC designers. Often a team of people is required both to reduce the design time (Fey and Paraskevopoulos, 1986) and because one person may simply not have all the design expertise required. Also, sophisticated and powerful computer hardware and software are needed. Typically, the more sophisticated the computer aided design (CAD) tools are, the higher the probability that the chip will work the first time. Given the long design and fabrication cycle for a full custom chip and its high cost, it is important that as much as possible of the design be automated, that design rule checking should be utilized, and that the circuit simulation be as complete and accurate as possible.

During the design phase, a substantial effort should be made to incorporate on the chip additional circuitry to help verify that the chip is working properly after it is fabricated, or to help identify the section or small circuit responsible for the chip not working, or verify that an error occurred during the fabrication process. For digital full custom circuits, a large number of testability techniques have been developed (Williams and Mercer, 1993), most of which are automated and easily incorporated in the design, given the proper software. For analog circuits there are no accepted universal testability methods. A unique test methodology for each circuit needs to be developed.

Technology selection for a particular full custom ASIC depends on the functions the chip has to perform, the performance specifications, and its desired cost.

8.7.3 Semicustom ASICs

The main distinguishing feature of semicustom ASICs, compared to full custom ones, is that the basic circuit building blocks, whether analog or digital, are already designed and proven to work. These basic circuits typically reside in libraries within a CAD system. The users simply select from the library the components needed, place them on their circuits, and interconnect them. Circuit simulation is also done at a much higher level than SPICE, and the designer is, therefore, not required to be familiar with either semiconductor or device physics.

Semicustom ICs are designed using either **gate arrays**, **standard cells**, analog arrays, **functional blocks** and PLDs such as field programmable gate arrays (FPGAs). Note that there does not exist a standard naming convention for these products within the industry. Often different manufacturers use different names to describe what are essentially very similar products. Gate arrays, standard cells, and FPGAs are used for digital designs. Analog arrays are used for analog designs and functional blocks are used for both.

Gate Arrays

A gate array consists of a regular array of transistors, usually arranged in two pairs of n- and p-channel, which is the minimum number required to form a NAND gate, and a fixed number of bonding pads, each incorporating an input/output (I/O) buffer. The major distinguishing feature of gate arrays is that they are partially prefabricated by the manufacturer. The designer customizes only the final contact and metal layers. Partially prefabricating the devices reduces delivery time and cost, particularly of prototype parts.

The layout of a simple 2048-gates CMOS gate array is shown in Fig. 8.72. The device consists of 16 columns of transistors and each column contains 128 pairs of n-channel and p-channel transistors. Between the columns are 18 vertical wiring channels, each containing 21 tracks. There are no active devices in the channels. There are 4 horizontal wiring tracks for each gate for a total of 512 horizontal tracks or *routes* for the whole array. The optimum number R of wiring tracks or routes per gate, of an array of a given number of gates, is given by the empirical formula (Fier and Heikkila, 1982)

$$R = 3CG^{0.124}$$

Where C is the average number of connections per gate and G is the number of gates in the array. For a two-input NAND gate, shown in Fig. 8.73, the number of connections C is 3, the two inputs A and B and

2048 GATES - CMOS GATE ARRAY

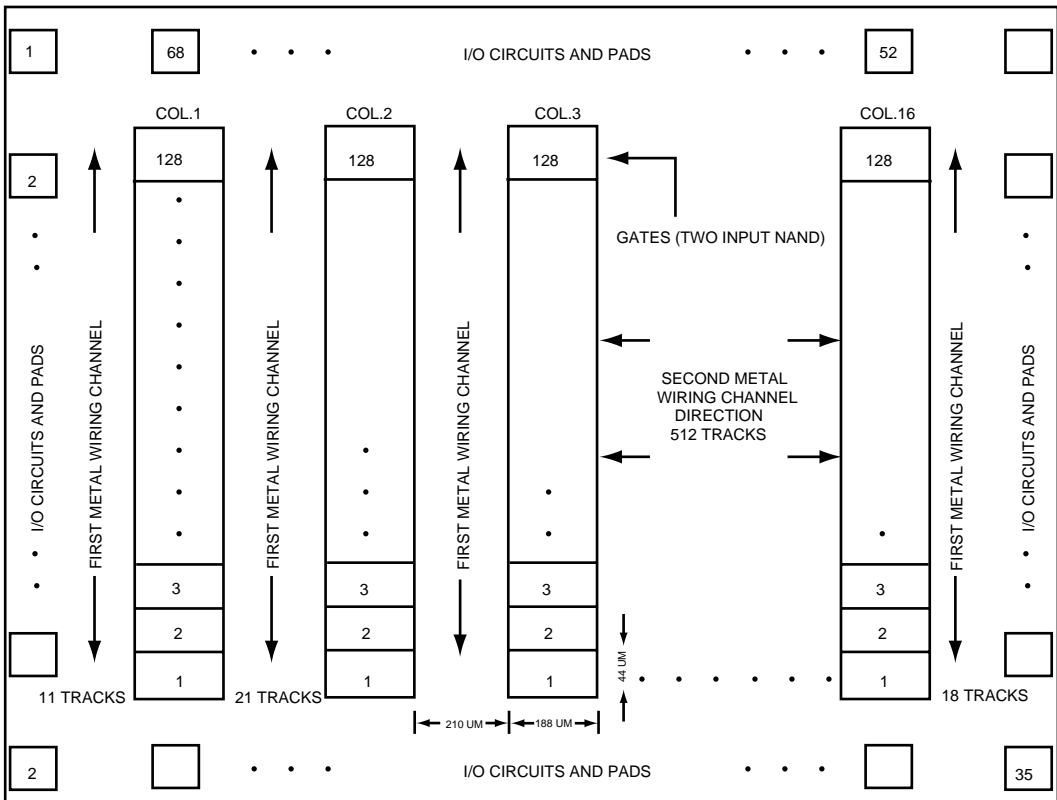

FIGURE 8.72 Schematic layout of a 2048-gates CMOS gate array.

the output AB , and for a 2048-gates array, the preceding formula gives $R = 23$. In this device 25 routes per gate are provided.

In the perimeter of the device 68 bond pads are arranged. Of these, 8 pads are needed for power and ground connections. Another empirical formula (Fier and Heikkila, 1982), based on Rent's rule, specifies that the number of I/O pads required to communicate effectively with the internal gates is given by

$$P = CG^a$$

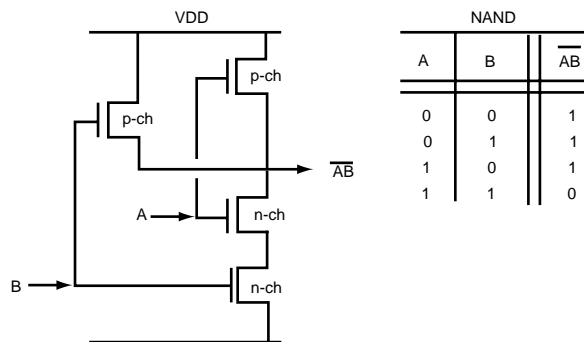

FIGURE 8.73 Electrical schematic of a CMOS NAND logic gate and its truth table.

FIGURE 8.74 Schematic layout of one of the 2048 uncommitted gates in a device column.

where P is the sum of input and output pads, C is again the number of connections per gate, G is the number of gates in the array and a is Rent's exponent having a value between 0.5 and 0.7. For large-scale integrated (LSI) circuits, typically $a = 0.46$. Assuming this value for a , then P is equal to 134 for $G = 2048$ and $C = 3$. This gate array, therefore, with only 60 I/O pads should be pad limited for many designs.

As mentioned previously, the process of designing with gate arrays begins with the designer drawing, with the aid of a CAD system, the circuit schematic representing the function the chip must perform. This activity is called **schematic capture**. The schematic, containing circuit elements or *cells*, such as inverters, NAND and NOR gates, flip-flops, adders, etc., is formed by getting these components from a specified library in the computer. Each of the cells has a number of representations associated with it. It has a schematic used, of course, in drawing up the complete circuit schematic. It has a functional description that specifies what the element does, for example, an inverter takes an 1 input and produces a 0 in its output and vice versa. Another file describes its electrical characteristics, such as the time delay between when the inputs reach a certain state and the time the output responds to that state, often referred to as the propagation delay, and it has a physical representation.

In the array shown in Fig. 8.72, before the customized layers are placed on the device, each of the 2048 gates appears schematically as shown in Fig. 8.74. There are two n-channel transistors on the left and two p-channel transistors on the right. There is also a ground or VSS buss line running vertically on the left and a VDD line on the right. Figure 8.75 shows the equivalent electrical schematic of the structure in Fig. 8.74. In Fig. 8.76 is shown only one pair of n- and p-channel transistors and locations within the device area where one of the customizing layers, the contacts, may be placed. The physical representation of a particular library cell contains information of how the uncommitted transistors in the device columns should be connected.

FIGURE 8.75 Equivalent electrical schematic of an uncommitted gate in the device column area of the gate array.

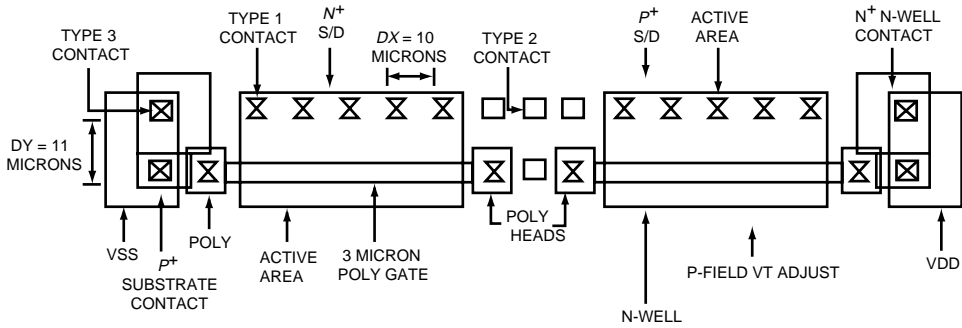

FIGURE 8.76 Layout of a single pair of n- and p-channel transistors in the device column showing how the contact locations are allocated.

As an example, in Fig. 8.77 is shown a portion of one of the 16 device columns in the array. [Figure 8.78](#) shows the location of the contact holes, shown as white squares, and the metal interconnects, for an inverter shown as the dark horizontal bars. An actual inverter circuit is realized by placing this inverter cell along anywhere in the column, as shown in [Fig. 8.79](#). [Figure 8.80](#) shows the electrical connections made in the gate array and in [Fig. 8.80\(b\)](#) is shown, for reference, the electric schematic for an inverter. Note that in [Fig. 8.79](#) and [Fig. 8.80](#), the polysilicon gates of the top and bottom n-channel transistors are connected to VSS

and the corresponding gates of the the p-channel transistors are connected to VDD. This is done to isolate the inverter from interfering electrically with another logic gate that may be placed above or below it.

Returning to the design process, after schematic capture is completed, the designer simulates the entire circuit first to verify that it performs the logic functions the circuit is designed to perform and then using the electrical specifications files, a timing simulation is performed to make sure the circuit will operate at the clock frequency desired. However, the timing simulation is not yet complete. In the electrical characteristics file of each cell, a typical input and load capacitance is assumed. In an actual circuit the load capacitance may be quite different. Therefore, another timing simulation must be done after the actual capacitance values are found for each node.

To do this, first from the circuit schematic, a *netlist* is extracted. This list contains exact information about which node of a given element is connected to which nodes of other elements. This netlist is then submitted to the *place and route* program. This program places all of the elements or cells in the circuit on the gate array, in a fashion similar to what was done in Fig. 8.79, and attempts to connect them as specified in the netlist. The program may iterate the placement of cells and interconnection or routing until all cells listed in the netlist are placed on the gate array and interconnected as specified.

The routing portion of the place and route program is called a *channel router*. It derives its name by the method it uses to interconnect the cells in the array. Also, the gate array architecture, shown in Fig. 8.72, with its vertical wiring channels and a single horizontal wiring channel, is selected so that this type of router can be used. Figure 8.81 shows the actual 2048-gates gate array, before customization and Fig. 8.82

FIGURE 8.81 Layout of the actual 2048-gates gate array before customization.

FIGURE 8.82 A custom circuit implementation on the 2048-gates gate array.

shows after it is completed with a custom circuit. In Fig. 8.83 a corner of the array is shown in higher magnification. The vertical darker lines are the first level metal interconnects and the horizontal lighter lines are the second level metal interconnects. This array requires four layers to be customized. These are the first and second level metals, contact, and the via. Vias are contacts exclusively between the two metal layers. Note that all internal wiring in the cells, like the inverter in Fig. 8.78, are made with first level metal and, therefore, the router is not allowed to route first level metal over the device areas.

Once the circuit is placed and routed, an extraction program is applied that does two things. First, it calculates the actual resistance and capacitance seen at each node of the circuit that is then fed back into the netlist for more accurate timing simulation; second, it extracts a new netlist of the circuit on the gate array that can be compared with the initial netlist. The two netlists should, of course, be identical. However, often manual intervention is required to finish either the placement or routing of a particularly difficult circuit and that could cause an inadvertent error to occur in the layout. The error is then detected by comparing this extracted netlist to the original one.

After the design is completed, **test vectors** must be generated. Two sets of test vectors are generated. The input set and the corresponding output set. Each test vector consists of a number of 1s and 0s. The input test vector has as many elements as the number of chip input pins and the output test vector, likewise, has as many elements as the number of output pins.

The input test vector is not, typically, similar to what the chip will see in actual operation. Instead, the goal is to select a set of input vectors that when applied to the chip will cause every internal node to change state at least once. The timing verification program is used for this task. The program keeps track of the nodes toggled, as each input vector is applied, and also saves the output vector. When the finished devices are received, the same input test vectors are applied in sequence, and the resulting output vectors are captured and

FIGURE 8.83 Closeup of a corner of the ASIC shown in Fig. 8.82.

compared to those obtained from the timing simulation runs. If the two match perfectly, the device is classified as good.

The purpose of this test is to detect whether, because of a defect during fabrication, an internal gate is not operating properly. Usually if a test can cause about 90% of the internal nodes to switch state, it is considered to provide adequate coverage. It would be desirable to have 100% coverage, but often this is not practical because of the length of time it would take for the test to be completed. Finally, because the test is done at the frequency at which the chip will operate, only minimal functional testing is performed.

Just as in the device columns any logic gate can be placed anywhere in any of the columns, each of the pads can serve as either an input, an output, or a power pad, again by customizing the four layers. Figure 8.84 shows an I/O buffer at the end of the prefabrication process. Figure 8.85 shows the contact and metal pattern to make the uncommitted pad an inverting output buffer and Fig. 8.86 shows the two together. Figure 8.87 shows the circuit schematic for the output buffer as well as the schematic when the pad is customized as an input buffer, the layout of which is shown in Fig. 8.88.

The gate array architecture presented here is not the only one. A number of different designs have been developed and are currently used. For each of the architectures, a different place and route algorithm is then developed to take advantage of that particular design. Gate arrays have also taken advantage of developments in silicon technology, which primarily consists of shrinking of the minimum dimensions. As a result, arrays with several million transistors per chip are presently in use.

Standard Cells

Designing with gate arrays is fairly straightforward and is utilized extensively by system engineers. However, gate arrays are quite inefficient in silicon area use since the number of transistors, the number of routing

FIGURE 8.84 Layout of an uncommitted I/O buffer. In this figure, the bonding pad is the rectangular pattern at the top, the n-channel transistor is on the left and the p-channel is located on the right.

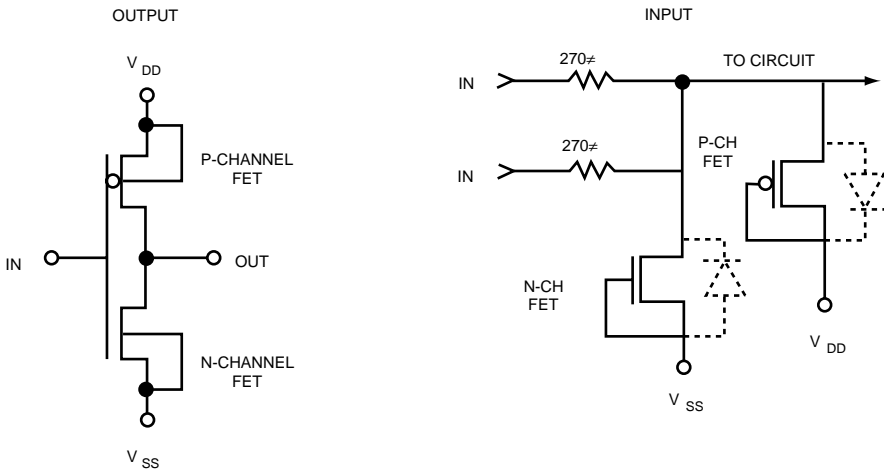

FIGURE 8.87 Electrical schematics of the input and output buffers. For TTL compatible output or input, or for other reasons, the buffers may use only some of the five segments of either the n- or p-channel transistors.

FIGURE 8.88 Completed layout of a simple noninverting input buffer.

tracks, and the number of I/O pads needed by a particular circuit does not always match the number of devices or pads on the array, which are, of course, fixed in number.

The standard cells design methodology was developed to address this problem. As was the case for gate arrays, a predesigned and characterized library of cells exists for the circuit designer to use. But, unlike gate arrays, the chip is laid out containing only the number of transistors and I/O pads specified by the particular circuit, resulting in a smaller, less expensive chip. Fabrication of a standard cells circuit, however, must start from the beginning of the process. This has two major drawbacks. First, the fabrication time for standard cells is several weeks longer than for gate arrays; second, the customer has to pay for the fabrication of the whole lot of wafers, whereas for gate arrays, only a small portion of the lot is processed for each customer. This substantially increases the cost of prototype parts.

Because standard cells are placed and routed automatically, the cells have to be designed with some restrictions, such as uniform height, preassigned locations for clocks and power lines, predefined input and output port locations, and others. Figure 8.89 shows the layout of three common cells from a standard cells library and Fig. 8.90 shows a completed standard cells chip. Its appearance is very similar to that of a gate array, but it contains no unused transistors or I/O pads and the minimum number of routing channels.

Functional Blocks

Advances in place and route software have made possible the functional blocks design methodology. Here the cells are no longer simple logic gates, but complete functions. The cells can be analog or digital and can have arbitrary sizes. Figure 8.91 shows an example of a digital functional block design. In the figure, the three white blocks are placed and routed automatically along with several rows of standard cells. In Fig. 8.92, a small linear charge-coupled device (CCD) image sensor, located in the center of the chip, and

FIGURE 8.89 Three standard cells. A two-input NAND gate is shown on the left, a D type flip-flop is in the middle, and a simple inverter is shown on the right.

FIGURE 8.90 Layout of a completed standard cell ASIC.

FIGURE 8.91 Layout of a digital functional block designed ASIC.

FIGURE 8.92 Layout of a mixed (combined analog and digital circuits on the same chip) functional block designed ASIC.

a few other analog circuits, located below it, are placed on the same chip with a block of standard cells that C produce all of the logic needed to run the chip. In this chip, care is taken as to both the placement of the various blocks and the routing because of the sensitivity of the analog circuits to noise, temperature, and other factors. Therefore, the designer had considerable input as to the placement of the various blocks and the routing, and the software is designed to allow this intervention, when needed.

Often the digital functional blocks are built by a class of software programs called **silicon compilers** or **synthesis tools**. With such tools circuit designers typically describe the functionality of their circuit at the behavioral level rather than the gate level, using specially developed computer languages called *hardware description languages* (HDL). These tools can quickly build memory blocks of arbitrary size, adders or multipliers of any length, PLAs, and many other circuits.

It should be obvious by now that the semicustom design approach makes heavy use of software tools. These tools eliminate the tedious and error prone task of hand layout, provide accurate circuit simulation, and help with issues such as testability. Their power and sophistication make transparent the complexity inherent in the design of integrated circuits.

Analog Arrays

Analog arrays are typically made in a bipolar process and are intended for the fabrication of high-performance analog circuits. Like gate arrays, these devices are prefabricated up to the contact level and, like all semicustom approaches, they are provided with a predesigned and characterized cell library. Because of the infinite variety of analog circuits, however, designers often design many of their own cells or modify the ones provided. Unlike digital circuits, the layout is done manually because analog circuits are more sensitive to temperature gradients, power supply voltage drops, crosstalk, and other factors and because the presently available software is not sufficiently sophisticated to take all of these factors into account.

The architecture of analog arrays is *tile* like, as shown in Fig. 8.93. Each tile is identical to all other tiles. Within each tile is contained a number of transistors, resistors, and capacitors of various sizes. The array also contains a fixed number of I/O pads, each of which can be customized with the last four layers to serve either as an input or output buffer. Figure 8.94 shows an actual circuit (Boisvert and Gaboury, 1992) implemented in a commercially available analog array.

FIGURE 8.93 Architecture of an analog array.

FIGURE 8.94 Example of an ASIC (Boisvert and Gaboury, 1992) implemented in a commercially available analog array.

Defining Terms

ASICs: The acronym of *application specific integrated circuits*; another name for such chips is *custom integrated circuits*.

Functional blocks: ASICs designed using this methodology are more compact than either gate arrays or standard cells because the blocks can perform much more complex functions than do simple logic gates.

Gate arrays: Chips that contain uncommitted arrays of transistors and are prefabricated up to a certain step after which they are customized for the particular application.

Nonrecurring engineering (NRE): Costs the foundry charges the ASIC customer. These costs include engineering time, the cost of making the masks, the cost of fabricating one lot of wafers, and for packaging and testing the prototype parts.

Standard cells: A design methodology for realizing ASICs. Compared to gate arrays, they make more efficient use of silicon.

Schematic capture: The process by which the functionality of the chip is captured in an electrical schematic, usually with the aid of a computer, and using components from a cell library resident in that computer.

Silicon compilers, synthesis tools: Software programs that can construct an ASIC whose functionality is no longer described by a circuit schematic but in a special high level computer languages, generally called hardware description languages or HDL.

Test vectors: A test scheme that consists of pairs of input and output. Each input vector is a unique set of 1s and 0s applied to the chip inputs and the corresponding output vector is the set of 1s and 0s produced at each of the chip's output.

Further Information

The ASIC field has been expanding rapidly since about 1980. The best source of current information is the two major conferences where the more recent technology developments are reported. These are the IEEE Custom Integrated Circuits Conference (CICC) held annually in May and the IEEE International ASIC Conference and Exhibit, held annually in September. *IEEE Spectrum Magazine* lists these conferences in the calendar of events. Apart from the regular technical sessions, educational sessions and exhibits by ASIC vendors are part of these two conferences.

An additional resource is the USC/Information Sciences Institute, 4676 Admiralty Way, Marina del Rey, CA 90292-6695, Telephone (213) 822-1511.

Finally, a selected number of papers from the CICC are published every year, since 1984, in special issues of the *IEEE Journal of Solid State Circuits*.

Additional information can also be found in a number of other conferences and their proceedings, including the Design Automation Conference (DAC) and the International Solid States Circuits Conference (ISSCC).

8.8 Digital Filters

Jonathon A. Chambers, Sawasd Tantaratana and Bruce W. Bomar

8.8.1 Introduction

Digital filtering is concerned with the manipulation of discrete data sequences to remove noise, extract information, change the sample rate, and perform other functions. Although an infinite number of numerical manipulations can be applied to discrete data (e.g., finding the mean value, forming a histogram), the objective of digital filtering is to form a discrete output sequence $y(n)$ from a discrete input sequence $x(n)$. In some manner or another, each output sample is computed from the input sequence—not just from any one sample, but from many, in fact, possibly from all of the input samples. Those filters that compute their output from the present input and a finite number of past inputs are termed *finite impulse response* (FIR), whereas those that use all past inputs are *infinite impulse response* (IIR). This chapter will consider the design and realization of both FIR and IIR digital filters and will examine the effect of finite wordlength arithmetic on implementing these filters.

8.8.2 FIR Filters

A finite impulse response filter is a linear discrete time system that forms its output as the weighted sum of the most recent, and a finite number of past, inputs. Time-invariant FIR filters have finite memory,

and their impulse response, namely, their response to a discrete input that is unity at the first sample and otherwise zero, matches the fixed weighting coefficients of the filter. Time-variant FIR filters, on the other hand, may operate at various sampling rates and/or have weighting coefficients that adapt in sympathy with some statistical property of the environment in which they are applied.

Fundamentals

Perhaps the simplest example of an FIR filter is the moving average operation described by the following linear constant-coefficient difference equation:

$$y(n) = \sum_{k=0}^M b_k x(n-k) \quad b_k = \frac{1}{M+1}$$

where

$y(n)$ = output of the filter at integer sample index n

$x(n)$ = input to the filter at integer sample index n

b_k = filter weighting coefficients, $k = 0, 1, \dots, M$

M = filter order

In a practical application, the input and output discrete-time signals is sampled at some regular sampling time interval, T seconds, denoted $x(nT)$ and $y(nT)$, which is related to the sampling frequency by $f_s = 1/T$ samples per second. For generality, however, it is more convenient to assume that T is unity, so that the effective sampling frequency is also unity and the Nyquist frequency (Oppenheim and Schaffer, 1989), namely, the maximum analog frequency that when sampled at f_s will not yield an aliasing distortion, is one-half. It is then straightforward to scale, by multiplication, this normalized frequency range, that is, $(0, 1/2)$, to any other sampling frequency.

The output of the simple moving average filter is the average of the $M+1$ most recent values of $x(n)$. Intuitively, this corresponds to a smoothed version of the input, but its operation is more appropriately described by calculating the frequency response of the filter. First, however, the z -domain representation of the filter is introduced in analogy to the s - (or Laplace-) domain representation of analog filters. The z transform of a causal discrete-time signal $x(n)$ is defined by

$$X(z) = \sum_{n=0}^{\infty} x(n)z^{-n}$$

where $X(z)$ is z transform of $x(n)$ and z is complex variable

The z transform of a delayed version of $x(n)$, namely, $x(n-k)$ with k a positive integer, is found to be given by $z^{-k}X(z)$. This result can be used to relate the z transform of the output $y(n)$ of the simple moving average filter to its input

$$Y(z) = \sum_{k=0}^M b_k z^{-k} X(z) \quad b_k = \frac{1}{M+1}$$

The z -domain transfer function, namely, the ratio of the output to input transform, becomes

$$H(z) = \frac{Y(z)}{X(z)} = \sum_{k=0}^M b_k z^{-k} \quad b_k = \frac{1}{M+1}$$

Notice the transfer function $H(z)$ is entirely defined by the values of the weighting coefficients $b_k, k = 0, 1, \dots, M$, which are identical to the discrete impulse response of the filter, and the complex variable z . The finite length of the discrete impulse response means that the transient response of the filter only lasts for $M+1$ samples, after which steady state is reached. The frequency domain transfer function for the

FIGURE 8.95 The magnitude and phase response of the simple moving average filter with $M = 7$.

filter is found by setting $z = e^{j2\pi f}$, where $j = \sqrt{-1}$, and can be written as

$$H(e^{j2\pi f}) = \frac{1}{M + 1} \sum_{k=0}^M e^{-j2\pi f k} = \frac{1}{M + 1} e^{-j\pi f M} \frac{\sin[\pi f(M + 1)]}{\sin(\pi f)}$$

The magnitude and phase response of the simple moving average filter, with $M = 7$, are calculated from $H(e^{j2\pi f})$ and shown in Fig. 8.95. The filter is seen clearly to act as a crude low-pass, smoothing filter with a **linear-phase** response. The sampling frequency periodicity in the magnitude and phase response is a property of discrete-time systems. The linear-phase response is due to the $e^{-j\pi f M}$ term in $H(e^{j2\pi f})$ and corresponds to a constant $M/2$ group delay through the filter. A phase discontinuity of $\pm 180^\circ$ is introduced each time the magnitude term changes sign. FIR filters that have center symmetry in their weighting coefficients have this constant, frequency independent group delay property that is very desirable in applications in which time dispersion is to be avoided, for example, in pulse transmission where it is important to preserve pulse shapes (Lee and Messerschmit, 1994).

Another useful interpretation of the z -domain transfer function is obtained by re-writing $H(z)$ as follows:

$$H(z) = \frac{\sum_{k=0}^M b_k z^{M-k}}{z^M} = \frac{b_0 z^M + b_1 z^{M-1} + \dots + b_{M-1} z + b_M}{z^M} = \frac{N(z)}{D(z)}$$

The z -domain transfer function is shown to be the ratio of two M th-order polynomials in z , namely, $N(z)$ and $D(z)$. The values of z for which $N(z) = 0$ are termed the zeros of the filter, whereas those for which $D(z) = 0$ are the poles. The poles of such an FIR filter are at the origin, that is, $z = 0$, in the z plane. The positions of the zeros are determined by the weighting coefficients, that is, $b_k, k = 0, 1, \dots, M$. The poles and zeros in the z plane for the simple moving average filter are shown in Fig. 8.96. The zeros, marked with a circle, are coincident with the unit circle, that is, the contour in the z plane for which

$|z| = 1$, and match exactly the zeros in the magnitude response, hence their name; the discontinuities in the phase response are shown in Fig. 8.95. The zeros of an FIR filter may lie anywhere in the z plane because they do not impact on the stability of the filter; however, if the weighting coefficients are real and symmetric, or anti-symmetric, about their center value $M/2$, any complex zeros of the filter are constrained to lie as conjugate pairs coincident with the unit circle or as quartets of roots off the unit circle with the form $(\rho e^{j\theta}, \rho e^{-j\theta}, (1/\rho)e^{j\theta}, (1/\rho)e^{-j\theta})$ where ρ and θ are, respectively, the radius and angle of the first zero. Zeros that lie within the unit circle are termed *minimum phase*, whereas those which lie outside the unit circle are called *maximum phase*. This distinction describes the contribution made by a particular zero

FIGURE 8.96 The pole-zero plot for the simple moving average filter with $M = 7$.

to the overall phase response of a filter. A minimum-phase FIR filter that has all its zeros within the unit circle can have identical magnitude response to a maximum-phase FIR that has all its zeros outside the unit circle for the special case when they have an equal number of zeros with identical angles but reciprocal radii. An example of this would be second-order FIR filters with z -domain transfer functions $H_{\min}(z) = 1 + 0.5z^{-1} + 0.25z^{-2}$ and $H_{\max}(z) = 0.25 + 0.5z^{-1} + z^{-2}$. Notice that the center symmetry in the coefficients is lost, but the minimum- and maximum-phase weighting coefficients are simply reversed. Physically, a minimum-phase FIR filter corresponds to a system for which the energy is rapidly transferred from its input to its output, hence, the large initial weighting coefficients; whereas a maximum-phase FIR filter is slower to transfer the energy from its input to output; as such, its larger coefficients are delayed. Such FIR filters are commonly used for modeling multipath mobile communication transmission paths.

The characteristics of the frequency response of an FIR filter are entirely defined by the values of the weighting coefficients $b_k, k = 0, 1, \dots, M$, which match the impulse response of the filter, and the order M . Various techniques are available for designing these coefficients to meet the specifications of some application. However, next consider the structures available for realizing an FIR filter.

Structures

The structure of an FIR filter must realize the z -domain transfer function given by

$$H(z) = \sum_{k=0}^M b_k z^{-k}$$

where z^{-1} is a unit delay operator. The building blocks for such filters are, therefore, adders, multipliers, and unit delay elements. Such elements do not have the disadvantages of analog components such as capacitors, inductors, operational amplifiers, and resistors, which vary with temperature and age. The direct or tapped-delay line form, as shown in Fig. 8.97, is the most straightforward realization of an FIR filter. The input $x(n)$ is delayed, scaled by the weighting coefficients $b_k, k = 0, 1, \dots, M$, and accumulated to yield the output.

An equivalent, but transposed, structure of an FIR filter is shown in Fig. 8.98, which is much more modular and well suited to integrated circuit realization. Each module within the structure calculates a partial sum so that only a single addition is calculated at the output stage.

Other structures are possible that exploit symmetries or redundancies in the filter weighting coefficients. For example, FIR filters with linear phase have symmetry about their center coefficient $M/2$; approximately one-half of the coefficients of an odd length, that is, M even, half-band FIR filter, namely, a filter that

FIGURE 8.97 Direct form structure of an FIR filter.

FIGURE 8.98 Modular structure of an FIR filter.

ideally passes frequencies for $0 \leq f \leq 1/4$ and stops frequencies $1/4 < f \leq 1/2$, are zero. Finally, a lattice structure as shown in Fig. 8.99 may be used to realize an FIR filter. The multiplier coefficients within the lattice $k_j, j = 1, \dots, M$, are not identical to the weighting coefficients of the other FIR filter structures but can be found by an iterative procedure. The attraction of the lattice structure is that it is straightforward to test whether all its zeros lie within the unit circle, namely, the minimum-phase property, and it has low sensitivity to quantization errors. These properties have motivated the use of lattice structures in speech coding applications (Rabiner and Schafer, 1978).

Design Techniques

Linear-phase FIR filters can be designed to meet various filter specifications, such as low-pass, high-pass, band-pass and bandstop filtering. For a low-pass filter, two frequencies are required, namely, the maximum frequency of the pass band below which the magnitude response of the filter is approximately unity, denoted the pass-band corner frequency f_p , and the minimum frequency of the stop band above

FIGURE 8.99 Lattice structure of an FIR filter.

which the magnitude response of the filter must be less than some prescribed level, named the stop-band corner frequency f_s . The difference between the pass- and stop-band corner frequencies is the *transition-bandwidth*. Generally, the order of FIR filter M required to meet some design specification increases with a reduction in the width of the transition band. There are three established techniques for coefficient design:

- Windowing
- Frequency sampling
- Optimal approximations

The windowing design method calculates the weighting coefficients by sampling the ideal impulse response of an analog filter and multiplying these values by a smoothing window to improve the overall frequency domain response of the filter. The frequency sampling technique samples the ideal frequency domain specification of the filter and calculates the weighting coefficients by inverse transforming these values. However, better results can generally be obtained with the optimal approximations method. The impulse response and magnitude response for a 40th-order optimal half-band FIR low-pass filter designed with the Parks-McClellan algorithm are shown in Fig. 8.100 together with the ideal frequency domain design specification. Notice the zeros in the impulse response. This algorithm minimizes the maximum deviation of the **magnitude response** of the design filter from the ideal magnitude response. The magnitude response of the design filter alternates about the desired specification within the pass band and above the specification in the stop band. The maximum deviation from the desired specification is equalized across the pass and stop bands; this is characteristic of an optimal solution.

The optimal approximation approach can also be used to design *discrete-time differentiators* and *hilbert transformers*, namely, phase shifters. Such filters find extensive application in digital modulation schemes.

Multirate and Adaptive FIR Filters

FIR filter structures can be combined very usefully with multirate processing elements. Such a filtering scheme is, however, time variant and as such may introduce some distortion during processing, but with careful design this can be minimized. Consider the design of a low-pass filter with $f_c = 1/8$; frequencies above this value are essentially to be eliminated. The frequency range between f_c and the Nyquist frequency, that is, $1/2$, therefore contains no useful information. The sampling frequency could, provided no aliasing distortion is introduced, therefore be usefully reduced by a factor of 4. Further processing, possibly adaptive, of the signal could then proceed at this reduced rate, hence, reducing the demands on the system design. This operation can be achieved in two ways: A time-invariant low-pass FIR filter, with $f_c = 1/8$, can be designed to operate at the original sampling rate, and its output can be down sampled, termed decimated, by a factor of four; or, more efficiently, the filtering can be performed in two stages, using the same simple half-band filter design twice, each operating at a lower sampling rate. These methods are shown diagrammatically in Fig. 8.101. The second scheme has considerable computational advantages and, because of the nature of

FIGURE 8.100 Impulse and magnitude response of an optimal 40th-order half-band FIR filter.

FIGURE 8.101 Multirate FIR low-pass filter structures: (a) method 1, (b) method 2.

half-band filters, it is also possible to move the decimators in front of the filters. With the introduction of modulation operations it is possible to use the same approach to achieve high-pass and band-pass filtering.

The basic structure of an **adaptive FIR filter** is shown in Fig. 8.102. The input to the adaptive filter $x(n)$ is used to make an estimate $\hat{d}(n)$ of the desired response $d(n)$. The difference between these quantities $e(n)$, is used by the adaptation algorithm to control the weighting coefficients of the FIR filter. The derivation of the desired response signal depends on the application; in channel equalization, as necessary for reliable communication with data modems, it is typically a training sequence known to the receiver. The weighting coefficients are adjusted to minimize some function of the error, such as the mean square value. The most commonly used adaptive algorithm is the least mean square (lms) algorithm that approximately minimizes the mean square error. Such filters have the ability to adapt to time-varying environments where fixed filters are inappropriate.

FIGURE 8.102 Adaptive FIR filter structure.

Applications

The absence of drift in the characteristics of digitally implemented FIR filters, their ability to reproduce, multirate realizations, and their ability to adapt to time-varying environments has meant that they have found many applications, particularly in telecommunications, for example, in receiver and transmitter design, speech compression and coding, and channel multiplexing. The primary advantages of fixed coefficient FIR filters are their unconditional stability due to the lack of feedback within their structure and their exact linear-phase characteristics. Nonetheless, for applications that require sharp, selective, filtering in standard form, they do require relatively large orders. For some applications, this may be prohibitive and, therefore, recursive; IIR filters are a valuable alternative.

8.8.3 Infinite Impulse Response (IIR) Filters

A digital filter with impulse response having infinite length is called an *infinite impulse response* (IIR) filter. An important class of IIR filters can be described by the difference equation

$$y(n) = b_0x(n) + b_1x(n - 1) + \dots + b_Mx(n - M) - a_1y(n - 1) - a_2y(n - 2) - \dots - a_Ny(n - N) \quad (8.27)$$

where $x(n)$ is the input, $y(n)$ is the output of the filter, and (a_1, a_2, \dots, a_N) and (b_0, b_1, \dots, b_M) are real-value coefficients.

We denote the impulse response by $h(n)$, which is the output of the system when it is driven by a unit impulse at $n = 0$, with the system being initially at rest. The system function $H(z)$ is the z transform of

$h(n)$. For the system in Eq. (8.27), it is given by

$$H(z) = \frac{Y(z)}{X(z)} = \frac{b_0 + b_1z^{-1} + \dots + b_Mz^{-M}}{1 + a_1z^{-1} + a_2z^{-2} + \dots + a_Nz^{-N}} \tag{8.28}$$

where N is called the filter order. Equation (8.28) can be put in the form of poles and zeros as

$$H(z) = b_0z^{N-M} \frac{(z - q_1)(z - q_2) \dots (z - q_M)}{(z - p_1)(z - p_2) \dots (z - p_N)} \tag{8.29}$$

The poles are at p_1, p_2, \dots, p_N . The zeros are at q_1, q_2, \dots, q_M , as well as $N - M$ zeros at the origin.

The frequency response of the IIR filter is the value of the system function evaluated on the unit circle on the complex plane, that is, with $z = e^{j2\pi f}$, where f varies from 0 to 1, or from $-1/2$ to $1/2$. The variable f represents the digital frequency. For simplicity, we write $H(f)$ for $H(z)|_{z=\exp(j2\pi f)}$. Therefore

$$H(f) = b_0e^{j2\pi(N-M)f} \frac{(e^{j2\pi f} - q_1)(e^{j2\pi f} - q_2) \dots (e^{j2\pi f} - q_M)}{(e^{j2\pi f} - p_1)(e^{j2\pi f} - p_2) \dots (e^{j2\pi f} - p_N)} \tag{8.30}$$

$$= |H(f)|e^{j\theta(f)} \tag{8.31}$$

where $|H(f)|$ is the magnitude response and $\theta(f)$ is the phase response.

Compared to an FIR filter, an IIR filter requires a much lower order than an FIR filter to achieve the same requirement of the magnitude response. However, whereas an FIR filter is always stable, an IIR filter can be unstable if the coefficients are not properly chosen. Assuming that the system (8.27) is causal, then it is stable if all of the poles lie inside the unit circle on the z plane. Since the phase of a stable causal IIR filter cannot be made linear, FIR filters are chosen over IIR filters in applications where linear phase is essential.

Realizations

Equation (8.27) suggests a realization of an IIR filter as shown in Fig. 8.103(a), which is called direct form I. By rearranging the structure, we can obtain direct form II, as shown in Fig. 8.103(b). Through transposition, we can obtain transposed direct form I and transposed direct form II, as shown in Fig. 8.103(c) and Fig. 8.103(d).

The system function can be put in the form

$$H(z) = \prod_{i=0}^K \frac{b_{i0} + b_{i1}z^{-1} + b_{i2}z^{-2}}{1 + a_{i1}z^{-1} + a_{i2}z^{-2}} \tag{8.32}$$

by factoring the numerators and denominators into second-order factors, or in the form

$$H(z) = c_0 + \sum_{i=1}^K \frac{b_{i0} + b_{i1}z^{-1}}{1 + a_{i1}z^{-1} + a_{i2}z^{-2}} \tag{8.33}$$

by partial fraction expansion. The value of K is $N/2$ when N is even, and it is $(N + 1)/2$ when N is odd. When N is odd, one of a_{i2} must be zero, as well as one of b_{i2} in Eq. (8.32) and one of b_{i1} in Eq. (8.33). According to Eq. (8.32), the IIR filter can be realized by K second-order IIR filters in cascade, as shown in Fig. 8.104(a). According to Eq. (8.33), the IIR filter can be realized by K second-order IIR filters and one scaler (i.e., c_0) in parallel, as depicted in Fig. 8.104(b). Each second-order subsystem can use any of the structures given in Fig. 8.103.

There are other realizations for IIR filters, such as state-space structure, wave structure, and lattice structure. See the references for details. In some situations, it is more convenient or suitable to use software realizations that are implemented by a digital signal processor.

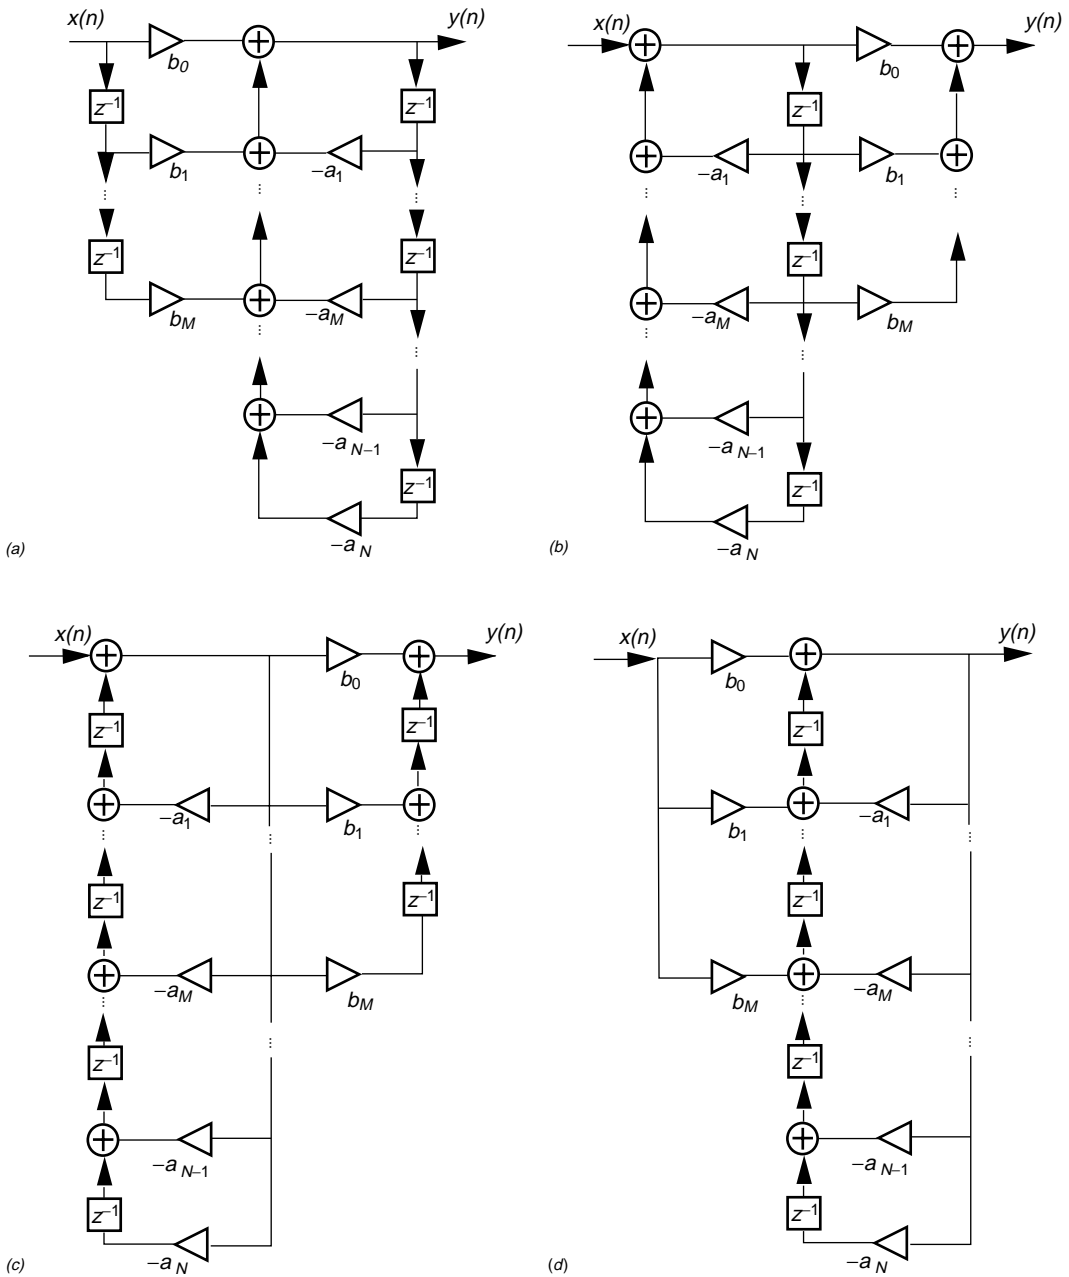

FIGURE 8.103 Direct form realizations of IIR filters: (a) direct form I, (b) direct form II, (c) transposed direct form I, (d) transposed direct form II.

IIR Filter Design

Designing an IIR filter involves choosing the coefficients to satisfy a given specification, usually a magnitude response specification. We assume that the specification is in the form depicted by Fig. 8.105, where the magnitude square must be in the range $(1/(1 + \epsilon^2), 1)$ in the pass band and it must be no larger than δ^2 in the stop band. The pass-band and the stop-band edges are denoted by f_p and f_s , respectively. No constraint is imposed on the response in the transition band, which lies between a pass band and a stop band.

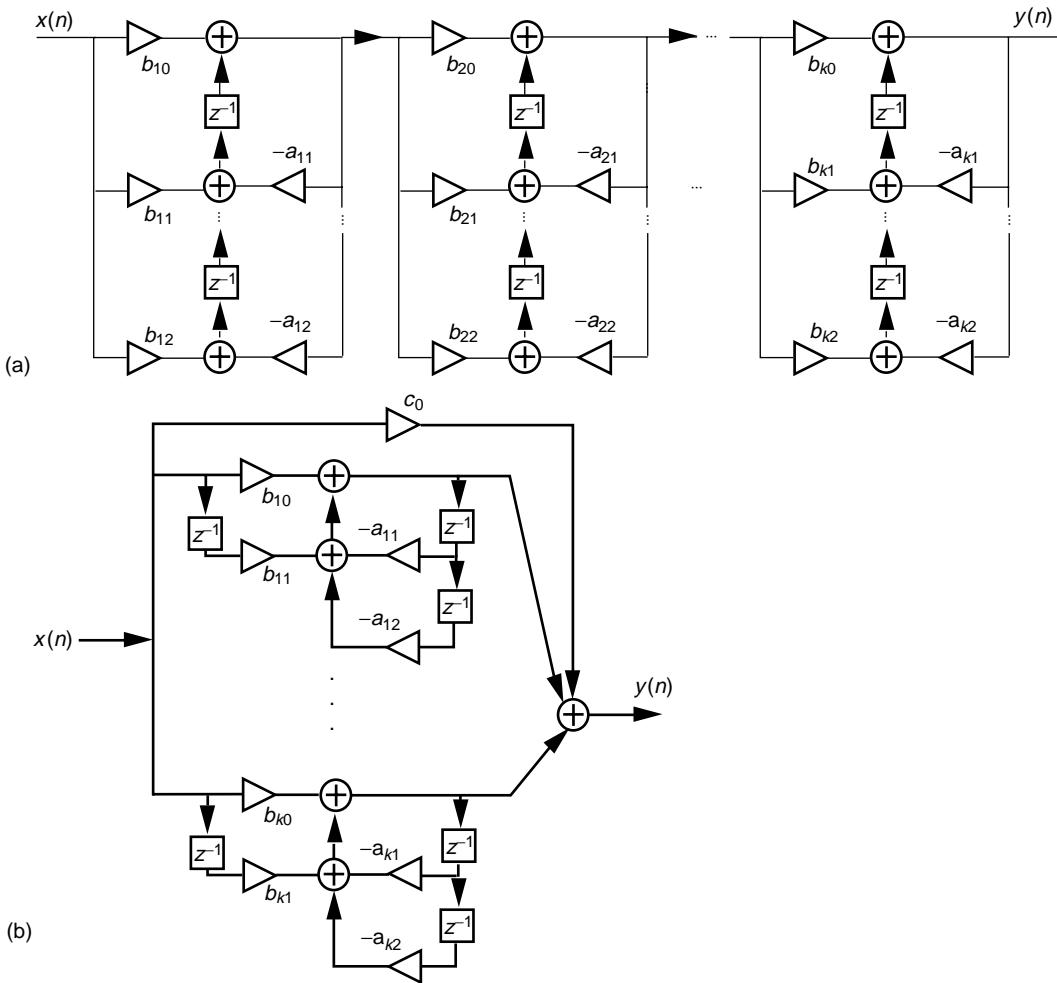

FIGURE 8.104 Realizations of IIR filters: (a) cascade form, (b) parallel form.

There are various IIR filter design methods: design using an analog prototype filter, design using digital frequency transformation, and computer-aided design. In the first method, an analog filter is designed to meet the (analog) specification and the analog filter transfer function is transformed to digital system function. The second method assumes that some digital low-pass filter is available and the desired digital filter is obtained from the digital low-pass filter by a digital frequency transformation. The last method involves algorithms that choose the coefficients so that the response is as close (in some sense) as possible to the desired filter. The first two methods are simple to do, and they are suitable for designing standard filters (low-pass, high-pass, bandpass, and bandstop filters). A computer-aided design requires computer programming, but it can be used to design standard and nonstandard filters. We will focus only on the first method and present some design examples, as well as a summary of some analog filters, in the following sections.

Analog Filters

Here, we summarize three basic types of analog low-pass filters that can be used as prototype for designing IIR filters. For each type, we give the transfer function, its magnitude response, and the order N needed to satisfy the (analog) specification. We use $H_a(s)$ to denote the transfer function of an analog filter,

FIGURE 8.105 Specifications for digital IIR filters: (a) low-pass filter, (b) high-pass filter, (c) bandpass filter, (d) bandstop filter.

where s is the complex variable in the Laplace transform. Each of these filters have all its poles on the left-half s plane, so that it is stable. We use the variable λ to represent the analog frequency in radians/second. The frequency response $H_a(\lambda)$ is the transfer function evaluated at $s = j\lambda$.

The analog low-pass filter specification, as shown in Fig. 8.106, is given by

$$\begin{aligned}
 (1 + \epsilon^2)^{-1} \leq |H_a(\lambda)|^2 \leq 1 & \quad \text{for } 0 \leq (\lambda/2\pi) \leq (\lambda_p/2\pi) \text{ Hz} \\
 0 \leq |H_a(\lambda)|^2 \leq \delta^2 & \quad \text{for } (\lambda_s/2\pi) \leq (\lambda/2\pi) < \infty \text{ Hz}
 \end{aligned}
 \tag{8.34}$$

where λ_p and λ_s are the pass-band edge and stop-band edge, respectively.

FIGURE 8.106 Specification for an analog low-pass filter.

FIGURE 8.107 Magnitude responses of low-pass analog filters: (a) Butterworth filter, (b) Chebyshev filter, (c) inverse Chebyshev filter.

Butterworth Filters

The transfer function of an N th-order Butterworth filter is given by

$$H_a(s) = \begin{cases} \prod_{i=1}^{N/2} \frac{1}{(s/\lambda_c)^2 - 2\text{Re}(s_i)(s/\lambda_c) + 1}, & N = \text{even} \\ \frac{1}{(s/\lambda_c) + 1} \prod_{i=1}^{(N-1)/2} \frac{1}{(s/\lambda_c)^2 - 2\text{Re}(s_i)(s/\lambda_c) + 1}, & N = \text{odd} \end{cases} \quad (8.35)$$

where $s_i = \exp\{j[1 + (2i - 1)/N]\pi/2\}$ and λ_c is the frequency where the magnitude drops by 3 dB. The magnitude response square is

$$|H_a(\lambda)|^2 = [1 + (\lambda/\lambda_c)^{2N}]^{-1} \quad (8.36)$$

Figure 8.107(a) shows the magnitude response $|H_a(\lambda)|$. To satisfy the specification in Eq. (8.34), the filter order is

$$N = \text{integer} \geq \frac{\log [\varepsilon/(\delta^{-2} - 1)^{\frac{1}{2}}]}{\log[\lambda_p/\lambda_s]} \quad (8.37)$$

and the value of λ_c is chosen from the following range:

$$\lambda_p \varepsilon^{-1/N} \leq \lambda_c \leq \lambda_s (\delta^{-2} - 1)^{-1/(2N)} \quad (8.38)$$

Chebyshev Filters (Type I Chebyshev Filters)

The N th-order Chebyshev filter has a transfer function given by

$$H_a(s) = C \prod_{i=1}^N \frac{1}{(s - p_i)} \quad (8.39)$$

where

$$p_i = -\lambda_p \sinh(\phi) \sin\left(\frac{2i - 1}{2N} \pi\right) + j \lambda_p \cosh(\phi) \cos\left(\frac{2i - 1}{2N} \pi\right) \quad (8.40)$$

$$\phi = \frac{1}{N} \ln \left[\frac{1 + (1 + \varepsilon^2)^{\frac{1}{2}}}{\varepsilon} \right] \quad (8.41)$$

and where $C = -\prod_{i=1}^N p_i$ when N is odd and $(1 + \varepsilon^2)^{-\frac{1}{2}} \prod_{i=1}^N p_i$ when N is even. Note that C normalizes the magnitude so that the maximum magnitude is 1. The magnitude square can be written as

$$|H_a(\lambda)|^2 = [1 + \varepsilon^2 T_N^2(\lambda/\lambda_p)]^{-1} \tag{8.42}$$

where $T_N(x)$ is the N th-degree Chebyshev polynomial of the first kind that is given recursively by $T_0(x) = 1, T_1(x) = x$, and $T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x)$ for $n \geq 1$. Figure 8.107(b) shows an example of the magnitude response square. Notice that there are equiripples in the pass band. The filter order required to satisfy Eq. (8.34) is

$$N \geq \frac{\log \{ [(\delta^{-2} - 1)^{\frac{1}{2}}/\varepsilon] + [(\delta^{-2} - 1)/\varepsilon^2 - 1]^{\frac{1}{2}} \}}{\log \{ (\lambda_s/\lambda_p) + [(\lambda_s/\lambda_p)^2 - 1]^{\frac{1}{2}} \}} \tag{8.43}$$

which can be computed knowing $\varepsilon, \delta, \lambda_p$, and λ_s .

Inverse Chebyshev Filters (Type II Chebyshev Filters)

For inverse Chebyshev filters, the equiripples are inside the stop band, as opposed to the pass band in the case of Chebyshev filters. The magnitude response square of the inverse Chebyshev filter is

$$|H_a(\lambda)|^2 = [1 + (\delta^{-2} - 1)/T_N^2(\lambda_s/\lambda)]^{-1} \tag{8.44}$$

Figure 8.107(c) depicts an example of Eq. (8.44). The value of $|H_a(\infty)|$ equals 0 if N is odd, and it equals δ if N is even. The transfer function giving rise to Eq. (8.44) is

$$H_a(s) = \begin{cases} C \prod_{i=1}^N \frac{(s - q_i)}{(s - p_i)}, & N \text{ is even} \\ \frac{C}{(s - p_{(N+1)/2})} \prod_{\substack{i=1 \\ i \neq (N+1)/2}}^N \frac{(s - q_i)}{(s - p_i)}, & N \text{ is odd} \end{cases} \tag{8.45}$$

where

$$p_i = \frac{\lambda_s}{\alpha_i^2 + \beta_i^2} (\alpha_i - j\beta_i); \quad q_i = j \frac{\lambda_s}{\cos\left(\frac{2i - 1}{2N} \pi\right)} \tag{8.46}$$

$$\alpha_i = -\sinh(\phi) \sin\left(\frac{2i - 1}{2N} \pi\right); \quad \beta_i = \cosh(\phi) \cos\left(\frac{2i - 1}{2N} \pi\right) \tag{8.47}$$

$$\phi = \frac{1}{N} \cosh^{-1}(\delta^{-1}) = \frac{1}{N} \ln[\delta^{-1} + (\delta^{-2} - 1)^{\frac{1}{2}}] \tag{8.48}$$

and where

$$C = \prod_{i=1}^N (p_i/q_i)$$

when N is even and

$$C = -p_{(N+1)/2} \prod_{\substack{i=1 \\ i \neq (N+1)/2}}^N (p_i/q_i)$$

when N is odd. The filter order N required to satisfy Eq. (8.34) is the same as that for the Chebyshev filter, which is given by Eq. (8.43).

Comparison

In comparison, the Butterworth filter requires a higher order than both types of Chebyshev filters to satisfy the same specification. There is another type of filters called elliptic filters (Cauer filters) that have equiripples in the pass band as well as in the stop band. Because of the lengthy expressions, this type of filters is not given here (see the references). The Butterworth filter and the inverse Chebyshev filter have better (closer to linear) phase characteristics in the pass band than Chebyshev and elliptic filters. Elliptic filters require a smaller order than Chebyshev filters to satisfy the same specification.

Design Using Bilinear Transformations

One of the most simple ways of designing a digital filter is by way of transforming an analog low-pass filter to the desired digital filter. Starting from the desired digital filter specification, the low-pass analog specification is obtained. Then, an analog low-pass filter $H_a(s)$ is designed to meet the specification. Finally, the desired digital filter is obtained by transforming $H_a(s)$ to $H(z)$. There are several types of transformation. The all-around best one is the bilinear transformation, which is the subject of this subsection.

In a bilinear transformation, the variable s in $H_a(s)$ is replaced with a bilinear function of z to obtain $H(z)$. Bilinear transformations for the four standard types of filters, namely, low-pass filter (LPF), high-pass filter (HPF), bandpass filter (BPF), and bandstop filter (BSF), are shown in Table 8.8. The second column in the table gives the relations between the variables s and z . The value of T can be chosen arbitrarily without affecting the resulting design. The third column shows the relations between the analog

TABLE 8.8 Bilinear Transformations for Standard Digital Filters

	Transformation (between s and z)	Frequency Relations (between f and λ)	Analog LPF Passband Edge	Analog LPF Stopband Edge
Digital LPF to/from analog LPF	$s = \frac{2}{T} \frac{1-z^{-1}}{1+z^{-1}}$ $z = \frac{(2/T)+s}{(2/T)-s}$	$f = \frac{1}{\pi} \tan^{-1}\left(\frac{\lambda T}{2}\right)$ $\lambda = \frac{2}{T} \tan(\pi f)$	$\lambda_p = \frac{2}{T} \tan(\pi f_p)$	$\lambda_s = \frac{2}{T} \tan(\pi f_s)$
Digital HPF to/from analog LPF	$s = \frac{T}{2} \frac{1+z^{-1}}{1-z^{-1}}$ $z = \frac{s+(T/2)}{s-(T/2)}$	$f = \begin{cases} -\frac{1}{2} + \frac{1}{\pi} \tan^{-1}\left(\frac{2\lambda}{T}\right), & \lambda \geq 0 \\ \frac{1}{2} + \frac{1}{\pi} \tan^{-1}\left(\frac{2\lambda}{T}\right), & \lambda \leq 0 \end{cases}$ $\lambda = \frac{T}{2} \tan[\pi(f+0.5)], \lambda \geq 0$	$\lambda_p = \frac{T}{2} \tan\left[\pi\left(f_p + \frac{1}{2}\right)\right]$	$\lambda_s = \frac{T}{2} \tan\left[\pi\left(f_s + \frac{1}{2}\right)\right]$
Digital BPF to/from analog LPF	$s = \frac{\tilde{s}^2 + \tilde{\lambda}_0^2}{W\tilde{s}}$ where $\tilde{s} = \frac{2}{T} \frac{1-z^{-1}}{1+z^{-1}}$	$\lambda = \frac{\tilde{\lambda}^2 - \tilde{\lambda}_0^2}{W\tilde{\lambda}}$ where $\tilde{\lambda} = \frac{2}{T} \tan(\pi f)$	$\lambda_p = \max\left\{\left \frac{\tilde{\lambda}_0^2 - \tilde{\lambda}_{p1}^2}{W\tilde{\lambda}_{p1}}\right , \left \frac{\tilde{\lambda}_0^2 - \tilde{\lambda}_{p2}^2}{W\tilde{\lambda}_{p2}}\right \right\}$ where $\tilde{\lambda}_{p1} = \frac{2}{T} \tan(\pi f_{p1})$ $\tilde{\lambda}_{p2} = \frac{2}{T} \tan(\pi f_{p2})$	$\lambda_s = \min\left\{\left \frac{\tilde{\lambda}_0^2 - \tilde{\lambda}_{s1}^2}{W\tilde{\lambda}_{s1}}\right , \left \frac{\tilde{\lambda}_0^2 - \tilde{\lambda}_{s2}^2}{W\tilde{\lambda}_{s2}}\right \right\}$ where $\tilde{\lambda}_{s1} = \frac{2}{T} \tan(\pi f_{s1})$ $\tilde{\lambda}_{s2} = \frac{2}{T} \tan(\pi f_{s2})$
Digital BSF to/from analog LPF	$s = \frac{W\tilde{s}}{\tilde{s}^2 + \tilde{\lambda}_0^2}$ where $\tilde{s} = \frac{2}{T} \frac{1-z^{-1}}{1+z^{-1}}$	$\lambda = \frac{W\tilde{\lambda}}{\tilde{\lambda}_0^2 - \tilde{\lambda}^2}$ where $\tilde{\lambda} = \frac{2}{T} \tan(\pi f)$	$\lambda_p = \max\left\{\left \frac{W\tilde{\lambda}_{p1}}{\tilde{\lambda}_0^2 - \tilde{\lambda}_{p1}^2}\right , \left \frac{W\tilde{\lambda}_{p2}}{\tilde{\lambda}_0^2 - \tilde{\lambda}_{p2}^2}\right \right\}$ where $\tilde{\lambda}_{p1} = \frac{2}{T} \tan(\pi f_{p1})$ $\tilde{\lambda}_{p2} = \frac{2}{T} \tan(\pi f_{p2})$	$\lambda_s = \min\left\{\left \frac{W\tilde{\lambda}_{s1}}{\tilde{\lambda}_0^2 - \tilde{\lambda}_{s1}^2}\right , \left \frac{W\tilde{\lambda}_{s2}}{\tilde{\lambda}_0^2 - \tilde{\lambda}_{s2}^2}\right \right\}$ where $\tilde{\lambda}_{s1} = \frac{2}{T} \tan(\pi f_{s1})$ $\tilde{\lambda}_{s2} = \frac{2}{T} \tan(\pi f_{s2})$

frequency λ and the digital frequency f , obtained from the relations between s and z by replacing s with $j\lambda$ and z with $\exp(j2\pi f)$. The fourth and fifth columns show the required pass-band and stop-band edges for the analog LPF. Note that the allowable variations in the pass band and stop band, or equivalently the values of ε and δ , for the analog low-pass filter remain the same as those for the desired digital filter. Notice that for the BPF and BSF, the transformation is performed in two steps: one for transforming an analog LPF to/from an analog BPF (or BSF), and the other for transforming an analog BPF (or BSF) to/from a digital BPF (or BSF). The values of W and $\tilde{\lambda}_0$ are chosen by the designer. Some convenient choices are: (1) $W = \tilde{\lambda}_{p2} - \tilde{\lambda}_{p1}$ and $\tilde{\lambda}_0^2 = \tilde{\lambda}_{p1}\tilde{\lambda}_{p2}$, which yield $\lambda_p = 1$; (2) $W = \tilde{\lambda}_{s2} - \tilde{\lambda}_{s1}$ and $\tilde{\lambda}_0^2 = \tilde{\lambda}_{s1}\tilde{\lambda}_{s2}$, which yield $\lambda_s = 1$. We demonstrate the design process by the following two examples.

Design Example 1

Consider designing a digital LPF with a pass-band edge at $f_p = 0.15$ and stop-band edge at $f_s = 0.25$. The magnitude response in the pass band is to stay within 0 and -2 dB, although it must be no larger than -40 dB in the stop band. Assuming that the analog Butterworth filter is to be used as the prototype filter, we proceed the design as follows.

1. Compute ε , δ , λ_p , λ_s , and the analog filter order. An attenuation of -2 dB means $10 \log_{10}(1+\varepsilon^2)^{-1} = -2$, which yields $\varepsilon = 0.7648$, and attenuation of -40 dB means $10 \log_{10}(\delta^2) = -40$, which gives $\delta = 0.01$. From Table 8.8, the analog pass-band and stop-band edges are $\lambda_p = (2/T) \tan(\pi f_p)$ and $\lambda_s = (2/T) \tan(\pi f_s)$. For convenience, we let $T = 2$, which makes $\lambda_p = 0.5095$ and $\lambda_s = 1.0$. Now, we can calculate the required order of the analog Butterworth filter from Eq. (8.37), which yields $N \geq 7.23$; thus, we choose $N = 8$.
2. Obtain the analog LPF transfer function. From Eq. (8.38), we can pick a value of λ_c between 0.5269 and 0.5623. Let us choose $\lambda_c = 0.54$. With $N = 8$, the transfer function is calculated from Eq. (8.35) as

$$H_a(s) = \frac{7.2302 \times 10^{-3}}{(s^2 + 0.2107s + 0.2916)(s^2 + 0.6s + 0.2916)} \cdot \frac{1}{(s^2 + 0.8980s + 0.2916)(s^2 + 1.0592s + 0.2916)} \quad (8.49)$$

3. Obtain the digital filter. Using the transformation in Table 8.8, we transform Eq. (8.49) to the desired digital filter by replacing s with $(2/T)(z-1)/(z+1) = (z-1)/(z+1)$ (since we let $T = 2$). After substitution and simplification, the resulting digital LPF has a system function given by

$$H(z) = H_a(s)|_{s=(z-1)/(z+1)} = \frac{4.9428 \times 10^{-4}(z^2 + 2z + 1)^4}{(z^2 - 0.9431z + 0.7195)(z^2 - 0.7490z + 0.3656)} \cdot \frac{1}{(z^2 - 0.6471z + 0.1798)(z^2 - 0.6027z + 0.0988)} \quad (8.50)$$

The magnitude response $|H(f)|$ is plotted in Fig. 8.108(a). The magnitude is 0.8467 at the pass-band edge $f_p = 0.15$, and it is 0.0072 at the stop-band edge $f_s = 0.25$, both of which are within the specification.

Design Example 2

Now, suppose that we wish to design a digital BSF with pass-band edges at $f_{p1} = 0.15$ and $f_{p2} = 0.30$ and stop-band edges at $f_{s1} = 0.20$ and $f_{s2} = 0.25$. The magnitude response in the pass bands is to stay within 0 and -2 dB, although it must be no larger than -40 dB in the stop band. Let us use the analog type I

FIGURE 8.108 Magnitude responses of the designed digital filters in the examples: (a) LPF (example 1), (b) BSF (example 2).

Chebyshev filter as the prototype filter. Following the same design process as the first example, we have the following.

1. Compute $\varepsilon, \delta, \lambda_p, \lambda_s$, and the analog filter order. From the first example, we have $\varepsilon = 0.7648$ and $\delta = 0.01$. From Table 8.8 and letting $T = 2$, we compute the analog pass-band and stop-band edges: $\tilde{\lambda}_{p1} = \tan(\pi f_{p1}) = 0.5095, \tilde{\lambda}_{p2} = \tan(\pi f_{p2}) = 1.3764, \tilde{\lambda}_{s1} = \tan(\pi f_{s1}) = 0.7265, \tilde{\lambda}_{s2} = \tan(\pi f_{s2}) = 1.0$. We choose $W = \tilde{\lambda}_{p2} - \tilde{\lambda}_{p1} = 0.8669$ and $\tilde{\lambda}_0^2 = \tilde{\lambda}_{p1}\tilde{\lambda}_{p2} = 0.7013$, so that $\lambda_p = 1.0$ and $\lambda_s = \min\{3.6311, 2.9021\} = 2.9021$. From Eq. (8.43), the required analog filter order is $N \geq 3.22$; thus, we choose $N = 4$.
2. Obtain the analog LPF transfer function. From Eq. (8.39) and with $N = 4$, we find the transfer function of the analog Chebyshev filter as

$$H_a(s) = \frac{1.6344 \times 10^{-1}}{(s^2 + 0.2098s + 0.9287)(s^2 + 0.5064s + 0.2216)} \tag{8.51}$$

3. Obtain the digital filter. Using Table 8.8, we transform Eq. (8.51) to $H(z)$ by replacing s with $W\bar{s}/(\bar{s}^2 + \tilde{\lambda}_0^2) = W(z^2 - 1)/[(z - 1)^2 + \tilde{\lambda}_0^2(z + 1)^2]$ since $T = 2$ and $\bar{s} = (z - 1)/(z + 1)$. After substitution and simplification, the resulting digital BSF is

$$H(z) = \frac{1.7071 \times 10^{-1}(z^4 - 0.7023z^3 + 2.1233z^2 - 0.7023z + 1)^2}{(z^4 - 0.5325z^3 + 1.1216z^2 - 0.4746z + 0.8349)} \cdot \frac{1}{(z^4 - 0.3331z^3 + 0.0660z^2 - 0.0879z + 0.3019)} \tag{8.52}$$

The magnitude response is plotted in Fig. 8.108(b), which satisfies the specification.

8.8.4 Finite Wordlength Effects

Practical digital filters must be implemented with finite precision numbers and arithmetic. As a result, both the filter coefficients and the filter input and output signals are in discrete form. This leads to four types of finite wordlength effects.

Discretization (quantization) of the filter coefficients has the effect of perturbing the location of the filter poles and zeroes. As a result, the actual filter response differs slightly from the ideal response. This *deterministic* frequency response error is referred to as *coefficient quantization error*.

The use of finite precision arithmetic makes it necessary to quantize filter calculations by rounding or truncation. *Roundoff noise* is that error in the filter output that results from rounding or truncating calculations within the filter. As the name implies, this error looks like low-level noise at the filter output.

Quantization of the filter calculations also renders the filter slightly nonlinear. For large signals this nonlinearity is negligible and roundoff noise is the major concern. For recursive filters with a zero or constant input, however, this nonlinearity can cause spurious oscillations called *limit cycles*.

With fixed-point arithmetic it is possible for filter calculations to overflow. The term *overflow oscillation*, sometimes also called *adder overflow limit cycle*, refers to a high-level oscillation that can exist in an otherwise stable filter due to the nonlinearity associated with the overflow of internal filter calculations.

In this section we examine each of these finite wordlength effects for both fixed-point and floating-point number representations.

Number Representation

In digital signal processing, $(B + 1)$ -bit fixed-point numbers are usually represented as two's-complement signed fractions in the format

$$b_0.b_{-1}b_{-2}\cdots b_{-B}$$

The number represented is then

$$X = -b_0 + b_{-1}2^{-1} + b_{-2}2^{-2} + \cdots + b_{-B}2^{-B} \quad (8.53)$$

where b_0 is the sign bit and the number range is $-1 \leq X < 1$. The advantage of this representation is that the product of two numbers in the range from -1 to 1 is another number in the same range.

Floating-point numbers are represented as

$$X = (-1)^s m 2^c \quad (8.54)$$

where s is the sign bit, m is the *mantissa*, and c is the *characteristic* or *exponent*. To make the representation of a number unique, the mantissa is *normalized* so that $0.5 \leq m < 1$.

Fixed-Point Quantization Errors

In fixed-point arithmetic, a multiply doubles the number of significant bits. For example, the product of the two 5-bit numbers 0.0011 and 0.1001 is the 10-bit number 00.00011011. The extra bit to the left of the decimal point can be discarded without introducing any error. However, the least significant four of the remaining bits must ultimately be discarded by some form of quantization so that the result can be stored to five bits for use in other calculations. In the preceding example this results in 0.0010 (quantization by rounding) or 0.0001 (quantization by truncating). When a sum of products calculation is performed, the quantization can be performed either after each multiply or after all products have been summed with double-length precision.

We will examine the case of fixed-point quantization by rounding. If X is an exact value then the rounded value will be denoted $Q_r(X)$. If the quantized value has B bits to the right of the decimal point, the quantization step size is

$$\Delta = 2^{-B} \quad (8.55)$$

Since rounding selects the quantized value nearest the unquantized value, it gives a value which is never more than $\pm\Delta/2$ away from the exact value. If we denote the rounding error by

$$\varepsilon_r = Q_r(X) - X \quad (8.56)$$

then

$$-\frac{\Delta}{2} \leq \varepsilon_r \leq \frac{\Delta}{2} \tag{8.57}$$

The error resulting from quantization can be modeled as a random variable uniformly distributed over the appropriate error range. Therefore, calculations with roundoff error can be considered error-free calculations that have been corrupted by additive white noise. The mean of this noise for rounding is

$$m_{\varepsilon_r} = E\{\varepsilon_r\} = \frac{1}{\Delta} \int_{-\frac{\Delta}{2}}^{\frac{\Delta}{2}} \varepsilon_r \, d\varepsilon_r = 0 \tag{8.58}$$

where $E\{ \}$ represents the operation of taking the expected value of a random variable. Similarly, the variance of the noise for rounding is

$$\sigma_{\varepsilon_r}^2 = E\{(\varepsilon_r - m_{\varepsilon_r})^2\} = \frac{1}{\Delta} \int_{-\frac{\Delta}{2}}^{\frac{\Delta}{2}} (\varepsilon_r - m_{\varepsilon_r})^2 \, d\varepsilon_r = \frac{\Delta^2}{12} \tag{8.59}$$

Floating-Point Quantization Errors

With floating-point arithmetic it is necessary to quantize after both multiplications and additions. The addition quantization arises because, prior to addition, the mantissa of the smaller number in the sum is shifted right until the exponent of both numbers is the same. In general, this gives a sum mantissa that is too long and so must be quantized.

We will assume that quantization in floating-point arithmetic is performed by rounding. Because of the exponent in floating-point arithmetic, it is the relative error that is important. The relative error is defined as

$$\varepsilon_r = \frac{Q_r(X) - X}{X} = \frac{\varepsilon_r}{X} \tag{8.60}$$

Since $X = (-1)^s m 2^c$, $Q_r(X) = (-1)^s Q_r(m) 2^c$ and

$$\varepsilon_r = \frac{Q_r(m) - m}{m} = \frac{\varepsilon}{m} \tag{8.61}$$

If the quantized mantissa has B bits to the right of the decimal point, $|\varepsilon| < \Delta/2$ where, as before, $\Delta = 2^{-B}$. Therefore, since $0.5 \leq m < 1$,

$$|\varepsilon_r| < \Delta \tag{8.62}$$

If we assume that ε is uniformly distributed over the range from $-\Delta/2$ to $\Delta/2$ and m is uniformly distributed over 0.5–1,

$$m_{\varepsilon_r} = E\left\{\frac{\varepsilon}{m}\right\} = 0$$

$$\sigma_{\varepsilon_r}^2 = E\left\{\left(\frac{\varepsilon}{m}\right)^2\right\} = \frac{2}{\Delta} \int_{\frac{1}{2}}^1 \int_{-\frac{\Delta}{2}}^{\frac{\Delta}{2}} \frac{\varepsilon^2}{m^2} \, d\varepsilon \, dm = \frac{\Delta^2}{6} = (0.167)2^{-2B} \tag{8.63}$$

From Eq. (8.60) we can represent a quantized floating-point value in terms of the unquantized value and the random variable ε_r using

$$Q_r(X) = X(1 + \varepsilon_r) \tag{8.64}$$

Therefore, the finite-precision product $X_1 X_2$ and the sum $X_1 + X_2$ can be written

$$fl(X_1 X_2) = X_1 X_2(1 + \varepsilon_r) \tag{8.65}$$

and

$$fI(X_1 + X_2) = (X_1 + X_2)(1 + \varepsilon_r) \quad (8.66)$$

where ε_r is zero mean with the variance of Eq. (8.63).

Roundoff Noise

To determine the roundoff noise at the output of a digital filter we will assume that the noise due to a quantization is stationary, white, and uncorrelated with the filter input, output, and internal variables. This assumption is good if the filter input changes from sample to sample in a sufficiently complex manner. It is not valid for zero or constant inputs for which the effects of rounding are analyzed from a limit cycle perspective.

To satisfy the assumption of a sufficiently complex input, roundoff noise in digital filters is often calculated for the case of a zero-mean white noise filter input signal $x(n)$ of variance σ_x^2 . This simplifies calculation of the output roundoff noise because expected values of the form $E\{x(n)x(n-k)\}$ are zero for $k \neq 0$ and give σ_x^2 when $k = 0$. If there is more than one source of roundoff error in a filter, it is assumed that the errors are uncorrelated so that the output noise variance is simply the sum of the contributions from each source. This approach to analysis has been found to give estimates of the output roundoff noise that are close to the noise actually observed in practice.

Another assumption that will be made in calculating roundoff noise is that the product of two quantization errors is zero. To justify this assumption, consider the case of a 16-bit fixed-point processor. In this case a quantization error is of the order 2^{-15} , whereas the product of two quantization errors is of the order 2^{-30} , which is negligible by comparison.

The simplest case to analyze is a finite impulse response filter realized via the convolution summation

$$y(n) = \sum_{k=0}^{N-1} h(k)x(n-k) \quad (8.67)$$

When fixed-point arithmetic is used and quantization is performed after each multiply, the result of the N multiplies is N times the quantization noise of a single multiply. For example, rounding after each multiply gives, from Eqs. (8.55) and (8.59), an output noise variance of

$$\sigma_o^2 = N \frac{2^{-2B}}{12} \quad (8.68)$$

Virtually all digital signal processor integrated circuits contain one or more double-length accumulator registers that permit the sum-of-products in Eq. (8.67) to be accumulated without quantization. In this case only a single quantization is necessary following the summation and

$$\sigma_o^2 = \frac{2^{-2B}}{12} \quad (8.69)$$

For the floating-point roundoff noise case we will consider Eq. (8.67) for $N = 4$ and then generalize the result to other values of N . The finite-precision output can be written as the exact output plus an error term $e(n)$. Thus

$$y(n) + e(n) = ([h(0)x(n)(1 + \varepsilon_1(n)) + h(1)x(n-1)(1 + \varepsilon_2(n))][1 + \varepsilon_3(n)] \\ + h(2)x(n-2)(1 + \varepsilon_4(n))\{1 + \varepsilon_5(n)\} + h(3)x(n-3)(1 + \varepsilon_6(n))(1 + \varepsilon_7(n)) \quad (8.70)$$

In Eq. (8.70) $\varepsilon_1(n)$ represents the error in the first product, $\varepsilon_2(n)$ the error in the second product, $\varepsilon_3(n)$ the error in the first addition, etc. Notice that it has been assumed that the products are summed in the order implied by the summation of Eq. (8.67).

Expanding Eq. (8.70), ignoring products of error terms, and recognizing $y(n)$ gives

$$e(n) = h(0)x(n)[\varepsilon_1(n) + \varepsilon_3(n) + \varepsilon_5(n) + \varepsilon_7(n)] + h(1)x(n-1)[\varepsilon_2(n) + \varepsilon_3(n) + \varepsilon_5(n) + \varepsilon_7(n)] + h(2)x(n-2)[\varepsilon_4(n) + \varepsilon_5(n) + \varepsilon_7(n)] + h(3)x(n-3)[\varepsilon_6(n) + \varepsilon_7(n)] \tag{8.71}$$

Assuming that the input is white noise of variance σ_x^2 so that $E\{x(n)x(n-k)\}$ is zero for $k \neq 0$, and assuming that the errors are uncorrelated,

$$E\{e^2(n)\} = [4h^2(0) + 4h^2(1) + 3h^2(2) + 2h^2(3)]\sigma_x^2\sigma_{\varepsilon_r}^2 \tag{8.72}$$

In general, for any N ,

$$\sigma_o^2 = E\{e^2(n)\} = \left[Nh^2(0) + \sum_{k=1}^{N-1} (N+1-k)h^2(k) \right] \sigma_x^2\sigma_{\varepsilon_r}^2 \tag{8.73}$$

Notice that if the order of summation of the product terms in the convolution summation is changed, then the order in which the $h(k)$ appear in Eq. (8.73) changes. If the order is changed so that the $h(k)$ with smallest magnitude is first, followed by the next smallest, etc., then the roundoff noise variance is minimized. Performing the convolution summation in nonsequential order, however, greatly complicates data indexing and so may not be worth the reduction obtained in roundoff noise.

Analysis of roundoff noise for IIR filters proceeds in the same way as for FIR filters. The analysis is more complicated, however, because roundoff noise arising in the computation of internal filter variables (state variables) must be propagated through a transfer function from the point of the quantization to the filter output. This is not necessary for FIR filters realized via the convolution summation since all quantizations are in the output calculation. Another complication in the case of IIR filters realized with fixed-point arithmetic is the need to scale the computation of internal filter variables to avoid their overflow. Examples of roundoff noise analysis for IIR filters can be found in Weinstein and Oppenheim (1969) and Oppenheim and Weinstein (1972) where it is shown that differences in the filter realization structure can make a large difference in the output roundoff noise. In particular, it is shown that IIR filters realized via the parallel or cascade connection of first- and second-order subfilters are almost always superior in terms of roundoff noise to a high-order direct form (single difference equation) realization. It is also possible to choose realizations that are optimal or near optimal in a roundoff noise sense (Mullins and Roberts, 1976; Jackson, Lindgren, and Kim, 1979). These realizations generally require more computation to obtain an output sample from an input sample, however, and so suboptimal realizations with slightly higher roundoff noise are often preferable (Bomar, 1985).

Limit Cycles

A limit cycle, sometimes referred to as a *multiplier roundoff limit cycle*, is a low-level oscillation that can exist in an otherwise stable filter as a result of the nonlinearity associated with rounding (or truncating) internal filter calculations (Parker and Hess, 1971). Limit cycles require recursion to exist and do not occur in nonrecursive FIR filters.

As an example of a limit cycle, consider the second-order filter realized by

$$y(n) = Q_r \left\{ \frac{7}{8}y(n-1) - \frac{5}{8}y(n-2) + x(n) \right\} \tag{8.74}$$

where $Q_r\{ \}$ represents quantization by rounding. This is a stable filter with poles at $0.4375 \pm j0.6585$. Consider the implementation of this filter with four-bit (three bits and a sign bit) two's complement fixed-point arithmetic, zero initial conditions ($y(-1) = y(-2) = 0$), and an input sequence $x(n) = \frac{3}{8}\delta(n)$

where $\delta(n)$ is the unit impulse or unit sample. The following sequence is obtained:

$$\begin{aligned}
 y(0) &= Q_r \left\{ \frac{3}{8} \right\} = \frac{3}{8} & y(1) &= Q_r \left\{ \frac{21}{64} \right\} = \frac{3}{8} & y(2) &= Q_r \left\{ \frac{3}{32} \right\} = \frac{1}{8} \\
 y(3) &= Q_r \left\{ -\frac{1}{8} \right\} = -\frac{1}{8} & y(4) &= Q_r \left\{ -\frac{3}{16} \right\} = -\frac{1}{8} & y(5) &= Q_r \left\{ -\frac{1}{32} \right\} = 0 \\
 y(6) &= Q_r \left\{ \frac{5}{64} \right\} = \frac{1}{8} & y(7) &= Q_r \left\{ \frac{7}{64} \right\} = \frac{1}{8} & y(8) &= Q_r \left\{ \frac{1}{32} \right\} = 0 \\
 y(9) &= Q_r \left\{ -\frac{5}{64} \right\} = -\frac{1}{8} & y(10) &= Q_r \left\{ -\frac{7}{64} \right\} = -\frac{1}{8} & y(11) &= Q_r \left\{ -\frac{1}{32} \right\} = 0 \\
 y(12) &= Q_r \left\{ \frac{5}{64} \right\} = \frac{1}{8} & & \dots & &
 \end{aligned}$$

Notice that although the input is zero except for the first sample, the output oscillates with amplitude $\frac{1}{8}$ and period 6.

Limit cycles are primarily of concern in fixed-point recursive filters. As long as floating-point filters are realized as the parallel or cascade connection of first- and second-order subfilters, limit cycles will generally not be a problem since limit cycles are practically not observable in first- and second-order systems implemented with 32-bit floating-point arithmetic (Bauer, 1993). It has been shown that such systems must have an extremely small margin of stability for limit cycles to exist at anything other than underflow levels, which are at an amplitude of less than 10^{-38} (Bauer, 1993).

There are at least three ways of dealing with limit cycles when fixed-point arithmetic is used. One is to determine a bound on the maximum limit cycle amplitude, expressed as an integral number of quantization steps. It is then possible to choose a wordlength that makes the limit cycle amplitude acceptably low. Alternately, limit cycles can be prevented by randomly rounding calculations up or down (Buttner, 1976). This approach, however, is complicated to implement. The third approach is to properly choose the filter realization structure and then quantize the filter calculations using magnitude truncation (Bomar, 1994). This approach has the disadvantage of slightly increasing roundoff noise.

Overflow Oscillations

With fixed-point arithmetic it is possible for filter calculations to overflow. This happens when two numbers of the same sign add to give a value having magnitude greater than one. Since numbers with magnitude greater than one are not representable, the result overflows. For example, the two's complement numbers $0.101 (\frac{5}{8})$ and $0.100 (\frac{4}{8})$ add to give 1.001, which is the two's complement representation of $-\frac{7}{8}$.

The overflow characteristic of two's complement arithmetic can be represented as $R\{ \}$ where

$$R\{X\} = \begin{cases} X - 2, & X \geq 1 \\ X, & -1 \leq X < 1 \\ X + 2, & X < -1 \end{cases} \tag{8.75}$$

For the example just considered, $R\{\frac{9}{8}\} = -\frac{7}{8}$.

An overflow oscillation, sometimes also referred to as an adder overflow limit cycle, is a high-level oscillation that can exist in an otherwise stable fixed-point filter due to the gross nonlinearity associated with the overflow of internal filter calculations (Ebert, Mazo, and Taylor, 1969). Like limit cycles, overflow oscillations require recursion to exist and do not occur in nonrecursive FIR filters. Overflow oscillations also do not occur with floating-point arithmetic due to the virtual impossibility of overflow.

As an example of an overflow oscillation, once again consider the filter of Eq. (8.74) with four-bit fixed-point two's complement arithmetic and with the two's complement overflow characteristic

of Eq. (8.75):

$$y(n) = Q_r \left\{ R \left\{ \frac{7}{8}y(n-1) - \frac{5}{8}y(n-2) + x(n) \right\} \right\} \tag{8.76}$$

In this case we apply the input

$$x(n) = \left\{ -\frac{3}{4}, -\frac{5}{8}, 0, 0, 0, \dots \right\} \tag{8.77}$$

giving the output sequence

$$\begin{aligned} y(0) &= Q_r \left\{ R \left\{ -\frac{3}{4} \right\} \right\} = Q_r \left\{ -\frac{3}{4} \right\} = -\frac{3}{4} & y(1) &= Q_r \left\{ R \left\{ -\frac{41}{32} \right\} \right\} = Q_r \left\{ \frac{23}{32} \right\} = \frac{3}{4} \\ y(2) &= Q_r \left\{ R \left\{ \frac{9}{8} \right\} \right\} = Q_r \left\{ -\frac{7}{8} \right\} = -\frac{7}{8} & y(3) &= Q_r \left\{ R \left\{ -\frac{79}{64} \right\} \right\} = Q_r \left\{ \frac{49}{64} \right\} = \frac{3}{4} \\ y(4) &= Q_r \left\{ R \left\{ \frac{77}{64} \right\} \right\} = Q_r \left\{ -\frac{51}{64} \right\} = -\frac{3}{4} & y(5) &= Q_r \left\{ R \left\{ -\frac{9}{8} \right\} \right\} = Q_r \left\{ \frac{7}{8} \right\} = \frac{7}{8} \\ y(6) &= Q_r \left\{ R \left\{ \frac{79}{64} \right\} \right\} = Q_r \left\{ -\frac{49}{64} \right\} = -\frac{3}{4} & y(7) &= Q_r \left\{ R \left\{ -\frac{77}{64} \right\} \right\} = Q_r \left\{ \frac{51}{64} \right\} = \frac{3}{4} \\ y(8) &= Q_r \left\{ R \left\{ \frac{9}{8} \right\} \right\} = Q_r \left\{ -\frac{7}{8} \right\} = -\frac{7}{8} & & \dots \end{aligned}$$

This is a large-scale oscillation with nearly full-scale amplitude.

There are several ways to prevent overflow oscillations in fixed-point filter realizations. The most obvious is to scale the filter calculations so as to render overflow impossible. However, this may unacceptably restrict the filter dynamic range. Another method is to force completed sums-of-products to saturate at ± 1 , rather than overflowing (Ritzerfeld, 1989). It is important to saturate only the completed sum, since intermediate overflows in two's complement arithmetic do not affect the accuracy of the final result. Most fixed-point digital signal processors provide for automatic saturation of completed sums if their *saturation arithmetic* feature is enabled. Yet another way to avoid overflow oscillations is to use a filter structure for which any internal filter transient is guaranteed to decay to zero (Mills, Mullis, and Roberts, 1978). Such structures are desirable anyway, since they tend to have low roundoff noise and be insensitive to coefficient quantization (Barnes, 1979).

Coefficient Quantization Error

Each filter structure has its own finite, generally nonuniform grids of realizable pole and zero locations when the filter coefficients are quantized to a finite wordlength. In general the pole and zero locations desired in a filter do not correspond exactly to the realizable locations. The error in filter performance (usually measured in terms of a frequency response error) resulting from the placement of the poles and zeroes at the nonideal but realizable locations is referred to as coefficient quantization error.

Consider the second-order filter with complex-conjugate poles

$$\lambda = r e^{\pm j\theta} = \lambda_r \pm j\lambda_i = r \cos(\theta) \pm jr \sin(\theta) \tag{8.78}$$

and transfer function

$$H(z) = \frac{1}{1 - 2r \cos(\theta)z^{-1} + r^2z^{-2}} \tag{8.79}$$

realized by the difference equation

$$y(n) = 2\lambda_r y(n-1) - r^2 y(n-2) + x(n) \tag{8.80}$$

Quantizing the difference equation coefficients results in a nonuniform grid of realizable pole locations in the z plane. The nonuniform grid is defined by the intersection of vertical lines corresponding to

quantization of $2\lambda_r$ and concentric circles corresponding to quantization of $-r^2$. The sparseness of realizable pole locations near $z = \pm 1$ results in a large coefficient quantization error for poles in this region. By contrast, quantizing coefficients of the normal realization (Barnes, 1979) corresponds to quantizing λ_r and λ_i resulting in a uniform grid of realizable pole locations. In this case large coefficient quantization errors are avoided for all pole locations.

It is well established that filter structures with low roundoff noise tend to be robust to coefficient quantization, and vice versa (Jackson, 1976; Rao, 1986). For this reason, the normal (uniform grid) structure is also popular because of its low roundoff noise.

It is well known that in a high-order polynomial with clustered roots the root location is a very sensitive function of the polynomial coefficients. Therefore, filter poles and zeroes can be much more accurately controlled if higher order filters are realized by breaking them up into the parallel or cascade connection of first- and second-order subfilters. One exception to this rule is the case of linear-phase FIR filters in which the symmetry of the polynomial coefficients and the spacing of the filter zeros around the unit circle usually permits an acceptable direct realization using the convolution summation.

Realization Considerations

Linear-phase FIR digital filters can generally be implemented with acceptable coefficient quantization sensitivity using the direct convolution sum method. When implemented in this way on a digital signal processor, fixed-point arithmetic is not only acceptable but may actually be preferable to floating-point arithmetic. Virtually all fixed-point digital signal processors accumulate a sum of products in a double-length accumulator. This means that only a single quantization is necessary to compute an output. Floating-point arithmetic, on the other hand, requires a quantization after every multiply and after every add in the convolution summation. With 32-bit floating-point arithmetic these quantizations introduce a small enough error to be insignificant for most applications.

When realizing IIR filters, either a parallel or cascade connection of first- and second-order subfilters is almost always preferable to a high-order direct form realization. With the availability of low-cost floating-point digital signal processors, like the Texas Instruments TMS320C32, it is highly recommended that floating-point arithmetic be used for IIR filters. Floating-point arithmetic simultaneously eliminates most concerns regarding scaling, limit cycles, and overflow oscillations. Regardless of the arithmetic employed, a low roundoff noise structure should be used for the second-order sections. The use of a low roundoff noise structure for the second-order sections also tends to give a realization with low coefficient quantization sensitivity. First-order sections are not as critical in determining the roundoff noise and coefficient sensitivity of a realization, and so can generally be implemented with a simple direct form structure.

Defining Terms

Adaptive FIR filter: A finite impulse response structure filter with adjustable coefficients. The adjustment is controlled by an adaptation algorithm such as the least mean square (lms) algorithm. They are used extensively in adaptive echo cancellers and equalizers in communication systems.

Causality: The property of a system that implies that its output can not appear before its input is applied. This corresponds to an FIR filter with a zero discrete-time impulse response for negative time indices.

Discrete time impulse response: The output of an FIR filter when its input is unity at the first sample and otherwise zero.

Group delay: The group delay of an FIR filter is the negative derivative of the phase response of the filter and is, therefore, a function of the input frequency. At a particular frequency it equals the physical delay that a narrow-band signal will experience passing through the filter.

Linear phase: The phase response of an FIR filter is linearly related to frequency and, therefore, corresponds to constant group delay.

Linear, time invariant (LTI): A system is said to be LTI if superposition holds, that is, its output for an input that consists of the sum of two inputs is identical to the sum of the two outputs that result from the individual application of the inputs; the output is not dependent on the time at that the input is applied. This is the case for an FIR filter with fixed coefficients.

Magnitude response: The change of amplitude, in steady state, of a sinusoid passing through the FIR filter as a function of frequency.

Multirate FIR filter: An FIR filter in which the sampling rate is not constant.

Phase response: The phase change, in steady state, of a sinusoid passing through the FIR filter as a function of frequency.

8.9 Multichip Module Technology

Paul D. Franzon

8.9.1 Introduction

Multichip module (MCM) technology allows bare integrated circuits and passive devices to be mounted together on a common interconnecting substrate. An example is shown in Fig. 8.109. In this photograph, eight chips are **wire-bonded** onto an MCM. MCM technology, however, is not just about packaging chips together; it can lead to new capabilities and unique performance and cost advantages. The purposes of this

FIGURE 8.109 Eight chips wire-bonded into an MCM. (Source: MicroModule Systems.)

chapter are as follows: to explain the different multichip module technologies, to show how MCMs can be employed to improve the price/performance of systems, and to indicate some of the more important issues in MCM-system design.

8.9.2 Multichip Module Technology Definitions

In its broadest sense, a multichip module is an assembly in which more than one integrated circuit (IC) are bare mounted on a common substrate. This definition is often narrowed in such a way as to imply that the common substrate provides a higher wiring density than a conventional **printed circuit board (PCB)**. The main physical components are shown in Fig. 8.110 and can be described as follows:

1. The substrate technology provides the interconnect between the chips (ICs or die) and any discrete circuit elements, such as resistors, capacitors, and inductors.
2. The chip connection technology provides the means whereby signals and power are transferred between the substrate and the chips.
3. The MCM package technology is the housing that surrounds the MCM and allows signals, and power and heat to be conducted to the outside world.

FIGURE 8.110 Physical technology components to an MCM.

What cannot be shown in Fig. 8.110 are several other components that are important to the success of an MCM:

1. The test technology used to ensure correct function of the bare die, the MCM substrate, and the assembled MCM.
2. The repair technology used to replace failed die, if any are detected after assembly.
3. The design technology.

There are many different versions of these technology components. The substrate technology is broadly divided into three categories:

1. **Laminate MCMs (MCM-L)** is shown in (Fig. 8.111). Essentially fine-line PCBs, MCM-Ls are usually constructed by first patterning copper conductors on fiberglass/resin-impregnated sheets as shown in Fig. 8.112. These sheets are laminated together under heat and pressure. Connections between conductors

FIGURE 8.111 Typical cross sections and feature sizes in printed circuit board and MCM-L technologies.

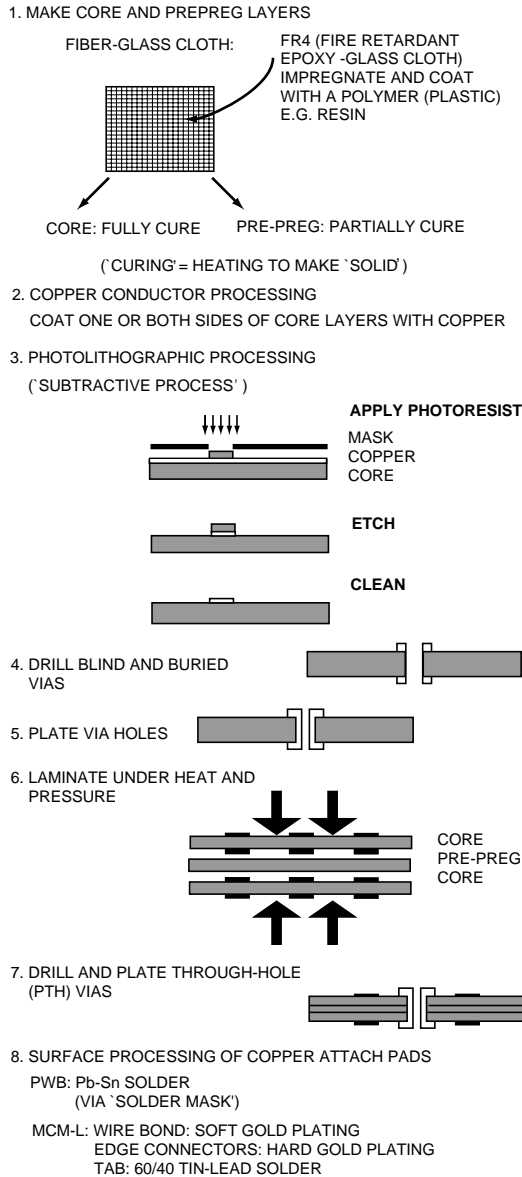

FIGURE 8.112 Basic manufacturing steps for MCM-Ls, using fiberglass/resin prepreg sheets as a basis.

on different sheets are made through via holes drilled in the sheets and plated. Recent developments in MCM-L technology have emphasized the use of flexible laminates. Flexible laminates have the potential for permitting finer lines and vias than fiberglass-based laminates.

2. **Ceramic MCMs (MCM-C)** are mostly based on pin grid array (PGA) technology. Typical cross sections and geometries are illustrated in Fig. 8.113 and the basic manufacturing steps are outline in Fig. 8.114. MCM-Cs are made by first casting a uniform sheet of prefired ceramic material, called green tape, then printing a metal ink onto the green tape, then punching and metal filling holes for the vias, and finally cofiring the stacked sheets together under pressure in an oven. In addition to metal, other inks can be used, including ones to print discrete resistors and capacitors in the MCM-C.

3. **Thin-film (deposited) MCMs (MCM-D)** are based on chip metalization processes. MCM-Ds have very fine feature sizes, giving high wiring densities (Fig. 8.115). MCM-Ds are made one layer at a time,

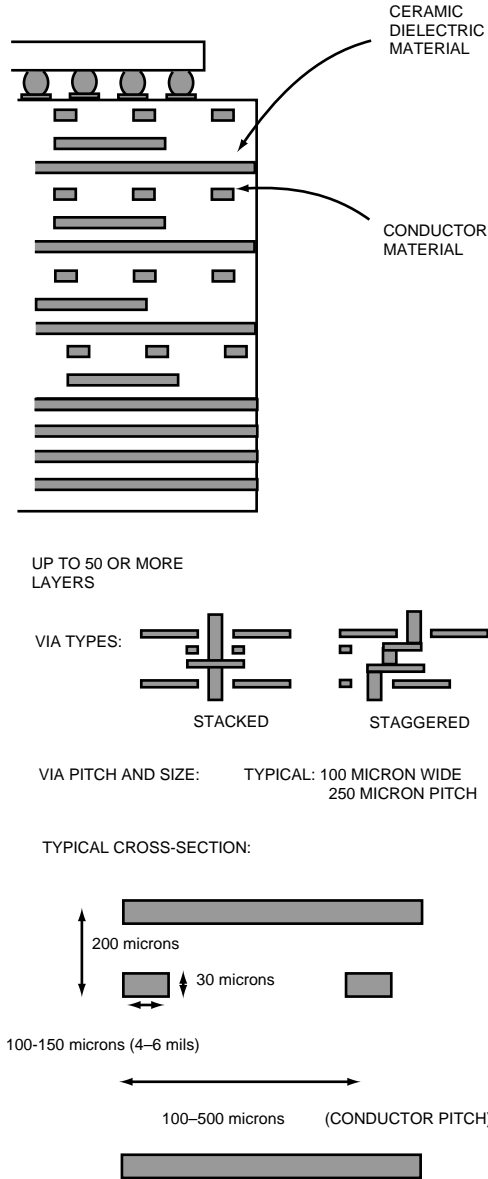

FIGURE 8.113 Typical cross sections and feature sizes in MCM-C technology.

using successive photolithographic definitions of metal conductor patterns and vias and the deposition of insulating layers, usually polyimide (Fig. 8.116). Often MCM-Ds are built on a silicon substrate, allowing capacitors, resistors, and transistors to be built, cheaply, as part of the substrate.

Table 8.9 gives one comparison of the alternative substrate technologies. MCM-Ls provide the lowest wiring and via density but are still very useful for making a small assembly when the total wire count in the design is not too high. MCM-Ds provide the highest wiring density and are useful in designs containing high pin-count chips; however, it is generally the most expensive technology on a per-unit-area basis. MCM-Cs fall somewhere in between, providing intermediate wiring densities at intermediate costs.

Current research promises to reduce the cost of MCM-Ls and MCM-D substrates. MCM-Ls based on flexible board technologies should be both cheaper and provide denser wiring than current fibreglass

FIGURE 8.114 Basic manufacturing steps for MCM-Cs.

FIGURE 8.115 Typical cross sections and feature sizes in MCM-D technology.

FIGURE 8.116 Basic manufacturing steps for MCM-Cs.

MCM-L technologies. Though the nonrecurring costs of MCM-Ds will always be high, due to the requirement to make fine feature photolithographic masks, the cost per part is projected to decrease as more efficient manufacturing techniques are brought to fruition.

The chip to substrate connection alternatives are presented in Fig. 8.117. Currently, over 95% of the die mounted in MCMs or single chip packages are wire bonded. Most bare die come suitable for wire-bonding, and wire bonding techniques are well known. **Tape automated bonding (TAB)** is an alternative to wire bonding. With TAB assembly, the chip is first attached to the TAB frame inner leads. These leads are then shaped (called *forming*); then the outer leads can be attached to the MCM. TAB has a significant advantage over wire bonding in that the TAB-mounted chips can be more easily tested than bare die. The high tooling costs, however, for making the TAB frames, makes it less desirable in all but high volume production chips. The wire pitch in wire bonding or TAB is generally 75 μm or more.

With **flip-chip solder-bump** attachment, solder bumps are deposited over the area of the silicon wafer. The wafer is then diced into individual die and flipped over the MCM substrate. The module is then placed in a reflow oven, where the solder makes a strong connection between the chip and the substrate. Flip-chip

TABLE 8.9 Rough Comparison of the Three Different Substrate Technologies: 1 mil = 1/1000 in \approx 25 μm

	Min. Wire Pitch, μm	Via Size, μm	Approx. Cost per Part $\$/\text{in}^2$	Nonrecurring Costs, \$
PCB	300	500	0.3	100
MCM-L	150	200	4	100–10,000
MCM-C	200	100	12	25,000
MCM-D	30	25	20	15,000

FIGURE 8.117 Chip attach options.

attachment has the following advantages:

- Solder bumps can be placed over the entire area of the chip, allowing chips to have thousands of connections. For example, a 1-cm² chip could support 1600 solder bumps (at a conservative 250- μ m pitch) but only 533 wire bonds.
- Transistors can be placed under solder bumps but cannot be placed under wire-bond or TAB pads. The reason arises from the relative attachment process. Making a good wire-bond or TAB lead attachment requires compression of the bond into the chip pad, damaging any transistors beneath a pad. On the other hand, a good soldered connection is made through the application of heat only. As a result, the chip can be smaller by an area equivalent to the total pad ring area. For example, consider a 100-mm² chip with a 250- μ m pad ring. The area consumed by the pad ring would total 10-mm², or 10% of the chip area. This area could be used for other functions if the chip were flipped and solder bumped. Alternatively, the chip could be made smaller and cheaper.
- The electrical parasitics of a solder bump are far better than for a wire-bond or TAB lead. The latter generally introduce about 1 nH of inductance and 1 pF of capacitance into a circuit. In contrast, a solder bump introduces about 10 pH and 10 nF. The lower parasitic inductance and capacitance make solder bumps attractive for high-frequency radio applications, for example, in the 5.6-GHz communications band and in high clock rate digital applications.
- The costs of flip-chip are comparable to wire bonding, beyond a certain point.

Flip-chip solder-bump, however, does have some disadvantages. The most significant follows from the requirement that the solder bump pads are larger than wire-bond pads (60–80 μ m vs. approximately 50 μ m). The solder-bump pads need to be larger in order to make the bumps taller. Taller bumps can more easily absorb the stresses that arise when the module is heated and cooled during assembly. As the thermal coefficient of expansion (TCE) of silicon is usually different from that of the MCM substrate, these two elements expand and contract at different rates, creating stresses in the connecting bumps. For the same reason, it is better to place the bumps in the center of the chip, rather than around the edge. By reducing the distance over which differential expansion and contraction occur, the stresses are reduced.

The larger bump pad sizes requires that the chips be designed specifically for solder-bumping, or that the wafers be postprocessed to distribute solder bumps pads over their surface, and wire (*redistribute*) these pads to the conventional wire-bond pads.

Another potential disadvantage arises from the lead content of the solder bump. Containing radioactive isotopes, most lead is a source of alpha particles that can potentially change the state of nearby transistors not shielded by aluminum. The effects of alpha particles are mainly of concern to dynamic random access memories (DRAMs) and dynamic logic.

8.9.3 Design, Repair, and Test

An important adjunct to the physical technology is the technology required to test and repair the die and modules. An important question that has to be answered for every MCM is how much to test the die before assembly vs. how much to rely on postassembly test to locate failed die. This is purely a cost question. The more the bare die are tested, the more likely that the assembled MCM will work. If the assembled MCM does not work, then it must either be repaired (by replacing a die) or discarded. The question reduces to the one that asks what level of bare die test provides a sufficiently high confidence that the assembled MCM will work, or is the assembled module cheap enough to throw away if a die is faulty.

In general, there are four levels of bare die test and burn-in, referred to as four levels of **known good die (KGD)**. In Table 8.10, these test levels are summarized, along with their impact. The lowest KGD level is to just use the same tests normally done at wafer level, referred to as the *wafer sort tests*. Here the chips are normally subject to a low-speed functional test combined with some parametric measurements (e.g., measurement of transistor curves). With this KGD level, test costs for bare die are limited to wafer test costs only. There is some risk, however, that the chip will not work when tested as part of the MCM. This risk is measured as the *test escape rate*. With conventional packaging, the chips are tested again, perhaps at full speed, once they are packaged, making the test escape rate zero.

If the MCM contains chips that must meet tight timing specifications (e.g., a workstation) or the MCM must meet high reliability standards (e.g., for aerospace), however, then higher KGD test levels are required. For example, a workstation company will want the chips to be speed-sorted. Speed-sorting requires producing a test fixture that can carry high-speed signals to and from the tester. The test fixture type usually used at wafer sort, generally referred to as a *probe card*, is usually not capable of carrying high-speed signals. Instead, it is necessary to build a more expensive, high-speed test fixture, or temporarily mount the bare die in some temporary package for testing. Naturally, these additional expenses increase the cost of providing at-pin speed sorted die.

Some applications require even higher levels of known good die. Aerospace applications usually demand burn-in of the die, particularly for memories, so as to reduce the chance of infant mortality. There are two levels of burned-in KGD. In the lowest level, the die are stressed at high temperatures for a period of time and then tested. In the higher level, the die are continuously tested while in the oven.

How do you decide what test level is appropriate for your MCM? The answer is driven purely by cost; the cost of test vs. the cost of repair. For example, consider a 4-chip MCM using mature ICs. Mature ICs tend to have very high yields, and the process engineers have learned how to prevent most failure modes. As a result, the chances are very small that a mature IC would pass the waferlevel functional test and fail in the MCM. With a test escape rate of 2%, there is only a 8% ($1 - 0.98^4$) chance that each MCM would need to have a chip replaced after assembly. If the repair costs \$30 per replaced chip, then the average excess repair cost per MCM is \$2.40. It is unlikely that a higher level of KGD would add only \$0.60 to the cost of a chip. Thus, the lowest test level is justified.

On the other hand, consider an MCM containing four immature ICs. The functional and parametric wafer-level tests are poor at capturing speed faults. In addition, the process engineers have not had a chance to learn how to maximize the chip yield and how to best detect potential problems. If the test escape rate was 5%, there would be a 40% chance that a 4-chip MCM would require a chip to be replaced. The average repair cost would be \$12 per MCM in this scenario, and the added test cost of obtaining speed-sorted die would be justified.

TABLE 8.10 Levels of Known Good Die and Their Impact

Known Good Die Level	Test Cost Impact	Test Escape Impact
Wafer level functional and parametric	Low	<1–2% fallout for mature ICs possibly >5% fallout for new ICs
At-pin speed sorted	Medium	Min. fallout for new digital ICs
Burned-in	High	Burn-in important for memories
Dynamically burned-in with full testing	Highest	Min. memory fallout

FIGURE 8.118 The effect of speed sorting on MCM performance.

For high-speed systems, speed sorting also greatly influences the speed rating of the module. Today, microprocessors, for example, are graded according to their clock rate. Faster parts command a higher price. In an MCM the entire module will be limited by the slowest chip on the module, and when a system is partitioned into several smaller chips, it is highly likely that a module will contain a slow chip if they are not tested.

For example, consider a set of chips that are manufactured in equal numbers of slow, medium, and fast parts. If the chips are speed sorted before assembly into the MCM, there should be 33% slow modules, 33% medium modules and 33% fast modules. If not speed sorted, these ratios change drastically as shown in Fig. 8.118. For a 4-chip module assembled from unsorted die, there will be 80% slow systems, 19% medium systems, and only 1% fast systems. This dramatic reduction in fast modules also justifies the need for speed-sorted die.

Design technology is also an important component to the MCM equation. Most MCM computer-aided design (CAD) tools have their basis in the PCB design tools. The main differences have been the inclusion of features to permit the use of the wide range of physical geometries possible in an MCM (particularly via geometries), as well as the ability to use bare die. A new format, the *die interchange format*, has been specifically developed to handle physical information concerning bare die (e.g., pad locations).

There is more to MCM design technology, however, than just making small changes to the physical design tools (those tools that actually produce the MCM wiring patterns). Design correctness is more important in an MCM than in a PCB. For example, a jumper wire is difficult to place on an MCM in order to correct for an error. Thus, recent tool developments have concentrated on improving the designers ability to ensure that the multichip system is designed correctly before it is built. These developments include new simulation libraries that allow the designer to simulate the entire chip set before building the MCM, as well as tools that automate the electrical and thermal design of the MCM.

8.9.4 When to Use Multichip Modules

There are a number of scenarios given as follows that typically lead to consideration of an MCM alternative.

1. You must achieve a smaller form factor than is possible with single chip packaging. Often integrating the digital components onto an MCM-L provides the most cost effective way in which to achieve the required size. MCM-D provides the greatest form factor reduction when the utmost smallest size is needed.
2. The alternative is a single die that would either be too large to manufacture or would be so large as to have insufficient yield. The design might be custom or semicustom. In this case, partitioning the die into a number of smaller die and using an MCM to achieve the interconnect performance of the large die is an attractive alternative.

3. You have a technology mix that makes a single IC expensive or impossible and electrical performance is important. For example, you need to interface a complementary-metal-oxide-semiconductor (CMOS) digital IC with a GaAs microwave monolithic integrate circuit (MMIC) or high bandwidth analog IC. Or, you need a large amount of static random access memory (SRAM) and a small amount of logic. In these cases, an MCM might be very useful. An MCM-L might be the best choice if the number of interchip wires are small. A high layer count MCM-C or MCM-D might be the best choice if the required wiring density is large.

4. You are pad limited or speed limited between two ICs in the single chip version. For example, many computer designs benefit by having a very wide bus (256 bits or more) between the two levels of cache. In this case, an MCM allows a large number of very short connections between the ICs.

5. You are not sure that you can achieve the required electrical performance with single chip packaging. An example might be a bus operating above 100 MHz. If your simulations show that it will be difficult to guarantee the bus speed, then an MCM might be justified. Another example might be a mixed signal design in which noise control might be difficult. In general MCMs offer superior noise levels and interconnect speeds to single-chip package designs.

6. The conventional design has a lot of solder joints and reliability is important to you. An MCM design has far fewer solder joints, resulting in less field failures and product returns. (Flip-chip solder bumps have shown themselves to be far more reliable than the solder joints used at board level.)

Though there are many other cases where the use of MCM technology makes sense, these are the main ones that have been encountered so far. If an MCM is justified, the next question might be to decide what ICs need to be placed on the MCM. A number of factors follow that need to be considered in this decision:

1. It is highly desirable that the final MCM package be compatible with single-chip packaging assembly techniques to facilitate manufacturability.
2. Although wires between chips on the MCM are inexpensive, off-MCM pins are expensive. The MCM should contain as much of the wiring as is feasible. On the other hand, an overly complex MCM with a high component count will have a poor final yield.
3. In a mixed signal design, separating the noisy digital components from the sensitive analog components is often desirable. This can be done by placing the digital components on an MCM. If an MCM-D with an integrated decoupling capacitor is used, then the on-MCM noise might be low enough to allow both analog and digital components to be easily mixed. Be aware in this case, however, that the on-MCM ground will have different noise characteristics than the PCB ground.

In short, most MCM system design issues are decided on by careful modeling of the system-wide cost and performance. Despite the higher cost of the MCM package itself, often cost savings achieved elsewhere in the system can be used to justify the use of an MCM.

8.9.5 Issues in the Design of Multichip Modules

The most important issue in the design of multichip modules is obtaining bare die. The first questions to be addressed in any MCM project are the questions as to whether the required bare die are available in the quantities required, with the appropriate test level, with second sourcing, at the right price, etc. Obtaining answers to these questions is time consuming as many chip manufacturers still see their bare die sales as satisfying a niche market. If the manufactured die are not properly available, then it is important to address alternative chip sources early.

The next most important issue is the test and verification plan. There are a number of contrasts with using a printed circuit board. First, as the nonrecurring engineering cost is higher for a multichip module, the desirability for first pass success is higher. Complete prefabrication design verification is more critical when MCMs are being used, so more effort must be spent on logic and electrical simulation prior to fabrication.

It is also important to determine, during design, how faults are going to be diagnosed in the assembled MCM. In a prototype, you wish to be able locate design errors before redoing the design. In a production module, you need to locate faulty die or wire bonds/solder bumps if a faulty module is to be repaired (typically by replacing a die). It is more difficult to physically probe lines on an MCM, however, than on a

FIGURE 8.119 The use of boundary scan eases fault isolation in an MCM.

PCB. A fault isolation test plan must be developed and implemented. The test plan must be able to isolate a fault to a single chip or chip-to-chip interconnection. It is best to base such a plan on the use of chips with **boundary scan** (Fig. 8.119). With boundary scan chips, test vectors can be scanned in serially into registers around each chip. The MCM can then be run for one clock cycle, and the results scanned out. The results are used to determine which chip or interconnection has failed. If boundary scan is not available, and repair is viewed as necessary, then an alternative means for sensitizing between-chip faults is needed.

The decision as to whether a test is considered necessary is based purely on cost and test-escape considerations. Sandborn and Moreno (1994) and Ng in Donane and Franzon (1992, Chap. 4) provide more information. In general, if an MCM consists only of inexpensive, mature die, repair is unlikely to be worthwhile. The cost of repair is likely to be more than the cost of just throwing away the failed module. For MCMs with only one expensive, low-yielding die, the same is true, particularly if it is confirmed that the cause of most failures is that die. On the other hand, fault diagnosis and repair is usually desirable for modules containing multiple high-value die. You do not wish to throw all of these die away because only one failed.

Thermal design is often important in an MCM. An MCM will have a higher heat density than the equivalent PCB, sometimes necessitating a more complex thermal solution. If the MCM is dissipating more than 1 W, it is necessary to check if any heat sinks and/or thermal spreaders are necessary.

Sometimes, this higher concentration of heat in an MCM can work to the designer's advantage. If the MCM uses one larger heat sink, as compared with the multiple heat sinks required on the single-chip packaged version, then there is the potential for cost savings.

Generally, electrical design is easier for a MCM than for a PCB; the nets connecting the chips are shorter, and the parasitic inductances and capacitances smaller. With MCM-D technology, it is possible to closely space the power and ground planes, so as to produce an excellent decoupling capacitor. Electrical design, however, cannot be ignored in an MCM; 300-MHz MCMs will have the same design complexity as 75-MHz PCBs.

MCMs are often used for mixed signal (mixed analog/RF and digital) designs. The electrical design issues are similar for mixed signal MCMs as for mixed signal PCBs, and there is a definite lack of tools to help the mixed signal designer. Current design practices tend to be qualitative. There is an important fact to remember that is unique to mixed signal MCM design. The on-MCM power and ground supplies are separated, by the package parasitics, from the on-PCB power and ground supplies. Many designers have assumed that the on-MCM and on-PCB reference voltages are the same only to find noise problems appearing in their prototypes.

For more information on MCM design techniques, the reader is referred to Doane and Franzon (1992), Tummula and Rymaszewski (1989), and Messner et al. (1992).

Defining Terms

Boundary scan: Technique used to test chips after assembly onto a PCB or MCM. The chips are designed so that test vectors can be scanned into their input/output registers. These vectors are then used to determine if the chips, and the connections between the chips are working.

Ceramic MCM (MCM-C): A MCM built using ceramic packaging techniques.

Deposited MCM (MCM-D): A MCM built using the deposition and thin-film lithography techniques that are similar to those used in integrated circuit manufacturing.

Flip-chip solder-bump: Chip attachment technique in which pads and the surface of the chip have a solder ball placed on them. The chips are then flipped and mated with the MCM or PCB, and the soldered reflowed to create a solder joint. Allows area attachment.

Known good die (KGD): Bare silicon chips (die) tested to some known level.

Laminate MCM (MCM-L): A MCM built using advanced PCB manufacturing techniques.

Multichip module (MCM): A single package containing several chips.

Printed circuit board (PCB): Conventional board found in most electronic assemblies.

Tape automated bonding (TAB): A manufacturing technique in which leads are punched into a metal tape, chips are attached to the inside ends of the leads, and then the chip and lead frame are mounted on the MCM or PCB.

Wire bond: Where a chip is attached to an MCM or PCB by drawing a wire from each pad on the chip to the corresponding pad on the MCM or PCB.

Acknowledgments

The author wishes to thank Andrew Stanaski for his helpful proofreading and for Fig. 8.119 and the comments related to it. He also wishes to thank Jan Vardaman and Daryl A. Doane for providing the tremendous learning experiences that lead to a lot of the knowledge provided here.

Further Information

Additional information on the topic of multichip module technology is available from the following sources:

The major books in this area are listed in the References.

The primary journals are the *IEEE Transactions on Components, Packaging and Manufacturing Technology, Parts A and B*, and *Advancing Microelectronics*, published by ISHM.

The foremost trade magazine is *Advanced Packaging*, available free of charge to qualified subscribers.

The two main technical conferences are: (1) The IEEE Multichip Module Conference (MCMC), and (2) the ISHM/IEEE Multichip Module Conference.

8.10 Testing of Integrated Circuits

Wayne Needham

8.10.1 Introduction

The goal of the test process for integrated circuits is to separate good devices from bad devices, and to test good devices as good. Bad devices tested as bad become yield loss, but they also represent opportunity for cost reduction as we reduce number of **defects** in the process. When good devices are tested as bad,

overkill occurs and this directly impacts cost and profits. Finally, bad devices tested as good signal a quality problem, usually represented as *defects per million* (DPM) devices delivered.

Unfortunately, the test environment is not the same as the operating environment. The test process may reject good devices and may accept defective devices as good. Here lies one of the basic problems of today's test methods, and it must be understood and addressed as we look at how to generate and test integrated circuits. Figure 8.120 shows this miscorrelation of test to use.

FIGURE 8.120 Test miscorrelations.

Bad devices are removed from good devices through a series of test techniques that enable the separation, by either voltage- or current-based testing. The match between the test process and the actual system use will not be addressed in this chapter.

8.10.2 Defect Types

Defects in an integrated circuit process fall into three broad categories. They are:

- Opens or abnormally high-resistance portions of signal lines and power lines that increase the series resistance between connected points. This extra resistance slows the charging of the parasitic capacitance of the line, thus resulting in a time delay. These defects also degrade voltage to a transistor circuit, which reduces levels or causes delays.
- Shorts, bridges, or resistive connections between layers of an integrated circuits, which form a resistance path in a normal insulating area. Given sufficiently low R value, the path may not be able to drive a 1 or a 0.
- Parameter variations such as threshold voltage and saturation current deviations changed by contamination, particles, implant, or process parameter changes. These usually result in speed or drive level changes.

Table 8.11 shows several types of defects and how they are introduced into an integrated circuit. It also describes electrical characteristics.

Defects, although common in integrated circuit processes, are difficult to quantify via test methods. Therefore, the industry has developed abstractions of defects called **faults**. Faults attempt to model the way defects manifest themselves in the test environment.

Traditional Faults and Fault Models

The most widely used fault model is the *single stuck-at fault* model. It is available in a variety of simulation environments with good support tools. The model represents a defect as a short of a signal line to a power supply line. This causes the signal to remain fixed at either a logic one or a zero. Thus, the logical result of an operation is not propagated to an output. Figure 8.121 shows the equivalent of a single stuck-at one or zero fault in a logic circuit. Although this fault model is the most common one, it was developed

TABLE 8.11 Typical IC Defects and Failure Modes

Defect	Source	Electrical Characteristic
Extra metal or interconnect	particle	ohmic connection between lines
Constrained geometry	insufficient or under etching	higher than normal resistance
Foreign material induced in the process in the process	contamination	varying resistance or short

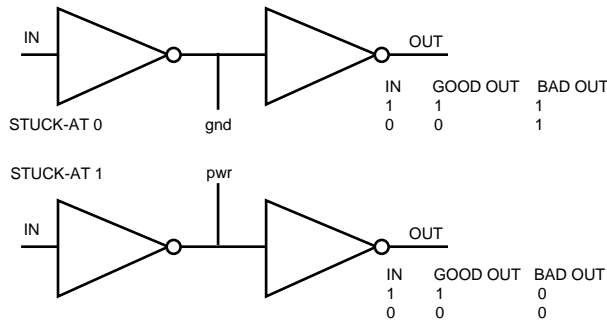

FIGURE 8.121 The single stuck-at model.

over 30 years ago, and does not always reflect today's more advanced processes. Today's very large-scale integrated (VLSI) circuits and submicron processes more commonly have failures that closely approximate bridges between signal lines. These bridges do not map well to the stuck-at fault model.

Other proposed or available fault models include:

- The *open fault model*: This model is for open circuits. Unfortunately in CMOS, missing contacts and transistors can exhibit correct behavior when switching at speed, even if some of the transistors or contacts are missing.
- The *leakage fault model*: This model assumes leakage in transistors and lends itself to an I_{DDQ}^2 test technique (discussed later in this chapter).
- *Timing fault models* (delay, gate and transition faults): All of these models assume a change in the AC characteristics of the circuit. Either a single gate, line, or block of circuitry is slower than needed or simulated, and this slow signal causes a problem with at-speed operation of the integrated circuit.
- *Pseudostuck-at model fault model* for I_{DDQ} : This model assumes nodes look like they are stuck at a one or zero logic level.
- *Voting fault models*, and bridge models: Adjacent lines are assumed connected and the logic result is an X (unknown), or a vote with the highest drive strength circuit dominating the logic level.
- Also for memory circuits.
- *Neighborhood pattern faults*: This fault assumes operations in one memory cell will affect adjacent memory cells (usually limited to the four closest cells).
- *Coupling faults*: This fault model assumes that full rows or columns couple signals into the cells or adjacent rows and columns.
- *Retention faults*: These faults are similar to the open fault for logic (discussed previously). Failures to this fault model do not retain data over an extended period of time.

There are many other fault models.

It is important to realize that the stuck-at model may not necessarily catch failures and/or defects in the fabrication processes. This problem is being addressed by the computer-aided design (CAD) industry. Today, numerous solutions are available, or on the horizon, that address the issues of fault models. Tools currently available can support delay faults. Bridging fault routines have been demonstrated in university research, and should be available from selected CAD vendors within a few years. Soon, we will not be confined to testing solely through the single stuck-at model.

² I_{DDQ} is the I_{IEEE} symbol for quotient current in a CMOS circuit.

FIGURE 8.122 Logic diagram and test set.

8.10.3 Concepts of Test

The main test method of an integrated circuit is to control and observe nodes. Doing this verifies the logical operation that ensures that the circuit is fault free. This process is usually done by generating stimulus patterns for the input and comparing the outputs to a known good state. Figure 8.122 demonstrates a classic case where a small portion of an integrated circuit is tested with a stimulus pattern set for inputs and an expected set for outputs. Note this test set is logic, not layout, dependent and checks only stuck at faults.

Types of Test

There are three basic types of test for integrated circuits. These are parametric tests, voltage tests, and current tests. Each has a place in the testing process.

Parametric tests ensure the correct operation of the transistors (voltage and current) of the integrated circuit. Parametric tests include timing, input and output voltage, and current tests. Generally, they measure circuit performance. In all of these tests, numbers are associated with the measurements. Typical readings include: $T_x < 334$ ns, $I_{OH} < 4$ mA, $V_{OI} < 0.4$ V, etc.

The next major category of testing is power supply current tests. Current tests include active switching current or power test, power down test, and standby or stable quiescent current tests. This last test, often called I_{DDQ} , will be discussed later.

The most common method of testing integrated circuits is the voltage-based test. Voltage-based test for logic operations includes functions such as placing a one on the input of an integrated circuit and ensuring that the proper one or zero appears on the output of the IC at the right time. Logical values are repeated, in most cases, at high and low operating voltage. The example in Fig. 8.122 is a voltage-based test.

Test Methods

To implement voltage based testing or any of the other types of tests, initialization of the circuit must take place, and control and observation of the internal nodes must occur. The following are four basic categories of tests:

- External stored response testing. This is the most common form for today’s integrated circuits and it relies heavily on large IC **automated test equipment (ATE)**.
- **Built-in-self-test (BIST)**. This is method of defining and building test circuitry onto the integrated circuit. This technique provides stimulus patterns and observes the logical output of the integrated circuit.
- **Scan** testing. Some or all of the sequential elements are converted into a shift register for control and observation purposes.
- Parametric tests. The values of circuit parameters are directly measured. This includes the I_{DDQ} test, which is good at detecting certain classes of defects. To implement an I_{DDQ} test, a CMOS integrated

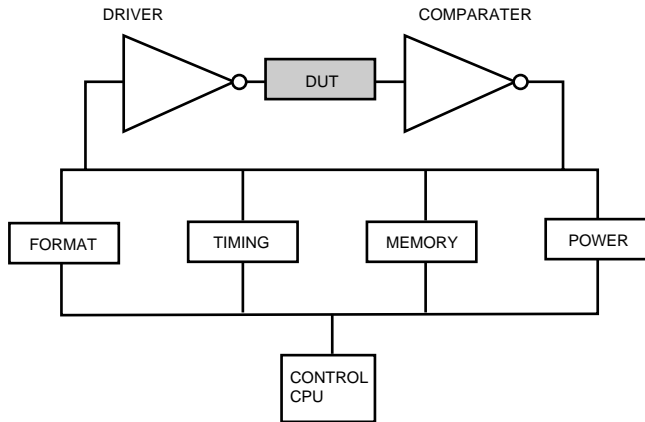

FIGURE 8.123 Stored response tester and DUT.

circuit clock is stopped and the quiescent current is measured. All active circuitry must be placed in a low-current state, including all analog circuitry.

External Stored Response Testing

Figure 8.123 shows a typical integrated circuit being tested by a stored response tester. Note that the patterns for the input and output of the integrated circuit are applied by primary inputs, and the output is compared to known good response. The process of generating stored response patterns is usually done by simulation. Often these patterns are trace files from the original logic simulation of the circuit. These files may be used during simulation for correct operation of the logic and later transferred to a tester for debug, circuit verification, and test. The patterns may take up considerable storage space, but the test pattern can easily detect structural and/or functional defects in an integrated circuit.

To exercise the **device under test (DUT)**, a stored response functional tester relies on patterns saved from the logic simulation. These patterns include input and output states and must account for unknown or X states. The set of patterns for functional test can usually be captured as trace files, or change files, and then ported to the test equipment. Trace or change files capture the logic state of the DUT as its logical outputs change over time. Typically, these patterns represent the logical operation of the device under test. As such, they are good for debugging the operation and design of integrated circuits. They are not the best patterns for fault isolation or yield analysis of the device.

BIST

The most common implementation of BIST is to include a **linear feedback shift register (LFSR)** as an input source. An LFSR is constructed from a shift register with the least significant bit fed back to selected stages with exclusive-OR gates. This feedback mechanism creates a polynomial, which successively divides the quotient and adds back the remainder. Only certain polynomials create pseudorandom patterns. The selection of the polynomial must be carefully considered. The LFSR source, when initialized and clocked correctly, generates a pseudorandom pattern that is used for the stimulus patterns for a block of logic in an integrated circuit.

The common method of output compaction is to use a **multiple input shift register (MISR)**. A MISR is an LFSR with the outputs of the logic block connected to the stages of the LFSR with additional exclusive-OR gates. The block of logic, if operating defect free, would give a single correct signature (see Fig. 8.124). If there is a defect in the block of logic, the resultant logic error would be captured in the output MISR. The MISR constantly divides the output with feedback to the appropriate stages such that an error will remain in the MISR until the results are read at the end of the test sequence. Because the logic states are compacted in a MISR, the results may tend to mask errors if the error repeats itself in the output, or if there are multiple errors in the block. Given a number of errors, the output could contain the correct answer

FIGURE 8.124 BIST implementation example with inputs and outputs.

even though the logic block contains errors or defects. This problem is called *aliasing*. For example, the output register shown in Fig. 8.124 is 20-bits long; 2^{20} is approximately one million, which means that there is a very high chance that without an aliasing defect, the output will be the correct state of one out of a million with a fault free integrated circuit.

It should be noted that the example is shown for combination logic only. Sequential logic becomes more difficult as initialization, illegal states, state machines, global feedback, and many other cases must be accounted for in the generation of BIST design and patterns.

Scan

Scan is a technique where storage elements (latches and flip-flops) are changed to dual mode elements. For instance, Fig. 8.125 shows a normal flip-flop of an integrated circuit. Also shown in Fig. 8.125 is a flip-flop converted to a scan register element. During normal operation, the D input and system clock control the output of the flip-flop. During scan operation, the scan clocks are used to control shifting of data into

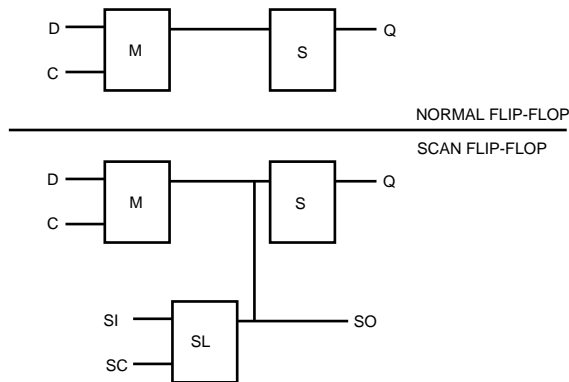

FIGURE 8.125 Example of a scan latch and flip flop.

and out of the shift register. Data is shifted into and out of the master and scan latch. The slave latch can be clocked by the system clock in order to generate a signal for the required stimulation of the logic between this scan latch and the next scan latches. Figure 8.126 shows latches and logic between latches. This method successfully reduces the large sequential test problem to a rather simple combinatorial problem. The unfortunate problem with scan is that the area overhead is, by far, the largest of all **design for test (DFT)** methods. This area increase is due to the fact that each storage element must increase in transistor count to accommodate the added function of scan.

FIGURE 8.126 Use of scan latch for logic.

Note that the scan latch contains extra elements for control and observation. These extra elements include the scan-clock (SC), scan-in (SI), and scan-out (SO). As shown in Fig. 8.126, the scan-clock is used to drive all scan latches. This controls the shift register function of the scan latch, and will allow a known one or zero to be set for each latch in the scan chain. For each scan clock applied, a value of one or zero is placed on the scan-in line, which is then shifted to the scan-out and the next scan-in latch. This shifting stops when the entire chain is initialized. At the end of the scan in sequence, a system clock is triggered, which launches data from the scan portion of the latch of the Q output. Then it goes through the combinational logic to the next stage D input where another system clock stores it in the latch. The next set of scan loads, and shifts out the stored value of the logic operation for comparison. If the logic operation was correct, the scan value will be correct in the shift out sequence.

I_{DDQ}

I_{DDQ} is perhaps the simplest test concept. Figure 8.127 shows a typical dual inverter structure with a potential defect. It also shows the characteristic of I_{DDQ} . The upper circuit is defect free, and the lower circuit has a leakage defect shown as R . I_{DDQ} is shown for each clock cycle. Note the elevated current in the defective circuit during clock cycle A. This elevated current is called I_{DDQ} . It is an easy way to check for most bridging and many other types of defects. The I_{DDQ} test controls and observes approximately half of the transistors in a IC for each test. Therefore, the test is considered massively parallel and is very efficient at detecting bridge defects and partial shorts. Another consideration is the need to design for an I_{DDQ} test. All DC paths, pullups, bus drivers, and contention paths must be designed for zero current when the clock is stopped. One single transistor remaining on, can disable the use of an I_{DDQ} test.

Note that V_{out} and I_{DD} in the defective case may be tolerable if the output voltage is sufficient to drive the next input stage. Not shown here is the timing impact of the degraded voltage. This degraded voltage will cause a time delay in the next stage.

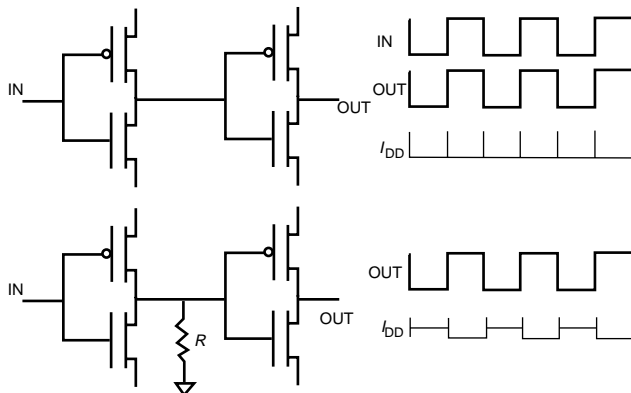

FIGURE 8.127 I_{DDQ} test values.

TABLE 8.12 Attributes of Test

Test Types	Complexity	Illegal States	Aliasing	Silicon Overhead	Test Pattern Generation Time
SCAN	Simple	Controlled	NA	Highest	Shortest
BIST	Complicated with latches	Big problem	Yes	Moderate	Moderate
Stored response	Very complicated	NA	NA	None-little	Longest
I_{DDQ}	Low	None	None	None	Simple

8.10.4 Test Tradeoffs

To determine the best type of test, one must understand the defect types, the logical function of the integrated circuit, and test requirements. Examples of test tradeoffs are included in Table 8.12. The rows in the table correspond to the test types as listed earlier: scan, BIST, stored response, and I_{DDQ} . The columns in the table depict certain attributes of test to be described here.

The first column is the test type. Column number two shows pattern complexity. This is the problem of generating the necessary patterns in order to fully stimulate and control the nodes of the integrated circuit. Column number three is illegal states. Often times the logic in integrated circuits, such as bidirectional bus drivers and signals, must be exclusively set one way or another. Examples include decoders, bus drivers and mutually exclusive line drivers. Tests such as scan and BIST, if not designed and implemented correctly, can damage the integrated circuit during the test process by putting the circuit into an internal contention state. Examples include two bus drivers on simultaneously when one drives high and the other drives low.

Aliasing is a common problem of BIST techniques. This is shown in column four. For example, consider a memory laid out in rows and columns and assume that one column is a complete failure. If there are multiple failures along the column, let us say 256, and if the signature length is 256, the output could possibly show a correct response even though the entire column or row of the memory is defective.

The next column shows overhead. Overhead is the amount of silicon area necessary to implement the specific types of test methods.

The final column is the time for test generation. The unfortunate relationship here is that the techniques with the highest area overhead have the most complete control and are easiest to generate tests. Techniques with the lowest area needs have the most complex test generation problem, and take the longest time. This is a complex trade off.

Tradeoffs of Volume and Testability

It is important to forecast the volume of the integrated circuit to be manufactured prior to selecting DFT and test methods. Engineering effort is nonrecurring and can be averaged over every integrated circuit manufactured. The testing of an integrated circuit can be a simple or a complex process. The criteria used for selecting the proper test technique must include volume, expected quality, and expected cost of the integrated circuit. Time to market and/or time to shipments are key factors, as some of the test techniques for very large integrated circuits take an extremely long time.

Defining Terms

Automated test equipment (ATE): Any computer controlled equipment used to test integrated circuits.

Built-in self-test (BIST): An acronym that generally describes a design technique with input stimulus generation circuitry and output response checking circuitry.

Defect: Any error, particle, or contamination of the circuit structure. Defects may or may not result in faulty circuit operation.

Design for test (DFT): A general term which encompasses all techniques used to improve control and observation of internal nodes.

Device under test (DUT): A term used to describe the device being tested by the ATE.

Fault: The operation of a circuit in error. Usually faulty circuits are the result of defects or damage to the circuit.

Linear feedback shift register (LFSR): A method of construction of a register with feedback to generate pseudo random numbers.

Multiple input shift register (MISR): Usually an LFSR with inputs consisting of the previous stage exclusive OR'ed with input data. This method compacts the response of a circuit into a polynomial.

Scan: A design technique where sequential elements (latches, or flipflops) are chained together in a mode that allows data shifting into and out of the latches. In general, scan allows easy access to the logic between latches and greatly reduces the test generation time and effort.

8.11 Integrated Circuit Packages³

Victor Meeldijk

8.11.1 Introduction

In 1958 the first IC invented had one transistor on it, when the first 8086 microprocessor debuted on June 8, 1978 it contained 29,000 transistors and ran at 5 MHz, the first Intel® Pentium® (1993) had roughly 3.1 million transistors and in 2004 the Intel® Pentium® 4 processor contains 55 million transistors and runs more than 600 times faster than the original 8086 processor at 3.06 GHz. In the near future microprocessors will have more than 1 billion transistors. As semiconductor devices become more complex, the interconnections from the die to the circuit hardware keep evolving. Devices with high clock rates and high-power dissipation, or with multiple die, are leading to various new packages.

The use of bare die in chip on board (COB) and multichip module (MCM) applications is increasing with designers looking for end item size and weight reduction (automotive applications have bond wires going directly from the die to a connector). The use of bare die eliminates the timing delays (caused by stray inductance and capacitance) associated with the leadframes and the device input/outputs (I/Os). For burst mode static RAMs, 1/2–2 ns or a 20% improvement in access time is achieved with bare die product. Small portable devices can also use flip-chip bonding.

IC packaging can be divided into the following categories:

- Surface mount packages (plastic or ceramic)
- Chip-scale packaging
- Bare die

³Portions of this chapter were adapted from: Meeldijk, V., 1995. *Electronic Components: Selection and Application Guidelines*, Chap. 12. Wiley-Interscience, New York. With permission.

FIGURE 8.128 Some typical IC packages for through-hole applications.

- Through-hole packages
- Module assemblies

In addition to bare die and surface mount techniques, there are still the older device packages for through-hole applications, where the lead of the package goes through the printed wiring board (see Fig. 8.128 and Fig. 8.129). Modules are also available that are assemblies of either packaged parts or die.

Although there are standards for some IC packages, such as the dual-in-line packages and the transistor outline (TO) registered Joint Electronic Device Engineering Council (JEDEC) packages, many IC packages styles are (initially) unique to the vendor that developed them (such as in 1990 when the Intel developed the molded plastic quad flat package).

All JEDEC (a subdivision of the Electronics Industries Association [EIA]) semiconductor outlines are included in their Publication 95 and terms are defined in their Publication 30, *Descriptive Designation System for Semiconductor Device Packages* (note: EIAJ is the Japanese EIA).

8.11.2 Surface Mount Packages

Plastic surface mount packages result in a device that is light, small, able to withstand physical shock and *g* forces, and inexpensive due to a one-step manufacturing process. The plastic is molded around the lead frame of the device. Work is still continuing on developing coatings for the die, such as polyimide, which may resolve hermeticity problems and coefficient of thermal expansion mismatches between the die and the plastic package.

Plastic parts shipped in sealed bags with desiccant are designed for 12 months storage and should only be opened when the parts are to be used. Parts stored for longer than this time, especially plastic quad

flatpack (PQFP) packaged devices, should be baked to remove moisture that has entered the package. Plastic packages are hygroscopic and absorb moisture to a level dependent on the storage environment. This moisture can vaporize during rapid heating, such as in a solder reflow process, and these stresses can cause package cracking (known as the popcorn effect). Subsequent high-temperature and moisture exposures can allow contaminants to enter the IC and cause failure at a later time due to corrosion. Consult the device manufacturer for details on proper device handling.

Hermetic packages, such as the older flat pack design or ceramic leadless chip carriers (CLCCs), are used in harsh applications (such as military and space applications) where water vapor and contaminants can shorten the life of the device. Thus they are used in mission critical communication, and navigation and avionic systems. The reliability of CLCC package connections can be further improved by the attachment of leads to the connection pads, to eliminate differences in the thermal coefficient of expansion between the parts and the circuit board material.

Metal packages, with glass seals, provide the highest level of hermetic sealing followed by glasses and ceramics (Fig. 8.130). These parts have a higher temperature range than plastic encapsulated parts (typically, from -55 to $+125^{\circ}\text{C}$ vs. 0 to 70°C , or 85°C , for plastic encapsulated devices). Although aluminum oxide, the most commonly used ceramic material, has a thermal conductivity that is an order of magnitude less than a plastic packaged device, in a ceramic sealed device the circuit die does not come into contact

FIGURE 8.130 Typical hermetic IC packages (from the left going clockwise): PGA, flat pack, VIL, LCC and DIP. The bottom photo shows the VIL from a different angle so both rows of pins can be seen.

with the ceramic packaging material. Thus, temperature cycling will not affect the die, and parts can withstand thousands of temperature cycles without damage (1000 temperature cycles would simulate 20 years use on a commercial airliner). Large die plastic encapsulated parts can fail after only 250 temperature cycles. As mentioned earlier, die coatings being developed may resolve this problem. One of the main drawbacks in specifying ceramic packaged devices is the more complicated (than plastic encapsulated parts) manufacturing process. These devices are made up of three ceramic layers, which result in a higher cost device. Availability is limited, and lead times are often longer than standard plastic devices.

Surface mount packages (and related packaging terms) include the following.

First is ball grid array (BGA) (Fig. 8.131 to Fig. 8.133), a packaging technique developed by IBM (also known as an overmolded pad-array carrier (OMPAC), a plastic version developed by Motorola, see Fig. 8.134). Leads, or pads, are replaced by solder balls that replace high pin count quad flatpacks (QFPs). Several hundred arrayed leads can be accommodated in areas that a few hundred peripherally arranged leads would occupy.

The package transfers heat more efficiently than a QFP. To further assist heat dissipation there is a metal-lid BGA that uses metal ribbons and thermal silicon to transfer heat to the package's metal lid (pioneered by Samsung Electronics South Korea).

A disadvantage of the BGA package is that solder connections cannot be visually inspected and removed parts cannot be reused without the parts being "re-balled." A major manufacturer however, reports a joint failure rate of only 6 ppm. Problems generally occur only from defective components, bad boards, setup errors, or worn/damaged machines in the assembly line.

FIGURE 8.131 A 256-pin perimeter BGA (no connections are under the die). (Source: Courtesy of AMKOR/ANAM-AMKOR Electronics, Chandler, AZ.)

FIGURE 8.132 A 255 bump BGA, 1.5-mm pitch between leads, 27 × 27 mm body size (Source: Courtesy of Motorola, Inc., Phoenix, AZ. © Motorola. With permission.)

FIGURE 8.133 A 1.27-mm staggered pitch, 313 bump BGA with distributed vias, 35-mm body size. (Source: Courtesy of Motorola, Inc., Phoenix, AZ. © Motorola. With permission.)

Other BGA versions include the perimeter lead BGA, which does not have any solder balls under the chip, uBGA (micro BGA). Reference J-STD-013, first issued by the EIA in 1996 (847-509-7000) for further information on BGA packages.

Other surface mount packages (and related packaging terms) follow:

- Biometric package—A package where the die is exposed but the interconnections are protected by a window frame and plastic encapsulant. Developed by Harris Corporation (Melbourne, FL) in 1996 for a sensor chip used to recognize a person’s fingerprint.
- caBGA—Chip array BGA (from Lattice Semiconductor). This package is 87% smaller than a comparable PLCC package.
- Ceramic ball grid array (CBGA).
- Ceramic column grid array (CCGA), invented by IBM, where solder columns replace the solder balls.
- Cerpack, a flatpack composed of a ceramic base and lid. The leadframe is sealed by a glass frit.
- Cerquad, a ceramic equivalent of plastic leaded chip carriers consisting of a glass sealed ceramic package with J leads and ultraviolet window capability.

FIGURE 8.134 A plastic (OMPAC) BGA. (Source: Courtesy of Motorola Inc. Phoenix, AZ. © Motorola. With permission.)

- Ceramic pin grid array (CPGA).
- Ceramic quad flat package with J leads (CQFJ).
- Ceramic quad flatpack (CQFP), an aluminum ceramic integrated circuit package with four sets of leads extending from the sides and parallel to the base of the IC.
- Ceramic small outline with J leads (CSOJ).
- Chip scale grid array (CSGA), like a BGA, but with a smaller solder ball pitch (0.5–0.65 vs. 1.3–2.5 mm). This is used for devices with 200 or more leads.
- Dual small outline package (DSOP).
- EDQUAD, a trademark of ASAT Inc. for a plastic package that incorporates a heat sink; available as thin QFP (TQFP) and QFP (see Fig. 8.135).
- Enhanced Plastic BGA (EPBGA)—developed by LSI Logic and made available in 1995, this package supports 313 to 750 leads and is designed for high frequency ASIC applications.
- FCBGA, Flip Chip BGA, a design by Fujitsu Microelectronics for use with high frequency, high I/O devices that is large enough to handle the thermal requirements of RISC processors, IP and ATM switching devices.
- FCOB, Flip Chip on Board
- Flatpack (or quad flatpack), one of the oldest surface mount packages, used mainly on military programs. Typically, flatpacks have 14–50 leads on both sides of the body on 0.050-in centers.
- Flat SIP, a single inline package except the leads have a 90° bend.
- Flatpack (FP).
- fpBGA—Fine pitch BGA.
- fpsBGA—Fine pitch super BGA.
- Gull winged leadless chip carrier (GCC). Although easier to inspect, it is weaker than the J lead.
- Gull wing, leads which exit the body and bend downward, resembling a seagull in flight. Gull wings are typically used on small outline (SO) package, but are very fragile, easily bent, and difficult to socket for testing or burn-in. J leads solve these problems.

FIGURE 8.136 An LCC package with C leads attached to compensate for the thermal coefficient of expansion mismatch between the part and the circuit board, thus lowering solder joint stresses. (Source: Courtesy of General Dynamics, Information Systems, Formerly Computing Devices International, Bloomington, MN.)

- Hermetic chip carrier (HCC).
- HD-PQFP, originated by Intel for a high density PQFP package with more than 196 leads with a 0.4-mm pitch.
- Heat spreader QFP package (HQFP), package has a copper heat spreader and heat sink.
- HQSOP, a hermetic QSOP package created by Quality Semiconductor in 1995 (Quality Semiconductor has since been acquired by IDT Semiconductor).
- Hermetic small outline transistor (H-SOT) packaged device.
- I lead, IC leads that are formed perpendicular to the printed circuit board making a butt solder joint.
- J leads, leads that are rolled under the body of the package in the shape of the letter J. They are typically used on plastic chip carrier packages.
- J bend leads, leaded chip carrier (JCC).
- J leaded ceramic chip carrier (JLCC).
- Leadless chip carrier (LCC), a chip package with I/O pads on the perimeter of the package. Cavity (lid) up packages, with the backside of the die facing the substrate, have heat dissipated through the substrate. These JEDEC B and C ceramic packages are not suitable for air-cooled systems or for the attachment of heat sinks. Cavity (lid) down parts, (JEDEC A and D) with the die facing away from the substrate, are suitable for air-cooled systems. Rectangular, ceramic leadless E and F are intended for memory devices, with direct attachment in the lid-up position. Computing Devices International devised patented C and S leads that can be attached, as shown in Fig. 8.136.
- Leadless ceramic chip carrier (LCCC), or ceramic leadless chip carrier. JEDEC registered type A must be socketed when on a printed circuit board or a ceramic substrate board, and type B must be soldered. The LCC minipack must be soldered onto printed circuit boards.
- Leaded ceramic chip carrier (LDCC), leaded ceramic chip carrier packages include JEDEC types A, B, C, and D. Leaded type B parts are direct soldered to a substrate. Leaded type A parts can be socketed or direct soldered, and include sub-categories: leaded ceramic, premolded plastic, and postmolded plastic (which are not designated as LDCC devices).
- Land grid array (LGA), an Intel package used for parts such as the 80386L microprocessor. The package is similar to a PGA except that it has gold-plated pads (called *landing pads*) vs. pins.
- Leadless inverted device (LID), a shaped metallized ceramic form used as an intermediate carrier for the semiconductor chip (die). It is especially adapted for attachment to conductor lands of a thick-film or thin-film network by reflow solder bonding.

- Little foot (a trademark of Siliconix), a tiny small outline integrated circuit (SOIC) package.
- Leadless ceramic chip carrier (LLCC).
- Mini-BGA (mBGA), developed by Sandia National Laboratories. Layers of polyimide and metal are applied to the die to redistribute original die pads from a peripheral arrangement into an area array configuration.
- Miniflat, a flat package (MFP) approximately 0.102–0.113 in high (2.6–2.85 mm) that may have leads on two or four sides of the package.
- Multilayer molded (MM) package, an Intel PQFP package with improved high-speed operation due to separate power and ground planes, which reduces device capacitance.
- MM-PQFP, isolated ground and power planes are incorporated within the molded body of the PQFP.
- MQFP—Metal Quad Flatpack. Sometimes used to refer to a plastic metric quad flat pack (such as Harris Corporation, Harris sold its semiconductor operations, now known as Intersil Corp.).
- MQuad, designed by the Olin Corporation, a high thermal dissipation aluminum package available in plastic leaded chip carrier (PLCC) and QFP packages (with 28–300 leads, and clock speeds of 150 MHz) (see Fig. 8.137).
- MSOP—miniature SOP.
- OMPAC, see BGA.
- Pad array carrier (PAD), a surface mount equivalent of the PGA package. This package extends surface mount silicon efficiency from 15 to 40%. A disadvantage of this package is that the solder joints cannot be visually inspected, although X-ray inspection can be used to verify the integrity of the blind solder connections (and to check for solder balls and bridging). Individual solder joints, however, cannot be repaired.
- Plastic (encapsulated) ball grid array (PBGA), see OMPAC.
- Plastic leaded chip carrier (PLCC) also known as PLDCC or a quad pack by some manufacturers, up to 100 pin packages, commonly 0.050-in pin spacing. Depending on the number of pins, pin 1 is in different locations but is confirmed by a dot in the molding, and the progression of the pin count continues counterclockwise. The leads are J shaped and protrude from the package. These parts

FIGURE 8.137 An MQUAD (trademark OLIN Corporation) package. (Source: Courtesy of Hawa Technologies (HTL) formerly Swire Technologies, San Jose, CA.)

can be either surface mounted or socketed. (This package was originally known as a *postmolded type A* leaded device.)

- Plastic quad flatpack (PQFP), this JEDEC approved package is used for devices that have 44–256 I/Os, 0.025-in lead spacing (EIA-JEDEC packages), 0.0256- and 0.0316-in spacing (EIAJ), and 0.0135-in pin spacing. This package has gull wing leads on all four sides and is characterized by bumpers on the corners. The body is slightly thicker than the QFP. PQFP packages are susceptible to moisture-induced cracking in applications requiring reflow soldering.
- Plastic surface mount component (PSMC).
- PSOP—plastic SOP (a term used by the Intel Corporation).
- Quad flat J (QFJ) leaded package.
- QFN—Quad Flatpack, no leads.
- Quad flatpack (QFP), a flatpack with leads on all four sides. The typical JEDEC approved pinouts are 100, 132, and 196, with lead pitch from 0.040 to 0.016 in. The EIAJ types are slightly thinner than the JEDEC equivalents (Fig. 8.138).
- Quarter quad flatpack (QQFT), see SQFT.
- Quad surface mount (QSM).
- Quarter-size small outline package (QSOP).
- Quad pack, see PLCC.
- QVSOP—Quad Very Small Outline Package, introduced by Quality Semiconductor (Note: Acquired by IDT Semiconductor) in late 1993. This package combines the body size of a half width, 14 pin SOIC, with the 25-mil lead pitch of a PQFP (or a 150 × 390 mil, 48 pin package). The package has designation JEDEC MO-154.
- Quad very small outline package (QVSOP), introduced by Quality Semiconductor. This package combines the body size of a half-width, 14-pin SOIC, with the 25-mil lead pitch of a PQFP (or a 150 × 390 mil, 48-pin package). The package has designation JEDEC MO-154.
- Repatterned die, see BGA.
- Square (body) chip carrier (SCC).
- Slam pack, a square ceramic package that looks like an LCC and is always used with a socket.

FIGURE 8.138 A QFP package. (Source: Courtesy of ASAT, Inc., Palo Alto, CA.)

- Small outline (SO) (with versions such as SO wide, SO narrow, or SO large), this design originated with the Swiss watch industry in the 1960s (and was reportedly nicknamed SO for Swiss Outline). It was used in the modern electronics industry by N.V. Philips (formerly known as Signetics in the U.S.) in 1971. This package is also known as a *mini-flat* (which has slightly different dimensions than the JEDEC parts by the Japanese). Common packages are SOD-323, SOD-523, SOD-123, see also SOT.
- Small outline IC (SOIC), 8–28 pin packages, commonly 0.050-in pin spacing, with gull wing leads. This package style is about 50–70% of the size of a standard dual in line package (DIP) part (30% as thick).
- Small outline package with J leads on two sides (SOJ). The leads are bent back around the chip carrier.
- Small outline large (SOL), generally refers to a package that is 0.300 mils wide vs 150 mils wide (for an SO package). It is a larger version of the small shrink outline package (SSOP).
- Small outline package (SOP), a package with two rows of narrowly spaced gull-wing leads (same as SOIC).
- Small outline transistor (SOT), a plastic leaded package originally for diodes and transistors but also used for some ICs (such as Hall effect sensors). Some common sizes are SOT-23, SOT-26, SOT-223, and the very small SOT-523.
- Small outline wide (SOW), see SOL.
- Shrink quad flatpack (or flat package) (SQFP), typically a 64-pin small quad flat package (1/4 height of QFT) with a lead pitch of 0.016 in or less. Also known as quarter quad flat pack (QQFT).
- Square surface mounting (SSM).
- Shrink small outline package (SSOP).
- Shrink small outline IC (SSOIC), a plastic package with gull-wing leads on two sides, with a lead pitch equal to or less than 0.025 in.
- Tape ball grid array (TBGA).
- Thin QFP (TQFP). Typical sizes are 1.0- and 1.4-mm body thickness, in sizes ranging from 10 × 10 mm to 20 × 20 mm and lead count from 64 to 144 leads.
- Thin small outline package (TSOP). The type-1 plastic surface mount parts have 0.5-mm gull-wing leads on the edges of the parts (the shorter dimension) rather than along the sides (longer dimension). The type-2 parts have the leads on the longer dimension. These packages are generally used for memory ICs.
- Thin shrink (or sometimes called scaled) small outline package (TSSOP), half the height of a standard SOIC. Also known as thin super small outline package by ICT, Inc. (San Jose, CA, see www.anachip.com) and thin small shrink outline, by Mictosemi Integrated products, formerly Linfinity Microelectronics (Garden Grove, CA).
- TVSOP, thin very-small outline package, by Texas Instruments in 1996 for the PCMCIA industry, the package meets the 1.2 mm height for PCMCIA cards. The package has low inductance (for a 14 pin package 2.31 to 2.85 nH and for a 100 lead package 2.58 to 5.51 nH) and capacitance (a 14 pin package had 0.30 to 0.34 pF, with the 100 lead package 0.28 to 0.89 pF). Lead resistance is 37 to 40 mOhm for a 14 pin package and 46 to 66 mOhm for a 100 lead package. Lead spacing is 0.4 mm, with the area of the 14 pin package 23 mm², and the 100 lead package 168.5 mm².
- UTLP, Ultra Thin Leadless package, developed by Silicon Systems, inc. (Tustin, CA). This package has a mounted height of 0.8 mm.
- Vertical mount package (VPAK), a package conceptually like a zig-zag package (ZIP) except instead of through-hole leads it has surface-mount leads (L shaped leads). This package was introduced by Texas Instruments in late 1991 for 4- and 16-Mb direct random access memories (DRAMs).

- Very small (and thin) quad flat package (VQFP). Lead pitch is 0.5 mm, with 32, 48, 64, 80, 100, 128, and 208 pins per package.
- Very small outline (VSO), usually used to denote 25-mil pitch packages with gull-wing leads.
- Very small outline package (VSOP), with 25-mil spaced leads at the ends of the package (also TSOP and SSOP and SSOIC).

8.11.3 Chip-Scale Packaging

This form of packaging technique is designed to have the size and performance of bare die parts but with the handling and testability of packaged devices. The package size is no more than 1.2 times the original chip with various techniques to connect the part to the circuit. Flip chips have enlarged solder pads (bumps or balls). Flip-chip packages include the controlled collapse chip connection (C4), developed by IBM, and the direct chip attachment (DCA), developed by Motorola. In 1964, IBM invented flip-chip interconnection technology to enable production-level joining of discrete transistors. There are various extremely small packages offered by semiconductor vendors, Fairchild has the Chip-Scale MicroPak®, a 6 terminal device is 1.45 square mm, an 8 lead device is 2.5 square mm. An SC-70 device with 6 leads is 4.2 square mm.

General designations are as follows:

- BLP—Bottom Leaded (Plastic) Package developed by LG Semicon (now Hyundai) (Cheonju, South Korea) where the chip leads are molded into the bottom of the plastic package, beneath the chip. This results in a package that is 0.48 to 0.82 mm thick. Packaged devices appeared in 1997.
- Bumped chip, see flip chip.
- FCA—flip chip attach.
- Flip chip—a semiconductor package where the I/O terminations are in the form of bumps on one side of the package (also called *bumped chip*). After the surface of the chip has been passivated, or treated, it is flipped over and attached to a matching substrate. A solder-bumped flip-chip is attached to a printed circuit carrier substrate by reflow soldering (vs. a ceramic substrate). A polymeric underfill reduces the strain of the thermal coefficient of expansion mismatch between the chip (CTE approximately 2–3) and the PCB substrate (approximately 14–17). CTE Flip Chip (C4) refers to Controlled Collapse Chip Connection. In 1994 flip chip manufacturing techniques only accounted for 2% of the 45 billion ICs produced. In manufacture, the primary failure mode for a flip chip on an MCM module is a short circuit.
- Micro SMT, a peripheral contact package formed using semiconductor fabrication techniques while the IC is in wafer form. This technology was developed by ChipScale, Inc. (San Jose, CA). The resulting device is not much larger than the bare die.
- MiniBGA, uses a predetermined grid array for the solder bumps and is similar to the flip chip.
- Repatterned die, see MiniBGA.
- Slightly larger than IC carrier (SLICC) package.
- MicroBGA (μ BGA), also known as *chip-scale packaging* (Mitsubishi); slightly larger than IC or SLICC packaging (Motorola, Inc). A package designed by Tessera, μ BGA consists of a flex circuit with gold traces bonded to the die pads. The die pads fan into an array of metal bumps used for the second-level assembly. An elastomeric adhesive is used to attach the flexible circuit to the chip. The package compensates for thermal mismatches between the die and the substrate, and the μ BGA can be clamped into a socket for tests before attachment in the final assembly (see Fig. 8.139).

8.11.4 Bare Die

Bare, or unpackaged, parts offer the smallest size, with no signal delays associated with the device package. Current issues related to unpackaged devices are packaging, handling, and testing. The most common

FIGURE 8.139 A μ BGA package. (Source: Courtesy of Tessera, San Jose, CA.)

bare die and tape packages (bare die mounted on tape) include the following:

- C4PBGA, an IC package developed by Motorola that attaches the IC die to a plastic substrate using the C4 process. It uses a multilayer substrate, unlike the chip-scale or SLICC package.
- Chip scale package (CSP), a Mitsubishi package where the IC is surrounded by a protective covering through which external electrode bumps on the bottom provide electrical contacts. The package, only slightly larger than the chip it houses, has a height about 0.4 mm.
- Chip on board (COB)—the die is mounted directly on the printed circuit substrate (or board). See also tape automated bonding (TAB) and tape carrier packages (TCB).
- Chip on flex (COF), a variation of COB but instead of bonding the bare die to a substrate, it is bonded to a piece of 0.15 in.-thick polyimide film (such as FR4) that has a top layer of gold-plated copper. The traces provide bonding areas for wires from the die and a lead pitch similar to QFP packages. It has approximately the same weight and height as COB but failed parts can be removed. It, however, uses about the same board real estate as QFP packages and is more expensive than COB because of the polyimide substrate.
- Demountable tape automated bonding (DTAB), developed by Hewlett–Packard. Mechanical screw and plates align and hold the IC to the board (pressure between the tape and the board provides the contact). The IC can be replaced by removing the screws (vs. a standard TAB package, which is soldered in place).
- GTE—glob top encapsulation, pertains to the glob of encapsulating material used in MCMs.
- Sealed chips on tape (SCOT), chips mounted on tape supported leads and sealed (usually with a blob of plastic).
- Tape automated bonding (TAB), see TCP.
- Tape carrier packages (TCP), formerly called TAB packages. The chip is mounted to a dielectric film, which has copper foil connection patterns on it. The chip is sealed with a resin compound. This device assembly is mounted directly to a circuit without a plastic or ceramic package. Some tape carrier packages resemble TSOP packages (with gull-wing leads) but are thinner because the bottom of the IC die is exposed. The TCP design is about one-half the volume and one-third the weight of an equivalent pin count TSOP.
- Tape carrier ring (TCR), or a guard ring package, similar to the TCP package but includes a plastic ring to support the outer rings during test, burn-in, and shipment.
- Ultra-high volume density (UHVD), a process developed by General Electric to interconnect bare ICs on prefabricated laminated polyimide film.

8.11.5 Through-Hole Packages

These packages, as the name implies, mount in holes (usually plated through with deposited metal) on the printed circuit board. These device packages include the following:

- Batwing, a package (sometimes a DIP type, but can be surface mounted) with two side tabs used for heat dissipation.
- Ceramic dual inline package (CERDIP). The DIP package was developed by Fairchild Semiconductor and Texas Instruments followed with a metal topped ceramic package that resolved problems with the early ceramic packaged parts.
- Dual inline package (DIL).
- Dual-inline package (DIP), a component with two straight parallel rows of pins or lead wires. The number of leads may be from 8–68 pins (although more than 75% of DIP devices have 14–16 pins), 0.100-in. pin spacing with width anywhere from 0.300-mil centers to 0.900-mil centers. The skinny (or shrink) DIP (SDIP) has 0.300-mil centers (spacing between the rows) vs. 0.600-mil centers. The SDIP usually has 24–28 pins. DIP parts may be ceramic (pins go through a glass frit seal), sidebraced (pins are brazed onto metal pads on the side of the package), or plastic (where the die is moulded into a plastic package). There is also a shrink DIP, another small package through-hole part.
- Plastic DIP (PDIP).
- Pin grid array (PGA), a plastic or ceramic square package with pins covering the entire bottom surface of the package. Lead pitch is either 0.1 or 0.05 in. perpendicular to the plane of the package. Packages have various pin counts (68 or more). The chip die can be placed opposite the pins (cavity up) or nested in the grid array (cavity array).
- Pinned uncommitted memory array (PUMA II), a PGA package application specific integrated circuit (ASIC) memory array with four 32-pad LCC sites on top of a 66 PGA. Each of the four sites can be individually accessed via a chip select signal thus allowing a user definable configuration (i.e., $\times 8$, $\times 16$, $\times 24$, $\times 32$). It provides for an ASIC memory array without tooling. The substrate is a multilayered cofired alumina substrate with three rows of 11 pins. There is a channel between the pins so that the part can be used with a heat sink rail (or ladder). Onboard decoupling capacitors are mounted in a recess in this channel. This type of device is available from various companies including Mosaic Semiconductor (1.12×1.12 in square), Cypress Semiconductor (their 66 pin PGA module, the HG01, is 1.09×1.09 max), and Dense-Pac Microsystems (Veraspac or VPAC family, 1.09×1.09 max.).
- Plastic pin grid array (PPGA).
- Quad inline package (QIP or QUIL).
- Quad inline package (QUIP)—similar to a DIP except the QUIP has a dual row of pins along the package edge. Row to row spacing is 0.100 in, with adjacent rows aligned directly across from each other.
- Skinny (or shrink) DIP (SDIP), see DIP.
- Shrink DIP, a dual inline package with 24–64 pins with 0.070-in lead spacing.
- Single inline (SIL).
- Single inline module (SIM)—electrical connections are made to a row of conductors along one side.
- Single inline package (SIP), a vertically mounted module with a single row of pins along one edge for through-hole mounting. The pins are 0.100 in. apart. SIPs may also include heatsinks.
- Skinny DIP (SK-DIP), see SDIP.
- Transistor outline-XX (TO-XX), refers to a package style registered with JEDEC.
- Vertical inline package (VIL).

- WOW—Wafer On Wafer, a wafer integration process by FormFactor, Inc, in 1998. A microspring, gold filaments coated with a flexible nickel alloy, is attached to the bonding pads of each die. This enables high speed testing and burn-in at the die level. Microspring contacts can be attached to the PCB so chips can be mounted directly to the PWB.
- Zig-zag inline package (ZIP). This may be either a DIP package that has all the leads on one edge in a staggered zig-zag pattern or a SIP package. Lead spacing is 0.050 in from pin to pin. In modules the leads are on both sides in a staggered zig-zag pattern. Lead spacing is 0.100 in between pins on the same side (or 0.050 in from pin to pin).

8.11.6 Module Assemblies

We use this terminology to refer to packaging schemes that take either packaged parts or bare die and use them to make an assembly. This may be by either mounting the parts to a substrate or printed circuit board or by stacking parts or die to create dense memory modules. This packaging scheme may be surface mount or through-hole. The circuit board assemblies may be through-hole (having pins) or designed for socket mounting (with conductive traces). Variations include the following:

- Dual-inline memory module (DIMM), pioneered by Hitachi, has memory chips mounted on both sides of a PC board (with 168 pins, 84 pins on each side). The DIMM has keying features for 5-, 3.3-, and 2.5-V inputs and for indicating whether it is made with asynchronous DRAMs or flash, static random access memory (SRAM) or DRAM ICs. There is also the SO DIMM or small outline dual in line memory module, which has 72 pins vs. 168 for standard DIMM modules.
- Full stack technology—packing 20–100 dice horizontally, in a loaf-of-bread configuration. This manufacturing method was developed by Irvine Sensors Corporation (see also short stack).
- HDIP module, a hermetic DIP module that has hermetically sealed components mounted on the top and bottom of a ceramic substrate. This package style is generally used in anticipation of a monolithic part (such as a memory device) that will be available at a later time that will fit the same footprint as the module.
- Hermetic vertical DIP (HVDIP) module, a vertically mounted ceramic module with pins along both edges (through-hole mounting). Components used in this module are hermetically sealed. Pins on opposite sides of the module are aligned and are on 0.100-in spacing.
- Leaded multichip module (LMM). An LMMC is an LMM connector.
- Multichip module (MCM), a circuit package with SMT (surface mount) IC chips (minimum of 2) mounted and interconnected via a substrate similar to a multilayer PC board. MCM-L has a substrate that can be FR-4 dielectric but is often polyimide based laminations (first standardized by JEDEC JC-11 committee). Other dielectric substrates are ceramic (MCM-C), which can have passive devices (resistors, capacitors, and inductors) built into the substrate; thin film (i.e., silicon and ceramic construction), with deposited conductors (which can have capacitors built into the substrate) (MCM-D); laminated film (MCM-LF) made up of layers of modified polyimide film; or multichip on a flexible circuit (MCM-F). In 1994, some manufacturers started manufacturing substrates with MCM-D thin-film deposits onto MCM-L laminate substrates in a technique pioneered by IBM. MCM devices inherently offer higher speed and performance at lower cost than conventional devices. Manufacturing issues associated with MCM design include availability of unpackaged die, how to test/inspect the die, and test/rework of the MCM module. MCM modules for military uses fall under MIL-PRF-38534 (see *memory cube*). There is also an MCM-V, with V standing for a vertical, which is a three-dimensional module. This design is also known as Trimrod, by the developer Thomson-CSF (now Thales) and the European Commission (see *memory cube*).
- Memory cube, a three-dimensional module consisting of stacked memory devices such as DRAMs or SRAMs.

- M-RFM, Modified Ring Frame 3-d packaging method developed by Professor Kyung-Wook Paik of the Korea Advanced Institute of Science and Technology (KAIST, Kaejon, Korea) and LG Semicon (now Hyundai) (South Korea) in 1998. In this method the IC wafer is separated into strips vs. individual die. The strip is placed on a polymer adhesive and a ring frame with a matching coefficient of thermal expansion is used to support the strip. A wafer thick layer of polymer adhesive is applied around and on top of the wafer strip. Metal traces are added to route the I/O to the edge of each die, then the die are separated, stacked and solder balls are added.
- NexMod—a module designed for RDRAM by High Connection Dencity, Inc. (HCD, in Sunnyvale, CA), that is a complete RAMBUS channel in one system incorporating termination resistors, clock generator, voltage regulator module, and memory chips.
- Ribcage, a trademark of Staktek Corporation for a three-dimensional memory module design. Also see Uniframe Stakpack Module.
- Short stack, a method of stacking semiconductor dice vertically, where memory ICs are assembled into a three-dimensional thin-film monolithic package with the same footprint as a single SRAM. Recent advances in stacking ICs include forming interconnects at the top of the wafer, adding vias for inner layer interconnections, thinning the wafers to less than 10 micrometers, and then stacking the chips. The via interconnections are made using IC insulating and deposition processes.
- Single inline memory module (SIMM), an assembly containing memory chips. The bottom edge of the SIMM, which is part of the substrate material, acts as an edge card connector. SIMM modules are designed to be used with sockets that may hold the SIMM upright or at an angle, that reduces the height of the module on the circuit board. Typical SIMM parts are 4×9 (4 meg memory by 9), 1×9 , 1×8 , 256×9 and 256×8 . Also 9-b data width SIMM modules are produced under license to Wang Laboratories, (now Getronics, NV) who developed the SIMM module and socket in the early 1980s as an inexpensive memory expansion for a small workstation.
- SLCC—Stackable Leadless Chip Carrier, developed by DPAC Technologies Corp. (formerly Dense-Pac Microsystems CA) is a multidimensional module) consists of stacked chip carriers. Stacking is accomplished by aligning the packages together and tin dipping each of the four sides. SLCC can achieve a density of 40:1 over conventional packages.
- Uniframe Stakpak Module, a tradename three-dimensional stack of TSOP memory ICs by Staktek Corporation.
- VDIP module, vertically mounted modules with plastic encapsulated components and epoxy encapsulated chips on them. VDIP modules have 0.100 in. spaced pins along both sides of the substrate, with the pins on the alternate sides aligned.
- WLCSP—Wafer level Chip Scale Package.
- Other Definitions:
 - Plastic encapsulated microcircuit (PEM).
 - Premolded plastic package (PMP).

8.11.7 Lead Finish

Reducing lead in the environment is an environmental health and safety issue that is of prime importance today. While a typical microprocessor has approximately 0.2 g of lead and a computer motherboard has 2 to 3 g of lead, and the whole U.S. electronic interconnection market uses less than 2% of the world's lead production, to address environmental concerns, there are various environmental directives limiting the use of lead and other hazardous substances. These directives, formulated by the European Union in a Directive of the European parliament and of the Council of the European Union are:

- End of Life Vehicles (ELV) Directive 2000/53/EC: It is in force since October 21, 2000. It states that products be free of heavy metals such as mercury, cadmium, hexavalent chromium, and lead. It

requires a recycling system be established by vehicle manufacturers for vehicles made after July 1, 2002 and for all vehicles regardless of date of manufacture by July 1, 2007. Lead can still be used as an alloying additive in copper and in solderable applications.

- The WEEE Directive: Waste Electrical and Electronic Equipment (WEEE) Directive 2002/96/EC, expands the recycling requirements of the ELV Directive to include a broad range of electronic and electrical appliances and equipment. WEEE went into effect on February 13, 2003. It is to be scheduled to become European national law by August 13, 2004, and be applicable to consumer-use products by August 13, 2005. Article 2(3), however, states “Equipment which is connected with the protection of the essential interests of the security of Member States, arms, munitions and war material shall be excluded from this Directive. This does not, however, apply to products which are not intended for specifically military purposes.”
- RoHS Directive: The Restriction of Hazardous Substances in Electrical and Electronic Equipment. This Directive 2002/95/EC establishes standards and limits for the hazardous material content in electronic and electrical equipment. The Directive went into effect on February 13, 2003. It is scheduled to become European national law by August 13, 2004 for be in force for products by July 1, 2006. Banned or restricted substances include lead, mercury, cadmium, hexavalent chromium, certain brominated flame retardants (PBBs), and polybrominated diphenyl ethers (PBDEs).

The recommended lead-free solder formulation is Sn-Ag-Cu for board assembly but there are other formulations such as Nickel-Palladium (NiPd), or Nickel-Palladium with Gold flash (NiPdAu). Passive components, to be compatible with a lower temperature Lead process (which is 215°C for 50/50 Tin/Lead formulations and 230°C for 40/60 formulations) and the higher lead-free process of up to 260°C, use pure matte Tin for their contacts. The use of lead in solder is partially based on several potential reliability issues. Pure Tin component leads have been shown to result in inter-metallic migration in the termination of the electronic component and the growth of tin whiskers which could cause short circuits (which is why there is an exemption for military use (only) components).

The National Electronics Manufacturing Initiative (NEMI) has addressed the problem of “tin whiskers” in lead-free assemblies. A tin whisker is defined by them as

A spontaneous columnar or cylindrical filament, which rarely branches, of monocrystalline tin emanating from the surface of a plating finish. Furthermore, tin whiskers may have the following characteristics:

- an aspect ratio (length/width) greater than 2
- can be kinked, bent, twisted
- generally have consistent cross-sectional shape
- may have striations or rings around it

Their recommended test method is:

- temperature cycling (−55 to + 85°C, approximately 3 cycles/h)
- temperature humidity tests at 60°C/93% RH
- ambient storage (air-conditioned facility)

(Note: Tin will undergo a phase transformation, becoming a powdery form called Tin Pest if Tin plated parts are stored for more than 1 week at temperatures below 13°C).

8.11.8 The Future

While it is difficult to predict the future based upon current trends, making products smaller, lighter, faster, more energy efficient, and less expensive will continue. With these trends will be the requirement to channel the heat away from components. One recent development in 2004 was the Perdue University announcement of a patented technique of a self-ventilating method where microfluidic-like layers pump

heat-laden air off-chip using a classic “corona wind” effect. The chip created ions between closely spaced carbon-nanotube electrodes and funneled the resulting air currents down microfluidic channels, allowing the heat to eject out of the sides of the chip.

9.1 Optical Fiber

Ken A. Chauvin

9.1.1 Introduction

Since its beginning, the proliferation of optical fiber has been tremendous by any standard. The uses of optical fibers today are numerous, with new applications continuously emerging. Telecommunications applications of optical fiber and its associated components are widespread, ranging from extensive global networks, to local telephone exchanges, to data centers, and most recently, the long awaited extension of optical fiber all the way to the subscriber premises (i.e., homes and businesses). Nontelecommunications applications for optical fiber are equally as diverse. In medicine, bundles of plastic optical fibers are used to inject light into, and to transmit images from, deep inside the body, allowing doctors to see internal areas without the need for overly invasive exploratory surgical procedures. Specialty optical fibers connected to weapons can support real-time guidance and targeting information using telemetry data provided by the weapon itself. Other applications include uses in control and instrumentation functions aboard automobiles, aircraft, ships, satellites, and in other commercial transportation applications, to name a few. [Sections 9.1](#) and [9.2](#) will primarily focus on the telecommunications-based uses of optical fiber, fiber optic cable, and the various associated fiber optic components needed to form a complete passive optical system.

Modern day telecommunications involve the transmission of voice, video, and data information over distances ranging from micrometers (1×10^{-6} m) to hundreds, or even thousands, of kilometers (km)

using various transmission means. Telecommunications systems continue to incorporate a significant amount of copper transmission media, such as twisted pair and coaxial cables, and the associated electronic equipment, as well as various wireless technologies, to transfer information from point to point. Most current telecommunications systems are complex structures typically comprising several different transmission media types as discussed above (also known as hybrids). This is done in order to take advantage of the strengths of each technology based on the needs of a specific application. However, only the passive fiber optic portions of such systems will be addressed herein.

[Section 9.1](#) covers basic principles of optical fiber operation, fiber manufacturing, and optical fiber design for the major different types of telecommunications-grade optical fibers currently used. [Section 9.2](#) includes information on fiber optic cable designs and applications, basic optical connectivity products, and relevant industry standards and guidelines for fiber optic cable.

Benefits of Optical Fiber Telecommunications Systems

Optical fiber provides many fundamental advantages over alternative transmission technologies for telecommunications applications. The comparatively limited performance of copper conductor based systems forces the use of expensive signal conditioning and regeneration equipment (e.g., amplifiers and repeaters) at much closer intervals than for fiber optic systems. A single line of a voice grade copper system (i.e., 56 kbs) longer than a couple of kilometers requires the use of in-line signal processing for satisfactory performance, and even then is subject to the electromagnetic effects of interfering radio frequency sources such as radio, television, cell phone, and air traffic control broadcasts.

As information throughput requirements increase with the demands of more data-intensive applications at the end-user premises, the spacing between the copper-based repeater points must decrease in order to maintain the same aggregate data rate capability over a given length. Contrast that to all-optical systems in which it is not unusual to transmit 10 gigabits per second data rates over hundreds of kilometers without the need for active signal processing between the transmitter and receiver. Additionally, as it becomes necessary to increase the data transmission capacity or coverage area of a telecommunications system, the diameter and weight of cables for copper conductor systems increase much more rapidly than for optical fiber systems, resulting in a proportionally higher increase in materials, installation, and maintenance related costs.

The small size of optical cables, coupled with readily available components that make efficient use of the optical fiber's transmission capabilities, enable them to be manufactured and installed in much longer lengths than copper cables. The virtually unlimited capacity of optical fiber also alleviates fears of incurring significant long-term costs associated with frequent system upgrades, extensions, or over-builds. The availability of long lengths of individual lightweight fiber optic cables, up to 10 km or more, also make the installation of fiber optic systems much safer, easier, and less expensive, than comparable copper-based systems. Because of their design, fiber optic cables can generally be installed with the same equipment historically used to install twisted pair and coaxial cables, allowing some consideration for the smaller size and lower standard tensile strength properties of fiber optic cable.

More importantly, fiber optic cable design has progressed to the point where it serves as an enabling technology for newer installation methods that are faster, less expensive, and less intrusive to the environment than traditional installation means. Optical cables can be installed in duct system spans of 4000 meters (m) or more depending on the condition, construction, and layout of the duct system, and the details of the installation technique(s) used. Even longer lengths of fiber optic cable can be installed aerially, trenched, or buried in the ground and ocean floor. These extra-long lengths of cable reduce the number of splice points, thereby making the overall installation of optical fiber based telecommunications systems more efficient. The small size of fiber optic cable also saves on valuable conduit space in buried duct applications. This feature becomes even more prevalent when considering some emerging cable types that are specifically designed for use with air-blown or air-assist installation techniques into miniature ducts that are only about one centimeter in diameter.

Another advantage of optical fiber and fiber optic cable is the inherent flexibility in design options, allowing for the development of innovative products for specific applications. Since optical fiber is a man-made composite glass structure, it can be custom designed to meet optimal cost/performance targets

in any number of specific applications. As it does not conduct electrical current and is not affected by electromagnetic interference, fiber optic cable can be made all dielectric, making it the ultimate in electromagnetically compatible transmission media. This eliminates such issues as dangerous ground loops, the effects of voltage spikes from the cycling of heavy electrical equipment, and requirements for separate conduits for metallic conductors. It also improves the security of controlled transmission rooms as it is much more difficult to tap a fiber optic line, and much easier to provide security for fiber optic cable.

9.1.2 General Construction

The basic construction of optical fibers used for telecommunications consists of a **core**, an integral **cladding**, and a protective **coating**. Figure 9.1 shows basic cross sections representing the two main types of optical fibers used for telecommunications.

The types of fibers used vary depending on the specific intended application. The most common fibers types used in long-haul, metro, or regional telecommunications systems are single-mode fibers, which can have an effective core diameter in the range of around 8–12 μm depending on the specific design and operating wavelength. Such fibers are capable of carrying data rates measured in terabits per second (1.0×10^{12} bits/sec) for significant distances. For comparatively short-reach applications, multimode fibers are usually preferred because of the relative ease of termination and the low cost of the associated electronics. These fibers find widespread use primarily in applications such as interbuilding local area networks (LANs), storage area networks (SANs) and data centers, intrabuilding backbone and horizontal distribution applications, and the like. The various single-mode and multimode fiber types will be discussed in more detail later in this chapter, in terms of the design and capabilities of each.

Fiber Core

For the common commercially available telecommunications fibers used today, the core is the central region of the fiber and is the area where the majority of the optical energy of a transmitted light pulse is concentrated. It consists of solid silica glass impregnated with dopant materials (mostly Germania), added to the glass structure to optimize its transmission properties by changing the material's **index of refraction**, or to facilitate fiber manufacturing. The distribution of dopants within the core can thus be manufactured-to-suit based on the desired light transmission properties for each particular type of optical fiber application. The resulting refractive characteristic of the core is referred to as its “refractive index profile”. Basic types of core size and index profile combinations are discussed in the section on fiber types.

FIGURE 9.1 Multimode and single-mode fiber cross-sections. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Fiber Cladding

The cladding is the layer of dielectric material that immediately surrounds the core of an optical fiber and completes the composite structure that is fundamental to the fiber's ability to guide light. The cladding of telecommunications grade optical fiber is also made from silica glass, and is as critical in achieving the desired optical performance properties as the core itself. For optical fiber to work, the core must have a higher index of refraction than the cladding or the light will refract out of the fiber and be lost. Initially multiple cladding diameters were available, but the industry swiftly arrived at a consensus standard cladding diameter of 125 μm , because it was recognized that a common size was needed for intermateability. A cladding diameter of 125 μm is still the most common, although other fiber core and cladding size combinations exist for other applications. Because of their similar physical properties it is possible, and in fact highly desirable, to manufacture the core and cladding as a single piece of glass which cannot be physically separated into the two separate components. It is the refractive index characteristics of the composite core-clad structure that guide the light as it travels down the fiber. The specific materials, design, and construction of these types of optical fibers make them ideally suited for use in transmitting large amounts of data over the considerable distances seen in today's modern telecommunications systems.

Fiber Coating

The third section of an optical fiber is the outer protective coating. The typical diameter of an uncolored coated fiber is 245 μm , but, as with the core and cladding, other sizes are available for certain applications. Coloring fibers for identification increases the final diameter to around 255 μm . The protective coating typically consists of two layers of an ultraviolet (UV) light cured acrylate that is applied during the fiber draw process, by the fiber manufacturer. The inner coating layer is softer to cushion the fiber from stresses that could degrade its performance, while the outer layer is made much harder to improve the fiber's mechanical robustness. This composite coating provides the primary line of physical and environmental protection for the fiber. It protects the fiber surface to preserve the inherent strength of the glass, protects the fiber from bending effects, and simplifies fiber handling. The colored ink layer has properties similar to the outer coating, and is thin enough that its presence does not significantly affect the fiber's mechanical or optical properties.

9.1.3 Basic Principles of Operation

Index of Refraction

In order to understand the basic physics of how light travels down an optical fiber it is first necessary to understand how light behaves in various transmissive media. Light travels at approximately 3.0×10^8 m/sec (186,000 mi/sec) in a perfect vacuum. In any other medium (air, water, glass, plastic, etc.) light travels at some slower speed depending on the specific material(s) employed and the physical structure of the given medium. The ratio of the speed of light in a vacuum to the speed of light in another medium is called the index of refraction (IOR) for that medium. Since it is a ratio of speeds there are no associated units, and because light travels fastest in a vacuum it is always a value greater than 1. The slower the light travels in a medium, the larger that medium's IOR (i.e., smaller denominator for a constant numerator). Index of refraction is typically represented by the letter "n" in equation form, or by the acronym "IOR" in text form.

There are two types of index of refraction values which are of interest. The first is the phase index value, which indicates how fast the phase of the light is traveling. This IOR value is used in essentially all of the related transmission equations, except for transit time. The second index value relates to how fast power travels down a fiber. This index value, called the group index, is the one of interest in determining transit times, and is the value employed when using an optical time domain reflectometer for distance calculations. The group index is often referred to as n_g and can be calculated from the phase index using the equation

$$n_g = n - \lambda \frac{dn}{d\lambda} \quad (9.1)$$

Snell’s Law

When light encounters a boundary between two transmissive mediums with differing index of refraction value, it may be reflected back into the first medium at the interface boundary, bent at a different trajectory (i.e., refracted) as it passes into the second medium, or some combination of the two (see Figure 9.2). The actual result depends on the angle the light strikes the interface (angle of incidence) and the wavelength-dependent index of refraction values for the two materials.

As the light passes from one medium to another, the refracted light obeys Snell’s law (see Equation 9.2). By convention, the angles used in calculating the light paths are measured from a line drawn normal to the axis of the core-clad boundary or fiber centerline.

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \tag{9.2}$$

Based on this relationship, as the angle of incidence (θ_1) increases, the angle of refraction (θ_2) approaches 90° . The angle θ_1 which results in $\theta_2 = 90^\circ$ is called the critical angle. For angles of incidence greater than the critical angle, the light is essentially reflected entirely back into the first medium at an angle equal to the angle of incidence. This condition is called “**total internal reflection**,” and it is the basic principle by which optical fibers work. The angle of the reflected light is called the angle of reflection.

Numerical Aperture

Since light must first be launched into the fiber before it can begin to propagate within it, it is also important to account for the refractive effects at the end of the fiber where it interfaces with a third medium at the transmitter source. This third medium is typically assumed to be air, which has an IOR very close to 1. To ensure that the transmitted light stays within the core, the light must first enter the fiber via the core-air interface (e.g., connector endface) at an angle that will not cause it to subsequently be refracted out of the fiber at the core-clad interface. If the allowable entrance angle for the light at the fiber endface is then rotated 360° around the ring formed by the cylindrical core-clad boundary, it creates a cone that defines the acceptable paths which light entering the fiber must follow in order to propagate within it (see Figure 9.3).

FIGURE 9.2 Refraction of light at boundary between different mediums. (Courtesy of Corning Cable Systems LLC and corning® Inc.)

The size of this “acceptance cone” is a function of the difference between the refractive index values for the core and the cladding. As it is not practical to specify an acceptance cone for a typical optical fiber, the result is usually referred to in terms of a mathematical value called the numerical aperture (NA). The numerical aperture (NA) is related to the acceptance cone by the following:

$$NA = \sin \theta_{NA} = \sqrt{n_1^2 - n_2^2} \tag{9.3}$$

Where

- n_1 = IOR material 1 (transmitting)
- n_2 = IOR material 2 (receiving)

FIGURE 9.3 Fiber Numerical Aperture and acceptance cone. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

After light enters an optical fiber it travels down the fiber in one or more stable propagation states called modes. The number of modes in an optical fiber can be from one to several hundred depending on the specific type of fiber and the characteristics of the transmitted light. Each **mode** in multimode propagation carries some portion of the light as it traverses the length of fiber. The number of modes (N_m) can be approximated by the following:

$$N_m \cong \frac{\left(D * NA * \frac{\pi}{\lambda} \right)^2}{2} \tag{9.4}$$

Where

λ = operating wavelength (nm)

D = core diameter (nm)

NA = Numerical Aperture

As can be seen from this equation, the number of modes within an optical fiber increases if the core diameter or numerical aperture increase, or if the transmitted wavelength decreases. Since it is somewhat intuitive that larger core fibers can carry more light energy and are easier to connect to, increasing the size of the core, and hence the number of modes, may at first appear to be desirable. However, increasing a fiber’s core size significantly can have a number of undesirable consequences depending on the specific application. The effects include a reduction in the aggregate data capacity due to the effects of modal **dispersion**, an increase in intrinsic **attenuation**, and a higher manufacturing cost due to the increased amount of dopant material needed to make the fiber. For multimode fiber, the number of modes also decreases as the wavelength is increased, however; that is not to say that the data rate capacity of the fiber increases as well. This issue is discussed later in more detail. For single-mode fibers there is only one mode present above a certain wavelength, which simplifies the understanding of the transmissive properties of the fiber. However, determining the actual data capacity of a single-mode fiber is more complicated than just accounting for the existence of a single mode. The contributing factors will also be discussed in more detail in the section on key fiber properties.

9.1.4 Key Fiber Properties

Operating Wavelength

The most significant and well-known parameter for any type of fiber is the specified operating wavelength(s). Telecommunications grade optical fibers operate in the near-infrared region of the electromagnetic spectrum (see Figure 9.4). While some custom fiber types designed for use in specialized applications may be optimized for operation at only one wavelength, most standard telecommunications optical fibers used today in fiber optic cables typically have two or more specified operating wavelengths, or wavelength regions. An operating wavelength region for standard fiber types may be specified as a nominal wavelength value with an associated tolerance, or simply as a range of wavelengths with a minimum and a maximum value (also known as an operating band). Examples of single-wavelength specialty fibers are those used in sensing applications, or ones used to carry power from a pump source to an optical amplifier. Specific types of these photonic fibers may be specified for operation at 780, 980, or 1480 nm. Note that it is physically possible to operate such fibers outside of the specified operating ranges; however, the actual performance in such regions is not as well defined, and may differ significantly from that in specified ones.

The most commonly specified operating wavelengths for multimode silica glass telecommunications fibers are 850 and 1300 nm. Those for single-mode fibers are 1310, 1550, and 1625 nm, although there may be others for specific fiber types or applications. Even though the fibers may physically be able to support transmission over an extended spectral range (e.g., 1260 to 1675 nm), the optical performance is typically referenced to the most commonly used operating wavelengths or regions in order to simplify the processes for specifying and ordering fiber and fiber optic products. The wavelengths used today are primarily driven by the historical operating characteristics of the available sources, such as light emitting diodes (LED) and lasers, and by intrinsic fiber performance attributes, such as attenuation and dispersion characteristics. The basic operating bands for single-mode fiber recommended by the International Telecommunication Union (ITU) are provided in Figure 9.5.

FIGURE 9.6 Single-mode fiber spectral attenuation curve. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Attenuation

Attenuation is the combined loss of optical pulse power resulting from internal and external factors as the light propagates within the optical fiber. Mathematically, attenuation is expressed as

$$\text{Attenuation (dB)} = 10 \log \left(\frac{P_{\text{in}}}{P_{\text{out}}} \right) \quad (9.5)$$

By convention optical fiber attenuation is reported as a positive value, and to be useful to the system designer it is usually normalized to a unit length. The resultant value is called the **attenuation coefficient** and it is normally expressed in units of decibels per kilometer (dB/km). The typical attenuation performance of a single-mode fiber as a function of wavelength is shown in Figure 9.6. A characteristic spectral attenuation curve for multimode fiber has a similar shape, but slightly higher attenuation at all wavelengths primarily due to the higher dopant concentration levels present in multimode fibers.

Optical fiber attenuation is caused by several factors both internal and external to the fiber. Fiber attenuation resulting from internal sources is referred to as **intrinsic** attenuation, while that resulting from external sources is referred to as **extrinsic** attenuation. The specific components of intrinsic and extrinsic attenuation are addressed in greater detail in the next section.

Intrinsic Attenuation Sources

Rayleigh Scattering

As a light pulse traverses the optical fiber, a small percentage of the light is scattered in all directions by the collision of photons with the materials that make-up the transmission medium, at the molecular level. This phenomenon is called **Rayleigh scattering**. *Rayleigh scattering* is the primary source of power loss in optical fiber, accounting for well over 95% of the total light lost, extrinsic factors aside. In simple terms, as light propagates in the core of the optical fiber it interacts with the atoms in the glass structure in a complex manner depending upon the energy of the light (i.e., wavelength) and the size of the particles in the specific material or materials used in the waveguide. Under certain conditions, photons may elastically collide with the atoms in the fiber matrix and be scattered as a result. Attenuation occurs when light is scattered at an angle that does not support continued propagation in the desired direction. The lost light is either diverted out of the core or reflected back to the transmitter source.

Less than 1% of the scattered light is reflected back, or “backscattered,” toward the transmitter source, and it is this effect that forms the basis by which **optical time domain reflectometers (OTDR)** operate. The OTDR is an important tool in fiber optics and is the piece of equipment most commonly used for

FIGURE 9.7 Sample OTDR trace. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

testing and troubleshooting fiber optic systems. A characteristic OTDR trace is provided in Figure 9.7. Because the reflected light comes from the light pulse the original pulse power decreases, adding to the total attenuation before it reaches the receiver. The slope of the OTDR trace represents the attenuation coefficient of the fiber for the particular wavelength of light being transmitted. The trace appears essentially straight, barring isolated events, because the overall attenuation coefficient of the fiber, which includes the Rayleigh backscatter coefficient, is assumed to be constant.

Absorption

Some small quantity of impurities can be introduced into the glass structure during the fiber manufacturing process. Large impurities significantly weaken the fiber structure and are screened out during proof testing, but very small impurities can exist which affect primarily the intrinsic optical properties of the fiber. Hydroxide bonds can also exist within the fiber in minute quantities, which, along with other impurities, can absorb light at various wavelengths near the primary operating bands. The light absorbed by the impurities is usually converted to heat, but in any event the original optical signal is attenuated in the process.

Absorption due to hydroxide bonds, most noticeable near 1383 nm (also known as the spectral water-peak region), has historically been the major source of absorption related losses, though recent advances in fiber manufacturing processes have all but eliminated such as an issue. Still, millions of kilometers of early generation single-mode fibers in use today may be measurably impacted by absorption losses associated

with hydroxide bonds, under certain conditions. In all but a few isolated cases these elevated attenuation values will have no significant impact on the performance of the affected systems during their design operational lifetimes. For emerging applications which make more efficient use of the total spectral range of optical fiber, such as for coarse wavelength division multiplexing (CWDM), these issues could be significant, so newer generations of fiber are designed to accommodate such uses. Unlike Rayleigh scattering, which would exist even in the purest optical glass fiber, absorption losses can be limited by controlling the amount of impurities in the glass. The contribution of absorption to optical fiber attenuation is typically limited to 2–3 % of the total power lost, but the actual amount is highly dependent on the transmitted wavelength.

Extrinsic Attenuation Sources

Macrobending

Macroscopic deviations in the straight-line axis of the optical path can result in light energy being refracted out of the optical fiber and lost. Examples of these macrobend sources are excessive bending and lateral compressive forces placed on the cable, which can then transfer the load to the fibers contained inside under extreme conditions (see Figure 9.8).

Macrobending is characterized by proportionally higher losses at longer transmission wavelengths in single-mode fiber (i.e., 1550 nm vs. 1310 nm).

For single-mode fiber, macrobend performance is linked to the mode-field diameter of the fiber at the wavelength of the transmitted light. Typically, the larger the mode-field diameter, the more the fiber will be susceptible to macrobending effects. The mode-field diameter is the effective light carrying region of a single-mode optical fiber and will be discussed in more detail later. Also, longer transmission wavelengths (e.g., 1625 nm) are more susceptible to the effects of macrobending. For example, a macrobend induced loss may severely attenuate a 1625 nm signal without significantly affecting the 1310 nm transmission performance of the same fiber. This characteristic of macrobend induced losses can be useful in troubleshooting installed systems when point losses are detected. Newer fiber coatings are being developed to improve the macrobend sensitivity performance of optical fibers, especially at the longer wavelengths operated over some single-mode systems. For multimode fiber, **macrobending** losses are essentially wavelength independent, although such fibers are not immune to the effects.

Microbending

Microbending is the result of discrete variations in the refractive index properties of an optical fiber waveguide caused by localized point stresses placed upon it. These stress-induced refractive anomalies result in light pulse energy being refracted out of the optical fiber and lost. Examples of microbend sources are fiber coating defects, fiber optic cable structural defects, or installation related cable damage (e.g., buffer tube kinking). Microbending, however, is an extremely localized phenomenon and the bend source may not be clearly visible upon inspection. Microbending is characterized by proportionally equivalent losses at all transmission wavelengths, making it somewhat akin to a point defect in the fiber's refractive index profile at the core-clad boundary (see Figure 9.9).

Cut-off wavelength- λ_{cc} (Single-mode fibers only)

As explained before, single-mode fiber allows only one mode of transmission if the transmission wavelength is longer than a certain value called the **cutoff wavelength**. Because of the degradation in transmission performance that occurs when small core single-mode fibers are allowed to transmit two or more modes for a significant distance, single-mode fibers are normally operated at wavelengths above this value. However, this value may be affected by cabling the fiber, which can help to strip out undesirable higher order modes, so the practical specified value for this parameter is “cable cutoff wavelength,” and represents the value

FIGURE 9.8 Fiber macrobend. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

FIGURE 9.9 Fiber microbend. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

for the fiber in cabled form. The cable cutoff wavelength values for the various fiber types are typically specified to be no greater than 1260 nm for fibers that operate in the 1310 nm operating region (also known as original-band), and 1480 nm for fibers that operate only in the 1550 nm operating region (also known as conventional-band) or higher (e.g., the long-band). See Figure 9.5 for information on the various single-mode fiber operating bands.

Mode-Field Diameter (Single-mode fibers only)

Unlike multimode fibers, which have a core that is well-defined both physically and optically, the light carrying region of a single-mode optical fiber is a function of the characteristic power density distribution of the fiber at a particular wavelength, which follows a Gaussian distribution. In single-mode fibers the optical power distribution extends beyond the physical boundaries of the core such that a portion of the light traversing the fiber travels in the cladding section, nearest to the core. The diameter of the region represented by the effective power distribution in these fibers is called the **mode-field diameter (MFD)**. The MFD is dependent on the transmission wavelength (see Figure 9.10).

Dispersion

In the early years of optical fiber telecommunications, attenuation was generally considered the limiting system performance attribute. As advances in fiber and amplification component designs have been brought to bear on the problem; achievable transmission distances and data rates subsequently became limited by another hurdle, optical signal dispersion. In its simplest form, dispersion causes the optical energy in a light pulse to spread in time (i.e., increase in pulse width) as it traverses the fiber (see Figure 9.11). This spreading reduces the peak pulse signal strength, which decreases the signal (carrier) to noise ratio, and increases the potential that sequential pulses may overlap. In extreme cases the result is a bit error, which occurs when the receiver is not able to discern one or more individual bits. The closer the bits are launched together (i.e., higher data rates), or the longer the system length, the greater the effects of signal dispersion.

FIGURE 9.10 Mode-field diameter. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

FIGURE 9.11 Pulse dispersion. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

There are three types optical signal of dispersion to consider and each has its own characteristics and challenges based on the specifics of the operating system. They are modal dispersion, chromatic dispersion, and polarization mode dispersion.

Modal Dispersion

As discussed earlier, light propagation in multimode fibers can take place in a number of stable transmission paths (i.e., modes) depending on the core size, numerical aperture, and system operating wavelength (see Fig 9.12). Because the various stable light paths in a multimode fiber have different total optical lengths, the light following the shortest overall path, near the center of the core, arrives at the receiver end of the fiber before light following the longer outer paths, assuming the speeds of all are constant. This type of dispersion is called modal dispersion. Since an individual pulse of light may comprise hundreds of modes in a multimode fiber, the potential for signal degradation due to modal dispersion is significant. In fact, the issue is so problematic that commercially viable silica-glass step-index multimode optical fibers have had extremely limited use in telecommunications applications. To combat this effect, telecommunications grade multimode optical fibers have a graded-index core that is discussed in more detail in the section on multimode fiber. The nature of modal dispersion is complex and it is not linear. As single-mode fibers have only one stable propagation path for any reasonable distance above the cut-off wavelength, modal dispersion is not a primary consideration in single-mode systems.

Chromatic Dispersion

Chromatic dispersion occurs in optical fiber systems because the pulse of light in the fiber is not truly monochromatic (i.e., it consists of many separate wavelengths). The amount of chromatic dispersion in a fiber is determined by the fiber's material composition and design, and by the light source's operating wavelength and **spectral width**. The spectral width represents the range of different wavelengths present in the transmitter output (see Figure 9.13). A wider spectral width implies a wider range of output wavelengths, which is less desirable than a narrow one with respect to chromatic dispersion effects. The units for chromatic dispersion are picoseconds of light pulse spread, per nanometer of laser spectral width factored to the fiber length (ps/nm·km). Chromatic dispersion can be either positive or negative.

FIGURE 9.12 Multimode Propagation. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

FIGURE 9.13 Spectral width. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

In a standard nondispersion-shifted single-mode optical fiber the chromatic dispersion is considered to be zero at or around 1310 nm (also known as the zero-dispersion wavelength). This means that signals transmitted near 1310 nm will incur relatively little chromatic dispersion, although the actual zero dispersion wavelength may range from 1302–1322 nm for a specific nondispersion-shifted fiber. At wavelengths longer than the zero dispersion wavelength, the dispersion of these fibers is positive, and at shorter wavelengths it is negative. A positive dispersion value indicates that longer wavelengths in the optical pulse travel faster than the shorter ones. Chromatic dispersion consists of two distinct components: material dispersion and waveguide dispersion (see Figure 9.14).

FIGURE 9.14 Single-mode fiber dispersion curve. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Material Dispersion

Material dispersion is a difference in the effective group IOR values for the various wavelengths within the light pulse, as a function of the material used to make the waveguide. The amount of material dispersion varies with the dielectric waveguide material and cannot be significantly altered without changing the materials used to make the fiber. Material dispersion increases proportionally with distance.

Waveguide Dispersion

Waveguide dispersion arises from the fact that a portion of the light traversing a single-mode optical fiber travels in the cladding while the remainder travels within the core (refer to discussion on MFD), which has a different effective IOR. For a given fiber, the fraction of the light carried by the cladding increases as the wavelength of the light increases so that the overall effective refractive index seen by the light, and hence its associated waveguide dispersion, is a function of wavelength. Again, as with material dispersion, the total pulse energy spreads out because each pulse consists of more than one discrete wavelength (i.e., not monochromatic) and the spreading increases proportionally with distance. However, unlike material dispersion, the waveguide dispersion properties of a fiber can be changed by changing the refractive index profile of the core. This will be discussed further in the section on dispersion-shifted single-mode fibers.

The net effect of chromatic dispersion can be minimized by using a source with a smaller spectral width, by operating near the zero dispersion wavelength of the fiber, or by compensating for dispersion in the system itself, as needed. Unlike modal dispersion, which only occurs to any significant degree in multimode fibers, chromatic dispersion is present in both fiber types. However, the effect of chromatic dispersion in multimode fibers is insignificant with respect to modal dispersion when used with laser sources, although some LED sources operating at 850 nm may produce significant levels of chromatic dispersion that affect system performance. Industry fiber standards primarily specify modal bandwidth as a measure of the data rate capability of multimode fiber. Equipment manufacturers must then consider the impact of source selection when they subsequently specify fiber modal bandwidth performance requirements for cabling used with the equipment. Conversely, industry standards for single-mode fiber specify chromatic dispersion as the primary parameter to be used in determining the fiber's dispersion performance.

Polarization Mode Dispersion

Polarization mode dispersion (PMD) is comparatively more complex a concept than the other types of optical fiber dispersion discussed earlier, and until relatively recently it wasn't even considered to be a limitation that needed to be specified or addressed. As the effects of system chromatic dispersion have been mitigated by improved, complex fiber designs, and by the availability of dispersion compensating modules, the increased distances of long-haul transmission systems have moved PMD to the forefront as a major performance limiting factor.

It is probably easier to understand PMD by recognizing that, despite the best efforts of fiber manufacturers, optical fibers do not have perfect radial symmetry with respect to physical dimensions, dopant concentrations, and stresses. The result is a difference in the effective index of refraction values along two axes (major and minor) of the fiber cross section. This effect is known as birefringence. Further, light pulses transmitted into these fibers are not linearly polarized and are generally assumed to be random in the orientation of their component electric fields. As the light coupled into a single-mode fiber traverses the length, it is resolved over time into two orthogonally-polarized modes that make up the fundamental mode. These modes are oriented to the two optical fiber axis present in the fiber. PMD occurs because the birefringent nature of the fibers causes these two orthogonal components to propagate at different speeds (see Figure 9.15). The result is a dispersing of the originally transmitted signal which, for simplicity, is assumed to be independent of the spectral content of the pulse and the operating wavelength.

At various points along the fiber a mechanism commonly called mode-mixing occurs, which results in an exchange of power between the two orthogonal modes. It is because of this effect that PMD is proportional to the square root of the length, rather than being linear. Since both birefringence and mode mixing are very sensitive to intrinsic and extrinsic factors, the PMD value can change every time a fiber or system span is measured. Mode mixing sites generally exist wherever the fiber is stressed; though that is not to say that stressing the fiber always produces lower measured PMD values.

FIGURE 9.15 PMD. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

PMD is only a concern in single-mode fiber systems because of the relatively higher data rates (10–40 Gb/s) and much longer distances involved. Since both of the polarized components carry a portion of the transmitted power any offset in the arrival time of the two acts to disperse the original signal, which becomes a more significant issue at higher data rates. In addition to limiting the operational transmission capacity of digital systems, it can result in composite second order distortions in analog systems such as those used for cable TV applications.

Although a comprehensive discussion on PMD is beyond the scope of this chapter, it's worthwhile to note that PMD is statistical in nature and is affected by virtually anything that stresses the fiber. Because of this the only way to effectively compensate for the effect is via real-time PMD compensation. Though currently not in widespread use at the time of publication, such devices are reportedly becoming available soon. These devices measure the instantaneous PMD and then utilize a complex array of polarization filters and electronics to provide compensation. Newer generation fibers are also specified to be less PMD sensitive, which is accomplished by reducing fiber manufacturing imperfections. Increasing the coupling between the two orthogonal components can also reduce PMD.

Multimode Fiber Bandwidth

The bandwidth of a multimode fiber is effectively a measure of its modal dispersion, which is the predominant factor that determines the fiber's data carrying capability. It is normalized to a length of fiber and is reported in units of MHz·km. Since cabling does not significantly affect the fiber's modal bandwidth, and because measurements are somewhat complex, it is typically measured by the fiber manufacturer on the bare fiber only. In addition, modal bandwidth does not behave in a linear fashion for systems employing over-filled launch (OFL) conditions (i.e., LED sources) because of the finicky nature of the higher order modes (i.e., those near the core-clad interface) excited by such sources. Therefore special care must be taken when estimating the data rate capacity of such systems. For example, a multimode fiber cut in half does not produce two fiber pieces having double the effective OFL modal bandwidth capability of the original length. Also, the linked OFL bandwidth capability of multiple fibers concatenated together cannot be determined simply by combining the performance of each. Even though there are equations for doing this they are beyond the scope of this chapter.

Newer generation multimode based systems employing vertical cavity surface emitting lasers (VCSELs) or other lasers not only display a higher bandwidth at the operating wavelength, they also display a more linear bandwidth response with respect to transmission distance. In these cases, primarily the lower and intermediate order modes are excited and carry the vast majority of the signal power, thereby mitigating the impact of the higher order modes. This condition is referred to as restricted-mode launch (RML). Effective modal bandwidth (EMB) represents the theoretical worst case restricted-mode launch bandwidth

FIGURE 9.16 Transmitter source spot sizes. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

(RML BW) of a fiber using any VCSEL transmitter meeting certain flux distribution requirements, as established by industry standards. EMB fiber performance is currently only specified for multimode fiber systems operating at 10 Gb/s. Rather than using VCSELs, EMB testing is accomplished by using a narrow beam laser and stepping it across the core of the multimode fiber in small increments (e.g., $2\text{--}5\ \mu\text{m}$). The results are then combined to show pulse delay as a function of radial fiber position at the wavelength of interest (i.e., 850 nm). The delay characteristics of the fiber are then used to ensure that the specified minimum EMB performance of the fiber, as required by industry standards, is met.

The effective launch area of a VCSEL is slightly smaller than the core of the multimode fiber and therefore does not create an over-filled launch condition (see Figure 9.16.) Even then, all current multimode fibers still incorporate a bandwidth value determined using OFL launch conditions (i.e., OFL BW.) So system designers may still need to account for the limitations of individual fibers if an equivalent RML BW or EMB is not included as well. This will change over time and laser-based RML BW performance is expected to eventually become the primary specified value for determining a multimode fiber's transmission capabilities.

Fiber Nonlinearities

As discussed earlier, the information carrying capacity of traditional optical systems is normally limited by attenuation and dispersion (or bandwidth). As the impact of these factors have been mitigated by significant improvements in the design of telecommunication systems and the performance of compensating modules, amplifiers, and other key electronic components, newer systems are experiencing a marked increase in the amount of data they carry, and the distances over which the data are transmitted. The result is an increase in the aggregate optical signal power transmitted over a single fiber, which results from the simultaneous multiplexing of many individual sources at different wavelengths, at several milliwatts each.

These high power operations give rise to an entirely different set of optical issues which are borne from the propagation of light at high intensities in optical fiber. The resulting phenomena are regarded as potentially major system performance-limiting factors, if not properly managed. These effects are collectively termed "fiber nonlinearities," which is derived from the fact that such are dependent on the intensity of light to some higher order power. Fiber nonlinear effects are also length dependent.

To complicate matters there are several factors that affect fiber nonlinear behavior and the impact such effects have on system design and performance. They include the effective size of the light carrying-region of the core, the number of optical channels being transmitted and their relative wavelength spacing, the length of the optical path, and the dispersion characteristics of the fiber. The optical power density within a fiber is a function of the core size, the individual wavelength power and the total input power. The effective length, which depends on both the fiber length and attenuation coefficient, determines the time over which interactions can occur. A high power density and longer available interaction time make for more severe fiber nonlinear behavior.

Raman Scattering

Raman Scattering has two forms, *spontaneous* and *stimulated*. Any light traversing a fiber experiences spontaneous Raman scattering, which is light scattered both forward and backward due to interactions between the optical signal and the vibrations of the silica molecules. Under certain conditions, the atoms in the fiber will absorb some of the light and then quickly re-emit photons with energies equal to the original photons, plus or minus the energy of a characteristic vibration of the atom. This effects both scatters the light and shifts its wavelength. Because of the random nature of the vibrations of the molecules, Spontaneous Raman scattering results in scattered light with a low power and a broad spectral width.

When the spontaneously scattered light gets to a high enough power, or when there is a deliberate signal at an appropriate wavelength, the power transfer to specific target wavelengths is stimulated because of the interaction of the light at those wavelengths and the molecules in the glass. This process results in stimulated Raman scattering (SRS), which is an extremely broadband effect that limits the useable high power bandwidth of optical fibers. SRS production is a function of the number of wavelengths being transmitted and the total number of amplified spans in the system. As no practical methods to fight SRS have been demonstrated to date, the only way to minimize the effect is to maintain the total source power output to levels below the power level that would result in a significant impact on system performance.

Signal degradation due to SRS for single channel systems occurs only at very high powers, typically in the 1 watt range. In optical fibers that simultaneously carry multiple optical channels (i.e., WDM systems), channels operating at shorter wavelengths may provide unwanted gain to channels operating at longer wavelengths. For example, a 1310 nm signal might be scattered and provide gain to a signal over the wavelength range of 1310 to 1430 nm, or longer. The gain carries the signature of the 1310 nm signal, effectively adding noise to the longer wavelength signals while also reducing the power of the 1310 nm signal. The threshold power required for degradation of longer wavelength channels is reduced as the number of channels carried by the fiber increases. In general, however, SRS is not a significant concern in current optical fiber systems because the threshold power levels are high.

Incidentally, the SRS effect has been successfully exploited with the advent of Raman amplifiers that amplify light signals using this principle. For example, light pumped in at 1480 nm is used to excite the atoms in a section of standard optical fiber forming part of a system link. When a signal pulse (e.g., 1550 nm) subsequently traverses that section of fiber, the excited atoms are stimulated to emit a photon at an energy equivalent to the signal transmission wavelength. Unlike erbium doped fiber amplifiers (EDFAs), which are discrete components, Raman amplifiers can work over kilometers of standard fiber actually forming part of the passive optical fiber span.

Stimulated Brillouin Scattering

Stimulated Brillouin scattering (SBS) occurs at the lowest threshold power levels of the various non-linear effects and can be observed at powers as low as several milliwatts, depending on the transmitter source and fiber characteristics. SBS occurs when signal power reaches a level that results in the generation of acoustic waves in the optical waveguide medium, through a process called electrostriction. The actual process

is somewhat complex and involves—the characteristics of the transmitted signal, *Spontaneous Brillouin scattering*, the electrostrictive nature of dielectric waveguides, and the speed of sound in the transmission medium. SBS is primarily an issue with analog system transmission and is not usually a concern for digital systems.

As the generated sound waves travel through the glass material, back toward the source, they induce spatially periodic compressions and rarefactions, which in turn cause localized changes in the IOR value of the transmission medium. These localized fluctuations in the fiber's refractive index scatter the light from subsequent pulses similar to the effect of a Bragg's grating, except that the frequency of the back-scattered light is shifted slightly. The reflected light combines with the input signal to reinforce the sound waves, via electrostriction, creating a circular feedback loop. Since the magnitude of this effect increases with increasing input optical power, once the threshold power for SBS is achieved, any subsequent increases in signal strength are essentially back-reflected to the transmitter source. This process effectively creates an upper limit to the power level that can be transmitted down the fiber. The output power of an erbium-doped fiber amplifier (EDFA), given sufficient input signal power, has the capability to produce SBS.

The formation of SBS is more complex than described herein and is aggravated by narrow spectral width transmitters, such as externally modulated lasers that are employed in systems operating at very high data rates, and in systems that employ dense wave division multiplexing (DWDM). Dithering the source output can significantly reduce the SBS threshold power level by delaying the generation of the sound waves in the fiber, but doing so increases the spectral width of the signal, which as we now know can cause other issues. Fiber design can also be used to inhibit the onset of SBS by increasing the threshold power required for SBS to occur. As SBS is related to the speed of the sound in the fiber, changing features that affect this parameter can affect the threshold power level as well. These can include changing the fiber strain and core dopant concentration characteristics.

Self Phase Modulation (SPM)

When a pulse of light passes through an optical fiber it loses energy at the leading edge as it interacts with and aligns the electric fields in the glass. If the pulse power is increased, more energy is transferred to the glass due to these interactions. This power loss causes the light at the front of the pulse to shift to a longer wavelength (red shift). The energy is subsequently transferred back from the glass to the light signal at the trailing edge of the pulse, causing light in that region to be shifted to a shorter wavelength (blue shift). In a fiber with a positive **dispersion coefficient**, the increased in wavelength at the front of the pulse extends the pulse front, while shortened wavelengths at the trailing edge slow down, extending the back of the pulse. Both of these effects therefore result in pulse broadening. The increased spectral width caused by the energy transferred at the pulse edges can also cause significant chromatic dispersion in high power systems. One mitigating factor in self-phase modulation is that, as the pulse spreads, the interaction length for the polarizing reactions with the glass also increases. This reduces the rate at which energy transfers to and from the light signal at the photon level, so pulse spreading does not increase rapidly once it initiates.

In fiber with a negative dispersive coefficient, the wavelength shifting of the light pulse at the leading and trailing edges results in pulse compression. As the longer wavelengths at the front of the pulse slow down, more light at the original signal wavelength interacts with the glass and the process continues. Likewise, at the rear of the pulse, the shorter wavelength light speeds up and moves forward in the pulse. For certain power levels, pulse widths, and fiber dispersion values, this effect can result in nondispersing signals called solitons. Some high data rate, long-length systems have been specifically designed to take advantage of this phenomenon for improved performance.

While SPM can be a problem, the specific combinations of optical power and dispersion needed to cause a significant performance issue are readily accounted for.

Cross Phase Modulation

Since each optical channel in a DWDM system operates at a different wavelength, pulses from the various channels travel through the fiber at different speeds due to chromatic dispersion effects. As a result, pulses at a fast wavelength will catch up to and pass through pulses at slower wavelengths. When two pulses

occupy the same section of fiber, an exchange of energy, as described in the section above on SPM, also occurs at the front and back edges of the overlapping area. Under these conditions, the light in both pulses increases in wavelength at the front of the overlap and decreases in wavelength at the back of the overlap. When the difference in the transit times for the two pulses is minimal, such as when the effective dispersion coefficients are close to zero the effect of cross phase modulation (CPM) can be significant. However, the specific combinations of optical power, channel spacing, and dispersion needed to make CPM a problem can be easily managed.

Four Wave Mixing

Another problem which can occur when two signals occupy the same physical location in a fiber is four wave mixing (FWM). FWM occurs when two or more “parent” channels in a WDM system combine to form “daughter” artifacts at the expense of their own power. In a WDM system with many channels at equally spaced frequencies, new wavelengths created by this effect can fall on top of existing channels, resulting in optical crosstalk. If the frequency spacing is not equal, the effect is an increase in system noise that lowers the signal to noise ratio of the operating channels. FWM is a more serious problem for WDM systems running over fibers with low chromatic dispersion values in the operating wavelength region because such a condition increases the amount of time when two or more channels are allowed to interact.

This effect, which is more difficult to account for, coupled with the advent of EDFAs, led to the development of nonzero dispersion-shifted fibers. Requiring a minimum amount of chromatic dispersion in the operating wavelength regions limits the time available for pulses at the various channel wavelengths to interact, which reduces the effects of FWM.

9.1.5 Fiber Manufacturing

There are many potential variations in the processes used to manufacture optical fiber, but the basic premise remains essentially the same for each. This section will introduce the basics of fiber manufacturing and briefly discuss the three primary methods currently employed to support the economical production of optical fiber on a large scale. They are outside vapor deposition (OVD), vapor axial deposition (VAD), and inside vapor deposition (IVD).

All fiber manufacturing processes involve the delivery of oxygen and volatile feed materials in gaseous form to a target reaction area. This reaction produces fine soot that adheres to a bait material or to other deposited soot in a process is generally referred to as “lay-down.” Depending on the specific portion of the fiber’s core-clad glass structure being created at a given moment, the mixture of reaction materials can be changed to vary the resulting dopant concentration so that the completed fiber has the desired refractive index profile. The more complicated the index profile, the more complex the laydown process. In any event, the laydown process must be tightly controlled to ensure that the completed fiber has the requisite optical and geometric properties.

Variations in the feed materials during the laydown process determine what type of fiber will be manufactured. Changes in the dopant concentration in the core section and the size of the core determine whether the fiber will be intended for multimode or single-mode applications. Also, other materials can be added to the outside of the cladding to enhance certain fiber mechanical properties. For example, carbon can be deposited on the outside of the cladding to hermetically seal the surface of the glass. The carbon layer impedes the migration of hydrogen, present in significant quantities in undersea applications, into the fiber core, which could significantly affect the fiber’s attenuation characteristics.

The process for making fiber, including the three primary lay-down process variants, are described in greater detail below

Outside Vapor Deposition

The outside vapor deposition (OVD) process uses a glass mandrel or seed rod placed in a lathe. The feed materials are delivered to the region near the rod surface by a gas-burner type assembly. The burner assembly traverses longitudinally alongside the bait rod as the lathe turns it to build-up the soot thickness

FIGURE 9.17 OVD laydown. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

in layers (see Figure 9.17). As more layers of porous glass soot are added, the chemical composition of each layer (i.e., dopants) is controlled as necessary to create a refractive index profile specific to the type of fiber being manufactured. Once enough layers have been deposited the seed rod is removed from the center before further processing.

Vapor Axial Deposition

The vapor axial deposition (VAD) process is basically similar to the OVD process, except that the soot is deposited by fixed burners located near the end of a vertically mounted seed rod. This type of process allows for several fixed burners to be used in laydown and the cylindrical soot rod created in this way is drawn upward as the burner assembly deposits additional layers (see Figure 9.18). Again, as in the OVD process, the seed rod is removed before the next step.

Inside Vapor Deposition

The IVD process was the first widely-used, commercially successful laydown process and utilizes a hollow tube vice a solid rod to capture the soot. The seed tube is placed horizontally in a lathe and a gas burner assembly or resonator moves along the outside of the tube surface. The feed materials flow into the seed tube and the soot is laid down on the inside at the desired target area, building inward toward the center of the tube (see Figure 9.19). In most IVD applications the seed tube remains to become the outer part of the glass cladding, so its optical characteristics are not as critical as the rest of the glass structure. Concentrations of the feed materials flowing into the tube are changed as in the other methods to alter the refractive properties of the final product as needed. IVD is in limited use today as the volume of fiber that can be produced is typically much lower, which has an effect on fiber and cable manufacturing efficiencies.

Consolidation

When the laydown process is complete, the resulting composite structure is called a “preform,” which is very delicate and has the appearance of a big piece of white chalk. The preform is then placed in a consolidation oven where it is densified into a thick rod of high-purity glass called a “blank.” This heating

FIGURE 9.18 VAD laydown. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

FIGURE 9.19 IVD laydown. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

FIGURE 9.20 Fiber consolidation. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

process, sometimes referred to as sintering, collapses the hole in the center of the preform, if present, forming a solid, ultra-transparent blank rod (see Figure 9.20). This blank is eventually placed in the draw tower which is where the optical fiber is actually produced.

Drawing the Fiber

In the drawing process the blank is mounted vertically in a draw tower and heated to about 2000°C at the bottom end. As the glass rod softens, a gob begins to pull away via the force of gravity, leaving behind a thin strand of fiber (see Figure 9.21). The speed, tension, and temperature of the draw are closely controlled to obtain consistent fiber dimensions. Vibrations, contamination, and other sources of mechanical stresses must be avoided during the draw process to guarantee a high strength glass fiber. An integral part of the draw process is the addition of the protective coating, which is applied and cured in layers as discussed earlier.

9.1.6 Fiber Types

There currently exists a plethora of different fiber designs for a wide range of uses. All telecommunications grade fibers can be divided into the two main types as described earlier, which are known as single-mode and multimode. These two types of fiber have vastly different transmission properties that make each of them ideal for certain applications. Within these two types of fibers there exist a number of different designs, each having properties optimized for specific applications. The various types of commercially available telecommunications fibers are discussed in the following section.

When designing and specifying a telecommunications system the key factors to consider are the transmissions speeds (i.e., data clock rates), operating distances and wavelength(s), and system installed costs, all of which play a role in choosing between the available transmission media. It is also critical to consider the flexibility and adaptability of the system, and thus its ability to support upgrades with minimal expense (i.e., future-proofing). Conversely, the expansion of an existing infrastructure requires that newer products also be backwards-compatible. There are, of course, numerous other items that should factor into the final design and purchase decisions, such as compliance to industry standards, but they will not be discussed in detail herein. With respect to what type of fiber to select, it is usually easy to decide between multimode

FIGURE 9.21 Fiber draw. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

and single-mode. Beyond that the selection process becomes somewhat more complicated. The following sections provide general information which can be used to understand the various specific types of single-mode and multimode fibers available. It is not intended to be construed as definitive guidance for selecting a specific fiber type for a particular application.

Single-mode Fibers

Single-mode fibers have historically operated in one of the primary wavelengths regions around either 1310 or 1550 nm, although applications that take advantage of the extended operating spectrum are already commercially available.

The strength of single-mode fibers lay in their inherently low attenuation and dispersion characteristics at the primary operating wavelengths. As a result, single-mode fibers are used in applications to transmit high data rates over distances from tens to thousands of kilometers, where the spacing between costly signal conditioning and amplification equipment needs to be maximized. Single-mode fibers can be generally categorized into two different types that are best differentiated optically by their dispersion characteristics, and physically by the shape of their refractive index profile (see Figure 9.22). Note that under visual

FIGURE 9.22 Single-mode fiber index profiles (Step and segmented-core). (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

inspection, or without the benefit of complex test equipment, it is impossible to tell the difference between any of the fiber types discussed here in were they to be viewed side by side.

Nondispersion-shifted Single-mode Fiber

Nondispersion-shifted single-mode fiber, sometimes referred to as standard single-mode fiber, was the first single-mode optical fiber type in widespread use in telecommunications systems. Nondispersion-shifted single-mode optical fiber normally has a simple step-index profile. It has a nominal zero-dispersion wavelength in the 1300 nm transmission window, but the dispersion coefficient increases as a function of increasing wavelength to a value of around 18 ps/nm•km in the 1550 nm transmission window (also known as conventional- or C-band). The exact dispersion characteristics of this fiber can be approximated by the use of the Sellmeier equation.

$$D(\lambda) \cong \frac{S_0}{4} \left[\lambda - \frac{\lambda_0^4}{\lambda^3} \right] \text{ps}/(\text{nm} \cdot \text{km}) \quad (9.6)$$

Where

- λ = operating wavelength (nm)
- λ_0 = zero dispersion wavelength (nm)
- S_0 = zero dispersion slope (ps/(nm² • km))

Dispersion-shifted Single-mode Fiber

Dispersion-shifted fiber is a type of single-mode fiber that has its nominal zero-dispersion wavelength shifted higher in the operating wavelength spectrum in order to optimize the fiber's dispersion properties at longer wavelengths. This was done to support newer generation long-haul telecommunications systems operating at longer wavelengths, where the intrinsic attenuation of the optical fiber is inherently lower. To achieve the desired dispersion properties the index profile of the core must be altered to shift the waveguide component of the fiber's chromatic dispersion coefficient. Recall that the other component, material dispersion, cannot be significantly altered without changing what the fiber is made of. The resulting characteristic index shape for these fibers is called the segmented-core index profile.

The first variants of dispersion-shifted fibers were designed such that the zero dispersion wavelengths were at the lowest point of the spectral attenuation curve for that generation of fibers, which was around 1550 nm. This gave the optimal combination of low attenuation and low dispersion for emerging long-haul applications, or so it was thought. These fibers were an obvious improvement over standard fibers for single-channel haul, high data rate systems, but as we now know their ability to support the multiple narrowly spaced channels that are used in DWDM systems is severely limited. The use of these early dispersion-shifted fibers eventually led to a better understanding of fiber nonlinear effects, and subsequently to the development of improved fiber designs.

Nonzero Dispersion-shifted Single-mode Fiber

In the early to mid-1990s, a better understanding of fiber nonlinear effects resulted in the development of nonzero dispersion-shifted fibers. These are fibers with segmented core profiles, but for which the zero dispersion wavelength is shifted such that it falls outside of the intended operating window, or windows. As mentioned before, some amount of dispersion (positive or negative) is desired to minimize nonlinear effects, although such cannot be eliminated entirely. The amount of dispersion is controlled by managing the zero dispersion wavelength and characteristic dispersion slope through the careful manipulation of the fiber's complex index profile. Again, too much dispersion is not desirable either as it causes other issues as addressed earlier. One characteristic of these fibers is that the light carrying region of the fiber is proportionally smaller than non-dispersion-shifted single-mode fibers. This results in a higher power density at a given source power level, which if severe enough can mitigate improvements in the fiber's nonlinear performance. The latest generation fibers are designed with a larger mode-field diameter to lower the transmitted power density, thereby reducing nonlinear effects.

TABLE 9.1 Key Single-mode Fiber Attributes – Cabled Fiber

Parameter	Non dispersion-shifted Single-Mode	Non-zero Dispersion-shifted Single-Mode
Mode Field Diameter	1310 nm 8.6 – 9.5 μm	—
	1550 nm 9.6 – 11.2 μm^{a}	8 – 11 μm^{b}
Numerical Aperture	0.13 – 0.14 (typical)	0.14 (typical)
Cutoff Wavelength	≤ 1260 nm	≤ 1480 nm
Cladding Diameter	125.0 \pm 1.0 μm	125.0 \pm 1.0 μm
Coating Diameter	245.0 \pm 10.0 μm	245.0 \pm 10.0 μm
Attenuation	1310 nm ≤ 0.4 dB/km	NA
	1550 nm ≤ 0.3 dB/km	≤ 0.3 dB/km
Dispersion	O-band ≤ 3.5 ps/nm \cdot km	NA
	C-band ≤ 18 ps/nm \cdot km	0.1 – 6 ps/nm \cdot km ²

^aNot typically specified by industry standards.

^bCertain variants of nonzero dispersion shifted single-mode fibers, such as those specifically designed to operate in metropolitan type applications with inexpensive Fabry-Perot laser sources, typically have different specified requirements.

It’s worthwhile noting at this point that the possibility of a one-fiber-does-all solution is not on the immediate horizon. The combination revolutionary-evolutionary nature of fiber development has been realized only because of the massive resources dedicated to its understanding. As the requirements placed on them increase, new fiber performance issues continue to be uncovered. While fiber designs advance to meet the challenge, each new operating limitation must be fully understood before design modifications can be made to counter its effects. The biggest challenge facing glass scientists is that altering a fiber design to improve upon one attribute typically comes at the expense of one or more other attributes. This means that current designs are a compromise of competing performance needs in order to optimize for what is most important, given a specific set of expanded operating conditions. As the exact nature of the propagation of electromagnetic fields through dielectric waveguides is very complex, the most likely scenario is that newer generations of fibers will continue to be semicustomized for a specific application or set of applications.

Table 9.1 summarizes some of the parameters for the various single-mode fiber types commonly used today (typical values for cabled fiber are shown). See Section titled “Optical Fiber Standards and Specifications,” for additional information on industry standards related to optical fiber.

Multimode Fibers

Multimode fibers are more suited for short distance applications where some distance capability can be sacrificed for a lower installed system cost based on the specific needs. In applications such as LANs, SANs, and data centers, all transmission equipment is located in reasonably close proximity to one another. In many such cases multimode fiber based systems are overall typically more economical because of the availability of comparatively inexpensive connectivity components and low cost electronics, such as LEDs and VCSELs. This allows the total system cost to be lower than an equivalent system based on single-mode fiber and the associated electronics.

Multimode fibers generally operate at one of the two primary wavelengths of 850 and 1300 nm. All telecommunication grade silica-glass multimode fibers are characterized by a graded (i.e., curved) refractive index profile. The core has an index of refraction that is highest at the center, which then falls off approximately in a parabolic shape to where the value is that of the pure glass cladding at the core-clad interface (see Figure 9.23). The primary core sizes for graded index multimode fibers in use today are 50 and 62.5 μm . Other larger core multimode fibers saw limited use early on in telecommunications applications, but these are rare today and current large core multimode fiber designs find service primarily in very-short-length, low data rate applications such as automotive, medical, and similar uses involving imaging or low-intensity lighting.

Recall from the information presented earlier that the dispersion effects from having numerous modes present in fiber could severely limit the data capacity, thereby making it useless for practical

FIGURE 9.23 MM graded-index profile. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

telecommunications. In order to address this, the refractive index of the core is modified so that the light traveling along the longest stable path (e.g., highest order mode), also travels with the fastest average speed. Near the outside of the core where the index of refraction is lower, the mode travels faster than at the middle of the core. The result is that all the signal modes reach the receiver end of the fiber at essentially the same time. This mode management allows the receiver to differentiate between successive pulses, even though each may consist of hundreds of individual modes. Since the index of refraction is also wavelength dependent, the modal dispersion properties of multimode optical fibers can be optimized for a particular wavelength, such as 1300 nm for 62.5/125 μm fiber, or 850 nm for 850 nm laser-optimized 50/125 μm fiber (see Fig. 19.24). They can also create a balance between the two, such as with standard 50/125 μm fiber.

Table 9.2 summarizes some of the parameters for the various multimode fiber types commonly used today (typical values for cabled fiber are shown). See Section titled, “Optical Fiber Standards and Specifications,” for additional information on industry standards related to optical fiber.

Special Use Fibers

Standard single-mode and multimode telecommunications fibers are not ideally suited for all related applications. Some of the more widely used types of specialty telecommunications fibers are described below.

Chromatic Dispersion Compensating Fiber

As discussed earlier, it is desirable to have some amount of chromatic dispersion at the operating wavelengths for fibers operating in the 1550 nm region or higher in multi-channel systems, in order to minimize fiber nonlinear effects. This causes the dispersion of the system to build up over long distances, to the point

FIGURE 9.24 Multimode Fibre Bandwidth Comparison. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

TABLE 9.2 Key Multimode Fiber Attributes – Cabled Fiber

Parameter	50/125	62.5/125 μm
Core Size	50 \pm 3.0 μm	62.5 \pm 3.0 μm
Numerical Aperture	0.200 \pm 0.015	0.275 \pm 0.015
Cladding Diameter	125.0 \pm 2.0 μm	125.0 \pm 2.0 μm
Coating Diameter	245.0 \pm 10.0 μm	245.0 \pm 10.0 μm
Attenuation 850 nm	\leq 3.5 dB/km	\leq 3.5 dB/km
1300 nm	\leq 1.5 dB/km	\leq 1.5 dB/km

1300 nm	\geq 500 MHz \cdot km	\geq 500 MHz \cdot km
EMB 850 nm	\geq 2000 MHz \cdot km ^(a)	NA

^aNew 50/125 μm fibers designed and specified primarily for use in 10 Gb/s serial systems laser-based systems, but can also be used for legacy applications.

^bMinimum bandwidth values vary from application to application.

where it can become a performance issue. To counteract this, dispersion compensating fiber can be added at points along the optical link to bring the aggregate system dispersion back down to near zero. This fiber has similar characteristics to other nonzero dispersion-shifted fibers, except that its dispersion coefficient and slope are opposite in sign to those of the system fiber being compensated, and the dispersion values are of a much higher order of magnitude. Dispersion compensating fiber is not typically cabled, but is instead employed in discrete components in the optical path. For long systems it is often necessary to insert dispersion compensating modules (DCMs) at various locations along the system before the accrued dispersion at any one point becomes excessive, to the point where it can no longer be effectively compensated. As these fibers also have an associated attenuation loss, optical amplifiers are often used in tandem with DCMs to boost the output signal strength.

Erbium-Doped Fiber

One of the key enabling technologies for DWDM systems transmitting in the 1550 nm operating window and higher was the advent of erbium-doped fiber amplifiers (EDFAs). EDFAs employ a rare-earth element, erbium, to amplify optical signals traveling through a fiber, including noise, independent of bit rate or protocol. EDFAs are generally referred to as “optical amplifiers” and employ a pump laser operating at 980 or 1480 nm to excite the erbium atoms. When an optical signal passes through the amplifier, the excited erbium atoms are stimulated to emit a photon at the appropriate energy level, similar to the operation of a Raman amplifier.

EDFAs amplify the transmission wavelengths between 1520 and 1630 nm and have output powers ranging from about 10 to 25 dBm. The erbium fibers are not cabled so EDFA modules are discrete components used throughout the system as needed. Optical amplifiers are used most routinely in long-haul Telco systems with one typically installed every 30–80 km along the system route, enabling system distances of 500 km or more before signal conditioning becomes necessary. EDFAs are also used in CATV systems in the links between head ends, or between head ends and hubs.

Polarization Maintaining Fiber

Polarization maintaining fiber (PMF) is designed for use in fiber optic sensor applications (e.g., interferometric sensors) and other polarization sensitive components. In PMF, the light maintains a constant state of polarization as it travels down the fiber due to the intrinsic high birefringence designed into such fiber types. One method of inducing the high birefringence needed is to manufacture a fiber core that is significantly elliptical in shape, while another method is to purposely include stress-inducing rods into the cladding area of the fiber. In these types of fibers, the mode traveling along the minor axis is intentionally attenuated to create the requisite single polarization state of the light.

Submarine Optical Fiber

Due to the great expense involved with the construction, placement, and maintenance of submarine optical fiber systems, component design is critical. As these are the longest telecommunications systems in use anywhere, managing factors such as attenuation and dispersion becomes even more crucial. To account for this submarine fibers have special design parameters to ensure they remain viable over the design life of the installation. These fibers typically have very small cores and correspondingly smaller attenuation coefficients. They are also hermetically sealed by incorporating carbon into the glass structure, as discussed earlier, to prevent the attenuation effects associated with hydrogen migrating into the fiber core region.

In regards to the dispersion issue, the use of DCMs is not viable due to the added system complexity and additional amplification requirements that would result. To address the dispersion issue in submarine systems, a second fiber type must be employed. This fiber has dispersion characteristics that are opposite in sign, but roughly equal in magnitude, to those of the other fiber in the system, at the operating wavelength(s). Unlike terrestrial systems, the dispersion compensating fiber used in submarines systems is cabled and becomes part of the overall system span. Therefore long submarine systems employ these paired fibers, which are alternated along each link to improve the overall system optical characteristics. The two fibers are typically used in equal lengths based on the specific dispersion properties of each. In practice this process is fairly complicated, which tends to increase the associated complexity and cost of such systems.

Radiation Hardened Fiber

Fibers exposed to high radiation levels show an increase in the attenuation coefficient due to a complex interaction between the radiation and some of the materials in the fiber's core. The reaction creates absorption bands at the most common operating wavelengths in the 1310 and 1550 nm regions. A radiation hardened fiber is designed to have reduced radiation sensitivity and also to recover quickly from radiation induced effects. Fibers with a high concentration of Germanium as a dopant have been found to operate and recover fairly well in a high radiation environment. Some dopants, such as phosphorous, are more susceptible to long-term radiation induced effects.

Hollow Core Fibers

A newer generation of fiber designs currently under development could potentially eliminate, or significantly reduce, some of the limitations inherent with the current generation of glass optical fibers. Rather than relying on dopants to achieve the requisite core refractive index profile, these fibers employ a matrix of air-filled holes. Some of the primary benefits of these fibers for telecommunications applications are the low dispersion characteristics, the elimination of fiber nonlinearities, and larger cores that support very high power applications. Add in the inherently low attenuation characteristics and materials cost, and these fibers become very attractive. Such fibers also show promise in a number of other useful applications outside of telecommunications, so developmental research continues.

9.1.7 Optical Fiber Standards and Specifications

Optical Fiber Standards Publications

With the plethora of fiber types available, it quickly became necessary early on to develop industry standards to support their use. Industry standards serve a number of functions, the primary ones of which are:

- Establish minimum acceptance criteria to ensure system performance
- Standardize basic design criteria to ensure the interoperability of fibers from the various suppliers
- Educate customers on key performance attributes
- Establish a level playing field for suppliers and manufacturers
- Enable innovation in optical fiber design and performance

Listed in Table 9.3 and Table 9.4 are some of the key telecommunications industry fiber standards employed today for the various optical fiber types. The standards are identified only by document number, publishing organization, and the specific fiber type. Users of industry standards should purchase these from a reliable source to ensure they have the latest applicable version.

TABLE 9.3 Single-mode Fiber Detailed Industry Standards

Single-mode Fiber Type	Industry Forum	Document Number	Fiber Designation
Dispersion Unshifted	TIA ^a	492-CAAA	Class IVa
	IEC ^b	60793-2-50	B1.1
	ITU ^c	G.652	G.652A or B

^aITU standards have not yet been updated to reflect the industry adoption of this fiber type.

^bITU is primarily a European organization. 62.5/125 μm fiber has not been widely adopted in Europe, so no supporting ITU Standard exists.

Fiber Attribute Specifications

One commonality between the various industry fiber standards are the specified attributes. Some minor differences may exist between the various standards for a particular attribute, but often such differences result primarily from when the documents were last updated, and only to a lesser extent by market preferences or technical factors. Note that each attribute has an associated industry standard test procedure. Refer to the relevant optical fiber Standards listed in Tables 9.3 and 9.4 for information on test procedures.

The key specified performance attributes for the various fiber types are listed in Table 9.5. Other secondary parameters not listed may also be specified, while others only characterized (i.e., informative vs. normative).

TABLE 9.5 Key Industry Standard Specified Fiber Attributes

Attribute	MM	Std SM	NZDS SM
Attenuation coefficient (fiber or cable)	X	X	X
Chromatic dispersion	X	X	X
Cladding diameter	X	X	X
Cladding noncircularity	X	X	X
Core diameter	X	—	—
Core-clad concentricity error	X	X	X
Cut-off wavelength (cable)	—	X	X
Macrobending loss	X	X	X
Modal bandwidth	X	—	—
Mode field diameter	—	1310 nm	1550 nm
Polarization mode dispersion	—	X	X

Defining Terms

Absorption: The attenuation component of an optical fiber which results from the complex interaction of photons with impurities in the glass structure as the light traverses a length of optical fiber. The absorbed optical energy is converted into vibrational energy (i.e., heat), which is typically reemitted at a different energy level.

Attenuation: The combination of optical energy losses from a light pulse traversing a length of optical fiber resulting from absorption and scattering, typically referred to as intrinsic attenuation, and bending losses, typically referred to as extrinsic attenuation, expressed in dB. However, attenuation is often used as a synonym for attenuation coefficient, expressed in dB/km.

Attenuation coefficient: The mathematical expression for optical power attenuation, typically expressed as a change in power measured in decibels (dB), normalized to a unit length (dB/km).

Chromatic Dispersion coefficient: The normalized chromatic dispersion value, normally with units of ps/(nm • km), from which the fiber chromatic dispersion can be calculated for a given fiber length, and spectral width.

Cladding: The layer of dielectric material that immediately surrounds the core of an optical fiber, the combination of which is fundamental to the ability of optical fiber to guide light at certain wavelengths. The cladding material for telecommunications grade optical fibers usually consists of a silica glass that cannot be physically separated from the core.

Core: The central region of an optical fiber consists of a silica-glass structure in which dopants are added to achieve the desired light transmission properties for a particular type of optical fiber. The distribution of dopants alters the index of refraction of the glass, which varies based on dopant concentration. The resulting refractive core properties are referred to as the index profile.

Dispersion: The spreading of the pulse width of a light pulse traversing a length of optical fiber. Pulse spreading from chromatic dispersion results from the interaction of the light pulse and the transmitting fiber medium, at the molecular level, and is highly dependent upon the spectral make-up of the light pulse and the physical structure of the glass both in material make-up and physical design characteristics. Pulse dispersion is generally undesirable as it reduces the signal (carrier) to noise ratio, and if severe enough, can result in bit errors.

Group index of refraction: The mathematical ratio of the power velocity of light in a perfect vacuum (numerator) to its velocity in a given medium (denominator). The group index of refraction is typically denoted by " n_g ." As light always travels fastest in a vacuum, the value of n_g for any material is always greater than 1. Caution must be taken that " n " and " n_g " are used appropriately, as " n_g " is used in calculations involving transit time.

Index of refraction: The mathematical ratio of the phase velocity of light in a perfect vacuum (numerator) to its velocity in a given medium (denominator). Index of refraction is typically denoted by " n ," or less frequently by the acronym "IOR." As light always travels fastest in a vacuum, the IOR value for any material is always greater than 1 and " n " is used in calculations other than for transit time.

Insertion loss: The measured loss in optical power resulting from the scattering of light at the physical boundary between two optical waveguides (e.g., fibers). The light scattering is caused by the localized disruption in the refractive properties of the optical path due to the insertion of discrete components such as connectors, mechanical splices, couplers, etc. For fusion splices, this loss is typically referred to as "splice loss."

Macrobending: Macroscopic deviations in the straight-line axis of the optical path which result in light pulse energy being refracted out of the optical fiber and lost. Examples of macrobend sources are excessive bending of the protective cable structure, or the placement of excessive compressive forces on the fiber optical cable. Macrobending is characterized by proportionally higher losses at longer transmission wavelengths (i.e., 1550 nm vs. 1310 nm in single-mode fiber).

Microbending: Discrete variations in the refractive index properties of an optical fiber waveguide caused by localized point stresses placed on the fiber that result in light pulse energy being refracted out

of the optical fiber and lost. Examples of microbend sources are fiber coating defects, fiber optic cable structural defects, or installation related cable damage. Microbending is characterized by proportionally equivalent losses at all transmission wavelengths.

Mode: A stable path of light in an optical waveguide characterized in complex terms by Maxwell's equations for an electromagnetic field distribution.

Mode field diameter (MFD): A measure of the distribution of the effective light carrying region of a single-mode optical fiber, which extends beyond the fiber core and includes a portion of the integral cladding layer.

Optical time domain reflectometer (OTDR): A device used to characterize the attenuation performance of an optical link by measuring the intensity of light reflected due to Rayleigh scattering as a light pulse traverses the optical path. OTDRs work on the principle that the amount of reflected light is directly proportional to the energy of the light pulse. OTDRs are useful in estimating the attenuation coefficient and in identifying defects and other localized losses, but are not considered a direct loss measurement.

Rayleigh scattering: Light scattering resulting from microscopic variations in the refractive index of an optical path that are proportionally small with respect to the wavelength of the transmitted light. The refractive index variations generally result from changes in material density or composition due to localized stresses or impurities.

Reflection: The redirection of a portion of a light pulse at the boundary of two dissimilar media back into the transmitting medium. The amount of light reflected, vice transmitted into the receiving medium, is a function of the wavelength dependent refractive indices of the two media and the angle at which the light is incident upon the boundary of the two.

Spectral width: The mathematical representation of the extreme wavelengths of the light spectrum that comprises an optical pulse. One method of specifying the spectral line-width of a transmitter is to measure the full-width half-maximum (FWHM) of the source output, or specifically the difference between the wavelengths at which the amplitudes are one-half of the maximum value of the entire pulse.

Total internal reflection: The complete reflection of a light pulse at the boundary of two differing mediums that occurs when the angle at which the light is incident upon the boundary, as measured from the normal, is greater than the critical angle.

9.2 Fiber Optic Cable

Ken A. Chauvin

Fiber optic cables serve a number of purposes, the primary one of which is to house the optical fiber contained inside and protect it from external stresses. The main sources of external stress are those associated with the shipping, handling, installation and termination of the optical fiber, and are relatively short in duration. Other external stresses, such as those experienced over the life of the installation due to the surrounding environment, are more long-term in nature. In addition to protecting the fiber, the cable structure must also organize the fibers and support the identification of individual fibers via printed legends, color coding, groupings, or some combination of the three.

Because the applications of optical fiber and fiber optic cable are diverse, so are the environments in which they are employed. Most environments fall into one of three main categories that are generally referred to as indoor, indoor/outdoor, and outdoor. These environments will be discussed in more detail

TABLE 9.6 Cable Application Considerations

Cable Attribute	Outdoor	Indoor/Outdoor	Indoor
Typical Operating Temperature Range	−40 to 70C	−40 to 70C	−20/0 to 70C
Typical Length	2–12 km	100–2000 m	2–300 m
Typical Fiber Counts	2–432+	2–144	1–24
Mechanical Durability	Excellent	Excellent	Good
Chemical resistance	Excellent	Good	Good
Waterblocking	X	X	—
UV resistance	X	X	—
Fire resistance	—	X	X

in the section on cable designs, but the key differentiating factors are

- Indoor: Resistant to spreading fire and generating smoke
- Outdoor: Resistant to solar radiation, water and moisture, and extreme temperatures and mechanical stresses

Applications in which single cables are used to transition from indoor to outdoor must therefore account for all of the above. Table 9.6 summarizes the primary considerations for the various environments.

For each environment there may be numerous other specific considerations that are germane to a particular application, such as sewer or shipboard environments, or to an installation method, such as aerial self-supporting or jetting into miniature ducts. As with the optical fibers there are a number of unique cable designs optimized for various combinations of application and installation method. The performance criteria for the most common designs are also specified by the various telecommunications industry forums, which will be discussed at the end of this section.

9.2.1 Applications Considerations

Even though the details of a particular cable design depend on the application environment and installation method, there are a few generalities. Various applications expose the cable to different mechanical and environmental conditions that have the potential to stress the fibers contained inside. As optical fiber technology continues to mature end-users are becoming concerned about expected fiber optic cable lifetimes, especially where early generation cables have been already in place for greater than 20 years. To date, no absolute performance model exists to accurately predict all potential failure mechanisms for every application or environment, so the best gauge of the health of a system is typically the optical properties of the cabled fiber.

The ultimate performance of cabled fiber depends on a number of factors including the cable environment, the type of installation, cable design, and the cable materials themselves. Factors which may affect certain installations are structural cable damage caused during or after initial installation, improper cable design, the quality of the splicing and closure work, exposure to periods of severe environmental loading or certain chemicals, or exposure to temperature and humidity conditions outside of specified operating performance ranges. Evidence of performance degradation can be elusive and is largely dependent on the specific characteristics of each installation and the type of cable design deployed.

Environment

Outdoor

Cables designed for placement outdoors are normally installed aerially, directly buried, or placed in underground ducts, using various installation methods. These products normally convey communications signals for extended distances and only penetrate the indoor environment far enough to support a transition to indoor cabling, such as in a telecommunications room. Specific applications range from very long-haul

spans running hundreds of kilometers (aerial, buried, or both), all the way to relatively short spans of 100 meters or less, such as from a network distribution point to an enduser business or residence in a fiber-to-the-premises (FTTP) system. In each case, the cable is exposed to the various rigors of the outdoor environment, which can be quite extreme for some areas of the world.

The specific type of cable employed in a given application depends primarily upon factors such as fiber type and fiber count, limitations on size, weight or cost, the proposed methods of installation and termination, and perhaps even the need for other specific performance capabilities. The latter may include items such as resistance to extraordinarily high compressive forces, temperatures, or electric field potentials (e.g., aerial installation along high-tension lines), or resistance to various chemicals or other organic hazards such as gnawing rodents.

Fiber-to-the-Home

The drop cable environment is basically a subset of the traditional outside plant environment. As fiber connections get closer to the home, cable designs are changing to adapt to this space. Cable fiber counts for such applications are typically very low (1 to 4 fibers) and the distances involved are much shorter than for traditional outside plant cable installations (hundreds of feet vs. of hundreds of miles). The relative criticality of the cables also is reduced somewhat since drop cables typically connect only one, or a few, residences or businesses vs. linking thousands of individual endusers across hundreds of communications channels, such as is found in long haul cable systems.

Although the installation methods are generally the same as other outdoor cables, the placement of drop cables often involves the use of manual labor to install, obviating the need for heavy equipment and high tensile loads. These cables can either be buried from the curb to the house, or can be hung aerially from the telephone pole to hardware mounted on the house. This unique environment lends itself to a special set of design criteria for such cable types. Since these cables supply only a limited number of endusers, which in many applications may be limited to a single premises, a cable failure is much less critical than a failure in a high density, high traffic, long haul distribution cable. For example, consider how often premises coaxial cables are severed by aggressive gardeners or homebuilders. This difference lets manufacturers design cables that can allow for a limited amount of fiber strain during mechanical and environmental loading, such as could be experienced in self-supporting aerial cable designs. This in turn allows for innovative cable designs and materials selection that can support lower cost product solutions, which is critical in enabling the deployment of affordable fiber-to-the-home systems.

Indoor

Premises cables are generally deployed to support backbone, horizontal, and interconnect applications. Higher fiber count tight buffered cables described later, can be used as intrabuilding backbones that connect a main cross-connect to an entrance facility or intermediate cross-connect. Likewise, lower fiber count cables can link an intermediate cross-connect to a telecommunications room (i.e., horizontal cross-connect) feeding multiple workstations. Simplex and duplex interconnect cables are commonly used to patch the optical signal from end equipment to the hardware containing the main distribution lines, in order to complete the passive optical path. These cables can also provide optical service to workstations, or can connect one patch panel to a second patch panel as in a cross-connect application.

In regards to cables designed for indoor-only use, the overriding consideration is to ensure that such cables do not significantly contribute to the spread of flame or the generation of smoke in the event of a fire, although there are other considerations. Indoor cables contain comparatively fewer fibers than outside plant cables, and infrequently go beyond 300 m. Also, because the opto-electronic equipment served by such cables is typically installed in an indoor, climate-controlled environment, these cables are not required to be as mechanically or environmentally robust as cables designed for placement outdoors. Therefore, the design considerations for indoor cables are significantly different than those for outdoor designs.

Although not as severe as those for outside plant cable, there are potential sources of stress for indoor cables that must be accounted for. In addition to stresses related to installation of the cable itself, inside plant cables must be flexible enough to support the tight bends experienced in cable trays and in the optical hardware which supports the overall intra-building cabling infrastructure. Indoor cables might

also be placed in close proximity to many other types of cables, including copper cables supporting communications or other low voltage applications. In tall buildings, high fiber count riser cables may go up several stories to reach the various building distribution points. Because of the relatively high number of terminations associated with such short distances, indoor cable must support quick and easy connectorization and be available in variety of fiber counts, ranging from one to two fibers for desktop applications all the way up to 144 fibers or more for building backbone distribution cables.

Indoor/Outdoor

Indoor/outdoor applications involve cables which typically run short distances to make interconnections within and between adjacent buildings. These cables are fully resistant to the typical outside plant environment, but the overall performance requirements are typically not as stringent as those for long-length outside plant communications cables. These cables are used primarily to avoid the need for a costly extra splice point where the telecommunication system cabling transitions from outside to inside, and thus are employed in only relatively short lengths.

Installation Methods

There are a number of diverse installation methods for the various spaces in which fiber optic cable is used. The installation methods discussed below are primarily associated with outside plant applications but may also have some uses in other environments. The relatively benign environment of the inside plant means that installation considerations are somewhat less critical, although this is not to say that they are not important.

Direct Buried

One of the most common and widely used installation methods is the placement of the cable directly into the ground, which is known as direct burial. The primary methods of direct burial are trenching, plowing, or placing cable into narrow grooves cut into hard surfaces, such as roadways or parking lots. The obvious advantage to these types of installations is the inherent measure of safety and stability provided by the cable surroundings, if left undisturbed, but even then these types of applications are not impervious to post-installation damage. Buried cables are subject to damage from dig-ups due to subsequent construction, lightning strikes, chemicals in the soil, gnawing rodents, and ground heaves. Protection against these dangers is somewhat accounted for in the design and construction of the cable itself, which may include the incorporation of a layer of protective metal armoring.

Trenching

In trenching installations, a trench is dug in the earth to an appropriate depth, usually 75 cm or more, and the cable or cables placed into it. The minimum depth of the trench used depends on a number of factors, but deeper is generally better from a protection standpoint. However, deeper trenches are also proportionally more expensive to make. The trench is then backfilled with a variety of materials to protect the cable, such as clean sand or soil. Direct buried installations are typically marked with tapes laid parallel to the cable, but placed closer to the surface, and markers located visibly above the surface, in an effort to prevent dig-ups. Buried cables are typically connected to one another via hermetically sealed closures located in buried hand holes or manholes along the route. These closures house and protect the splices or connectors used to connect sections of cable.

Plowing

For installation by plowing, a groove is plowed into the ground normally using a vibratory plow with the cable laid through a covered trough to the bottom of the plow. As the plow moves forward, the cable is laid in the opening and the soil falls back on top to cover it up. The major benefit to using plows is the relative speed at which the cable can be placed, though such installations are relatively shallow and therefore more likely to be damaged by subsequent construction. For this reason, plowing is generally limited to short lengths of low fiber count cables, such as those used in campus environments or in emerging access market type applications (i.e., drop cable).

FIGURE 9.25 Road cable installation. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Roadway Grooves

For cables designed specifically for placement in road surfaces, such as asphalt or concrete, the process for installation involves placing the cable in a narrow groove (about one inch wide) cut into the hard surface of a road or parking lot. The cable can be secured in place with special “hold-down” spacers pressed into the groove on top of the cable. The remainder of the groove is then filled with bitumen—a common road repair material (see Figure 9.25). Since the process can be done as a continuous operation, it minimizes the disruption to traffic. This method also boasts a minimal impact to the useful life of the roadway because the groove is very narrow. Conversely, traditional roadway trenching methods are comparatively more disruptive, costly, and can also significantly reduce the life expectancy of the roadway.

Buried Duct

In duct installations, the duct is first installed below ground usually by trenching. The fiber optic cable is subsequently installed within the duct using a number of methods that are described below. One benefit of using duct is that several ducts comprising a duct bank can be installed simultaneously. As ducting is generally less expensive than the cable itself, this has the potential benefit of reducing the system first-installed cost. Additional fiber optic cables can then subsequently be installed on an as-needed basis to support future growth, vs. all at once. This method minimizes the likelihood of damaging installed cable when new cables are added as each can be installed into a separate protective duct. Since the ducting itself must also be durable to be placed in the ground, it affords the cable some additional measure of mechanical protection. This means that cables designed for installation in ducts need not be as rugged as cable designed for direct-burial applications, which typically equates to a lower cost for these types of cables. Such cables are generally not armored; hence the term duct cable is often used to describe all-dielectric cables designed for placement in such ducts.

The most common method for a duct installation is to pull the cable through the pre-installed duct with a pulling rope or tape. Pulling distances, and thus installed cable lengths, can be increased by the use of pulling lubricants and mid-span assists, thereby allowing one longer cable to be pulled into sequential segments of duct. It is imperative during such operations to ensure that the cable is not damaged by applying excessive tension, by pulling the cable around overly restrictive bends in the conduit or through damaged conduit, or by using guide sheaves or rollers that are too small. In some cases cables can be pulled into duct in groups of two or more, or pulled in on top of other existing cables, but doing so can significantly reduce achievable installation distances and increase the likelihood of damage to the cables themselves.

Another method of installing cable into duct is by moving the cable along the duct length using the action of a high-velocity air or other compressed fluid acting on the cable jacket. Air-assisted installation

techniques, sometimes referred to as jetting, typically involve pushing the cable with a tractor mechanism while blowing compressed gases into a pre-installed duct or miniature duct at a high speed. This technique allows the cable to “float” inside the duct during installation, minimizing forces placed on the cable due to friction between the cable jacket and the duct wall. If done properly, cables can be installed into ducts using this type of method for distances of up to 5500 ft or more, without the use of mid-assist machines. Longer distance can be achieved by installing the cable via a combination of pushing, pulling, and jetting. Such installations can reach deployment speeds up to over 200 ft/min depending upon the specific characteristics of the duct, the route, and the cable being installed. Installation performance can also be improved by keeping the temperature and humidity content of the compressed gases low. Some lubricants can be used with jetting-type installation methods, but care must be taken as using these improperly could actually be detrimental to the installation effort.

The most popular application for jetting is to support the placement of relatively small cables with diameters ranging from about 4 to 8 mm, and fiber counts up to 72 or more, into miniature ducts around one centimeter in diameter. This method enables the efficient use of premium duct space by allowing larger traditional ducts, such as 1 to 1-¹/₂ in. sizes, to be subdivided into many smaller ones. The result is a honey-comb of miniature ducts that can be populated with cost-reduced miniature cable types specifically designed for installation with high pressure fluid methods.

Since the distances that cables can be placed into ducts may vary significantly depending upon the installation method used and the specific characteristics of the cable and ducting, most cable manufacturers have computer software that estimates achievable distances and cable loading during installation. For accurate calculations these programs require detailed information on the physical and material characteristics of the duct and cable(s) in order to determine an accurate coefficient of friction and cable loading characteristics. Critical duct physical characteristics are the inner diameter, section lengths, changes in elevation, and the number and location of bends, including bend radii and directions. This information is best determined by an accurate route survey conducted on the system prior to the placement of the cable. Key cable characteristics are diameter weight, and jacket material, which can be obtained by contacting the cable manufacturer, and the number of cables being installed.

Aerial Installations

The common methods for placing cables aerially include lashing the cable to a pre-installed steel messenger wire, or employing the use of cable designed to be self-supporting. Self-supporting fiber optic cable designs are usually based on one of two primary designs. Figure-8 self-supporting aerial cables (Figure 9.30(c)) consist of a fiber optic cable core and integrated messenger, typically made from stranded steel. Both the cable and the messenger share a common outer jacket resulting in the characteristic shape that gives these cables their name. All-dielectric, self-supporting (ADSS) aerial cables (Figures 9.30 (a and b)) contain no metallic elements and are usually round or oval in shape, although some are offered in a “Figure-8” design as well. In round cable designs, dielectric aramid yarn is stranded around the cable core or inner jacket to provide the necessary tensile strength for aerial applications.

Aerial applications for fiber optic cable offer unique challenges. Planning for aerial cable installation includes taking into account proper clearances over hazards, the cable types and physical properties, and the mechanical stress loading placed on the cable over the life of the installation, due to the environment. Proper planning requires knowing the “sag and tension” characteristics of the cable once installed. Sag is the amount of vertical distance an aerial cable will hang, or droop from an imaginary straight line drawn between successive attachment points. The tension is the force that the ends of the cable experience under various installation and environmental conditions at the attachment points. Understanding the stresses placed on a cable installed aerially is important to ensure that safe operating conditions are not exceeded, cable lifetime shortened, or that dangers from material failures do not occur.

When planning for the aerial installation of fiber optic cables there are several important factors to consider with respect to the design, specification, installation, and performance of the optical plant. Fiber optic cables used in aerial applications must not only be able to withstand high tensile loads over the life of the installation, but they are also subject to the full range of harsh environmental conditions of the

unprotected outside plant. With any aerial installation, factors such as cable design (size, fiber count, tensile properties, etc.), span distance, installation method, installation tension, and environmental loading conditions (temperature, wind and ice) need to be addressed. As with duct installations, major manufacturers of fiber optic cables designed to be placed aerially can offer guidance on achievable span distances for a given cable by accounting for the prevailing environmental conditions. The primary limiting conditions for a typical aerial installation are the allowable cable sag, the tensile rating of the cable messenger (if used) or attachment hardware, and the allowable cable strain or fiber attenuation at maximum environmental loading.

Another potential hazard to aerial fiber optic cable installations is that, given certain environmental conditions, the cable could experience additional stresses from oscillating wind-induced motions. One type of cable motion is Aeolian vibration, which can occur with sustained low velocity winds. Aeolian vibrations cause the cable to resonate, or sing, at frequencies of around 50–100 Hz depending on the specifics of the installation. Aeolian vibrations are most common in long spans of round cable installed at high tensions, and have the effect of wearing away the cable sheath or fatiguing attachment hardware at the support points. Another wind-induced cyclic cable loading mechanism is galloping, which is characterized by larger amplitude and lower frequency movement. Galloping occurs at higher wind speeds on nonconcentric cable designs, such as “Figure-8” cables or round cables that have their shapes distorted by ice accumulations. Aerial cable galloping has the effect of overloading the attachment hardware, causing it to fail. Although these two phenomena may not affect the cable’s optical performance to a significant extent, they are considerations for selecting hardware to properly support aerially installed cable. For this reason the selection of proper attachment hardware is a critical part of any aerial installation.

There are also a number of other potential hazards that must be accounted for when installing cables aerially because of the obvious exposure. These include shotgun damage, lightning strikes, gnawing rodents, and even the effects of high electric field potentials in installations where the cable is co-located near high tension power lines. Dielectric cables can minimize the effects of lightning or high field potentials, but do not render such cables impervious to their effects. Armoring can improve the survivability of cables to mechanical damage from gunshot and rodents, but adds considerable weight which can limit achievable span distances.

Indoor

The fact that most indoor cable is placed by hand in cable trays or pulled for very short distances into duct, conduit, or the like, makes the installation aspect somewhat less critical of a consideration for such designs. In some tall buildings the cable might be placed vertically for several stories, but must then be supported periodically along its length to prevent excessive stress from being placed on it.

9.2.2 Cable Components

Fiber Elements

Fibers in fiber optic cables are primarily offered in one of three basic forms, each with its own advantages and limitations as described below.

Individual Colored Fiber

Bare fiber is supplied by the manufacturer with diameter of about 245 μm . Most fiber is coated by the cable manufacturer with a thin layer of ink for the purpose of identification. Once colored, the fiber can be placed in a number of different cable designs for a variety of uses. The primary benefit of using loose individual fibers is the relative ease of manufacturing and the fact that the fibers can be packed relatively densely, especially for low fiber count applications. The main disadvantages to this design are that each fiber must be spliced individually and it is not recommended that fiber in this form be used to support the direct termination of fiber optic connectors. This can increase the cost of the materials, time, and space needed for installing these types of cable designs, and the differential costs can increase at higher fiber counts.

Ribbon Fiber

Ribbon cables employ groups of individual fibers locked in a tight planar array by the application of a matrix material that is similar to the coating placed on individual fibers (see Figure 9.26). The cured matrix then holds them parallel to one another, but generally enables the fibers to be physically separated into smaller groups by hand or with the use of specially designed ribbon-splitting tools. Ribbon fibers come in group sizes ranging from 2 to 36, but 12-fiber ribbons are currently the most commonly used in North America, especially in the outside plant. The advantages of ribbon cables are the greater fiber packing densities at high fiber counts, and the fact that all the fibers in two ribbons of the same type can be spliced to one another simultaneously in one operation. Current mass-fusion splicing equipment can support splicing up to 24 fibers at a time, resulting in significant cost savings for high fiber count installations. The cost benefit of splicing ribbon cable is not generally considered significant below fiber counts of about 72 for most applications, but low fiber count ribbons may still find uses where size restrictions are more of a consideration, such as in buried duct applications.

FIGURE 9.26 12-fiber ribbon. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Buffered Fiber

For the vast majority of indoor cables, individual uncolored or colored optical fibers are coated with a buffer material to increase the diameter (see Figure 9.27). Although a number of sizes are available, 900 and 500 μm are the most common. The primary benefit of these fibers is that they are inherently more rugged, easier to handle, and can be directly terminated with standard field-installed optical fiber connectors. These features make them ideal for applications where fiber counts are low but which are termination intensive. Because of the added materials, buffered fiber cables are not well suited for high fiber count or long-distance applications due to the increased size, weight, and cost. To assist in the removal of the buffer layer from the fiber for termination or splicing purposes, these fibers may be coated with a low-friction slip layer applied to the coated fiber before the buffering process. These thin slip layers do not affect the performance of the fiber or the ability to strip the acrylate coating from the glass fiber itself.

FIGURE 9.27 900 μm buffered fiber. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

These features make them ideal for applications where fiber counts are low but which are termination intensive. Because of the added materials, buffered fiber cables are not well suited for high fiber count or long-distance applications due to the increased size, weight, and cost. To assist in the removal of the buffer layer from the fiber for termination or splicing purposes, these fibers may be coated with a low-friction slip layer applied to the coated fiber before the buffering process. These thin slip layers do not affect the performance of the fiber or the ability to strip the acrylate coating from the glass fiber itself.

Core Elements

Buffer Tubes and Subunits

The fundamental building block of any fiber optic cable is the buffer tube or subunit (see Figure 9.28). Buffer tubes are primarily associated with outdoor fiber optic cables and serve to house and organize the individual fiber elements. They typically contain a waterblocking material to protect the fiber from water ingress and to help isolate them from external stresses. The tube materials used must be flexible, yet provide sufficient hoop strength to ensure adequate mechanical resistance to crushing forces

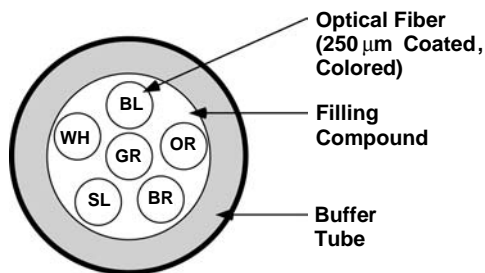

FIGURE 9.28 Cable buffer tubes (loose, ribbon, and bundled fiber). (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

during installation and operation. Buffer tubes may contain just a few fibers and be relatively small in size, or may contain up to a thousand fibers or more in a single central tube. In addition to providing protection to the optical fibers, buffer tubes also serve to aid in the identification of individual fibers in multi-tube designs, and allow for groups of fibers to be protected when routed inside an optical closure or other optical hardware for termination.

In the case where the size of the buffer tube is small and several are located within the same cable core, multiple buffer tubes are stranded in a concentric, helical pattern that reverses direction periodically. The reason for this is to improve the performance of the cable under temperature and tensile load extremes, as well as in relatively tight bends, and to improve mid-span fiber accessibility. For cables with a large number of buffer tubes, the tubes may be arranged in two or more layers using the same type of stranding process for each.

Central tube designs are also fairly prevalent and typically support a smaller outer cable diameter for a given fiber count. In high fiber count ribbon applications, this can be a major benefit such as when the available ducting has a relatively small diameter. For central tube designs housing loose fibers, the identification of individual fibers is aided with the use of colored thread binders that also serve to segregate the fibers into groups, usually in multiples of twelve.

Most inside plant cables do not use buffer tubes, but may instead use subunits to organize the fibers within an overall outer cable sheath. A subunit serves many of the same purposes as a buffer tube except that it does not contain water blocking materials and it is usually made from materials that are chosen primarily for their fire-resistance properties. In some of these unitized designs the subunit itself may be structurally equivalent to a complete indoor cable. This allows the individual subunits to be broken away from the rest of the cable and routed independently, in order to deliver one or more fibers to where they are needed within a building. Such cables are usually called break-out, or fan-out, cables. The latter generally refers to cable in which each subunit contains only one fiber.

Not all cables require the use of buffer tubes in the traditional sense and some emerging designs may be tubeless to keep the overall cable size to a minimum. In these cases a single cable jacket may function as both a buffer tube and a jacket, with the fibers contained inside in a either loose, buffered, or ribbon form. However, such designs have seen only limited use and typically must rely on external structures such as trays, tubes, ducts, or microducts for additional protection.

Strength Members

The strength members of a cable are ultimately what enable it to survive the rigors of installation and the effects of large temperature extremes that might be experienced in various applications. Strength members themselves can take on a variety of forms and be placed in many different locations throughout the cable structure including centrally, in parallel inside the cable jacket, and applied as yarn rovings helically wound around the cable core or inner jacket. The most common strength members are glass-reinforced plastic (GRP) rods, rovings of aramid or fiberglass yarns, and steel wires that may be applied individually or as a unit of stranded steel wires. Even though the various other materials within the cable may contribute to the overall strength of the composite structure, discrete strength elements are usually needed for the purpose of meeting installation and in-service tensile performance requirements.

In stranded tube and stranded unit designs a central GRP or steel rod is typically used. The rod may be coated, called up-jacketing, for proper dimensional sizing to provide mechanical support to the fiber-bearing elements. In some indoor designs a group of yarns may also be used, upjacketed or not, to support the stranding of small units or individual 900 μm buffered fibers. The first layer of buffer tubes or subunits are then stranded around the central member and held in place by binding yarns. This central strength member serves a number of purposes, including acting as the primary tensile strength element, providing a means with which to anchor the cable to any hardware in which it is terminated, providing structural support to the stranded tubes or subunits also provide stiffness to the cable to prevent plastic elements from kinking during placement.

In central tube designs a buffer tube occupies the middle of the cable, so strength members must be placed elsewhere. To ensure adequate tensile strength, rigid GRP or steel rods, or the like, are usually

bonded to the overall cable sheath to achieve the necessary tensile properties. These rigid elements cannot simply be placed loosely between the core and sheath as they would be prone to shift during the extreme bending or torsion forces experienced during installation, thereby potentially giving the cable unwieldy handling characteristics. These cable designs usually employ 2–6 rods placed on opposing sides of the cable, inside the sheath. As a result, the finished cable may exhibit preferential bend characteristics similar to those of noncircular cable types such as “Figure-8” designs.

Helically stranded tensile yarns can also provide the primary means of tensile strength for certain cable types, and can also be used to provide increased tensile strength for stranded or central tube designs through the use of dielectric yarns helically wrapped in one or more layers around the core. Tensile yarns are often used in lieu of rigid elements for indoor cables as such designs are required to be more flexible. The yarns, when used, can be held in place by a single binding yarn to aid in the manufacturing process. For low count indoor designs, the yarns may be applied in parallel to the core elements.

In some other designs the central strength element may also organize the fibers. In a slotted core or slotted rod type of cable, the central member is upjacketed with a thick layer of plastic incorporating grooves extruded in the outside. Buffer tubes, fiber bundles, or ribbons can then be placed in the grooves and covered with binders or tape to hold them in place. Other designs such as submarine or OPGW cables employ other materials as discussed later on.

Waterblocking

The effective blocking of water in cables employed in the outside plant is critical in preventing the ingress and migration of water throughout the cable. The presence of water in the cable can result in the crushing of fiber-bearing elements due to freezing effects, or can allow water to migrate into sensitive electronics or splice closures if not properly blocked. Even though optical fibers can generally survive for extended periods exposed to water alone, the long-term effects are not well understood and water may eventually cause the protective fiber coating to delaminate over long periods, especially if high temperatures are present as well.

Historically, cable waterblocking has been effectively achieved via the use of thixotropic gels. While very effective at blocking water, such materials are also useful in isolating fibers from external stresses by increasing the mechanical robustness of the cable. However, the use of such gels can present compatibility issues that affect cable material selection, and are a nuisance for installers terminating cables. They also can add significant weight to the cable itself resulting in shorter achievable installation distances for duct and aerial applications. Still, such designs have proven their mettle with hundreds of thousands of kilometers of such cable types successfully installed and continuing to operate error free for 20 years and beyond in direct buried, duct, and aerial applications.

Newer generation cables are employing gel-free, dry-core technologies to provide the waterblocking performance of the cable, should the protective jacket be compromised. These dry designs rely on the use of super absorbent polymers (SAPs), which absorb the water and swell on contact to keep the water from migrating further into the cable. They are generally applied to interstitial spaces in the core via the use of tapes, strings, and strength yarns. SAPs materials provide the cable with water blocking performance equivalent to the traditional gel designs, so they can be used in any normal outside plant environment. The primary benefit of such materials is that they are considerably less messy to work with than gels and can significantly reduce installation times. The performance of SAPs may be affected by exposure to moisture having a high ionic content, such as brackish water, so special tapes may be required in some cases. For completely gel-free designs, SAPs may be applied in powder, yarn, or other forms to the inside of the buffer tubes.

Other Core Components

Other elements not discussed above may be contained in cables designed for specific applications. These include binding yarns to hold buffer tubes or strength elements in place during manufacturing, filler rods to lend symmetry to certain stranded core designs, copper or coaxial wire for communications or

other low-power applications, and additional tapes for improved moisture, shielding or flame resistance characteristics. Most cable designs also incorporate one or two special high tensile strength yarn cords, called ripcords, which can be used to split the outer jacket longitudinally for ready access to the core elements inside.

Sheath Elements & Options

Jacket Materials

In selecting a material for an outdoor cable jacket a manufacturer must choose one that is not only cost-wise, but also one having optimal performance characteristics for the intended environment. The characteristics considered crucial for a fiber optic cable jacket are toughness, tensile strength, heat and chemical resistance, flexibility, and long-term environmental stability. For the best combination of these factors, as well as cost, polyethylene is the material of choice for the vast majority of outside plant cable manufacturers. Various grades of polyethylene such as low, medium, and high density are available for applications requiring specific performance attributes.

Various additives can also be mixed in with the polyethylene resin by the material suppliers to enhance other material properties, as needed, to resist the demands of a specific type of environment. Carbon black (or furnace black) is the most common additive and is used to improve the jacket material's resistance to the effects of solar radiation. Adding carbon black also gives outside plant cables their characteristic black color. Other UV stabilizers in limited use allow for jacket colors other than black but may not be as effective.

Some specialized materials can be used to significantly improve the performance of the jacket in the presence of strong electrical fields. Track-resistant polyethylenes (TRPE) are used to inhibit cable jackets from eroding away when used in aerial applications that require the cable to be installed in areas of high electric field potentials. Tracking is an electrical phenomenon that occurs when a current induced on the surface of the cable jacket is interrupted, resulting in arcing. The current is established when water, from rain or fog, is mixed with contaminants in the air such as dust, pollution, salt spray, etc. The mixture coats the surface of a cable and sets up a conductive path in the presence of an electric field gradient. As the cable begins to dry, the path is interrupted and arcing occurs. The arcing creates grooves (tracking) in the cable jacket, which eventually deepen until the jacket wears through. Tracking is normally not an issue for cables installed near electrical systems with transmission voltages at or below 115 kV, but can occur at lower line voltages depending on the specifics of the installation environment.

Other materials such as alumina trihydrate and magnesium hydroxide can be added to polyethylene to provide some measure of fire resistance. The resultant materials are termed flame-retardant polyethylenes (FRPE). FRPE jacket materials are used in place of standard fire-resistant cable jackets when there are concerns that other compounds would release excessive combustion byproducts that are life-threatening, or which could damage sensitive electronics, if burned. Such materials do not have the same level of fire-resistance as the polyvinyl chloride (PVC) and polyvinylidene fluoride (PVDF) materials commonly used for indoor cable, so there are tradeoffs to consider when looking at the need for fire-resistance. Note that since jacket tracking is effectively caused by localized heating of the jacket material, some TRPEs and FRPEs may have similar material characteristics.

In cases where the polyethylene alone cannot be made to resist certain chemicals, such as hydrocarbon fuels, other materials can be extruded over the outer polyethylene jacket for an additional measure of protection for exposed cable. In these cases the added materials themselves may not be ideally suited for use as a stand-alone cable jacket due to certain material properties, cost, or other considerations. However, when extruded over a base polyethylene outer jacket the overall sheath combination results in composite structure that is resistant to a wide range of operating conditions and environmental concerns. Oversheaths consisting of nylon are available from some manufacturers and can be useful in heavy industrial environments where exposure to known aggressive chemicals is likely. Nylon also has been shown to improve the sheath's resistance to boring insects.

As stated before, the primary consideration for indoor cable is to ensure that the cable does not significantly contribute to the spread of flame and/or the generation of smoke in the event of a fire. Other attributes such as durability, a wide operating temperature range, flexibility, and cost are important as well, though not usually as critical as with outside plant applications. The materials most often used for indoor cables are PVC and PVDF which have excellent fire-resistant properties, but they are comparatively more expensive than those used for outdoor applications and may not perform well at very low temperatures.

Cable Sheaths and Armoring

Outside plant cables are categorized as either duct or armored. Armored cables are typically specified for direct-buried applications when the cable may be subject to attack by gnawing rodents, or if the conditions otherwise warrant the need for additional mechanical durability. Examples of the latter are when the cable is to be buried in rocky soil, or when exposure to gunshot is a concern. Metallic armoring may also be used to simplify the ability to locate buried cable through a process called toning. The major tradeoffs for employing cables with metallic armoring are that they are typically more expensive, and the metallic components will require bonding and grounding for safety everywhere the cable is terminated, or enters a building. By comparison, it is usually more expensive to install a single duct and to populate it with a cable versus just installing a single armored cable.

Several types of armors exist for use based on the needs of the application. Metallic armor tapes are usually corrugated before being formed concentrically around the cable core to allow for better flexibility in handling and installation. Depending on the manufacturing process, the armor may be sealed by bonding the polymer coating, if present, at the overlap. Most cable manufacturers use an electrolytic chrome-coated steel (ECCS) tape coated with a polymer layer to inhibit corrosion. ECCS armor provides a superior overall performance at a lower cost than other armor types. Stainless steel armor, which is sometimes used, is more corrosion resistant than the standard steel tapes, but is significantly more expensive and more difficult to form around the cable core. Copper clad steel tape may also be used as a moisture barrier, or in cables designed specifically for high temperature/steam-resistant applications. Another common moisture barrier option is laminated aluminum polyethylene (LAP).

A popular armoring choice for indoor cable designs is interlocking, or BX, armor. BX armor starts out as a flat strip of aluminum or steel metal which is roll formed to create a "hook" on each side of the tape. The tape is then helically wrapped around a finished cable with successive layers locking into previous layers. The result is a very rugged and highly flexible cable that can be used in applications where exposed cable may require an extra measure of security, or where excessive impact or compressive forces are possible. Because of the relatively high cost associated with their use, such armors are primarily relegated to indoor applications where shorts lengths of cable are exposed to potential damage, such as in a manufacturing plant where cables connecting equipment on the shop floor are exposed to mobile heavy equipment traffic.

For applications requiring all-dielectric cables, but for which the presence of protective armoring is also desired, some manufacturers offer dielectric armored cable designs. The armoring for these types of cables consists of an aramid tape or thick annular layer of aramid yarns wound around the cable core. The yarns may provide some protection against gnawing rodents and shotgun blasts, but these designs have only seen limited use. Protection against rodents in an all dielectric design can also be achieved by increasing the thickness of the standard outside cable jacket to increase the overall cable OD. In these cases the finished cable OD must usually be on the order of one inch or more, which may not be practical for cables with relatively small cores or low fiber counts, or in certain applications.

All-dielectric (duct) cables are used in applications where the additional protection afforded by metallic armoring is not needed or not wanted. Duct cable refers to all-dielectric cable designed primarily for use in a conduit, although such cable may be used in other applications as well. Some such uses are in aerial lashed installations, or in limited direct buried applications where the below-grade environment is more benign and rodent attacks are not a concern. All-dielectric cables may also be

preferred in high lightning and high voltage areas in order to eliminate potential safety issues from induced currents.

Other materials may be incorporated into the overall cable sheath, such as shields, moisture barriers, and identification tapes. These materials see fairly limited use because of the minimal benefit/cost return they provide. Specific cable designs may also employ sheath constructions consisting of multiple jackets and layers of armor to improve the cable survivability in extremely harsh environments.

9.2.3 Cable Types

Combining the various attributes discussed to this point enables the construction of a wide range of cable types for various applications. The most common cable designs are described later on and the design of choice for a particular application depends on a number of factors. The primary considerations are fiber count, installation method, and the environment. Specific designs based on the basic constructions discussed (i.e., stranded loose-tube, central tube, and tight buffered), but which are specialized for a particular application, are discussed in Section 9.2.4.

Table 9.7 compares the major attributes of the various basic cable designs.

Stranded Loose Tube Cable

Stranded (buffer tube) loose tube cables are the most common design of fiber optic cable and were also the first ones in widespread use. The primary benefits of these designs are the large operating temperature window, the ability to access fiber within a short length of cable (midspan), and the relatively small size at moderate fiber counts when individual colored fibers are used. These designs can be easily adapted to almost every environment and application including direct buried, duct, aerial lashed, aerial self-supporting, and indoor. Common stranded loose tube cable types are illustrated in Fig 9.29.

Single Tube

The primary benefit of single tube designs is that they can have the smallest outer diameter size for a given fiber count. At counts above 12, the fibers must be grouped into ribbons or bundled together with colored threads to support the identification of individual fibers. Typical single tube cables are shown in Fig 9.30.

TABLE 9.7 General Comparison of Cable Design Attributes

Cable Attribute	Individual Colored Fibers		Ribbon fiber		
	Stranded Tube	Central Tube	Loose Tube	Central Tube	Buffered Fiber
	Operating temperature range	Best	Good	Good	Good
High fiber count density (≥ 144)	Poor	Good	Good	Best	Poor
Moderate fiber count density (24 to 144)	Good	Good	Poor	Good	Poor
Low fiber count density (≤ 24)	Good	Best	Poor	Poor	Good
Midspan	Best	Good	Best	Good	NA
Splicing cost	Fair	Good	Best	Best	Poor
Fire resistance	Limited	Limited	Limited	Limited	Best
Direct termination	Fair	Fair	Fair	Fair	Best

Note: The intent of this table is to provide a simple comparison for various basic cable constructions. Special cable designs, including those employing exotic materials, can show an improvement over standard products in one or more categories

Buffered Fiber Cables

Tight buffered cables were the first generation of premises cables. The name ‘tight buffered’ is derived from the layer of thermoplastic or elastomeric material that is applied directly over the fiber coating as discussed earlier. The buffer coating on the fiber makes it easier to handle and supports direct termination with fiber optic connectors (Fig 9.31).

9.2.4 Specific Cable Designs

A number of specific cable designs, based on the basic constructions listed earlier, are also available for certain applications. Some of the most common types are described further along with their potential uses.

Self-Supporting Aerial Cables

Standard terrestrial cables are often used for aerial applications, but in such cases they must be lashed to an existing aerial support messenger in the field, which increases installation time and cost. Conversely, aerial self-supporting cables can be installed much more quickly since the tensile bearing elements are integral to the cable design itself. Self-supporting cable types are usually a variation of the stranded loose tube design containing individual colored fibers, though other variations such as central tube ribbon designs may see limited use.

One type of self-supporting aerial cable is the Figure-8 cable design. In this design the cable core and separate tensile strength member are co-extruded under the same outer jacket. Although the tensile element is usually a stranded steel wire, other materials, including dielectric ones, can be used. Most all-dielectric self-supporting (ADSS) cable types are of a concentric design and employ one or more annular layers of strength elements around the cable core, or inner jacket if used, to provide the requisite tensile strength. Other variations exist for specific applications, such as low fiber count drop cables, which may use a GRP rods.

Miniature Duct Cable

One way to improve the efficient use of premium duct space is to subdivide the ducts using bundles of miniature ducts, each one of which can house a separate mini-cable. Because the primary source of locomotion for such installations is the force of a high velocity fluid acting on the cable jacket, the forces placed on the cable during installation are minimal. The ducting also provides additional mechanical protection for individual cables and isolates them from one another. For such applications, the size of the

cable is more important than its ultimate mechanical durability, so resistance to tensile forces and other high mechanical loads, such as impact or compression, can be traded off somewhat to achieve an overall smaller cable cross section (Fig. 9.33).

Road Cable

To reduce the issues associated with installing cable in the last mile of all-optical networks, especially in densely populated metropolitan-type environments, alternative deployment methods are being developed.

FIGURE 9.32 Aerial self-supporting loose tube cable examples: (a) Solo[®] short or medium, (b) SST (dielectric) Drop, (c) ALTOS[®] (d) SST Figure-8 Drop. (Courtesy of Corning Cable Systems LLC and Corning[®] Inc.)

FIGURE 9.32 (Continued).

One promising method is the use of road cable, which is a specialized cable design optimized for installation within road surfaces. Road cable is a small, but very robust, cable utilizing a central metallic tube to house the optical fibers. This central metal tube is similar to that used as the core element of an OPGW or submarine type cable, and helps to achieve the necessary thermal, corrosion resistance, and strength properties. The tube is then jacketed with standard jacket materials to complete the cable (Fig. 9.34).

Ribbon Interconnect Cable

In addition to the standard buffered type fibers used in indoor systems, variations of loose tube and ribbon cable designs are also employed for certain applications. One design seeing widespread use is

FIGURE 9.33 Microcable examples: SST Optimizer™. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

FIGURE 9.34 Road cable example: MCS® Road. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

FIGURE 9.35 Ribbon interconnect cable example: RIC Cable (at least the 12F one. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

based on the 12-fiber optical fiber ribbon typically associated with long-haul OSP systems. With the increase in data center and storage area network type applications utilizing high density transceivers and multi-fiber connectors, it became necessary to improve upon the density of traditional low-fiber count indoor cable. The easiest way to accomplish this was to package ribbon fibers in flame-retardant materials, and not much else. An example of a ribbon interconnect cable (RIC) is included herein (Fig. 9.35).

Very Low Temperature Cable

To support the deployment of fiber networks in very cold environments (-55 to -60°C), modifications of standard cable designs are typically needed to improve their low temperature performance. The primary concern is protecting the fibers from stresses induced by the differential contraction of the various cable materials at low temperature extremes. This is usually best achieved by optimizing the basic stranded core concept to isolate the fibers, while allowing for the differential expansion and contraction forces. Since these cables are otherwise not distinctly different from standard stranded loose-tube designs representative cross-sectional pictures are not included.

Hybrid and Composite Cables

Often it becomes necessary to combine various fiber types, or even fiber and fiber copper communications conductors, in the same location for some telecommunications cabling needs. Rather than having separate cables for each type of conductor, various fiber types and copper communications media can be packaged together under a single overall sheath. This reduces installation costs and space requirements that could otherwise become problematic when installing several separate cables in the same location. Composite cables consist of both optical fiber and metallic conductors used for telecommunications, such as copper twisted pairs or coaxial cable, while hybrid cables contain two or more distinct types of optical fiber. Hybrid cables are otherwise not physically distinct from other types of fiber optic cables. The various media can be used together with each supporting a different application, such as voice over the copper and data or video over the fiber (Fig. 9.36).

FIGURE 9.36 Composite cable example. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Submarine Cable

Fiber optic cables connect every continent on earth (except Antarctica) in the form of submarine cables. These cables are specially designed for the rigors of a submarine environment such as high pressures, strong currents, biological attacks from sharks and other predators, and boating hazards such as anchors or trawler nets. The basis for the core cable is a hermetically sealed metallic tube that provides the primary protection for the fibers. The most common submarine cables incorporate one or more layers of steel rods around the core cable which are then flooded with an asphaltic compound for additional protection. This steel rod armoring increases cable strength, provides mechanical protection, and ensures the cable is sufficiently negatively buoyant such that it stays on the bottom of the ocean. In coastal applications, the cable may also be buried for additional security.

A variation of the submarine cable used for shallow water type applications on land uses a standard terrestrial cable design as the core cable instead of a steel tube. These cables are usually adequate for depths of a few hundred feet or less, and are typically much less costly than true transoceanic submarine cables (Fig. 9.37).

FIGURE 9.37 Submarine cable example. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Optical Ground Wire Cable

The concept of integrating fiber optic cables with electrical power transmission systems can be attractive to some electric utility companies wishing to use their extensive infrastructure to generate additional revenue. However, the environment of such does not support standard cable designs due to the very long distances between towers. In these cases, standard ground wires (or shield wires) can be replaced by composite structures called optical ground wire, which contain optical fibers. Optical ground wire cable designs typically incorporate a sealed aluminum tube roll formed over the optical fibers or fiber unit. Aluminum alloy and aluminum clad steel wires surround the tube, giving the cable the requisite electrical and tensile properties. Since any electric currents present on the wire travel on the outside, the fibers are not affected by the presence of high electric field potentials unless overheated.

9.2.5 Fiber Optic Cable Standards and Specifications

Standards and specifications exist for fiber optic cables for the same reasons they exist for optical fiber. Key industry standards and specifications for fiber optic cable are addressed herein.

Fiber Optic Cable Standards Publications

Following are some of the key telecommunications industry fiber optic cable standards employed today for the various fiber optic cable types. For the sake of brevity, the standards are identified only by document number, the publishing organization, and the respective cable types or applications. Users of industry standards should purchase these from a reliable source to ensure they have the latest applicable version.

Cable Attribute Specifications

Each optical cable design normally undergoes a series of mechanical and environmental tests to ensure the cable performs as designed once deployed in the field. The tests are designed to simulate the installation, operating, and environmental conditions the cable will experience over its lifetime. Table 9.9 lists several tests typically performed on each cable design. In most tests, the acceptance criteria usually consist of attenuation measurements, visual inspections, or both.

As with optical fiber, various industry cable standards specify common performance attributes and each attribute has an associated test procedure, not listed here. Refer to the individual cable standards listed in Table 9.8 for detailed information on test methods and acceptance criteria.

TABLE 9.8 Fiber Optic Cable Detailed Industry Standards

The following are the key specified performance attributes for the various fiber optic cable types. Other secondary parameters are also specified, while some are only characterized (i.e., recommended or typical).

Other Industry Cable Standards

Installation

The *National Electrical Code*^{®*} (NEC^{®*}) is a document issued every three years by the National Fire Protection Association^{®*}. The document specifies the requirements for the safety of premises wire and cable installations, and also sets requirements to minimize the risk and spread of fire in commercial buildings and individual dwellings. Section 770 of the NEC defines the requirements for fiber optic cables. Although the NEC is advisory in nature, its content is generally adopted by local building authorities as Code.

The *National Electrical Safety Code*^{®**} (NESC^{®**}) addresses the safety of persons and equipment during the installation, operation, or maintenance of electric supply and communication lines, and the associated equipment. The NESC contains the basic guidance considered necessary for the safety of both the installers and the general public as a result of such installations. For example, the NESC contains information of the various environmental conditions that aerial cable plants may be exposed to in the different geographic regions of the U.S., which must be accounted for to ensure their survivability.

Testing

Each optical cable design normally undergoes a series of mechanical and environmental tests to ensure the cable performs as designed once deployed in the field. The tests are designed to simulate the installation, operating, and environmental conditions the cable will experience over its lifetime. Table 9.8 lists several applicable industry standards, while Table 9.9 lists tests typically performed on each cable design. Standard optical, mechanical, and environmental test procedures are defined in industry standard fiber optic test procedures (FOTPs). FOTPs are published as the TIA/EIA-455 series of documents. Each FOTP provides

the information needed to conduct testing, including equipment and measurement specifications, and test set-ups, but they do not generally include acceptance criteria, which are instead listed in the various detailed industry product standards. The TIA also publishes a number of different standards that relate directly to certain applications, such as TIA-568, “Commercial Building Telecommunications Cabling Standard.” The TIA also develops optical fiber system level test procedures (OFSTPs) that are published as the TIA-526 series of documents.

Identification

The most widely referenced standard for identification by means of color coding is EIA/TIA-598, “Color Coding of Fiber Optic Cables.” This document outlines the standard color coding and identification sequence used for fiber and fiber units, such as buffer tubes or binding threads. The twelve primary colors used and their sequence are listed in Table 9.10.

9.2.6 Optical Fiber Connectivity

Because of the distances involved or for reasons of complexity, fiber optic cables are almost never installed in continuous point-to-point links from transmitter to receiver. Optical fibers must be terminated at desired locations, spliced into long continuous spans, and connected to opto-electronic hardware or each other to support the construction of the passive optical system. The fibers are joined by one of two methods, splicing or connectorizing. In either case the termination must be protected within fiber optic hardware.

Splicing

Splicing is the joining of two separate fibers to create a continuous length of fiber. The fibers are aligned by one of several methods and then joined together physically and optically by one of two basic categories of splicing, mechanical or fusion.

In mechanical splicing, the ends of two separate fibers are physically held in place and aligned with the end faces of the fibers butted together. An index matching gel may occupy the space between the two fibers to minimize the amount of light reflected at the interface. Some light is reflected because the ends of the fibers are not in perfected alignment, so even though there is physical contact an air gap may exist if not for the gel. The internal components of the mechanical splice body must be precisely designed, manufactured, and assembled to ensure that the fiber cores are properly aligned, in order to minimize power loss due to a lateral core offset at the splice point. Mechanical splicing has relatively few applications as the performance is not as good as fusion splicing. It is primarily used in laboratories for fibers undergoing optical testing or in the emergency restoration of damaged sections of cable as a temporary fix until the system can be permanently repaired using fusion splicing techniques.

Fusion splicing is the permanent joining of two fibers by physically fusing them together to form a continuous length of glass fiber. In fusion splicing, the fibers are heated to their softening point of about 2000°C. The heat source is a pair of electrodes that create an electric arc to melt the ends of the optical fibers, which are then mated in the softened phase. After the electrical heat source is removed, the glass quickly cools and solidifies. Fusion splicing has significant benefits over mechanical splicing and is, therefore, used almost exclusively in outside plant, long-haul telecommunications systems to join fibers. Since no air gap is present in a completed fusion splice the amount of reflected light lost due to refractive index differences is inherently minimal, so index matching gel is not needed. Most importantly, fusion splicers can incorporate a variety of active alignment techniques to optimize the splice characteristics to improve the overall splice loss and to reduce reflected light, which can degrade the optical system’s performance. Some fusion splicers can intentionally create precise high loss values, such as might be needed to attenuate signals that are too high for sensitive electronics in the receiver.

The primary methods of active fiber alignment employed by fusion splicers are profile and power through. In profile alignment systems (PAS), the splicer uses LEDs to light each fiber end from two sides and the profiles are then detected by cameras placed opposite the LEDs. The splicer then aligns the fiber core or cladding positions relative to each other, prior to initiating the fusion process. In power-through systems, or light injection/detection (LID[®]) systems, light is injected into one fiber and the power through the joint is continuously monitored by a receiver reading the other fiber. The splicer adjusts the alignment of the fibers in two or three axes to maximize the light coupled between them. The fuse time can be automatically optimized by the fusion splicer based on the prevailing environmental conditions to ensure that the minimum splice loss is achieved. In splicers where the power through is continuously monitored throughout, the splicing process is stopped when the loss is at its lowest level, as determined by a fitted curve representing the change in the power through value over time (Fig. 9.38).

Most splicers in use today can only splice one pair of fibers at a time, which can result in long installation times and increases the associated costs for high fiber count systems. For systems employing ribbon fiber cables, however, entire ribbons can be spliced together at once. Mass fusion splicers can simultaneously splice from 2 to 24 fibers, with 36 fiber splicers becoming available in the near future. Unlike with single fiber splicing, mass fusion splicers are not currently available with active alignment systems because of the inherent complexities involved in the simultaneous alignment and splicing of multiple fiber pairs. As a result, mass fusion splicers use metal or rigid polymer plates which have a series of parallel V-shaped grooves precisely machined into the top. The spacing of the V-grooves is roughly equal to the spacing

FIGURE 9.38 Splice time vs. optical loss curve. (Courtesy of Corning Cable Systems LLC and Corning[®] Inc.)

of the fibers in the ribbon matrix to simplify the fusion process and minimize alignment issues. Average splice loss values are slightly higher for mass fusion splices because the alignment is highly dependent on the cleanliness of the V-grooves and the glass geometries of the individual fibers. Also, special tooling is needed to strip and cleave the ribbonized fibers, increasing the start-up costs. Still, the benefits of mass fusion splicing for high fiber count systems are worth the added expense, as the overall cost to install a system can be significantly reduced due to the time saved in splicing alone.

Fiber Optic Connectors

Fiber optic connectors are devices that are installed (terminated) upon fiber ends to allow for the interconnection and remating of optical fibers. The ferrule of each connector houses the fiber and is the specific part of the connector aligned in a connector pair. When two connectors are mated, the fiber endfaces are mechanically aligned and held in physical contact to achieve the requisite **insertion loss** and reflectance performance. The connector also allows the fiber to be easily mated into the input and output ports of transceivers.

Fiber optic connectors are designed to be disconnected and reconnected easily by hand, which is an important feature in systems that are often reconfigured based on the needs of the time, such as in premises-type applications. They are available in a variety of designs and commonly employ a spring-loaded mechanism to establish and maintain the physical contact between the two connector end-faces. Most connectors also incorporate a keying scheme to ensure that the fiber end faces are consistently mated in the same position. While the majority of connectors are designed for only one fiber, some designs can house up to 24 optical fibers. The most common fiber optic connector designs in use are displayed in Fig. 9.39.

Connector Alignment and Mating

The alignment of the fibers in a connector pair is dependent upon the geometry of the optical fiber, the connector ferrules, and the sleeve in the adapter used to align the two connector ferrules. To aid in fiber alignment, some connector ferrules are tuned so as to align any offsets in the optical fiber position in the same direction with every connector, typically to the 0 or 180° relative position. This minimizes the light loss between two randomly mated connectors. The loss of optical power across a connector pair is called **insertion loss** and it is the most common parameter measured in evaluating the expected system performance.

Because index matching gels are not used to mate two connectors the joint may have an air gap that can create reflections. If large enough, these reflections can degrade system performance by a couple of methods. The reflected light can affect the operation of the transmitter, or can reduce the optical signal margin by adding to the overall system noise. As a result, the quantity of light reflected at the interface, or reflectance, is controlled by the connector polishing process and is specified in the relevant industry standards for certain applications. Reflectance affects both multimode and single-mode fiber systems, but is more of a concern for single-mode applications, especially in analog video systems. A spring is often used to force the two ferrules together and to maintain contact in a mated connector pair, which helps mitigate the amount of reflected light. Also the endface of the connector ferrules may be angled to further limit the reflectance in systems that are most sensitive to its effects. The most common angle used is 8°, which is common in CATV applications.

Installation

Factory Installed Connectors

Optical connectors may be terminated upon the optical cable in the factory or in the field. In the factory, the optical fiber is secured to the connector ferrule with epoxy, typically heat-cured, and the connector endface is polished by machine or by hand. The polishing process produces the endface geometry, (radius of curvature, apex offset, and fiber undercut) that is needed to ensure good optical performance (Fig 9.40).

FIGURE 9.40 Connector endface geometry: (a) Radius of Curvature, (b) Protrusion/Undercut, (c) Apex Offset. (Courtesy of Corning Cable Systems LLC and Corning® Inc.)

Customers employing such products do so because they find value in the relatively lower installation times and associated labor cost savings, as well as the guaranteed factory-polished performance. However, damage from shipping, installation, or other means of improper handling, as well as the presence of contaminants in the field, can sometimes affect the performance of such products. In many cases product performance can be restored simply by cleaning. However, when cleaning is not enough, products can often be field-repaired depending on the exact nature of the issue.

To terminate optical cable in the field, a fiber optic pigtail may be used. A pigtail is typically a single- or multi-fiber cable that has been connectorized at the factory on one end only. The other end remains nonterminated and is spliced to the installed cable. This joint can be either a fusion splice or a mechanical splice. After splicing, the splice point is placed inside a protective splice tray, which is then housed in fiber

optic hardware designed for indoor or outdoor use, as appropriate. Pigtail splicing yields factory quality performance while allowing connectors to be installed after the optical cable is placed.

Field Installed Connectors

For direct termination in the field connectors can be installed with an epoxy and polish procedure similar to that used in the factory. However, to speed up the termination process, a quick-cure anaerobic curing agent is often used. An adhesive and primer are mixed together to start the curing process and outside stimuli are not needed.

The as-installed performance of field installed connector products is largely dependent upon the skill of the craftsperson, as well as the conditions under which they are installed. In any event, the performance distribution of field terminated products is generally not as tight as products terminated by factory automated means, nor are the quality checks performed usually as detailed. Such product can be installed successfully in a wide range of applications but may not be appropriate in all cases. The success of such products also depends upon the system budget or specified acceptance criteria. Specifying field-terminated products at performance levels that challenge their capabilities can lead to significant scrap rates. Properly planning, specifying, ordering, and installing such products (i.e., following the manufacturers recommended procedures) can reduce scrap rates to low levels.

An even more advanced method of field termination utilizes no-epoxy, no-polish connectors. An optical fiber stub is cured into place in the fiber ferrule and polished at the factory. The field fiber is matched up to the fiber stub and a mechanical or fusion splice is made as appropriate inside the connector body. These connectors are typically very quick to install and require few consumables. Although single- and dual-fiber no-epoxy, no-polish connectors are the most common types used, twelve-fiber mechanical splice connectors are also available for use on ribbons.

Since fiber optic connectors must typically be terminated upon 900 μm buffered fibers, a fan-out kit with 900 μm tubing is used when directly connectorizing outside plant loose tube cables, where the fiber is normally only coated to 250 μm .

9.2.7 Chapter Summary

Optical fiber and fiber optical cable have dramatically changed the face of telecommunications over the last 20 years. As the industry matures the installation of optical cables and associated equipment will continue to reach further into businesses, schools, and homes, bringing a wider variety of services and improved quality of life to end users. In order to properly design, specify, order, install and grow an optical system, whether for a LAN, SAN, or a nationwide telecommunications network, knowing the basics of fiber and cable are critical in ensuring the completed system will support the user's telecommunications needs both presently and far into the future.

Defining Terms

Attenuation: The combination of optical energy losses from a light pulse traversing a length of optical fiber resulting from absorption and scattering, typically referred to as intrinsic attenuation, and bending losses, typically referred to as extrinsic attenuation, expressed in dB. However, attenuation is often used as a synonym for attenuation coefficient, expressed in dB/km.

Cladding: The layer of dielectric material that immediately surrounds the core of an optical fiber, the combination of which is fundamental to the ability of optical fiber to guide light at certain wavelengths. The cladding material for telecommunications grade optical fibers usually consists of a silica glass that cannot be physically separated from the core.

Core: The central region of an optical fiber consists of a silica-glass structure in which dopants are added to achieve the desired light transmission properties for a particular type of optical fiber. The distribution of dopants alters the index of refraction of the glass, which varies based on dopant concentration. The resulting refractive core properties are referred to as the index profile.

Insertion loss: The measured loss in optical power resulting from the scattering of light at the physical boundary between two optical waveguides (e.g., fibers). The light scattering is caused by the localized disruption in the refractive properties of the optical path due to the insertion of discrete components such as connectors, mechanical splices, couplers, etc. For fusion splices, this loss is typically referred to as “splice loss.”

9.3 Optical Transmitters

Charles H. Cox, III

9.3.1 Introduction

The basic building block for any optical fiber system is the optical link, that is, all of the components necessary to take the desired electrical signal and modulate it onto an optical carrier, the fiber and other optical components to convey the optical signal from source to destination, and the components required to recover the desired electrical signal from the optical carrier. In this section the components that make up the optical transmitter will be reviewed.

There are primarily three wavelengths that are used in fiber optic links. All are in the near-infrared portion of the electromagnetic spectrum at wavelengths slightly longer than $0.65 \mu\text{m}$, which is the red end

of the visible spectrum. By far the dominant wavelengths in use at present are located in bands around 1.3 and 1.55 μm . The choice of these particular wavelength bands is based on the availability of certain desirable fiber properties, such as low attenuation (1.55 μm) or zero wavelength dispersion (1.3 μm). Early fiber optic links operated around 0.85 μm ; this wavelength was chosen primarily because it corresponded to the availability of the first laser diodes. Although this wavelength offers neither of the fiber advantages of the longer wavelengths, it is still of interest because it offers the nearest term prospect for integration of gallium arsenide (GaAs) electronics with diode lasers, which at 0.85 μm are made in the GaAs material system.

Conceptually an optical transmitter could be based on modulating any one of the same properties of an RF carrier that are commonly modulated in an RF transmitter, that is, the optical carrier's amplitude, phase, or frequency. Although commonly referred to as amplitude modulation, strictly speaking AM of an optical carrier is *intensity modulation*, since in direct detection systems the square of the electric field amplitude is what is actually detected. We will concentrate on intensity modulation in this discussion.

Intensity modulation can be implemented using one of two general approaches (Cox, 1990). With *direct modulation*, the electrical modulating signal is applied directly to the laser to change its intensity. This implies that the modulating signal must be within the modulation bandwidth of the laser. As will be seen, only semiconductor diode lasers have sufficient bandwidth to be of practical interest for direct modulation. The alternative to direct modulation is *external*, or *indirect*, modulation. With *external modulation*, the laser operates continuous wave (CW), and intensity modulation is impressed via a device that is typically external to the laser. Since there is no modulation requirement on the laser for external modulation, this removes a major restriction on the choice of lasers that can be used for external modulation. Although both methods achieve the same end result, an intensity modulated optical carrier, there are a number of fundamental and implementational issues concerning these two approaches that gives each distinct advantages.

9.3.2 Direct Modulation

There are many books devoted entirely to various aspects of lasers in general and diode lasers in particular to which the reader can refer for detailed information (Thompson, 1980; Agrawal, 1986). However, it will facilitate the discussion in this section if we recall the two basic requirements for laser operation: the ability to produce stimulated emission and a cavity that is resonant at the stimulated emission wavelength. To produce light from a semiconductor is easy: forward biasing a semiconductor diode junction, which has been fabricated in a suitable material, results in the emission of *spontaneous* radiation. This is the basis for a light-emitting diode (LED). To produce laser light from a semiconductor requires a structure where an inverted population consisting of both electrons and holes can be set up, from which the spontaneous emission can trigger stimulated emissions. In a semiconductor the inverted population can be created and maintained by passing a DC current through the diode junction that has provisions to confine the electrons and holes.

The second criterion for laser operation is that these stimulated emissions must occur within an optical cavity that is resonant at the stimulated emission wavelength. The most common type of optically resonant cavity for diode lasers is one formed by two parallel, plane mirrors. Such a cavity is referred to as a Fabry-Perot after the original developers of this type of optical resonator. In a Fabry-Perot cavity, resonance exists for any wavelength, which after reflections off of both of the mirrors, is again in phase with the original wave. The wavelengths for which this criterion is satisfied are referred to as the Fabry-Perot modes of the cavity. It should be noted that if the range of energies over which stimulated emission can occur includes more than one Fabry-Perot mode, the laser can emit on several of those modes simultaneously.

Figure 9.41 shows a diode junction for generating the inverted population combined with a Fabry-Perot resonant cavity. When the junction is forward biased, one can obtain laser emission from such a structure. To get some of the light out of the cavity at least one, and often both, of the mirrors are only partially reflecting. It turns out to be easy to fabricate such mirrors in a single crystal material such as a semiconductor

FIGURE 9.41 Semiconductor diode laser using a Fabry-Perot cavity.

since these materials crack or cleave along crystal planes, thereby insuring automatically that the resulting surfaces are optically smooth and parallel to each other. A convenient reflection magnitude is also easy to obtain: the Fresnel reflection at the crystal-to-air interface is about 32%, which is acceptable given the high gain of semiconductor lasers. To ensure a linear optical power vs. current function and a stable spatial optical mode, the light must be confined to a single-spatial-mode waveguide between the mirrors. Presently diode lasers for direct modulation are *index guided*, which means that the light is confined by increasing the refractive index of a narrow stripe, so that the light is guided within the stripe via total internal reflection. The increased index in the horizontal direction is via a compositional change in the semiconductor, whereas the vertical index increase is provided via semiconductor layers with a different refractive index.

A *Fabry-Perot diode laser* as described is by far the most common type as it is the laser that is in every CD player in the world. Optical powers from microwatts to tens of watts are commercially available and at a number of wavelengths of interest to fiber optics. However, as we shall see, the performance of this type of laser may be lacking in the more demanding applications. Part of the reason can be traced to the multiple Fabry-Perot modes. Hence, it would be desirable if it were possible to construct a cavity that is resonant at only one optical wavelength. The technique that has been adopted to improve the optical frequency selectivity of the cavity is to place a grating along the cavity, as shown in Fig. 9.42. The period of the grating is chosen such that there is only one resonant wavelength within the range where the semiconductor has significant stimulated emission. The balance between the magnitudes of the grating and facet reflections depends on the details of the laser design. In designs that require the grating reflections to dominate over the facet reflections, the facet reflections can be suppressed by antireflection coating the facets. *Lasers with internal grating are commonly referred to as distributed feedback (DFB) lasers*, since the reflections are distributed along the cavity. As will be seen, for a number of figures of merit DFBs outperform Fabry-Perots.

Direct Modulation Figures of Merit

Threshold Current

A typical plot of optical power P vs. laser current I for a diode laser is shown in Fig. 9.43. As the current is increased from zero, initially the optical output is dominated by spontaneous emission, and the output increases slowly with current. At low currents the probability of stimulated emission is low and so most of the spontaneous emission is absorbed by the semiconductor. Increasing the current increases the number

FIGURE 9.42 Semiconductor diode laser using a distributed feedback cavity.

of spontaneously generated photons, thereby increasing the number of stimulated photons. Eventually a current is reached where the number of stimulated photons equals the number of absorbed photons, which is defined as *transparency*. Above this current level stimulated emission begins to dominate the optical output, and the output increases at least 100 times more rapidly with laser current. *Extrapolating the straight line portion of the stimulated-emission dominated region down to where it intersects the current axis defines the threshold current.* This current is an important measure of laser performance because if it is too high, the heating caused

FIGURE 9.43 Plot of a representative optical power vs laser current for a diode laser.

by passing a large current through the junction will preclude operating the laser CW. Typical values of threshold current for present commercially available lasers are in the 5–50 mA range, with the lowest threshold current for an experimental device being around 0.5 mA (Lau, 1988). The threshold current increases with temperature which, usually necessitates some form of temperature control. This topic will be discussed in more detail subsequently.

Quantum and Slope Efficiency

Another laser figure of merit that comes from the *P vs. I* curve is the *slope efficiency* S_L . This is simply the incremental slope of the *P vs. I* curve at a given laser bias current I_B , and is defined as

$$S_L(\text{at } I = I_B) = \Delta P(I_B) / \Delta I_B$$

The higher the S_L is, the higher the efficiency in converting electrical modulation to optical modulation. Thus, the slope efficiency is an important parameter in link design. The slope efficiency is of practical utility because it can be easily measured on a packaged device without knowing any of the details of the laser's design or fabrication.

A closely related parameter is the *external differential quantum efficiency* η_L , which is the ratio of emitted photons to injected electrons. The quantum efficiency can be related to the slope efficiency as follows:

$$\eta_L = (e\lambda / hnc) S_L$$

where

- e = electron charge
- λ = wavelength
- nc = velocity of light in the semiconductor

Frequency Response

A typical diode laser frequency response for small amplitude modulation is shown in Fig. 9.44. As can be seen from this plot, the modulation bandwidth extends from DC to the relaxation resonance. The frequency of the relaxation resonance, f_{relax} , is proportional to the square root of bias current above threshold and inversely proportional to the geometric mean of the lifetimes of the carriers in the inverted population, τ_n , and the photons in the laser cavity, τ_p ,

$$f_{relax} \propto \sqrt{(I - I_{th})/\tau_p \tau_n}$$

For diode lasers, the relaxation resonance is usually at least 1 GHz, typically 5–10 GHz; the maximum experimentally demonstrated is about 30 GHz (Ralston, 1994; Morton, 1992). All other types of lasers have relaxation frequencies less than 1 MHz, and so with respect to this parameter diode lasers are the only lasers with sufficient bandwidth for practical applications. Although the relaxation resonance sets the maximum bandwidth, other factors such as distortion may limit the usable bandwidth to less than the relaxation frequency. To achieve maximum bandwidth, it is necessary to operate the diode laser at a bias far above laser threshold. However, the final decision as to where to bias the laser must be tempered by the consideration of other laser parameters, such as the decrease in slope efficiency with increasing bias above threshold as shown in Fig. 9.43.

FIGURE 9.44 Plot of a typical frequency response for a high-frequency diode laser. (Lester, 1991)

Relative Intensity Noise (RIN)

Recall that in laser operation stimulated emission dominates. But the spontaneous emission does not cease when stimulated dominates, thereby contributing one source of the small fluctuations in the laser intensity. In intensity modulated systems, these small fluctuations limit the minimum amplitude of the desired signal that can be used for modulation. The most commonly used measure of the laser amplitude fluctuations is the relative intensity noise (RIN) (Yammoto, 1983); it is defined as

$$RIN \propto \langle i^2 \rangle / \langle \bar{I} \rangle^2$$

where

- i^2 = mean square photocurrent
- \bar{I} = average photocurrent.

Typical RIN values for Fabry-Perot lasers are from –120 to –140 dB Hz, whereas for DFB lasers values in the range from –150 to –165 dB Hz are common. Even with the lower RIN of DFBs, the link noise figure of directly modulated links is dominated by the RIN.

A typical plot of RIN vs. frequency for both Fabry-Perot and DFB lasers is shown in Fig. 9.45. The RIN frequency spectrum follows that of the small-signal frequency response with a peak in the RIN at the relaxation resonance. At low frequencies the RIN has a $1/f$ dependence. There is a broad, flat midband region, which ends with peaking in the RIN at the relaxation resonance. The RIN has its maximum value when the laser is biased near threshold. The RIN decreases as the square of increases in the laser bias above threshold, as can also be seen in Fig 9.45.

FIGURE 9.45 Plot of typical diode laser RIN vs. frequency with laser bias above threshold as a parameter.

Although it is common to think of the RIN as a single number, in some applications it is also important to know the RIN spectrum. For example, in applications where the laser output passes through a significant amount of a dispersive medium, such as a fiber, the effects of RIN increase if the laser has multiple modes. This is because in a multimode laser, an increase in the amplitude of one mode reduces the inverted population for all of the other modes in turn reducing their amplitude. Consequently, at different instants in time, the various modes have different amplitudes. Therefore, the resulting amplitude fluctuations for an *individual* mode in the presence of multiple modes can be much *greater* than the RIN of the combination of all the modes (Thompson, 1980, Sec. 7.7).

Frequency Chirp

The optical frequency of the mode or modes in a diode laser depends on the optical path length within the laser cavity. In turn the path length depends on the carrier density, which in turn depends in part on the amplitude of the modulating signal. The combination of all these effects is that the amplitude of the modulating signal changes the *frequency* as well as the intensity of the laser output. This incidental modulation of the optical frequency is referred to as *frequency chirp*. The change in laser frequency with laser drive current is positive, that is, an increase in drive current results in an increase in optical frequency. A typical value of chirp for a DFB is 1.2 GHz/mA. This is an important parameter in high-frequency, long-distance systems, since the chirp causes dispersion of the signal through the fiber, thereby limiting the distance-bandwidth capabilities of the link.

RF Impedance

Electrically a diode laser looks like, well, a diode, albeit a poor one. The doping profile results in a very low reverse breakdown voltage. This fact, combined with the laser’s high speed, makes a diode laser particularly susceptible to damage from noise spikes and power supply glitches. When forward biased, the diode laser impedance can be modeled by the equivalent circuit shown in Fig. 9.46. At low frequencies the diode equivalent impedance is dominated by a small resistance, typically about 5 Ω. At higher frequencies the junction capacitance and bond wire inductance dominate the diode impedance. A typical Smith chart plot of a packaged diode laser impedance is shown in Fig. 9.47. As can be seen in this figure, the low-frequency impedance is dominated by the package bond wire inductance.

FIGURE 9.46 Schematic diagram of diode laser impedance model.

In many applications it is important to match the diode impedance to the system impedance, often 50 or 75 Ω real. Impedance matching can reduce the link RF-to-RF loss and improve the link noise figure, thereby increasing the intermodulation-free dynamic range. Since the diode impedance is less than the system impedance, the series inductance of the bond wire and packaging can limit the ability to match the real part of the diode impedance to the system impedance.

FIGURE 9.47 Smith chart plot of diode laser impedance for laser bias at twice threshold current.

Linearity

Analog systems almost invariably have a linearity requirement. The problem is that no realizable device is purely linear. To state this formally, the power series expansion of any realizable device’s transfer function has nonzero coefficients for at least some of the terms other than the linear one. The effects of these nonlinear terms is clearly seen by examining the output spectrum when two, closely spaced sine waves of frequencies f_i and f_j are input, as shown in Fig. 9.48. The output spectrum consists partly of harmonics of the form mf_i and mf_j for each input sine wave, where m is the order of the harmonic. For clarity only the second- and third-order harmonics are shown in the figure: $2f_1, 3f_1, 2f_2,$ and $3f_2$.

The output also contains intermodulation (IM) terms, which are of the form $mf_i \pm nf_j$, where $m + n$ is the order of the intermodulation term. The figure also shows the two second-order and the four third-order IM terms. Recall that for applications with a bandwidth of less than one octave, the third-order distortion produces the dominant intermodulation signals that fall within the system pass band. Measures of third-order distortion include the intermodulation-free dynamic range (IM-free DR) and the composite triple beat (CTB). For broad-band, that is, multioctave, applications, both second- and third-order distortion terms are important. Second-order measures of distortion include the IM-free DR, which this time contains both second- and third-order spurious signals, and the composite second order (CSO). The IM-free DR is used primarily by the radar and communication fields, where the presence of two strong signals could complicate the detection of a weaker signal. Consequently the IM-free DR is measured using two, closely spaced, equal amplitude CW RF signals. The CTB and CSO are used primarily by the community antenna television

The output also contains intermodulation (IM) terms, which are of the form $mf_i \pm nf_j$, where $m + n$ is the order of the intermodulation term. The figure also shows the two second-order and the four third-order IM terms. FIGURE 9.49 (a) IM-free DR for a Fabry-Perot, dashed curve, and DFB laser vs. laser bias at a fixed frequency; (b) IM-free DR for a Fabry-Perot vs. frequency at a fixed bias (Roussell, 1997).

(CATV) industry and are measured using a multi channel signal generator with the number and spacing of the channels chosen to equal the intended application. Since the measurement conditions for CTB and CSO are application specific, there is no exact conversion factor between IM-free DR and CSO/CTB. However, there are approximate techniques for converting between the two measures (Kim, 1989).

In an intensity modulated link the amplitude of the intermodulation terms depend primarily on the linearity of the modulation device, in this case the diode laser. *The IM-free DR is defined as the maximum difference between the noise floor and the fundamental output, which produces distortion terms of equal amplitude to the noise floor.* The noise floor in turn depends on the link bandwidth (BW), which varies by application. Consequently to make the IM-free DR measurements have general applicability, the results are often given in terms of a 1-Hz bandwidth. To use such results in a specific application simply requires scaling the 1-Hz data to the application bandwidth. The bandwidth scaling exponent depends on the order of the dominant distortion: for second-order distortion, the IM-free DR scales as $(BW)^{1/2}$ or the square root of bandwidth, for third-order distortion, the IM-free DR scales as $(BW)^{2/3}$.

The IM-free DR of diode lasers depends primarily on the laser type, the laser bias, the RF frequency, and the amount of the laser’s own light that is reflected back into the laser. Experimental data for the first three parameters will be presented here. Figure 9.49(a) is a plot showing the IM-free DR of a typical Fabry-Perot and DFB lasers vs. laser bias at a fixed RF frequency. With the RF modulation amplitude fixed, the IM-free DR initially increases as the laser bias is increased above threshold. Once the bias is far enough above threshold to avoid clipping of the modulation waveform, the IM-free DR settles down to a value that is independent of bias, at least until the curvature of the P vs. I curve starts to become appreciable at high laser bias. Fixing the bias of a Fabry-Perot laser, Fig. 9.49(b) is a plot of IM-free DR vs. modulation frequency. Recall that the higher the bias, the higher the relaxation frequency. Consequently, the bias current for highest dynamic range increases as the operating frequency increases closer to the laser resonance frequency.

Linearization

Several important applications, such as the distribution of cable TV signals, require greater IM-free DR than is commonly available from the intrinsic performance of diode lasers. For these applications, the IM-free DR, or equivalently the CSO/CTB, can be increased through any one of a number of techniques. Although the details of these techniques are often proprietary to the company that developed them, the general approaches are well known.

A block diagram of *predistortion* (Bertelsmeier, 1984), the most common approach to linearization, is shown in Fig. 9.50(a). If the nonlinear transfer function, which is limiting the IM-free DR, is well known and stable, a circuit with the inverse of the nonlinearity can be inserted before the diode laser. The cascade of the two nonlinearities then has a more linear transfer function than the original single nonlinearity. However this is an open-loop approach, and so any changes in the offending nonlinearity will not trigger

FIGURE 9.50 Block diagrams of linearization techniques: (a) predistortion, (b) feedback, (c) feed-forward.

a correction in the compensating nonlinearity. The results can range from less increase in IM-free DR to a degradation in IM-free DR! On the positive side, predistortion is simple to implement and does not limit the frequency response.

The *feedback* approach (Straus, 1978) to linearization, as shown in Fig. 9.50(b), can compensate for changes in the offending nonlinearity. However, feedback has its own limitations. Primary among them is the need to limit the phase delay around the feedback loop so that the loop is stable. Compounding this problem is the lack of feedback amplifiers with sufficient performance above about 150 MHz. Thus, to utilize feedback at high frequencies requires a substantial development effort covering feedback amplifier design and monolithic integration of this amplifier and the diode laser.

The third general category of linearization is *feedforward* (Hassin, 1993) and is shown in block diagram form in Fig. 9.50(c). This is probably the most complex to implement because it usually requires two diode lasers. This approach relies on the fact that lower amplitude modulation signals generate lower levels of distortion products. Thus, the distortion introduced by modulating the first laser is added back, but out of phase, to the second laser. However, because of the lower amplitude of the distortion signal used to modulate the second laser, the distortion by the second laser is much smaller.

The latter two techniques have in common that they can compensate for any order of nonlinearity, as opposed to predistortion, which is used primarily to cancel a particular order of nonlinearity, such as third order. Results for any of these techniques are not generally available because of the proprietary nature of the manufacturer's efforts. However it is known that, in general, these approaches have demonstrated about a 5-dB increase in the IM-free DR.

Direct Modulation Implementation Issues

Temperature Stabilization

Several diode laser parameters are temperature dependent, among them threshold current and slope efficiency. The threshold current increases with increasing temperature, eventually making lasing action impossible. The slope efficiency decreases with increasing temperature, and the leakage current around

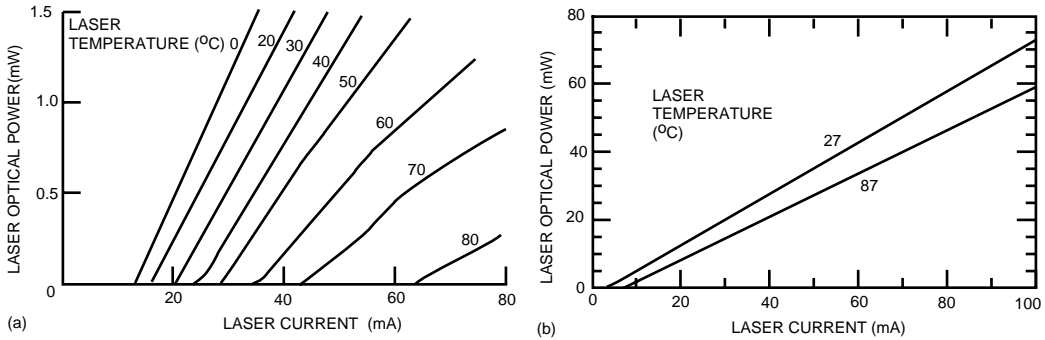

FIGURE 9.51 Plots of diode laser optical power vs. diode current with diode junction temperature as a parameter for: (a) a representative laser, (b) a laser designed for a low-temperature coefficient (Kazarinov, 1995).

the laser junction increases with temperature, which leads to a bending over of the laser’s P vs. I curve. Figure 9.51(a) is a plot showing all of these effects. This trend is to first order independent of the laser cavity design, that is, Fabry-Perot or DFB.

The traditional way around the temperature dependence is to hold the laser at a constant junction temperature. This has led to diode laser packages which include thermoelectric coolers (TECs) and thermistors. By changing the direction of the current through the TEC, this device provides the capability to heat the junction when the ambient is too cold and cool the junction when the ambient is too high. When combined with the appropriate power supply and feedback controller, the diode temperature can be held constant over a range of 100°C of ambient change. However, the TEC can require up to 2 A at the temperature extremes, which may be a burden in some system designs.

A more recent trend is to design lasers whose performance parameters are less temperature dependent. One way to accomplish this is to change the laser’s semiconductor layer structure. For example, a significantly lower temperature dependence is shown in Fig 9.51(b) which is a similar plot to Fig. 9.51(a) but for a laser in which the simple single active layer has been replaced by a multiple quantum well structure.

Fiber Coupling and Packaging

Virtually all diode lasers for communication applications needs to be coupled to a fiber. The desire to do the fiber coupling as efficiently as possible is hampered by the disparity between the wide, elliptical divergence of the laser beam and the narrow, circular acceptance angle of the fiber. Single-mode fibers, which are required for most applications because of their high distance-bandwidth product, have a numerical aperture of 0.12. Most lasers have an elliptical beam with a maximum numerical aperture of 0.5. The consequence of this numerical aperture mismatch is that the fiber coupling efficiency is typically around 10%. By lensing the end of the fiber, the fiber coupling can be increased to 70%. More radical approaches, include tapering the laser waveguide so that the laser produces a lower divergence, more circular beam.

Figure 9.52(a) is a photograph of a typical commercially available laser diode. The combination of the micrometer-scale tolerances and the rapid falloff in coupling efficiency with displacement, has forced most manufacturers to use active alignment for best results. The cost of active alignment adds to the laser cost, in some cases doubling it. Automated fiber coupling equipment is generally available.

The fiber coupling problem is further exacerbated in applications where an optical isolator, which will be discussed in more detail in the next section, must be inserted between the laser and the fiber. Isolators are typically most effective for collimated light, which means that circularizing and collimating optics need to be placed between the laser and the isolator. Even with all this paraphernalia, it is still possible to achieve fiber-coupled slope efficiencies of 0.2 W/A.

In many applications the concern is not the fiber coupling efficiency *per se* but the range of coupling efficiencies from unit to unit and/or over temperature. Unit-to-unit variation can eat into the design margin of the optical link, thereby forcing the user to design to the minimum fiber-coupled slope efficiency. Even in laser packages where the temperature of the laser is controlled, typically this does not include the fiber

FIGURE 9.52 (a) Photograph of a typical commercially available fiber-coupled diode laser, (b) photograph of a fiber-coupled diode laser with an optical isolator.

attachment assembly. Figure 9.53 is a plot of the fiber-coupled slope efficiency vs. temperature for six lasers from three manufacturers. As can be seen, there is significant variation, both among manufacturers and among lasers from the same manufacturer. Thus, the link designer must also account for changes in fiber-coupled slope efficiency over temperature in the design.

Optical Isolation

Several of the laser’s parameters, among them the laser’s relative intensity noise and the laser’s optical modes, are a strong function of the optical reflections of the laser’s own light back into the laser cavity (Hirota, 1981). Thus, in high-performance applications, it is important to provide at least 30-dB, and often 60-dB, attenuation of the optical reflections. One simple way to provide the desired fiber-to-laser attenuation is to intentionally increase the coupling loss between the laser and the fiber. For example, by making the laser-to-fiber coupling -30 dB, optical reflections are attenuated by 60 dB, since they must traverse this loss twice. Increasing the coupling loss has the benefit of significantly simplifying the fiber coupling problem already discussed, thereby reducing the laser cost substantially. However, this approach is only useful in applications where there is substantial link margin since the reduced fiber coupling

FIGURE 9.53 Plot of fiber-coupled slope efficiency vs. temperature for six diode lasers from three manufacturers.

attenuates the desired laser-to-fiber coupling as well. Continuing the example, 30 dB of fiber coupling loss results in 60 dB of RF-to-RF link loss.

An optical isolator provides a means of dramatically reducing the undesired fiber-to-laser coupling while only slightly decreasing the desired laser-to-fiber coupling. Typically an isolator introduces 1 dB of laser-to-fiber loss while providing 30 dB attenuation for fiber-to-laser reflections. Figure 9.52(b) is a photograph showing how an isolator is included in a fiber-coupled laser package. An isolator is clearly the superior solution technically, but results in increased laser package cost.

9.3.3 External Modulation

In contrast to direct modulation, external modulation requires two components: a laser that operates CW and a modulator that imposes the desired intensity modulation. Although slightly more complex, as will be seen, external modulation has several fundamental advantages over direct.

Modulators and Figures of Merit

Materials

The key material property for making a modulator is that a change in an electrical parameter must alter an optical property of the material. Other material properties that are also important are the optical loss and the stability, both thermal and optical. There are three classes of materials from which a modulator can be made: *inorganics*, *semiconductors*, and *nonlinear polymers*.

By far the most common modulator material is the inorganic lithium niobate, which is the benchmark material against which all newcomers are judged. In lithium niobate an applied electric field alters the optical index of refraction. The parameter that gives the optical index change per unit of applied electric field is the electro-optic coefficient, which is usually designated as r . The strongest electro-optic coefficient in lithium niobate is r_{33} . To use this coefficient requires an electrode configuration and modulator waveguide layout where the electric field and the optical polarization are along the z axis of the lithium niobate. A more meaningful measure of a material's electro-optic sensitivity is given by $n^3 r$; however, the justification of this figure of merit is beyond the scope of this discussion (Yariv, 1975).

As grown, electro-optic materials, such as lithium niobate, have an average electro-optic coefficient of zero, since all of the molecular dipole moments are randomly oriented. To align all of these dipole moments requires a process called poling: the material is heated above its Curie temperature, an electric field is applied, and then with the field still on, the material is cooled below its Curie temperature, thereby freezing the alignment of all the dipole moments. For wavelengths longer than about $1 \mu\text{m}$, lithium niobate is quite stable over time and with optical power. For shorter wavelengths, some of the light is absorbed, which causes undesirable optical phase shifts. This later process is referred to as the *photorefractive effect*.

The most widely used method of forming low-loss waveguides in lithium niobate is by *diffusing in titanium* (Schmidt, 1974). Low-loss guides can also be formed by exchanging some of the lithium atoms with hydrogen, then annealing; this process is referred to as *annealed proton exchange* (Shah, 1975). The waveguide propagation losses are about the same for both processes.

Lithium niobate has probably succeeded not because it is the best with respect to sensitivity, loss, or stability, but because it has a reasonable combination of all three. However, lithium niobate is not without its drawbacks. Principal among them is the fact that it is not a semiconductor, and this makes integration with lasers, detectors, and electronics difficult at best. As was already mentioned, lithium niobate suffers from photorefractive effects at wavelengths less than about $1 \mu\text{m}$. It is also difficult to process; etching, for example, is virtually impossible. These limitations have led to the investigation of alternate materials. Within the inorganic family there are other materials such as strontium barium niobate, which have a substantially higher electro-optic coefficient. But the waveguide optical loss is high. Further, higher electro-optic coefficient materials typically have Curie temperatures nearer room temperature, which makes thermal stability more of a problem.

Semiconductors are another class of materials that can exhibit the desired electro-optic effect. Although the electro-optic coefficient is lower in these materials, this deficiency can be partially offset by the higher

n and the tighter optical waveguide confinement, which permits a tighter overlap between the electrical and optical fields. The tighter confinement, however, means higher fiber-to-waveguide coupling losses and somewhat higher waveguide losses. However, in direct bandgap semiconductors there is another mechanism, *electroabsorption* (EA), which can produce modulation. To appreciate the basis for this modulation approach recall that the longest wavelength absorbed by a semiconductor corresponds to the bandgap energy of the semiconductor. In some semiconductor structures, the effective bandgap energy is a function of the applied electric field. Consequently, if the wavelength to be modulated is chosen such that the semiconductor is almost transparent at zero applied electric field, then this wavelength is increasingly attenuated as the electric field is increased. This effect is greatly enhanced by using quantum wells, and in such semiconductor devices the modulation response can exceed that of lithium niobate. In principal semiconductor-based modulators have the advantage that they can be integrated with other electronic devices. However, this advantage has been only partially realized in practice largely because the fabrication parameters such as doping and layer composition can be quite different for optical and electronic devices.

Polymers are the third category of electro-optic materials. Based on nonlinear organic molecules, polymer modulators offer the potential for significant increase in electro-optic sensitivity. The basis for this hope lies in the considerable design flexibility afforded by polymers. In the inorganics and the semiconductors, the electro-optic properties are directly tied to the crystal structure; pick a crystal and you take whatever electro-optic properties come along with that crystal. With polymers, there exists considerably greater flexibility in designing a polymer that has the desired combination of properties. The myriad polymer structures combined with a plethora of dopants or chromophores offer an incredible array of possibilities. The belief is that somewhere within this array lies the utopian combination of modulator parameters.

Modulator Configurations

Early bulk modulators simply placed electrodes on a block of lithium niobate. The resulting electric field alters the phase of an optical wave passing through the lithium niobate. This configuration results in a relatively weak coupling between the electrical and optical fields. The low sensitivity of these modulators limits their application to sensing high electric fields such as those around power lines. Orders of magnitude greater sensitivity is possible by confining the light to an optical waveguide (Alferness, 1982). Electrodes placed along the waveguide produce much tighter coupling between the electrical and optical fields than is possible with bulk modulators.

As was mentioned in the Introduction, the most common optical modulation format presently in use is intensity modulation. And *the most common modulator design for accomplishing intensity modulation is based on a Mach-Zehnder interferometer*. The layout of a Mach-Zehnder modulator (MZM) (Martin, 1975), is shown in Fig. 9.54(a). The waveguides all propagate a single optical mode. The incoming CW light from the laser is typically split equally and fed into two ideally equal length arms, whose outputs recombine to feed the modulator output waveguide. With zero voltage on the modulator electrodes, the light in the two arms arrives at the output combiner in phase, as shown in the top half of Fig. 9.54(b). Thus, this bias condition results in maximum transmission through the modulator. When a voltage is applied to the electrodes, the resulting electric field, which is perpendicular to the waveguide, alters the refractive index in the two arms. Since the electro-optic effect is field-direction dependent, applying the voltage to the center electrode causes the index in one arm to increase and to decrease in the other arm. The effect of these index changes is the introduction of a relative phase shift between the light in the two arms when they recombine. The out-of-phase light attempts to excite higher order modes in the output waveguide, as indicated in the bottom half of Fig. 9.54(b). But since this guide is also single mode, all of these higher order modes are attenuated after propagating a sufficient distance. Thus, as the electrode voltage increases, the intensity in the output waveguide is decreases. For a sufficiently high voltage, the light in the two arms is 180° out of phase. All of the light is now in higher-order modes and none is in the fundamental mode. Consequently, no light propagates in the output waveguide. Further increasing the electrode voltage begins to bring the light in the two arms closer in phase until eventually they are completely in phase again. Thus the MZM transfer function is periodic in voltage, as shown by the solid curve in Fig. 9.55.

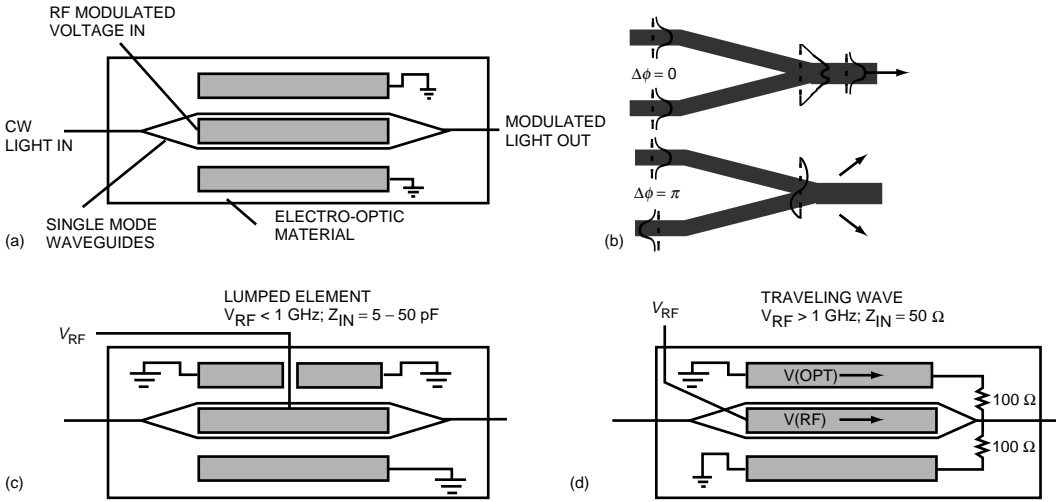

FIGURE 9.54 (a) General layout of an intensity modulator based on a Mach-Zehnder interferometer, (b) detail of output waveguides, (c) electrode configuration for lumped element modulators, (d) electrode configuration for traveling wave modulators.

A modulator similar to the MZM is based on a *directional coupler* (Papuchon, 1975). In a standard coupler, two waveguides are run parallel and close enough to each other that evanescent coupling can occur between them. The length of the coupling region is selected so that the desired degree of power is coupled from one guide to the other. To make a modulator from this passive coupler simply requires placing electrodes parallel to the waveguides, as shown in Fig. 9.56. The electric field from the electrodes alters the refractive index, which changes the coupling ratio, thereby altering the power between the two output guides. As can be seen from the dashed curve in Fig. 9.56, the directional coupler transfer function is not periodic and is more complex than the MZM. Directional couplers theoretically offer about the same modulation response, bandwidth, and linearity as MZMs, but they are much more difficult to fabricate, especially if long electrode lengths are required. The directional coupler is favored over the MZM when a compact 2×2 switch is desired.

FIGURE 9.55 Modulation voltage to optical power transfer function for a MZM (solid line) and directional coupler modulator (dashed line).

As was mentioned previously, semiconductors also offer the possibility of modulators based on the EA effect. The good news is that an *EA modulator* (Yu, 1995) has the potential for higher linearity, because it is not based on an interference of two phase modulated beams. The bad news is that there are several technical challenges to overcome. One is that the wavelength of the CW source must be matched to the absorption edge to within about 40 nm to get reasonable modulation sensitivity. Because the modulation depends on absorption, there is a tradeoff among insertion loss, drive voltage, and extinction. Another technical challenge in selecting the wavelength arises from the fact that the absorption change is a strong function of the wavelength separation between the material bandgap and the wavelength to be modulated. In turn this means that the modulation slope efficiency is temperature sensitive, since the material bandgap wavelength is temperature dependent. A third technical challenge is the maximum optical power handling capacity of EA modulators. Since in the off state ideally all of the incident optical power is absorbed by the

FIGURE 9.56 General layout of an intensity modulator based on a directional coupler.

EA modulator, scaling the performance of EA modulators to higher optical powers is not as straightforward as with interferometric modulators.

RF Impedance

For a low-frequency, Mach-Zehnder modulator, the impedance is dominated by the electrode capacitance and resistance as shown in Fig. 9.57. A Smith chart plot for a MZM is shown in Fig. 9.58. Unlike the laser diode, a modulator on lithium niobate has no junctions; consequently the impedance is independent of modulator bias. As was the case with the diode laser, it is often important to match the modulator impedance to the system impedance, typically 50 or 75 Ω real. However, unlike the diode laser, modulators fabricated in electro-optic materials that are also piezoelectric can have perturbations in their impedance due to coupling of some of the modulation signal into compressional waves. The coupling can be significant at frequencies where the modulator crystal is resonant. The dashed curve in Fig. 9.58 shows an acoustic resonance at 150 MHz. A number of techniques (Betts, Ray and Johnson, 1990) have been developed to suppress these acoustic modes to insignificant levels, as is evidenced by the solid curve in Fig. 9.56.

High-frequency modulators use traveling wave electrodes, for reasons described in the Frequency Response section. In this configuration the modulator impedance is ideally determined by the termination resistance at the end of the traveling wave electrodes. In practice the electrodes have loss that affects the impedance.

V_{π} or Switching Voltage

The voltage needed to change the modulator from on to off is an important figure of merit. In an MZM, this voltage introduces 180°, or π radians, of phase

FIGURE 9.57 Schematic diagram for a MZM with lumped element electrodes.

FIGURE 9.58 Smith chart plot of modulator impedance for lumped electrode MZM with (solid line) and without (dashed line) acoustic mode suppression.

shift; consequently it is referred to as V_π , as shown by the solid curve in Fig. 9.55. In a directional coupler modulator, which is often used for switching, this voltage is referred to as the switching voltage V_s , as shown by the dashed curve in Fig. 9.55. Although these definitions seem simple enough, there are several issues that require care to make sure the appropriate V_π is used in each case. For example, if the modulator includes separate electrodes for bias and modulation, these electrodes are typically of different lengths. Thus, the V_π used for bias control design is different from the V_π for link gain calculations. At DC, the voltage applied at the input connector is the voltage that appears across the modulator electrodes. However, as the frequency increases, the packaging and modulator impedance can result in a difference between these two voltages. Thus the DC V_π , in general, does not equal the RF V_π . Typical values of V_π for the modulating electrodes of commercially available lithium niobate modulators is 1–10 V, with the record low voltage of 0.3 V (Betts, 1989). The lower V_π correspond to lower frequency modulators. The commercially available GaAs MZM is a 20-GHz traveling wave device (see the next section for details about traveling wave modulators) with a V_π of 5.2 V (Walker, 1991), whereas a similar lithium niobate MZM would have a V_π of 3.7 V (Noguchi, 1993). MZMs in polymers with similar frequency response have V_π in the range 5–11 V (Wang, 1995). In analog links, the link gain depends on the inverse square of V_π or V_s , so even small decreases in this voltage can have a significant impact on link performance.

Frequency Response

The maximum frequency of the electro-optic effect in lithium niobate is probably in the hundreds of gigahertz. Thus, in practice the upper limit on the frequency response is set by electrical considerations. The key parameter that divides modulators into one of two types is the ratio of the modulation period of the maximum modulation frequency to the optical transit time past the electrodes. If the optical transit time is short relative to the period of the maximum modulation frequency, then the modulator signal will essentially be constant during the optical transit time. In this case the electrodes can be treated as lumped elements, see Fig. 9.54(c), which means that the upper 3-dB frequency is simply determined by the RC rolloff due to the electrode capacitance and resistance as shown in Fig. 9.57. A typical frequency response of a low-frequency MZM is shown in Fig. 9.59(a).

At high frequencies where the period of the maximum modulation frequency is less than the optical transit time, lumped element electrodes would be ineffective because the modulation voltage would change during an optical transit time. The traditional method to achieve efficient modulation in this case is to make the electrode into a transmission line so that the electrical power copropagates with the optical power. Although this so-called velocity matched condition is easy to understand, it turns out to be difficult to implement. The reason for the difficulty is that in a straightforward design, the optical propagation velocity is about twice as fast as the microwave propagation velocity, which in turn is due to the much higher dielectric constant of lithium niobate at microwave frequencies (~100 GHz) as compared to the

FIGURE 9.59 Frequency response of: (a) a lumped element modulator (Becker, 1984), (b) a velocity matched external modulator in lithium niobate (Noguchi, 1994).

dielectric constant at optical frequencies (~ 300 THz). Initial attempts at velocity matching were achieved by altering the electrode design (Alferness, 1984), but at a penalty of an increased V_π due to the smaller electrical-to-optical overlap.

Several groups (Noguchi, 1994; Gopalakrishnan, 1992; Dolfi, 1992) have demonstrated velocity matched modulators without significantly increased V_π . The frequency response shown in Fig. 9.59(b) has a V_π of 5 V and an upper 3-dB frequency of 75 GHz. It is important to note that bandwidth of modulator designs are commonly presented in terms of the frequency where the *optical* response is down by 3 dB. Since the electrical response of a link is the square of the optical response, the *electrical* response would be down 6 dB at the optical 3-dB bandwidth. The 3-dB electrical bandwidth is typically about half the optical bandwidth. Once a velocity match is achieved, it is theoretically possible to have an arbitrarily low V_π by simply making the electrodes longer. Unfortunately, the advantages of longer electrodes are limited in practice by the loss of the electrodes.

As the frequency goes up, it becomes increasingly difficult to couple the modulation signal to the electrodes. An elegant solution to this problem is to use radiative coupling in which the modulator electrode consists of dipole antennas. Coupling is accomplished when these dipoles are *illuminated* by the modulation signal from a waveguide. By segmenting the electrode and angling the modulator crystal with respect to the end of the waveguide, velocity matching can be achieved. Modulation at 94 GHz has been demonstrated using this technique (Bridges, 1990).

Optical Loss

There are three principal contributions to the optical loss. One is the loss of the straight waveguides. This loss is measured in decibels per centimeter and is typically 0.1–0.2 in lithium niobate, 0.5–1.0 in GaAs and 1 in polymers. The requirement for single-mode guides in most modulators constrains the tradeoff between optical loss and the magnitude of the refractive index step between the waveguide core and surrounding material. The larger the difference is in indices, the smaller the guide and the larger the waveguide loss, primarily due to Rayleigh scattering. In lithium niobate the waveguides are formed by doping, either titanium or protons, so that the index and hence the waveguide dimensions are essentially continuously adjustable. In semiconductor guides, the index delta is set by growing different materials such as gallium arsenide and aluminium gallium arsenide. Consequently, the index step is essentially set by the materials.

The need for low-loss straight waveguide drives modulator designers to use small index differences. Consequently, the light is weakly confined in the integrated waveguides and, therefore, only small bends (on the order of 1° in lithium niobate) can be made in straight waveguides without incurring substantial loss. However, even with small bends and careful fabrication, waveguide bends and branches are still a significant source of loss.

To be useful in systems virtually all modulators need to be coupled to optical fibers. The usual result of the waveguide loss-delta refractive index tradeoff discussed previously is that the waveguide optical mode field is smaller than the fiber's mode field diameter. Consequently, the fiber coupling loss is also a significant contributor to the total optical loss. The lowest fiber coupling losses have been achieved using confined core single-mode fibers attached to lithium niobate. In GaAs the index delta is larger, consequently, the waveguide is smaller and the fiber coupling loss is higher.

Adding all of these losses together results in fiber-to-fiber losses of commercial devices for the Mach-Zehnder configuration of 3–5 dB in lithium niobate and 10–12 dB in GaAs.

Linearity

Unlike the diode laser, the transfer function of many modulators is easily expressible in a simple analytical form. For example, the Mach-Zehnder transfer function is a simple raised cosine, $1 + \cos \phi$, as shown by the solid curve in Fig. 9.55. Consequently, the linearity is a predictable function of the chosen bias point. For example, operating a Mach-Zehnder at $V_\pi/2$ forces all of the even-order distortion terms to zero. Using this bias point in a broad-band application means that the IM-free DR is determined by the odd-order distortion, which is dominated by the third-order term. Recall that for narrow-band systems the second-order distortion terms fall outside the pass band and consequently can be filtered out. Thus, for such applications the bias point can be moved away from $V_\pi/2$ with no system consequence. One reason

FIGURE 9.60 Mach-Zehnder modulator IM-free DR with modulator biased at $V_{\pi}/2$.

for operating away from $V_{\pi}/2$ is to achieve a slightly lower noise figure (Farwell, 1993). For maximum IM-free DR in narrow-band applications, one would like to find a bias point where the third-order distortion is zero. In the Mach-Zehnder the only bias points where the third-order distortion is zero also force the fundamentals to zero, which means that these bias points are of limited interest. However, in the directional coupler modulator, bias points exist where either the second- or the third-order distortion is zero without the fundamental going to zero.

A typical plot of third-order IM-free DR for a Mach-Zehnder biased at $V_{\pi}/2$ is shown in Fig. 9.60. Although the data in this plot were taken at 60 MHz, they should be valid at any frequency. This is because for a modulator, unlike the diode laser, the shape of the electrical-to-optical transfer function is independent of RF frequency. This has been experimentally demonstrated up to 20 GHz (Betts, Cox and Ray, 1990). A directional coupler modulator, when biased where the second-order distortion is zero, has almost identical third-order IM-free DR.

Linearization

Although the IM-free DR for external modulators is high, it still may not be sufficient for some applications in CATV and antenna remoting. One way to increase the IM-free DR is to use any of the techniques described previously for the diode laser. However, because the transfer function of many modulators can be expressed analytically, this opens up an alternate class of all-optical linearization techniques. It is important to keep in mind a key distinction between these two classes of approaches. The *electronic* approaches generally target reducing the total distortion regardless of the order. Consequently, these approaches are most effective when the distortion has significant contributions at several orders. The *optical* approaches attempt to reduce a particular order of distortion, which makes these approaches most effective when the distortion is dominated by one order.

The optical approaches (Bridges, 1995) are based on connecting two or more modulators in series or parallel under the constraint that the transfer function of the combination is more linear under some bias condition than any of the individual transfer functions. The percentage bandwidth plays an important role in these all-optical linearization techniques; narrow-band applications, such as antenna remoting, require that the third-order distortion be reduced, but this can be done at the expense of *increasing* the second-order distortion. On the other hand wide-band applications, such as CATV, require that the third-order distortion must be reduced *without* increasing the second-order distortion. The upper limit on the IM-free DR improvement; regardless of the approach, is the *signal-to-noise dynamic range*, SNDR. This bound leaves substantial room for improvement; under typical operating conditions a standard Mach-Zehnder has an IM-free DR of 110 dB $\text{Hz}^{2/3}$ whereas the SNDR is 160 dB Hz.

Broad-band linearization of a Mach-Zehnder can be accomplished by connecting two Mach-Zehnders in either series (Skeie, 1991) or parallel (Korotky, 1990), as shown in simplified block diagram form in

FIGURE 9.61 Three all-optical approaches to linearization of a Mach-Zehnder; broadband linearization can be accomplished via either: (a) parallel connection or, (b) series connection; (c) narrow-band linearization using a series connection.

Fig. 9.61. The bias control of either approach can be relatively complex, because the bias voltages for minimization of the second and third order are interdependent. For example, in the series approach, four bias voltages are required; one on each of the Mach-Zehnders and one on each of the directional couplers. However, IM-free DR improvements of 10–15 dB have been reported.

Recall that for a Mach-Zehnder there is no bias point where the thirds go to zero without the fundamentals also going to zero. Thus some form of linearization, for example, multiple modulators in the present discussion, is required for improved IM-free DR in narrow-band applications. However narrow-band linearization of a Mach-Zehnder is significantly simpler than broad-band linearization. Figure 9.61(c) shows a series connected Mach-Zehnder for narrow-band linearized performance (Betts, 1994). Although superficially similar to the broad-band modulator shown in Fig. 9.61(b), notice that the narrow-band configuration avoids the need for the two controllable directional couplers, thereby cutting in half the number of control voltages. Figure 9.62 is a plot of the IM-free DR for a narrow-band

FIGURE 9.62 IM-free DR of a narrow-band, series-linearized Mach-Zehnder with bias control error as a parameter. For reference the IM-free DR of a standard Mach-Zehnder is also shown. (Betts, 1994).

series linearized Mach-Zehnder modulator. Note that with perfect bias control, the third-order distortion is completely canceled leaving only the fifth-order distortion, as evidenced in the plot by the distortion terms lying on a line with a slope of five. Under these conditions the IM-free DR of a linearized modulator scales as $(BW)^{4/5}$ rather than the $(BW)^{2/3}$ as a standard Mach-Zehnder does. It can be seen from the plot that with perfect bias control, 30 dB of improvement over a standard Mach-Zehnder is possible. However, the plot also shows the effects of bias voltage errors. In addition to the reduction in IM-free DR improvement, it is also important to note that the intermodulation signals no longer follow a single slope. This complicates the scaling of the results to bandwidths other than the measurement bandwidth, since no single power law is valid. Perhaps the best way to handle these cases is to measure and always specify the IM-free DR in the intended application bandwidth.

It is also possible to linearize a directional coupler modulator. As was mentioned previously, a directional coupler has bias points where either the second- or the third-order distortion theoretically go to zero. Thus for narrow-band applications the proper choice of bias point produces *linearized* performance. This converts the linearization problem to a bias control problem: the higher the required IM-free DR, the tighter the bias control needs to be. Consequently, linearization as is being discussed here is only required on directional couplers for wide-band applications, where both the second- and the third-order distortion must be suppressed. One way to achieve wide-band IM-free DR improvement in these modulators would be to move the second- and third-order nulls so they occur at the same voltage. It turns out that this is possible by adding an extra pair of electrodes to the directional coupler (Farwell, 1991). Only a DC bias (no RF modulation) is applied to this auxiliary electrode. This bias is adjusted in conjunction with the bias on the main RF electrodes to achieve minimum distortion of the second- and third-order distortion. Although it is theoretically possible to achieve linearization with only one additional pair of electrodes, in practice the control algorithm is significantly simpler if a third electrode pair is added.

Lasers for External Modulation and Figures of Merit

Types of Lasers

The source for a standard external modulation link operates CW; thus, there are no modulation requirements on the laser. This removes the primary constraint, which in the direct modulation case limited the laser choice to semiconductor lasers. Conceptually, then, any type of laser could serve as the source for an external modulation link. Early external modulation links used semiconductor diode lasers, but more recently the majority of external modulation links have been fed by solid-state lasers.

It is important to keep in mind that unlike the electronics field, the laser field uses semiconductor and solid state to reference two distinctly different types of lasers. Semiconductor lasers are almost exclusively excited or pumped electrically by passing an electric current through a diode junction. Typical semiconductor laser materials include GaAs for lasers emitting around $0.8 \mu\text{m}$ and indium phosphide-based materials for lasers emitting either at 1.3 or $1.55 \mu\text{m}$. The exact emission wavelength can be set by choosing the composition of the active layer, for example, in GaAs lasers the wavelength can be changed from 0.87 to $0.64 \mu\text{m}$ by changing the concentration of aluminum from 0 to 40%. Solid-state lasers, the label for a class of lasers *not* including semiconductor lasers, are universally pumped optically. Common solid-state lasers used for fiber communication links include neodymium doped yttrium aluminum garnet, or Nd:YAG, which can be designed to emit at 1.06 or $1.3 \mu\text{m}$, and erbium lasers which emit around $1.55 \mu\text{m}$. Unlike their semiconductor counterparts, the emission wavelength of solid-state lasers is fixed by the energy levels in the host crystal. Consequently, in general the emission wavelength of solid state-lasers is much more strictly confined. The first solid-state lasers were pumped using gas discharge or flash lamps. This was relatively inefficient since only one of the flash lamp's myriad emission lines fell on the absorption wavelength of the solid state material. More recently semiconductor diode lasers have been designed that can emit all their energy at the solid-state absorption wavelength. Consequently, these diode-pumped solid-state lasers are more compact and more efficient (Koechner, 1995).

As was discussed in a previous section, external modulators are available that can handle almost 0.5 W of optical power, provided that this is at a wavelength where photorefractive effects are negligible. Further,

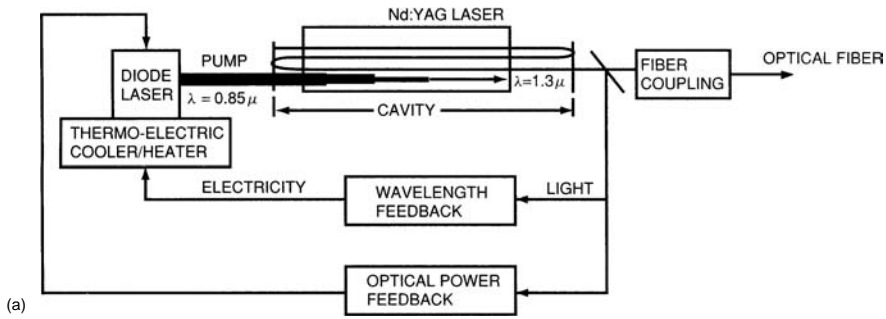

FIGURE 9.63 (a) Representative diagram, (b) photograph of a diode-pumped Nd:YAG laser.

the laser emission wavelength needs to be at one of the three common ones where single-mode optical fibers are available. A solid-state laser that meets both of these requirements is the Nd:YAG. Although the most common wavelength for these lasers is $1.06 \mu\text{m}$, this is not a common fiber wavelength nor is it long enough for photo-refractive effects in lithium niobate to be negligible. Thus for external modulation applications a secondary emission wavelength of Nd:YAG at $1.319/1.338 \mu\text{m}$ is used. The strength of this longer wavelength is about half of the line at $1.06 \mu\text{m}$, and so it is still possible to obtain sufficient optical power with reasonable efficiency.

A representative diagram of a diode-pumped solid-state laser is shown in Fig. 9.63(a). The solid-state laser cavity basically consists of the Nd:YAG rod and two mirrors. The mirror from which the desired output is taken is coated to transmit a portion of the $1.3\text{-}\mu\text{m}$ light and totally reflect the $0.8\text{-}\mu\text{m}$ pump light. The mirror at the other end of the cavity is coated to totally reflect the $1.3\text{-}\mu\text{m}$ light and antireflection coated to pass the $0.8\text{-}\mu\text{m}$ pump light. The nominal wavelength of the diode laser is chosen to correspond to the absorption wavelength of the Nd:YAG. To maintain laser operation, two feedback loops are generally

required. One feedback loop keeps the pump emission wavelength at the same wavelength as the Nd:YAG absorption peak. Since the emission wavelength of diode lasers is temperature dependent, one way to do this is by using a feedback loop to change the diode laser temperature. The other feedback loop maintains a constant 1.3- μm optical power, typically via a feedback loop which controls the pump laser current. Since the 1.3- μm optical power depends on both the pump wavelength and the pump power, care must be taken in designing these feedback loops to ensure the desired operation. Figure 9.63(b) is a photograph of a commercially available diode-pumped solid-state laser.

The required optical power is also available from diode lasers. However, there are several drawbacks that limit the applicability of diode lasers at present. One is the wavelength: historically high-power diode lasers have only been available around 0.8 μm , which is well within the spectral range for photorefractive damage in lithium niobate. Another is that these high-power diode lasers achieve the power by forming linear arrays of individual diode lasers. As a result, these arrays have very low coupling efficiency to optical fibers. A third reason has to do with the high relative intensity noise of most diode lasers, a point that will be discussed in more detail in the RIN section. Diode laser designers have begun to address these shortcomings. For example, there is a diode laser that couples into a fiber 50 mW of 1.3- μm light from a single laser cavity, that is, not an array (Chen, 1995).

Spectrum and Output Power

Unless special laser cavity design features are included, the laser's spectral output contains emissions at more than one wavelength. Each of these emission wavelengths or lines corresponds to a different longitudinal mode of the laser cavity. Since it is the total optical power that is important in an intensity modulated link, and since it would be considerably more difficult to obtain the high optical powers in a single laser mode, all CW lasers for general purpose external modulation links are multimode. Care must be taken to distinguish the multiple *cavity* modes of a laser in this discussion from the multiple *propagation* modes of a multi-mode fiber. Thus, it is entirely possible to send the multiple laser cavity modes down the single propagation mode of a fiber.

For fiber applications, a Nd:YAG laser can be designed to operate on one of two lines near 1.3 μm : 1.319 or 1.338 μm . At either of these wavelengths, the laser will have multiple longitudinal modes. In Nd:YAG the total optical power is not spread uniformly among all of the lasing modes, but concentrated in two modes. To increase the number of modes generally requires changing the host crystal; for example, yttrium lanthanum fluoride- (YLF-) based lasers typically have their power distributed among seven modes.

The total optical power from a Nd:YAG laser operating at 1.3 μm can exceed 0.75 W. Largely because of their excellent beam quality, the fiber coupling efficiency for YAGs is typically 80%. Thus, over 0.5 W of fiber-coupled 1.3- μm light is now commercially available. Single-mode YAG lasers produce about a factor of 10 less power.

Relative Intensity Noise

Figure 9.64(a) is a plot of the RIN for a Nd:YAG laser. In comparing these data with the diode laser RIN shown in Fig. 9.45, it is clear that the RIN spectrum of solid-state lasers has the same basic shape as that for diode lasers. The most significant difference is that the relaxation frequency occurs at a much lower frequency. Since direct electrical modulation of the laser intensity is only feasible for frequencies below the relaxation oscillation, it is clear from this figure why solid-state lasers are rarely used for direct modulation. The low relaxation resonance also means that the operating frequencies of virtually all links are at frequencies above the relaxation peak. The RIN decreases as the square of the ratio of the operating frequency to the relaxation frequency. With relaxation frequencies around 100 kHz and operating frequencies of at least 10 MHz, the RIN of solid state is negligible in most applications.

In addition to the relaxation peak, there are peaks in the RIN spectrum at frequencies that correspond to the difference in frequency between the longitudinal modes. The typical mode spacing of early diode-pumped solid-state lasers was about 4 GHz. This puts the first intermodal RIN peak outside the

FIGURE 9.64 (a) Typical RIN spectrum for a Nd:YAG laser, (b) RIN spectrum from (a) appearing as sidebands around a single 52-MHz CW carrier.

bandwidth of many applications, such as CATV distribution. However, for wide-band data communication or high-frequency antenna remoting, it is desirable to have wider longitudinal mode spacing. To meet these needs, lasers with intermodal spacing of up to 40 GHz have been developed. Of course, the needs of these applications can also be met with single-mode lasers, albeit at a sacrifice in optical power.

The process of external intensity modulation translates the solid-state laser RIN spectrum up to the modulation carrier frequency resulting in RIN spectrum sidebands about each carrier of the modulation signal. To see an example of this process, consider the case where the modulation signal was a single 52-MHz CW carrier. Figure 9.64(b) shows this carrier with the solid state laser RIN from Fig. 9.64(a) appearing as side-bands. For some applications, these sidebands, especially the relaxation peak, can limit system performance. Fortunately this peak occurs at a low enough frequency that it is possible to use feedback to suppress the peak. The remainder of the solid-state laser RIN below the relaxation peak is due to the diode pump laser. Since the laser responds to modulation at frequencies below the relaxation peak, the low-frequency RIN at the output of the solid-state laser is simply a pass through of the RIN from the diode pump laser. As was seen previously, the diode laser has RIN that extends up into the gigahertz, but this higher frequency RIN is effectively filtered out by the solid-state laser’s weak response to modulation above its relaxation frequency.

Implementation Issues

Maximum Optical Power (Cox, 1993)

As was previously mentioned, the RF performance of externally modulated links improves with increases in optical power. Thus, it is advantageous to operate such links at the maximum practical power. The highest optical power level in the link occurs in the fiber between the laser and the modulator. If the length of the fiber between these two components can be kept to less than a few hundred meters, then the maximum optical power will not be limited by stimulated Brillouin scattering in the optical fiber. The source end of a fiber CATV distribution network would fit this condition. In such cases the maximum optical power is limited by the modulator. In waveguide modulators, the power is probably ultimately limited by heating from the residual absorption of the guide and by nonlinear effects in the guide. In practice, the maximum power is limited by imperfections in the fiber attachment.

The power limit is wavelength and modulator configuration specific. The preceding results are all for MZMs operating at $1.3 \mu\text{m}$. Lithium niobate MZMs should be able to handle this same high power at longer wavelengths, although there does not appear to be experimental data to support this conjecture. At shorter wavelengths, that is, less than about $1 \mu\text{m}$, photorefractive effects limit the usable maximum optical power. The power level for the onset of photorefractive effects depends on the waveguide formation process and the material. Consider the following results at $0.85 \mu\text{m}$, a common diode laser wavelength. Titanium guides in lithium niobate show photorefractive damage at optical powers below 1 mW. However, as reported by Suchoski (1995), proton exchange guides in lithium niobate can support greater than 10 mW before the onset of photorefractive degradation, and proton exchange guides in lithium tantalate can support over 100 mW.

The optical power limits in other materials have not been as extensively studied. In GaAs, a MZM has been operated with 10 mW (Roussell, 1997), but the upper limit is unknown. It has been reported that more than 40 mW can propagate in an InGaAsP/InP waveguide (Yu, 1995). In this case also the upper limit is unknown. However, the upper limit for the EA modulator is expected to be lower than the MZM because when off, the EA modulator is absorbing all of the optical power, whereas the MZM disperses the optical power out of the guide and into the substrate when off.

Bias Control

To obtain the desired RF performance, primarily IM-free DR and noise figure, an external modulator needs to operate at a specific point along its transfer curve. A number of factors, among them temperature and photo-refractive effects, can shift the modulator operating point by at least the V_π voltage over time. Thus, to maintain a specific operating point typically requires some form of bias control circuit. There are lots of bias control techniques, and so the selection of the appropriate technique depends on application considerations and the particular bias point one is trying to maintain. A straightforward bias control approach to maintain bias points where either the second- or the third-order distortion is zero is to add a low frequency sine wave to the DC on the bias electrode. The sine wave perturbs or dithers the bias point, causing harmonics of the dither frequency to appear on the modulated optical signal. For ease of explanation, assume one desires to maintain a bias point where the second-order distortion is zero. The desired bias point is maintained by detecting the dither's second harmonic and using a feedback loop to adjust the modulator bias until the second harmonic is minimum. In an analogous manner the third harmonic can be used to maintain the bias point at a third harmonic null point.

Although a dither-based bias controller can maintain the bias point with a high degree of precision, the presence of a dither signal, however small, may be intolerable in some applications. There are several alternatives to a dither controller: however, perhaps the most elegant is to design and fabricate the modulator such that no controller is required. Such passively stabilized modulators have been demonstrated (Greenblatt, 1995). These approaches have reduced the bias drift by two orders of magnitude over an unstabilized modulator, which is sufficient for narrow-band applications using standard, that is, non linearized, modulators. To use passive bias in linearized applications or in broad-band applications will require another order of magnitude improvement in passive bias stability.

Polarization

In most electro-optic materials, the magnitude of the electro-optic coefficient depends on the polarization of the optical wave. For example, in lithium niobate the electro-optic coefficient is about three times larger for transverse electric (TE) light than it is for transverse magnetic (TM) light. Consequently, the V_π for TE light is about 3 times lower than for TM light. Since the link gain is proportional to $1/V_\pi^2$, variations in the polarization would cause up to a 10-dB change in link gain. Thus, in most applications it is essential that the polarization of the light at the modulator input be maintained over time. Since micro-bends in regular single-mode fiber cause random shifts in the state of polarization, it is generally unsuitable for use on modulator inputs. Therefore, virtually all modulator inputs have polarization maintaining (PM) single-mode fiber. Although this fiber is available from several manufacturers, at present it is at least a factor of 50 more expensive than regular single-mode fiber. PM fiber also requires special connectors and fiber fusing techniques. The costs and constraints of PM fiber have led to the investigation of alternatives.

Perhaps the most straightforward approach to eliminating the need for polarization would be to build a polarization independent modulator. For example, in lithium niobate, the next strongest electro-optic coefficient is r_{13} , which is about 1/3 as large as r_{33} . This coefficient can be used to build a polarization independent modulator since it applies to polarizations on both the x and y axes. Polarization independent modulators have been built, but their performance is substantially lower than the modulators that require polarized light (Spickermann, 1994).

Since it is almost never acceptable to trade RF performance for polarization independence, research has focused upon keeping the standard polarization sensitive modulators but eliminating the polarization maintaining fiber. One approach is to use a polarization controller at the modulator input to remove the changes in polarization that are introduced by standard single-mode fiber. By introducing controlled bends in a short piece of single-mode fiber placed just before the modulator, the polarization state can be restored to the required state. Most polarization controllers have a finite range and, consequently, must be reset periodically. Also packaging constraints at the modulator may preclude the use of such a controller.

Another approach to delivering polarized light to the modulator is the combination of a depolarized laser source, regular single-mode fiber and a polarizer at the modulator. The depolarized source (Burns, 1991) generates light of two orthogonal linear polarizations and launches these down a regular single-mode fiber. Microbends still alter the polarization states of each of these light waves, but on average the power in each linear polarization remains constant. At the modulator the desired linear polarization is extracted by passing the light through a polarizer. Alternatives for the polarizer include a length of *polarizing* fiber and proton exchange waveguides, which support only one polarization. Among the tradeoffs of the depolarized source approach is the loss of 3 dB of optical power as a result of the polarization process at the modulator.

Packaging and Fiber Attachment

These areas are a mixed bag relative to the corresponding areas with a diode laser. In several respects the tasks are easier with an external modulator. There is no junction, at least when the modulator is fabricated in either an inorganic or a polymer. Thus, there is no need to maintain a specific operating temperature, which eliminates the need for a TEC and thermistor. Also there is no feedback of optical power, which eliminates the rear facet photodiode commonly found in a diode laser package.

However, an external modulator is much larger than a diode laser and it has a relatively long aspect ratio: a typical modulator is a few millimeters wide and 60 mm long, whereas a typical diode laser chip is about 1 mm². To further complicate mounting a modulator, many of the inorganics including lithium niobate, have thermal expansion coefficients that are different for the three crystal directions. Despite these obstacles, several mounting techniques have been developed that permit the modulator to be used over 100°C temperature range and up to 15-Gs shock.

In virtually all cases the modulator has two fiber attachments, instead of the one the diode laser required. The fiber coupling loss in lithium niobate is low because the waveguide mode is reasonably closely matched to the fiber mode. However, active alignment is still required, which today is done manually. Automated fiber attachment equipment is in development to eliminate this labor intensive, and hence costly, step.

Figure 9.65 shows packaged MZMs from three commercial manufacturers.

Optical transmitters are rarely used as stand-alone components; more frequently they are used in conjunction with optical receivers as described in the next section to form a link for conveying an electrical

signal over an optical fiber. For a discussion on how optical transmitters and receivers can be connected together to form a link, see, for example, Cox (1990) and Seeds (1992).

9.4 Optical Receivers

Paul Kit-Lai Yu

9.4.1 Introduction: Terminology in Optical Detection and Material Considerations

Semiconductor materials are commonly employed for optical detection mainly because the semiconductor detectors are usually small, require a low bias voltage, and can be easily assembled with the rest of the receiver. In semiconductors, photons interact with electrons and are absorbed in processes whereby the electrons make a transition from a lower to a higher energy state. These electrons are detected in an external circuit. The absorption is dependent on the photon energy and each material has its characteristic absorption spectrum. The absorption spectrum can be sensitive to electric field and temperature variations.

The absorptivity α_0 , defined as the incremental decrease in optical intensity per unit length per unit incident power, is usually referred to as the *absorption coefficient* of the material. The photon energy $h\nu$ (where h is Planck's constant and ν is frequency) and wavelength λ are simply related by

$$\lambda = \frac{1.24}{h\nu} \quad (9.7)$$

where λ is measured in micrometer and $h\nu$ in electron volt.

The absorptivity α_0 describes the power decay of an optical beam as a function of its penetration into a given material. In general, a large α_0 is desirable in an optical detector for getting a high optical-to-electrical signal conversion efficiency. A small α_0 would require a large absorption region for sufficient absorption to take place. Too large an α_0 , however, can result in a small penetration depth, and many of the high-density electrons and holes generated can be lost via near-surface recombination and are not detected.

An important performance parameter of an optical detector at a given wavelength is the **external quantum efficiency** η . It is defined as the ratio of the number of electrons generated to the number of incident photons before any photogain occurs. Here η takes into account the surface reflection loss and other losses in the detector. In general, η depends on the absorptivity of the materials and the dimensions of the absorption region. The photogain M can result from carrier injection in semiconductor materials, as in the case of photoconductive devices (see Sec. 9.4.3), or from impact ionization, as in the case of avalanche photodiodes (see Sec. 9.4.2).

The **responsivity** R , in amperes per watt, of a detector is the ratio of the output electrical response to the input optical power and can be expressed as

$$R = M\eta \frac{q}{h\nu} \quad (9.8)$$

where q is the electronic charge. For many applications, the optical power reaching the photodetector is small, and the responsivity remains unchanged as the optical power is varied slightly. The relation between R (or η) and wavelength is usually referred to as the **spectral response** characteristics. For applications where a large optical power level is incident on the detector, the responsivity can drop as a result of the carrier screening effect, as in the case of photodiode. Nonlinear response can also be a consequence of detection saturation.

The response speed of a photodetector can be very important for many analog and digital applications. The characteristics 3-dB **cutoff frequency** $f_{3\text{dB}}$ is inversely proportional to the response time of the detector. The $f_{3\text{dB}}$ can also be greatly reduced when detection saturation sets in.

The response time τ depends on the transit time of electrons and holes in the detector, the carrier diffusion process, the carrier multiplication process in the semiconductor, as well as the circuit time constant. Usually, τ can be determined from the $f_{3\text{dB}}$ obtained from a frequency modulation response measurement with a modulated optical carrier generated by direct modulation, or by external modulation

of laser light, or simply by optical mixing of two laser sources whose emission wavelengths are temperature tuned. Alternatively, τ can be determined from the time-domain response of the detector when it is excited by optical pulses, such as those generated by mode-locked lasers, or those from a gain switched laser driven by a comb generator. Provided that the rise time and the fall time of the optical pulse are much shorter than those of the detector, τ can be estimated from both the rise time and fall time of the detector current pulse. For very high-speed detector (>40 GHz), a high-speed sampling oscilloscope is usually used to measure the total time-domain response, including the detector response time, the effect of the finite optical pulse width and the finite response time of the sampling circuit. The detector response can be de-embedded from the total time-domain response.

For detectors with photogain, an additional figure of merit, the *gain-bandwidth* (MB) product is defined. It is simply the product of the 3-dB bandwidth and the DC gain. In many cases, the MB product is closely related to device geometry and device parameters.

The quality of detected signals can be deteriorated by the presence of noise. The noise performance is a main concern in determining the overall system dynamic range for analog applications, and in determining the bit-error-rate for digital applications. Noise can arise from the transmitter, the electrical and optical amplifiers, and the receiver. For fiber-optic links, the common noise sources are the laser intensity noise; the Poisson (shot) noise due to the quantized nature of photons and the finite response time of the detector; dark current noise due to generation and recombination of carriers in the detection region; and thermal (Johnson) noise due to the resistance of the external load of the detector. For far-infrared focal plane array application, the background radiation constitutes an additional noise source. Three commonly used measurements of noise performance are the signal-to-noise (S/N) ratio, **noise equivalent power** (NEP), and **specific detectivity** (D^*) (Keyes, 1980). The S/N ratio is simply the ratio of detected electrical signal power to the noise power at the output of the detector (or receiver). The NEP of a detector is the optical power that must be incident on the detector so that S/N equals unity for a given wavelength, detector temperature, and resolution bandwidth. The specific detectivity is the inverse of the NEP normalized to the square root of the detector area A and the bandwidth B ,

$$D^* = \frac{\sqrt{AB}}{\text{NEP}} \quad (9.9)$$

(although the noise equivalent power is normally used to characterize the sensitivity of a photodiode, the specific detectivity is commonly used even when the incident flux is larger than the detector).

For an optical detector, materials with good crystallinity and with high purity are usually preferred so as to minimize trappings and recombinations of photogenerated carriers at defect sites. In cases where heterostructure is used, close matching of crystal lattice constants of different materials ensures good interface quality. This is usually a safeguard against premature failure of detectors, as *interfacial states* or *traps* can cause gradual degradation of the dark current characteristics. In addition, two material-related issues are commonly encountered in detector designs: namely, the doping profile in the detection region of the device and the nature of the metal-semiconductor contact. The doping level affects the effective depletion region width and can be designed to fine tune the carrier transport. For instance, a low doping level of the depletion region is often desirable for photodiodes for fast carrier sweepout at low bias voltage, as well as for small device capacitance. The properties of the metal-semiconductor contact can affect carrier injection (and, thus, gain), the response speed, and the saturation optical power levels (and, thus, linearity) of the detector, as the contact itself can be viewed as a potential barrier.

For valence-band-to-conduction-band (or, simply, band-to-band) transition of electrons that involves the absorption of a photon, which is called the *intrinsic absorption process*, the photon energy is larger than that of the bandgap for large α_0 (Pancove, 1971). There are many ways to detect photons with an energy less than the bandgap energy. For instance, for far-infrared detection, such as those in an extrinsically doped silicon impurity band photoconductor, the photoabsorption occurs as the electron makes a transition from an impurity level within the bandgap to the nearby band. Free-carrier absorption can take place when the electron makes a transition within the same band while a photon is being absorbed. However, free-carrier absorption becomes significant only in the presence of large electron (or hole)

density ($>10^{18} \text{ cm}^{-3}$). The absorption spectrum can change in the presence of an electric field. The Franz-Keldysh effect in bulk semiconductor and the quantum confined Stark effect in quantum wells exploits the electric field dependent shift of the absorption edge for below bandgap absorption (Pancove, 1971). These effects are currently used for various optical switches as well as for traveling-wave waveguide photodetector where a smaller α_0 can be counteracted with a longer interaction length (Kato et al., 1992). For semiconductors, the band-to-band absorption process, so far, results in the largest absorptivity simply due to the abundance in valance band and conduction band states available for optical transition.

Indirect bandgap semiconductors depend on a phonon or impurity assisted band-to-band transition process for absorption near the bandgap energy. This process has a smaller probability to occur when compared with transitions in the direct bandgap material, resulting in small absorptivity near band edge energy.

9.4.2 Photodiodes

Photodiodes typically have an absorption region where a strong electric field is applied so that the photo-generated carriers can be swept out to produce a current or voltage signal in an external circuit. Common types of photodiodes are *pn* junction photodiodes, *p*-intrinsic-*n* (PIN) photodiodes, Schottky junction photodiodes, and avalanche photodiodes (APDs).

A *pn* photodiode usually consists of a simple p^+n (or n^+p) junction. For surface normal detection, the optical signal is incident at the top (or the bottom) surface. For some devices, such as optical switches or waveguide photodiodes, the optical beam can be incident parallel to the junction (Kato et al., 1992). In normal operation, the diode is reverse biased to drift apart the photogenerated electrons and holes collected at the depletion region. The external circuit load detects a signal current as the photogenerated carriers traverse the depletion region. The induced current stops when the carriers reach the bulk material outside the depletion region. The phenomenon gives rise to the transit time limit of the response speed. For a given velocity distribution $v(x)$ of the carriers and the thickness of the depletion region W , the carrier transit time T_{tr} can be estimated from

$$T_{tr} = \int_0^W \frac{dx}{v(x)} \quad (9.10)$$

Typically, for III-V semiconductors, each micrometer of the depletion region corresponds to about 10 ps of transit time when carriers are drifted at saturated velocity ($\sim 10^7 \text{ cm/s}$).

The external quantum efficiency η of a top-illuminated photodiode with a thin *p* region is given by

$$\eta = (1 - R_0) \left[e^{-\alpha_0 W_1} (1 - e^{-\alpha_0 W}) + (e^{-W_0/L_n} - e^{-\alpha_0 W_1}) \left(\frac{\alpha_0}{\alpha_0 + 1/L_n} \right) + e^{-\alpha_0 (W_1 + W)} \left(\frac{\alpha_0}{\alpha_0 + 1/L_p} \right) \right] \quad (9.11)$$

where R_0 denotes the reflectivity at the air-semiconductor interface, W_1 is the *p* region thickness, and L_n and L_p are diffusion lengths of electrons in the *p* region and holes in the *n* region, respectively. The first term inside the square bracket of Eq. (9.11) accounts for the photogenerated carriers within the depletion region; the second and third terms account for those in the *p* and *n* regions, respectively. For III-V photodiodes of this configuration, provided that the depletion region is sufficiently thick and the absorption coefficient there is in excess of 1000 cm^{-1} , the absorption in the *n* region can be ignored. In the case of heterojunction PIN photodiodes, for instance, where the *p* region consists of materials transparent to the incident photons, W_1 can be set to zero and the second and third terms can be ignored. As can be seen from Eq. (9.11), η can be enhanced by reducing R_0 . One way to achieve this is by depositing an antireflection coating on the input facet of the photodiode. The quantum efficiency in some optimized heterojunction photodiodes can reach a value as high as 95% (Wake et al., 1987).

There is no internal photogain in photodiodes when carriers are swept out by a moderate strength electric field (10^3 – 10^4 V/cm). The responsivity of photodiodes can be obtained from Eq. (9.8) by setting M to unity. For instance, *pn* junction photodiodes made on silicon substrate with a resistivity less than

100 Ω-cm can have a depletion width of about 10 μm and a responsivity of ~ 0.4 A/W at 0.8–0.9-μm wavelength.

For homostructure *pn* junction photodiodes, it is difficult to optimize the quantum efficiency and the transit time at the same time due to the fact that the depletion region width depends on the applied electric field. This can be further complicated by the nonlinear relationship between the electron velocity and the electric field.

PIN Photodiodes

The PIN photodiode, consisting of a low-doped (either *i* or π) region sandwiched between *p* and *n* regions, can be a popular alternative to the simple *pn* photodiode. At a relatively low reverse bias, the intrinsic region becomes fully depleted, and the total depletion width, including those from the *p* and *n* regions, remains almost constant as the peak electric field at the depletion region is increased. A schematic diagram of a PIN photodiode with light incident from the left is shown in Fig. 9.66(a); its energy band diagram at reverse bias is depicted in Fig. 9.66(b). Typically, for a doping concentration of ~ 10¹⁴–10¹⁵ cm⁻³ in the intrinsic region, a bias voltage of 5–10 V is sufficient to deplete several micrometers, and the electron velocity also reaches the saturation value. As mentioned earlier, however, transit time is not the only factor affecting the response speed of the PIN photodiode. Carrier diffusion and the resistance-capacitance (RC) time constant can also be important. For *p* and *n* regions less than one diffusion length in thickness, the response time due to diffusion alone is typically 1 ns/μm in *p*-type silicon and about 100 ps/μm in *p*-type III–V materials. The corresponding value for *n*-type III–V materials is several nanoseconds per micrometer due to the lower mobility of holes. To minimize the diffusion effect, very thin *p* and *n* regions can be employed; alternatively, a *p* or *n* region transparent to the incident light can be used (Wake et al., 1987).

For the 1.0–1.55-μm wavelength range suitable for optical fiber communication, germanium and a few III–V compound semiconductor alloys stand out as candidate materials for PIN photodiodes, primarily because of their large absorption coefficients. The absorption edge of germanium is near 1.6 μm at room temperature. Its α_0 is almost flat and is in the 10⁴ cm⁻¹ range over the 1.0–1.55-μm wavelength region (Ando et al., 1978). In comparison, silicon’s absorption edge is near 1.1 μm. There are problems, however, in using germanium for making PIN photodiodes. Because of its small bandgap, the dark current arising from across the bandgap generation–recombination processes can degrade the signal-to-noise ratio.

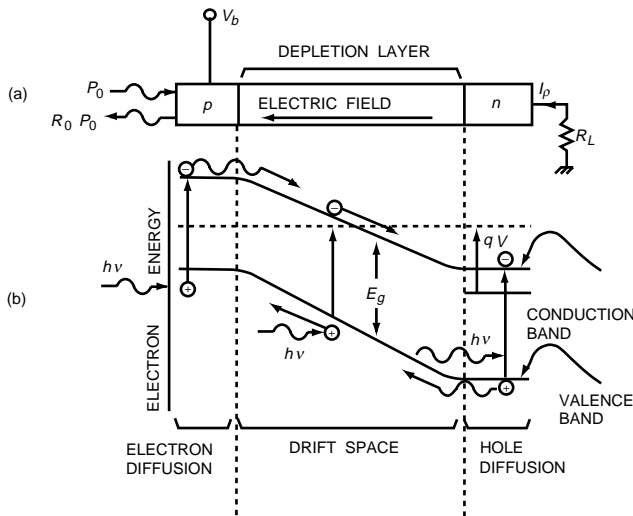

FIGURE 9.66 A PIN photodiode in operation: (a) structure: P_0 incident power, V_b bias voltage, R_0 reflectivity, I_p photocurrent, R_L load resistor, (b) energy band diagram at reverse bias, E_g bandgap energy.

This is further aggravated by the surface recombination. So far, no satisfactory surface passivation technique has been found for germanium PIN photodiodes, and the surface leakage current tends to be very high and unstable, especially at high ambient temperature.

III–V compound semiconductors have largely replaced germanium as materials for fiber-optical compatible detectors. By properly selecting the material composition of III–V materials, they can be lattice matched to each other. For heterostructure PIN photodiodes, one can choose a material composition at the intrinsic region with a bandgap smaller than those of the p and n regions, while at the same time with an absorption edge wavelength sufficiently above the photon wavelength. The materials of particular interest are the ternary alloys $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ and the quaternary $\text{In}_x\text{Ga}_{1-x}\text{As}_y\text{P}_{1-y}$ alloys lattice matched to InP. As is the case with germanium, unpassivated InGaAs surfaces also exhibit an unstable dark current. This problem, however, can be alleviated by passivating the surface with polyimide. PIN detectors of excellent performances in the 1–1.6- μm wavelength range have been demonstrated in the InGaAs/InP material system. To achieve a PIN photodiode with high yield and high reliability, planar fabrication process is often preferred; leakage current less than 25 pA has been achieved in some semiplanar photodiodes (Patillon et al., 1990).

For high-speed applications, both the junction area and the intrinsic layer thickness need to be small. An external resonant microcavity approach has been proposed to enhance η in such a situation (Dentai et al., 1987). In this approach the absorption region is placed inside a high Q cavity so that a large portion of the photons can be absorbed even with a small detection volume. An integral lens can be incorporated in the backside of the photodiode for focusing more photons to the detection region.

Two generic InGaAs/InP PIN photodiodes, top-illuminated and back-illuminated photodiodes, are commonly used. With liquid-phase epitaxy, a simple top-illuminated InGaAs/InP homojunction photodiode is usually made, due to the problem of *layer melt back* when the InP is grown on top of the InGaAs. With the advent of vapor-phase epitaxy employing high purity halide sources, and the metalorganic chemical vapor deposition using high purity hydride sources, one can readily make the InP–InGaAs–InP double heterostructure PIN photodiodes (Wake et al., 1987). Typically, a layer of $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ with an absorption edge at 1.65 μm is grown on top of the InP material. The residual doping level of InGaAs layer is usually in the 5×10^{14} – $5 \times 10^{15}\text{cm}^{-3}$ range. A mesa is subsequently etched to provide electrical isolation and to define the junction area. Surface passivation materials (such as polyimide) and antireflection coating layer are then deposited. Dark currents below subnanoamperes have been observed for 50- μm -diam devices. Speeds higher than 20 GHz have been achieved. Lifetimes of 10^8 h have been observed. The disadvantage of this simple structure is that the contact area needed for forming the bonding pad introduced additional capacitance and dark current to the photodiodes.

Back illumination is possible for material systems whose substrates are transparent to the optical beam. In this case, the active-layer thickness is selected such that at the operating bias, the electric field punches through to n^+ -InP material. In principle, a back-illuminated photodiode has the same basic features as the top-illuminated photodiode, although η can be reduced by the free-carrier absorption in the relatively thick substrate, as well as by the optics employed in light coupling. The main advantage of back illumination, as can be seen from Fig. 9.67, is that the front side is not needed for light coupling; therefore, for the same InGaAs optical detection area, the back-illuminated diodes have lower capacitance and lower dark current than those of the front-illuminated diodes. Optimal designs for broadband (>40 GHz) matching of PIN photodiodes can be obtained by considering the transit time, the geometric configuration including the diode area, and the transmission line characteristics together (Zhu et al., 1995).

FIGURE 9.67 Schematic diagram of an InGaAs/InP PIN photodiode with back illumination and side wall passivation.

Schottky Photodiodes

Schottky photodiodes can consist of an undoped semiconductor layer (usually n type) on bulk material and a metal layer deposited on top to form a Schottky barrier. An example is shown in Fig. 9.68. The metal is in the form of a very thin film ($\sim 100 \text{ \AA}$) so that it is semitransparent to the incident radiation. Because of the strong electric field developed near the metal-semiconductor interface, photogenerated holes and electrons are separated and collected at the metal contact and in the bulk semiconductor materials, respectively. By increasing the reverse bias to these diodes, both the peak electric field and the width of the depletion region inside the undoped layer can be increased and, thus, the responsivity can be increased. The complete absorption of optical signals within the high field region ensures high-speed performance, as absorption outside the high field region generates a diffusion current. Again, the undoped layer should not be too thick, as the photodiode response speed can then become transit time limited.

In comparison with PIN photodiodes, Schottky photodiodes are simpler in structure. Unfortunately, although good Schottky contacts are readily made on GaAs, for long wavelength InGaAsP/InP materials, stable Schottky barriers are difficult to achieve. One compromising approach to stabilize the barrier height is to employ a thin p^+ -InGaAs layer between the metal and the detection layer (n -InGaAs). Recently, by placing a Au-Schottky contact on n -In_{0.52}Al_{0.48}As, which is lattice matched to InP, a wide spectral response range (0.4–1.6 μm) Schottky photodiode with a responsivity of 0.34 A/W at 0.8 μm and 0.42 A/W at 1.3 μm has been demonstrated (Hwang, Li, and Kao, 1991). Low-temperature molecular beam epitaxial (MBE) GaAs with much As precipitates for effective buried Schottky barriers has also been investigated for 1.3- μm detection.

For comparison, GaAs Schottky photodiodes with a 3-dB bandwidth larger than 100 GHz and operating at less than 4-V reverse bias have been reported (Wang and Bloom, 1983). This high speed is attained by restricting the photosensitive area to a very small mesa ($5 \times 5 \mu\text{m}^2$) to minimize capacitance and by using a semitransparent platinum Schottky contact such that good responsivity ($\sim 0.1 \text{ A/W}$) can be achieved with topside illumination.

Avalanche Photodiodes

Avalanche photodiodes are based on the *impact ionization effect*. When free carriers generated by photoabsorption are accelerated by a strong electric field, they gain sufficient energy to excite more electrons from the valence band to the conduction band, thus giving rise to an internal current gain (Emmons, 1967). Avalanche photodiodes usually require a higher bias voltage than PIN photodiodes to maintain the high electric field. Also, the current gain is not a linear function of the applied voltage and is quite sensitive to temperature variations.

Figure 9.69(a) shows a schematic diagram of a classic silicon avalanche photodetector that consists of an n^+ contact, a p -multiplying region, a π -drift region, and a p^+ contact. The corresponding electric field profile is depicted in Fig. 9.69(b). In operation, under the large reverse-bias voltage, the depletion region extends from the n^+ to the p^+ contact, with avalanche multiplication occurring in the high field region. When an electron-hole pair is photogenerated, electrons are injected into the multiplying region provided that the light is mostly absorbed to the right of the multiplication region shown in Fig. 9.69(b). Similarly, hole injection occurs for light absorbed to the left. Mixed injection of both carriers occurs for light absorbed inside the avalanche region. The doping profile and the position of the multiplication region need to be optimized for each material system to meet the receiver requirements. In general, it is important that carriers with a higher ionization coefficient are injected into the multiplying region in

FIGURE 9.68 Schematic diagram of a GaAs Schottky photodiode.

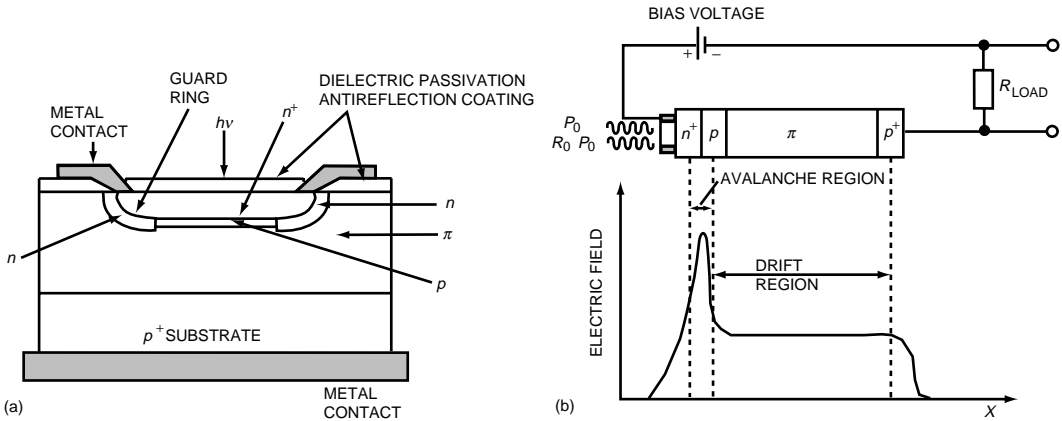

FIGURE 9.69 Schematic diagram of a silicon APD: (a) structure, (b) electric field distribution.

order to have the minimum excess noise due to the multiplication process. For instance, silicon APDs are generally designed so that electrons are the primary carriers that undergo multiplication since electrons in silicon have a larger ionization coefficient than holes. Consequently, both the hole injection or mixed injection are to be avoided. For low-noise silicon APDs, a long drift region is incorporated to ensure a large η and pure electron injection. The guard ring in the planar structures, shown in Fig. 9.69(a), prevents edge breakdown at the perimeter of the multiplying region. Reverse-bias voltage of up to 400 V is common for this kind of diode because of the large voltage drop across the long drift region.

The electric field required for impact ionization depends strongly on the bandgap of the material. The minimum energy needed for impact ionization, known as the *ionization threshold energy*, influences strongly the ionization rates (or coefficients) for electrons (α) and holes (β). These quantities are defined as the reciprocal of the average distance traveled by an electron or a hole, measured along the direction of the electric field, to create a secondary electron-hole pair. It should be noted that the threshold energy can be estimated by taking into account the conservation of carrier energy, crystal momentum, and group velocity during the ionization process. Avalanche multiplication is the manifestation of many consecutive occurrences of this process.

The multiplication is generally a three-body collision process and is, consequently, statistical in nature. As a result, it contributes a statistical noise component in excess of the shot noise already present in the diode. This excess noise has been studied for the case of arbitrary α/β ratios for both uniform and arbitrary electric field profiles (McIntyre, 1972). For the uniform electric field case, the excess noise factor for electrons F_n and holes F_p are given as

$$F_n = M_n \left[1 - (1 - k) \left(\frac{M_n - 1}{M_n} \right)^2 \right] \tag{9.12}$$

and

$$F_p = M_p \left[1 - \left(1 - \frac{1}{k} \right) \left(\frac{M_p - 1}{M_p} \right)^2 \right] \tag{9.13}$$

where $k = \beta/\alpha$ and M_n and M_p are the DC multiplication factors for pure electron and pure hole injection, respectively.

The DC multiplication factor M_n and M_p depend on α and β , as well as the width W_a of the avalanche region. For the case where $\beta = 0$, M_n can be expressed as

$$M_n = \frac{1}{1 - \int_0^{W_a} \alpha e^{-\alpha x} dx} \tag{9.14}$$

If an uniform field is assumed in the avalanche region, α becomes independent of position. M_n of Eq. (9.14) then increases exponentially with the number of ionizing carriers in the high field region, and no sharp breakdown will occur. Under these conditions, a current pulse is induced when the photogenerated electron starts to drift toward the multiplication region. The pulse increases in magnitude during the electron transit time through the high field region due to the electron impact ionization. It is reduced to zero once the last hole is swept outside the high field region. Neglecting the transit time inside the absorption region, the current pulse width is approximately the average of electron and hole transit times and decreases a little as the gain increases. The corresponding excess noise F (see Eq. (9.12) and Eq. (9.13)) is small because when M increases, statistical variation of the impact ionization process only causes a small fluctuation in the total number of carriers. Therefore, for low excess noise APDs, the ionization rate for one type of carrier should be much greater than that of the other, and the carrier with the larger ionization coefficient should initiate the multiplication process.

When both electron and hole ionize at the same rate (i.e., $\alpha = \beta$), APDs become quite noisy. In the case of a uniform electric field, the current gain can be expressed as

$$M_n = M_p = \frac{1}{1 - \alpha W_a} \tag{9.15}$$

which gives rise to a sharp breakdown ($M \rightarrow \infty$) situation as αW_a approaches unity. This corresponds to the situation when, on the average, each injected electron or hole produces one electron-hole pair during the transit through the high field region. The secondary electron and hole drift in opposite directions and gain energy in the avalanche region and generate further electron-hole pairs. This process persists for a long time when the gain is large. It is clear that for this situation with a large gain, there are fewer ionizing carriers in the high field region than the case when $\alpha \gg \beta$ (or $\beta \gg \alpha$). Thus, any statistical variation in the impact ionization process can produce a large fluctuation in the gain and cause considerable excess noise.

The gain can be a function of the signal frequency and can be approximated by

$$M(\omega) = \frac{M_0}{[1 + (\omega M_0 \tau_{\text{eff}})^2]^{1/2}} \tag{9.16}$$

where M_0 is the DC gain, ω is the angular frequency and τ_{eff} is approximately equal to $(\beta/\alpha)\tau_{\text{av}}$, where δ is a parameter ranging from $\frac{1}{3}$ (at $\beta = \alpha$) to 2 (at $\beta \ll \alpha$) and τ_{av} is the average transit time. Figure 9.70 depicts the theoretical gain-bandwidth product as a function of M_0 for various α/β values.

For analog fiber-optic link applications, the noise floor at the receiver end is an important parameter in determining the overall link performance. For APD-based receiver, the noise floor can consist of the laser relative intensity noise, the receiver thermal noise, and the APD noise associated with the photocurrent. The APD noise power can be expressed as

$$i_{n,\text{APD}}^2 = 2qB[I_d + q\eta P_0/h\nu]M^2F \tag{9.17}$$

where η is the quantum efficiency at unity gain, I_d is the dark current of the APD without multiplication, and F is the excess noise factor expressed in Eqs. (9.12) and (9.13). When the noise of the APD is dominant, further increase in M becomes less attractive for improving the link linear dynamic range performance.

Silicon APDs are used in the wavelength range of 0.4–1.0 μm because of the low dark current and a large α/β . The structure shown in Fig. 9.69(a) is employed in the case of silicon APDs to obtain carrier multiplication with very little excess noise. The high field n^+p junction serves as an electron-initiated

FIGURE 9.70 Normalized 3-dB bandwidth as a function of M_0 for several values of the ionization ratio k . For pure electron injection $k = \beta/\alpha$, for pure hole injection $k = \alpha/\beta$. Here, τ_{av} is the average of the electron and hole transit times in the avalanche region.

avalanche region and can be formed by diffusion or ion implantation. At bias below the breakdown of the n^+p junction, the π region is depleted. Beyond this point, the voltage drop across the wide π region increases with bias faster than that across the n^+p , thus increasing the operating bias range for multiplication. The full depletion of the π region is essential for high response speed, as electrons generated by the absorption within the π region can then drift to the n^+p region with high velocity. Holes, on the other hand, drift opposite to the electrons and, thus, a pure electron current is injected into the multiplication region. (Although there are some hole injections due to the absorption in the n^+ region and the avalanche region, they are much smaller in number than the electrons absorbed in the long drift region.) An excess noise factor of 4 at a gain of 100 has been achieved in such an APD. The response speed is limited mostly by the transit time across the π region. To increase the response speed without increasing the operating voltage, a built-in field in the π region can be profiled by grading the doping profile so as to enhance the carrier velocities. As for PIN photodiodes, an antireflective coating can be deposited at the back contact to increase η of a relatively narrow π region. Response times of 150–200 ps have been achieved.

For fiber-optic applications, germanium and III–V APDs have been used instead of silicon APDs because the spectral response of silicon cuts off near $1.1 \mu\text{m}$. As can be estimated from Fig. 9.71, β/α ratio for germanium has a maximum value of 2. A relatively high excess noise factor ($F \approx 1/2M$), in addition to a relatively high dark current noise, is present in germanium APDs due to the small bandgap and surface leakage. Usually, for germanium APD, the usable gain is only around 10. Beyond this point, the noise power increases as M^3 and the signal to power ratio quickly degrades. By reducing the detection area of the APDs, dark current in the nanoampere range can be achieved.

III–V APDs are attractive alternatives to germanium APDs because the material band gap can be tailored to achieve both high absorption and low dark current. Early APD work in the ternary InGaAs and quaternary InGaAsP system have shown rather low usable gain because the difference in α and β in these materials is not as high as that in silicon. For homojunction InGaAs devices, the dark current increases exponentially with reverse bias as the bias approaches avalanche breakdown. This is attributed to the tunneling current effect, which is more profound in materials with small bandgap. To reduce the

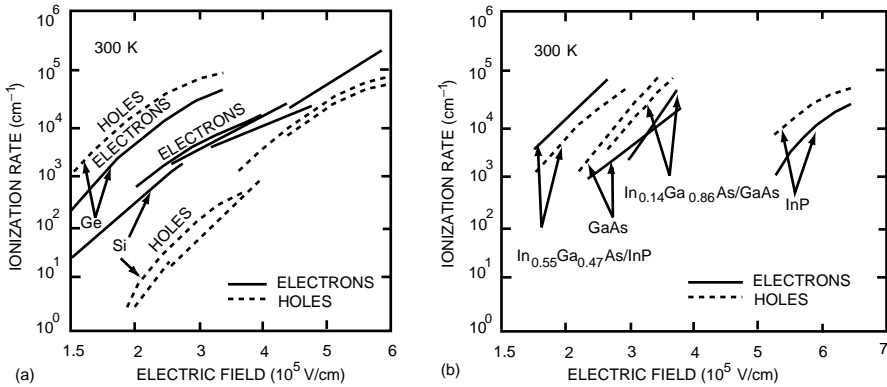

FIGURE 9.71 Experimental obtained ionization rates at 300 K: (a) silicon and germanium, (b) GaAs, InP, $\text{In}_{0.14}\text{Ga}_{0.86}\text{As}/\text{GaAs}$, $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}/\text{InP}$.

tunneling current, a heterostructure that separates the absorption region from the multiplication region was proposed and is depicted in Fig. 9.72 (Susa et al., 1981). This is known as the *separate absorption and multiplication* (SAM) APD. With this arrangement, the low bandgap InGaAs material does not experience a high electric field, and thus the tunneling effect is reduced. The absorption in this structure takes place in the low bandgap material, which, like the silicon APDs, is low doped. The multiplication takes place in the wide bandgap *pn* junction, which usually consists of InP. Consequently, the noise of the SAM APDs reflects much of the ionization process in InP. Reasonably small unmultiplied dark currents are observed for APDs with an InGaAsP absorption region (nanoampere range) and InGaAs absorption region (tens of nanoamperes), whereas the gain is maintained in the range of 10–60. As in the case of silicon APDs (doubly zinc-diffused) guard ring structure can be used in a planar structure (see Fig. 9.69(a)) to prevent the edge breakdown at high field.

Trapping of holes at the InGaAs/InP heterojunction has been observed, which greatly degrades the speed of the APD. To overcome this problem, an additional layer of quaternary InGaAsP with intermediate energy bandgap (or layers of graded bandgap region) is incorporated. A relatively low-noise (as compared with germanium) APD can be achieved with proper layer thickness and doping profile. For instance, at a gain of 10, APDs with an excess noise figure of 5, a dark current of 20 nA, and a bandwidth in excess of 1 GHz have been demonstrated.

FIGURE 9.72 InGaAsP/InP APD with separated absorption and multiplication regions. The intermediate InGaAsP layer is for reducing the hole-trapping effect. GR stands for *guard ring*.

Traveling-Wave and Waveguide Photodiodes

When designing a high-speed photodiode, one has to consider a number of tradeoffs. These tradeoffs can be related to the intrinsic layer thickness W , as η , carrier transit time, and the RC circuit time constant all depend on W . For conventional top- or back-illuminated photodiodes, on the one hand, W needs to be thin to reduce the transit time. By doing so, on the other hand, η and the RC time constant are compromised. To reduce the RC time effect, the detection area needs to be reduced, and this further reduces η , as illustrated in Fig. 9.73 (Bowers and Burrus, 1987).

Waveguide photodiode relieves somewhat the tradeoff between the speed and η . This type of detector is generally side illuminated with light guided parallel to the intrinsic layer and incrementally absorbed. The optical waveguide structure for the waveguide is similar to that of the double heterostructure lasers. As example of a waveguide photodiode for 1.3–1.5- μm detection is shown in Fig. 9.74, where the mesa structure is used to confine the light in the lateral direction. Side illumination and optical waveguiding increases the interaction length of the light with the absorbing intrinsic layer. Efficiency η is limited by the coupling efficiency at the fiber to the waveguide interface and the scattering loss along the waveguide. When compared to the area photodiode, the waveguide photodiode usually has a smaller η since the cross section of the waveguide is not closely matched with that of the single-mode fiber. Because of the side illumination, however, the same value of η can be maintained as the total junction area is varied; therefore the waveguide detector has an improved bandwidth-efficiency performance when compared to a conventional detector. Efficiency η as high as 68% has been achieved for a waveguide photodiode with $f_{3\text{ dB}}$ greater than 50 GHz (Kato et al., 1992). In contrast, as can be seen from Fig. 9.73, a conventional PIN photodiode with a η of 68% will be limited to a $f_{3\text{ dB}}$ of about 30 GHz.

The waveguide photodiode whose cross section is shown in Fig. 9.74 consists of a rib-loaded PIN waveguide section integrated with a microwave coplanar transmission line on a semi-insulating InP substrate. The rib is 5 μm wide at the top and 20 μm long, the intrinsic InGaAs layer is 0.35 μm thick. For waveguide and photodiode, the $f_{3\text{ dB}}$ is presently limited by the transit time across the intrinsic region and the RC time effect. Using a mushroom-mesa structure to reduce the RC time constant, a 110-GHz bandwidth waveguide photodiode with a η of 50% has been achieved.

A traveling-wave photodetector is a subset of the waveguide photodiode with the electrode designed to support traveling electrical waves so that the characteristic impedance is matched to that of the external

FIGURE 9.73 The $f_{3\text{ dB}}$ and η vs intrinsic layer thickness for PIN photodiode with surface normal illumination; r is the diode radius.

FIGURE 9.74 A cross-sectional view of an InGaAs/InP PIN waveguide photo-detector.

circuit (Giboney et al., 1995). The $f_{3\text{dB}}$ is limited by the transit time across the intrinsic region and the velocity mismatch. The RC time constant is no longer a consideration for speed in the case of traveling wave photodiode, and the device can be viewed as a terminated section of a transmission line with a position-dependent photocurrent source distributed along its length, instead of being a lumped circuit element. The velocity-mismatch bandwidth limitation depends on α_0 and the mismatch between optical group velocity and microwave phase velocity. Bandwidth as high as 172 GHz has been reported for a GaAs/AlGaAs traveling-wave photodiode detecting in the 800–900-nm wavelength range (Giboney et al., 1995). The intrinsic GaAs region is 1 μm wide, 0.17 μm thick, and 7 μm long.

As noted earlier, the waveguide configuration poses a limitation to η due to the fiber coupling. The coupling can be improved through the use of lensed fibers, antireflection coating at the waveguide facet, or laterally tapered waveguide section.

9.4.3 Photoconductors

Photoconductive devices depend on the change in the electrical conductivity of the material upon irradiation. Although photoconductive effects in semiconductor materials have been studied for a long time, only recently are they employed for high-sensitivity, high-speed detection. In semiconductors, two types of photoconductors, extrinsic and intrinsic, are commonly used. For the intrinsic case, photoconduction is produced by the band-to-band absorption. The α_0 can be very large ($\sim 10^4 \text{ cm}^{-1}$), in this case due to the large density of electronic states associated with the conduction and valence bands. For the extrinsic case, photons are absorbed at the impurity level and, consequently, free electrons are generated in the n -type semiconductor and free holes are generated in the p -type semiconductor. Extrinsic photoconduction is characterized by a lower sensitivity due to the smaller number of impurity states available for absorptive transition. These devices are usually operated at low temperatures (e.g., 77 K) to freeze out impurity carriers.

For the metal-semiconductor-metal (MSM) photoconductor shown in Fig. 9.75, a voltage is applied across the electrodes and light is illuminated from the top. The photosignal generates either a voltage change across a resistor in series with the photoconductor or a current change through the device. Frequently, the signal is detected as a change in voltage across a resistor matched to the dark resistance of the detector.

Performance Figure of Merit

The photoconductive gain M of photoconductors can be expressed as

$$M = \frac{\tau_n}{t_n} + \frac{\tau_p}{t_p} \tag{9.18}$$

where τ_n and τ_p are the lifetimes of the excess electrons and holes, respectively, and t_n and t_p are the corresponding transit times across the device. For cases where electron conduction is dominant and the response time of the device is τ , the gain-bandwidth product can be expressed as

$$MB = \frac{\tau_n}{t_n} \frac{1}{\tau} \tag{9.19}$$

FIGURE 9.75 A MSM photoconductor fabricated in a microstrip-line configuration on semi-insulating InP.

For material with little carrier trapping, the response time is determined by carrier lifetime. As device dimensions get smaller, however, the response time can be altered by the nature of the metal contact and the method of biasing. With nonalloyed contacts to the MSM device, Schottky barriers can be formed at the metal–semiconductor interfaces, and the depletion region extends across the length of the photoconductor. In this case, the device operates more or less like a photodiode with τ_n replaced by t_n , and its MB value becomes $1/\tau$ (see Eq. (9.19)).

When a steady optical beam with power P_0 is incident on the photoconductor, the optical generation rate of electron-hole pairs, as a function of the distance x into the sample, is given by

$$g(x)dx = \frac{(1 - R_0)P_0}{h\nu} \alpha_0 e^{-\alpha_0 x} dx \quad (9.20)$$

from which η can be obtained as

$$\eta = (1 - R_0)(1 - e^{-\alpha_0 D}) \quad (9.21)$$

where D is the effective sample thickness. The steady-state excess electron and hole concentrations, Δn and Δp (as calculated from η , τ , and the device geometry), can be incorporated in the change of conductivity $\Delta\sigma$ given by

$$\Delta\sigma = q(\Delta n\mu_n + \Delta p\mu_p) \quad (9.22)$$

where μ_n and μ_p are the electron and hole mobilities, respectively.

For many signal-processing applications, the ratio of the on-resistance to the off-resistance of the photoconductive device is an important parameter, although the off-resistance is primarily limited by the material resistivity in the dark. The on-resistance depends on the carrier mobility and the excess carriers generated.

Because of the low surface recombination velocity of InP-related materials, planar photoconductive devices on iron-doped semi-insulating InP have been extensively studied. This material has a room temperature resistivity of 10^5 – 10^8 Ω -cm and an electron mobility of 1500–4500 $\text{cm}^2/\text{V-s}$ depending on the crystal quality and iron concentration. The carrier lifetime ranges from less than 1 ps to 3 ns.

Array and Switch Applications

A typical photoconductor structure consists of either (1) a single narrow gap made on a metal stripe deposited on semi-insulating InP or (2) interdigitated MSM electrodes deposited on the substrate. Response times as short as 50 ps have been achieved in both devices. As noted earlier, the nature of metal contacts on semiconductors affects much of the device performance. For devices with nonalloyed Schottky contacts, a unity M is observed. However, the response time, especially the fall time, is shorter than that of devices with alloyed contacts. Alloyed contact devices show lower contact resistance and a higher photoconductive gain. Various contact materials (such as Au/Sn and Ni/Ge/Au), as well as alloying conditions (such as alloying temperature and duration), have been investigated. Compared to photodiodes, the planar photoconductor has advantages such as the ease of optoelectronic integration, especially with field effect transistor (FET) circuits.

A photoconductive device can function as a current switch. However, this requires a low on-resistance. For alloyed contact devices, the current-voltage characteristics are linear at low voltage, and the current tends to saturate at increased voltage. The current saturation is believed to be caused by electrons transferred from a high-mobility valley to a low-mobility valley, especially at the contact region where the electric field is relatively strong.

For 1.0–1.6- μm spectral range, InGaAs lattice matched to InP has been considered for photoconductive detectors. It is an attractive material due to its high saturation drift velocity. Compared to semi-insulating InP, however, semi-insulating InGaAs materials obtained so far tend to be less resistive ($\sim 10^5$ Ω -cm) with a typical dark resistance in the range of $\text{k}\Omega$, which compromises the device performance.

FIGURE 9.76 A diode-bridge type sample-and-hold circuit employing photoconductive switches.

Because of the fact that InP can be used to detect radiation ranges from near-IR to UV region with a good responsivity, it becomes very attractive for wide spectral response range detection. Together with its small surface recombination velocity, very fast detection (<90 -ps rise time) has been achieved at the X ray wavelengths where $\alpha_0 \sim 10^3 \text{ cm}^{-1}$. Recently, such devices have been considered for analog to digital (A/D) conversion where an analog electrical signal is time sampled and coded into a digital format. In this application, photoconductive devices operate as a time switch triggered by laser pulses and serve in the tracking of the analog signal voltage. When compared to electrical A/D, this can lead potentially to less time jitter as well as higher sampling rates. Up to 6-b resolution with a sampling rate greater than 1×10^9 samples per second has been predicted with the InP photoconductive switches.

For direct optoelectronic sample and hold, a photoconductor switch is placed between a signal source and a charging hold capacitor. Upon optical illumination, the switch is in the on-state. This scheme can be limited by the small hold capacitance required and by the time required to turn off the switch. To overcome the nonideal off-resistance of the photoconductive switches, it has been proposed and demonstrated that, by integrating the switches in a Wheatstone Bridge configuration, as shown in Fig. 9.76, when the laser pulses are fired accurately to steer the current for charging the hold capacitor, high-speed sample and hold can be achieved with high charging capacity and with low time jitter (Sun et al., 1991).

Another application of photoconductive device is in the generation of high-power, picosecond duration, electrical pulses. The photoconductor operates as a switching element that is connected via a low-impedance transmission line at the output side to a terminating load resistor. With the switch in the off-state, the input side of the line is charged to a high voltage. Upon laser excitation, the switch is turned on, and a high-power electrical pulse propagates down the transmission line. The on-impedance of the switching element needs to be much smaller than the line impedance so that a small fraction of the voltage (and, thus, power dissipation) drops across the switching element. The carrier lifetime determines the maximum time window when the switch is in the on-state. Silicon photoconductive switches have been used to generate gigawatt pulse power, and the duration of the electrical pulse is in the nanosecond range, depending on the length of the charging transmission line (Giorgi et al., 1988). Presently, III-V materials are inferior to silicon materials because of their relative shorter carrier lifetimes, which limit the duration of the electrical pulse. A photodiode switch has been investigated as an alternative to the photoconductive switch for such applications. Megawatt to gigawatt electrical pulses can potentially be generated (Giorgi et al., 1988). A detailed description of the switching mechanism is given in Sun et al. (1992).

9.4.4 Nonlinearity in Photodetectors

For many application such as analog fiber-optic links, both the link RF efficiency and spur-free dynamic range can be improved by using high optical intensity. Consequently, it is of interest to obtain high-speed photodetectors that can operate without saturation under a large optical intensity. Photodetector saturation causes nonlinear distortion (Hayes and Persechini, 1993). Possible causes of the saturation are absorption saturation, electric field screening due to the external circuit effect, and electric field screening due to the space charge in the intrinsic layer.

Absorption saturation occurs when there is a significant filling of the conduction and valence band states available for a given photon wavelength. For InGaAs materials, for instance, this corresponds to an electron concentration in excess of $2 \times 10^{17} \text{ cm}^{-3}$ and a hole concentration in excess of 10^{18} cm^{-3} . These concentrations are higher than carrier concentrations at which the space charge screening effect becomes important (Sun et al., 1992). The screening effect due to the external circuit primarily arises from the series resistance outside the junction region of the detector. For example, for a series resistance of $50 \text{ } \Omega$, a photocurrent of 10 mA gives rise to a voltage reduction of 0.5 V across the intrinsic region. This represents a small reduction when compared to typical bias ($>5 \text{ V}$) across the detector.

Both photoconductor and photodiode operate under a high electric field to sweep out the free carriers; however, at a high flux of photogenerated carriers, the applied electric field can be screened by the electric field due to the electron-hole pairs. The nonlinear response can arise from a redistribution of the intrinsic region electric field, which is accompanied by a spatially dependent hole and electron velocity distributions (Williams, 1994). Consequently, the harmonics signal levels increase at high optical intensities. In the extreme case, even the fundamental RF signal response is affected. In principle, this screening effect can be reduced by subjecting the photodiode to a large reverse bias. Figure 9.77 shows the effect of bias to the frequency response of a waveguide photodetector under a high optical flux. Figure 9.78 shows the fundamental and second harmonics signal at -10 V as a function of the photocurrent. Additional nonlinear effect observed at high bias situation has been attributed to absorption at the highly doped contact layer of the photodiode (Williams, 1994).

FIGURE 9.77 Waveguide photodiode frequency response with 10-mW optical power incident on the detector and at various detector bias voltages V_b .

FIGURE 9.78 The fundamental (5 GHz) and second harmonic signal of a waveguide photodiode as a function of photocurrent. The fundamental signal is the beat signal between two frequency-stabilized YAG lasers.

Defining Terms

Cutoff frequency ($f_{3\text{dB}}$): The frequency at which the photodetector output decreases by 3 dB from the output at DC (or some low-frequency value).

External quantum efficiency (η): Number of electrons generated per incident photon.

Noise equivalent power (NEP): The amount of light equivalent to the noise level of the device.

Responsivity (R): The ratio of the output current to the input optical power, amperes per watt.

Specific detectivity (D^*): Inverse of the noise equivalent power normalized to the square root of the detector area and the resolution bandwidth.

Spectral response: The relation the responsivity (or external quantum efficiency) and wavelength.

9.5 Optical System Design

David E. Rittenhouse

9.5.1 Introduction

Previously, optical fiber networks were designed to satisfy specific application(s) requirements, data, voice, or video. However, today the true benefits of optical fiber are being realized and used to design a structured cabling solution independent of specific applications—allowing for the effective use of fiber as a **universal transport system (UTS)**. With the establishment of standards for fiber type, performance, connectors, and components, the most significant design consideration now is connectivity, allowing the network to be flexible, manageable, and expandable. By complying with standards for the passive components, specifically, ANSI/TIA/EIA-568A (TIA, 1995), the designer maximizes the prospects for future applications compatibility as systems change or new ones are implemented.

System Planning: Structured Cabling

Structured cabling will support both the applications of today as well as the future. UTS and optical fiber does just that, allowing today's systems to grow gracefully as requirements change without concern of obsolescence.

Fiber is the most attractive medium for structured cabling because of its ability to support the widest range of applications, at the fastest speeds, for the longest distance. Additionally, fiber has a number of intrinsic advantages beneficial to any application at any speed. Fiber is immune to electromagnetic interference (EMI) and radio frequency interference (RFI). Therefore, its signals cannot be corrupted by external interference.

Just as it is immune to EMI from outside sources, fiber produces no electronic emissions and, therefore, is not a concern of the Federal Communications Commission (FCC) or European emissions regulations. Crosstalk does not occur in fiber systems, and there are no shared sheath issues as with multipair UTP cables. Because all-dielectric cables can be used, grounding concerns can be eliminated and lightning effects dramatically reduced. Optical fibers are virtually impossible to tap, making it the most secure media type. Most importantly, optical bandwidth cannot be adversely affected by installation conditions. Compare this to the dramatic effects that an installer can have with crosstalk in a copper system.

A structured cabling solution should be designed and planned for in three distinct segments.

- **Interbuilding backbone**
- **Intrabuilding backbone**
- **Horizontal distribution**

Interbuilding Backbone

In campus environments, whether that be a university, industrial park, or military base, optical fiber is used extensively and sometimes exclusively in the interbuilding backbone. Carrying a complete spectrum of services, it is used for voice, data, and video applications. A cabling network is established from either a single hub or multiple hubs **main cross connect (MC)** in the facility to the **intermediate cross connects (IC)** in each building. The use of outside plant cables containing a combination of both 62.5- μm and single-mode fibers is the most common.

Intrabuilding Backbone

The intrabuilding backbone connects the intermediate cross connect in the building with each **telecommunications closet (TC)** and **horizontal crossconnect (HC)** within that building. An optical fiber intrabuilding backbone has emerged as the medium of choice for intrabuilding data backbone transmissions because of its ability to support multiple, high-speed networks in a much smaller cable without crosstalk concerns. Additionally, more users are using fiber to support voice and private branch exchange (PBX) applications in the intrabuilding backbone by placing small, remote PBX shelves at the telecommunications closet, eliminating the need for copper in the intrabuilding backbone altogether.

Horizontal Cabling

Fiber for horizontal applications is a reality because of the recent advances in the technology easing installation, reducing the overall system cost, and offering a system that is reliable, flexible, certifiable, and future proofed. Fiber horizontal systems can be implemented for today's network requirements, such as ethernet and token ring, and can easily accommodate growth to higher speed networks such as FDDI, ATM, fiber channel, and beyond. There is no concern that crosstalk, EMI/RFI, and FCC issues will be uncovered when frequencies are increased.

Whereas FTTD provides excellent benefits for the traditional 90-m, single-user cable network, the benefits of optical fiber—high bandwidth, low attenuation, and system operating margin—allow greater flexibility in cabling design. For open-systems furniture applications, the use of the multiuser outlet can be implemented to ensure the long-term survivability of the **horizontal cabling** network in the rapidly changing office area. Many users desire centralized hubs and switches in the building vs. the use of decentralized hubs and switches in each telecommunication closet. The increased distance capabilities of fiber and lack of crosstalk allows the user to implement centralized electronics with **centralized cabling**. This allows for simple administration, efficient use of electronic ports, and easy implementation of various network applications throughout the building.

Patch Cords and Equipment Cables

Although not part of the cabling infrastructure, patch cords and equipment cables are an important link in the network. Patch cords and equipment cables are factory-terminated assemblies, typically two fiber, used to connect equipment at cross connects and outlets or as cross-connect jumpers to connect two separate cabling segments.

Universal Transport System

The design philosophy in a universal transport system, as described in the following sections, will help the designer/user to plan and implement a backbone and horizontal network. This network will be application independent and will avoid recabling expenses. The communication network planner can be assured of maximum cable plant flexibility as well as minimum installation and administration costs by following the UTS recommendations. Thus, whether installing a complete fiber optic infrastructure or a simple **point-to-point link** for a specific application, the UTS end user receives a cabling system of maximum utility.

9.5.2 Network Design and Installation

One of the most challenging series of decisions a telecommunications manager makes is the proper design of an optical fiber cabling plant. Optical fiber cable, which has extremely high bandwidth, is a powerful telecommunications media that supports voice, data, video, and telemetry/sensor applications. However, the effectiveness of the media is greatly diminished if proper connectivity, which allows for flexibility, manageability, and versatility of the cable plant, is not designed into the system.

The traditional practice of installing cables or cabling systems dedicated to each new application is all but obsolete. Instead, designers and users alike are learning that proper planning of a structured cabling system can save time and money. For example, a cable that is installed for point-to-point links should also meet specifications for later upgrades as it becomes part of a much larger network. As a result, duplications of cable, **connecting hardware**, and installation labor can be avoided by anticipating future applications and providing additional fibers for unforeseen applications, as well as interfacing with local service providers.

UTS recommends a structured cabling design philosophy that uses a physical hierarchical star topology. The hierarchical star offers the user a communications transport system that can be installed to efficiently support all logical topologies (*star, bus, point-to-point, ring*).

The guidelines presented here follow the general recommendations set forth by the TIA/EIA-568A cabling standard (TIA, 1995). This section will begin with an overview of the different logical topologies commonly used today. Following will be a discussion of the physical implementation of these logical topologies in the different premises environments (interbuilding backbones, intrabuilding backbones, and horizontal cabling).

A note regarding logical vs. physical topologies. The term logical topology refers to the method by which different nodes in a network communicate with one another. It involves protocols, access, and convention at the electronic circuit level. Physical topology simply refers to the physical arrangement of the cabling or cabling system by which nodes are attached (Fig. 9.79).

Logical Topology

To be universal for all possible applications, a structured cabling plan must support all logical topologies. These topologies define the electronic connection of the systems nodes. Fiber applications can support the following logical topologies:

- Point-to-point
- Star
- Ring
- Bus

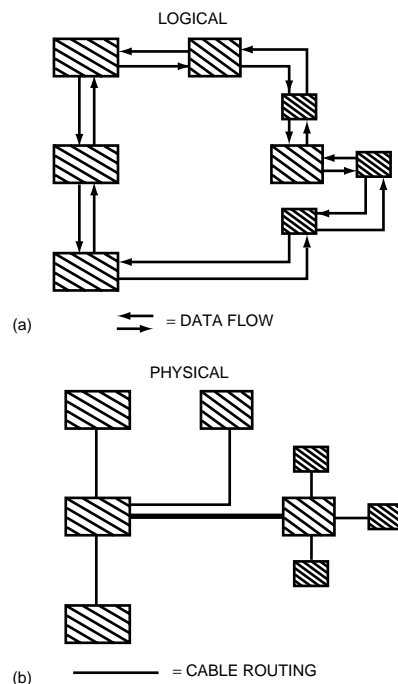

FIGURE 9.79 Networking topologies: (a) Logical, (b) Physical.

FIGURE 9.80 Logical point-to-point system.

Point-to-Point

Point-to-point logical topologies are still common in today’s customer premises installations. Two nodes requiring direct communication are directly linked by the fibers, normally a fiber pair: one to transmit, one to receive (Fig. 9.80). Common point-to-point applications include:

- Fiber channel
- Terminal multiplexing
- Satellite up/down links
- ESCON
- Telemetry/sensor

Star

An extension of the point-to-point topology is the logical star topology. This is a collection of point-to-point topology links, all of which have a common node that is in control of the communications system (Fig. 9.81). Common star applications include:

- A switch, such as a PBX, ATM, or data switch
- A security video system with a central monitoring station
- An interactive video conference system serving more than 2 locations

FIGURE 9.81 Logical star configuration.

FIGURE 9.82 Logical counter-rotating ring system.

Ring

The logical ring topology, common in the data communications area, is supported by two primary standards: (1) the token ring (IEEE 802.5) and (2) FDDI (ANSI X3T9). In this topology, each node is connected to its adjacent nodes in a ring (Fig. 9.82). Examples of ring topologies are:

- FDDI
- Token ring

Nodes are connected in single or dual (counter-rotating) rings. With counter-rotating rings (most common), two rings transmit in opposite directions. If one node fails, one ring automatically loops back on the other, allowing the remaining nodes to function normally. This requires two fiber pairs per node rather than the one pair used in a simple ring. FDDI networks typically utilize a counter-rotating ring topology for the backbone and a single ring for the horizontal.

Logical Bus

The logical bus topology is also utilized by data communications and is supported by the IEEE 802.3 standards. All nodes share a common line (Fig. 9.83). Transmission occurs in both directions on the

FIGURE 9.83 The logical bus topology.

common line rather than in one direction, as on a ring. When one node transmits, all of the other nodes receive the transmission at approximately the same time. The most popular systems requiring a bus topology are

- Ethernet
- Manufacturing automation protocol (MAP)
- Token bus

Physical Topologies, Logical Topology Implementation

All of the logical topologies noted earlier are easily implemented with a physical star cabling scheme, as recommended by the TIA/ EIA-568A cabling standard (TIA, 1995). Implementing logical point-to-point and star topologies on a physical star is straightforward.

Whereas the use of data networks that utilize bus or ring topology are predominant in the market, that is, ethernet, token ring, and FDDI, with the benefits of physical star cabling, electronic vendors and standards have developed solutions designed to interface with a star network. These applications are typically implemented with an intelligent hub or *concentrator*. This device in simple terms establishes the bus or ring in the backplane of the device and the connections are made from a central location(s). Therefore, from a physical connection these networks appear to be a star topology and are quite naturally best supported by a physical star cabling system.

Physical Stars Vs. Physical Rings

There are some situations where a physical ring topology would seem appropriate. But as can be seen in the following comparison of an optical fiber physical star topology to a physical ring topology, where advantages are indicated by a plus sign and disadvantages by a minus sign, a physical star topology is the best topology for supporting the varied requirements of a structured cabling system.

Physical Star

- + 1. It is flexible, supports all applications and topologies.
- + 2. It has acceptable connector loss with topology compatibility.
- + 3. Centralized fiber cross connects make administration and rearrangement easy.
- + 4. Existing outdoor ducts are often configured for the physical star, resulting in easy implementation.
- + 5. It easily facilitates the insertion of new buildings or stations into the network.
- + 6. It supported by TIA/EIA-568A cabling standard.
- 7. Cut cable will result in node failure unless redundant routing is used.
- 8. More fiber length is used than in a logical ring topology.

Physical Ring

- 1. It is less flexible.
- 2. It has unacceptable connector loss if star or bus logical topologies are required.
- 3. Connectors are located throughout system, making administration and rearrangement difficult.
- 4. Physical implementation can be difficult, often requiring new construction.
- 5. Insertion of new buildings or stations into a physical ring can cause disruptions to current applications or inefficient cable use.
- 6. Even with ring topology applications, the majority, if not all nodes, must be present and active.
- + 7. There is node survivability in event of cable cut if cable truly utilizes redundant paths.
- + 8. Less fiber lengths are used between nodes.

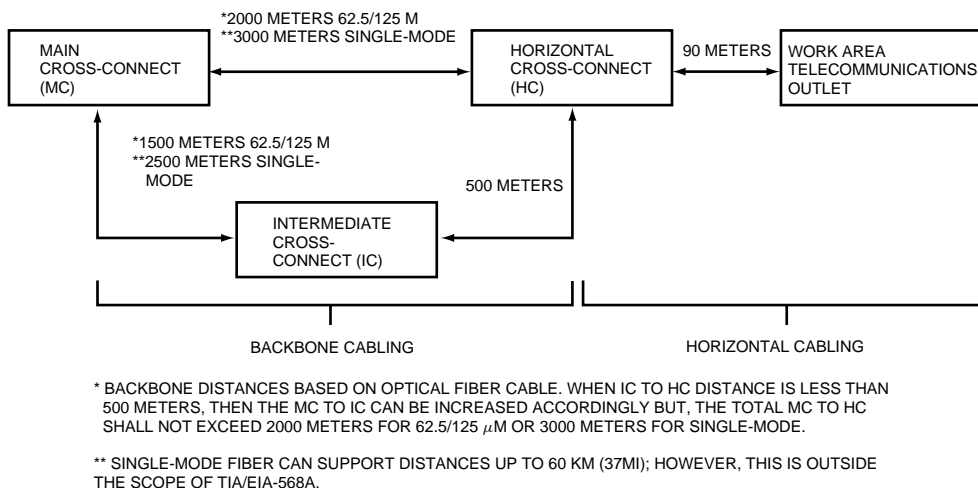

FIGURE 9.84 Commercial building telecommunications cabling standard (TIA/EIA-568A).

Redundancy and Zero Downtime

As protection against system downtime, many systems employ redundant electronic devices coupled to fibers in the same cable. The redundant system takes over immediately upon failure of the primary system. This protects against active device failure, although it does not help in the rare instance of a complete cable cut.

The ultimate protection against system downtime is achieved through redundant cable routing. Redundant fibers are placed in a second route to immediately take over in the event a cable is damaged. Redundant routing should be considered when zero downtime for the physical cable plant is required.

Physical Star Implementation

TIA/EIA-568A Cabling Standard

The more important recommendations of the TIA/ EIA-568A standard(TIA, 1995) as they relate to optical fiber and topologies are summarized as follows. The standard is based on a hierarchical star for the backbone and a single star for horizontal distribution (Fig. 9.84).

The rules for backbone cabling include a 2000-m for 62.5/125- μ m (3000-m for single mode) maximum distance between the main cross connect and the **horizontal cross connect (HC)**, and a maximum of one intermediate cross connect between any HC and MC. The MC is allowed to provide connectivity to any number of ICs or HCs and the ICs are allowed to provide connectivity to any number of HCs.

The standard does not distinguish between interbuilding (outside) or intrabuilding (inside) backbones since these are determined by the facility size and campus layout. In most applications, however, one can envision the MC to IC being an interbuilding backbone link and the IC to HC being an intrabuilding backbone link (Fig. 9.85). The exceptions to this would be large high-rise buildings in which the backbone may be entirely inside the building or a campus containing small buildings with only one HC per building, thereby eliminating the requirement for an IC.

The horizontal cabling is specified to be a single star linking the horizontal cross-connect closet to the work area telecommunications outlet with a distance limitation of 90 m (Fig. 9.86). This distance limitation is not based on fiber capabilities but rather, it is based on copper distance limitations to support data requirements.

568SC Polarity

The simplex SC connector and **adapter** are keyed to ensure the same orientation of the connector upon mating. Upon installation of the duplex yoke, to make two simplex SC connectors into a duplex 568SC, the keying establishes the orientation of one fiber to the other (polarity) because the 568SC connector can only

FIGURE 9.85 Backbone cabling system.

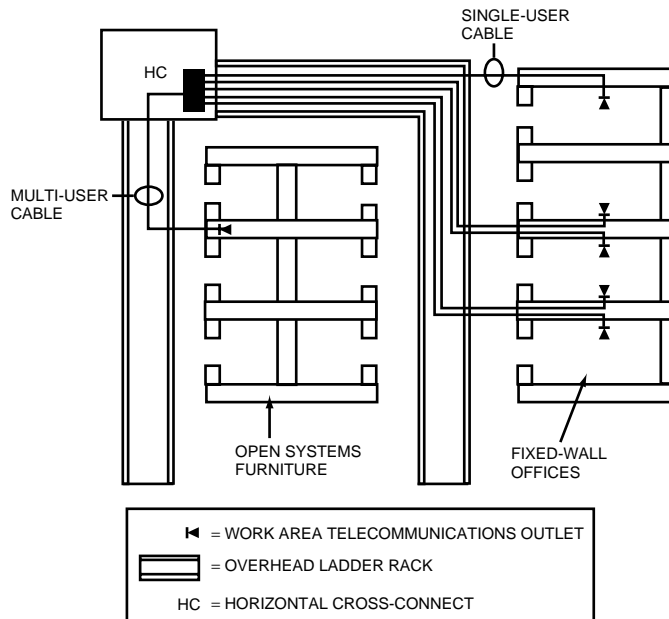

FIGURE 9.86 Horizontal cabling network.

FIGURE 9.87 568SC connection configuration.

insert into the receptacle in one direction. The two connectors are now labeled as *position A* and *position B* (Fig. 9.87). It is important to note, the 568SC connector does not ensure correct polarity by itself.

To achieve transmit-to-receive polarity in an optical network, an odd number of crossovers must occur. A duplex fiber circuit comprises two fibers and is installed to pair an odd numbered fiber with the next consecutive even numbered fiber (1 with 2, 3 with 4). To achieve transmitter-to-receiver connectivity, the odd numbered fiber, if connected to the **transmitter** on one end, must connect to the receiver on the other end. The specified 568SC adapter performs a crossover in and of itself, that is, position A to position B. Therefore, if all patch cords and the cabling plant are duplexed, there will always be an odd number of crossovers. An even number of crossovers is impossible. An even number of crossovers would cause a transmitter to transmitter connection.

Polarity is managed at the patch panel or outlet. Based on the orientation of the adapter in the panel, the connector can either be installed in an A-B orientation or a B-A orientation (Fig. 9.87).

It is recommended that adapters be installed in opposite orientations on each end of the link (Fig. 9.88). By installing the adapter in opposite orientations, the installer still connects the fiber to the patch panel or outlet in a normal manner, that is, counting from top to bottom, left to right. On one end, however, fiber 1 is in position A and on the other end, it is in position B and so forth for the other fibers. Additionally, TIA/EIA-568A recommends the proper orientation of each adapter in the network based on whether it is at the main, intermediate, or horizontal cross connect, or at the outlet (TIA, 1995) (Fig. 9.89).

Interbuilding Backbone

The interbuilding backbone cabling is the segment of the network that typically presents the designer and user with the most options, especially in large networks. The interbuilding backbone is also, typically, the most constrained by physical considerations such as duct availability, right of way, and physical barriers. For this reason, this section will present a number of options for consideration.

FIGURE 9.88 Crossover cabling with 568SC.

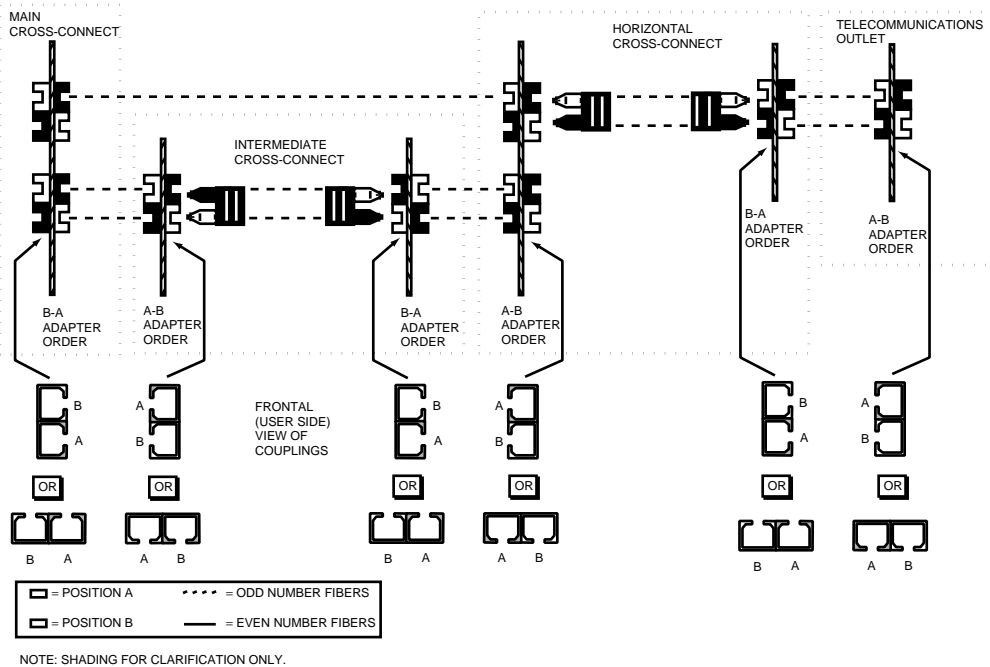

FIGURE 9.89 568SC adapter orientation in the network.

FIGURE 9.90 Interbuilding backbone (one-level hierarchy).

In smaller networks (both in number of buildings and geographical area), the best design involves linking all of the buildings requiring optical fibers to the MC. The cross connect in each building then becomes the IC linking the HC in each building to the MC (Fig. 9.90).

The location of the MC should be in close proximity to (if not collocated with) the predominant **equipment room**, that is, data center, or PBX. Ideally, the MC is centrally located among the buildings being served, has adequate space for the cross-connect hardware and equipment, and has suitable pathways linking it with the other buildings. This network design would be compliant with the TIA/EIA-568A standard (TIA, 1995). Some of the advantages of a single hierarchical star for the interbuilding backbone are listed:

- Provides a single point of control for system administration
- Allows testing and reconfiguration of the system's topology and applications from the MC
- Allows easy maintenance for security against unauthorized access
- Allows graceful change
- Allows for the easy addition of future interbuilding backbones

Larger interbuilding networks (both in number of buildings and geographical area) often found at universities, industrial parks, and military bases may require a two-level hierarchical star. This design provides an interbuilding backbone that does not link all of the buildings to the MC. Instead, it uses selected ICs to serve a number of buildings. The ICs are then linked to the MC. This option may be considered when the available pathways do not allow for all cables to be routed to an MC or when it is desirable to segment the network because of geographical or functional communication requirement groupings. In large networks, this often translates to a more effective use of electronics such as multiplexers,

FIGURE 9.91 Interbuilding backbone (two-level hierarchy).

routers, or switches to better utilize the bandwidth capabilities of the fiber or to segment the network (Fig. 9.91).

It is recommended that no more than five ICs be used, unless unusual circumstances exist. If the number of interbuilding ICs is kept to a minimum, then the user can experience the benefits of segmenting the network without significantly sacrificing control, flexibility, or manageability.

It is strongly recommended that when such a hierarchical star for the interbuilding backbone is used, it be implemented by a physical star in all segments. This ensures that flexibility, versatility, and manageability are maintained. However, there are two main conditions where the user may consider a physical ring for linking the interbuilding ICs and MC. These are (1) that the existing conduit supports it or (2) that the primary (almost sole) purpose of the network is FDDI or token ring. It is seldom recommended to connect the outlying buildings in a physical ring (Fig. 9.92). The ideal design for a conduit system that provides a physical ring routing would dedicate X number of fibers of the cable to a ring and Y number of fibers to a star by expressing (not terminating) fibers through the ICs directly back to the MC (Fig. 9.93). This allows the end user the best of both worlds, although the design requires a more exacting knowledge of present and future communication requirements.

Intrabuilding Backbone

The intrabuilding backbone design between the building cross connect (MC or IC) and the HC is usually straightforward, though various options sometimes exist. A single hierarchical star design is recommended between the building cross connect and the HCs (Fig. 9.94). The only possible exception occurs in an extremely large building, such as a high rise, where a two-level hierarchical star may be considered (Fig. 9.95). The same options and decision processes apply here. Sometimes, building pathways link HC to HC in

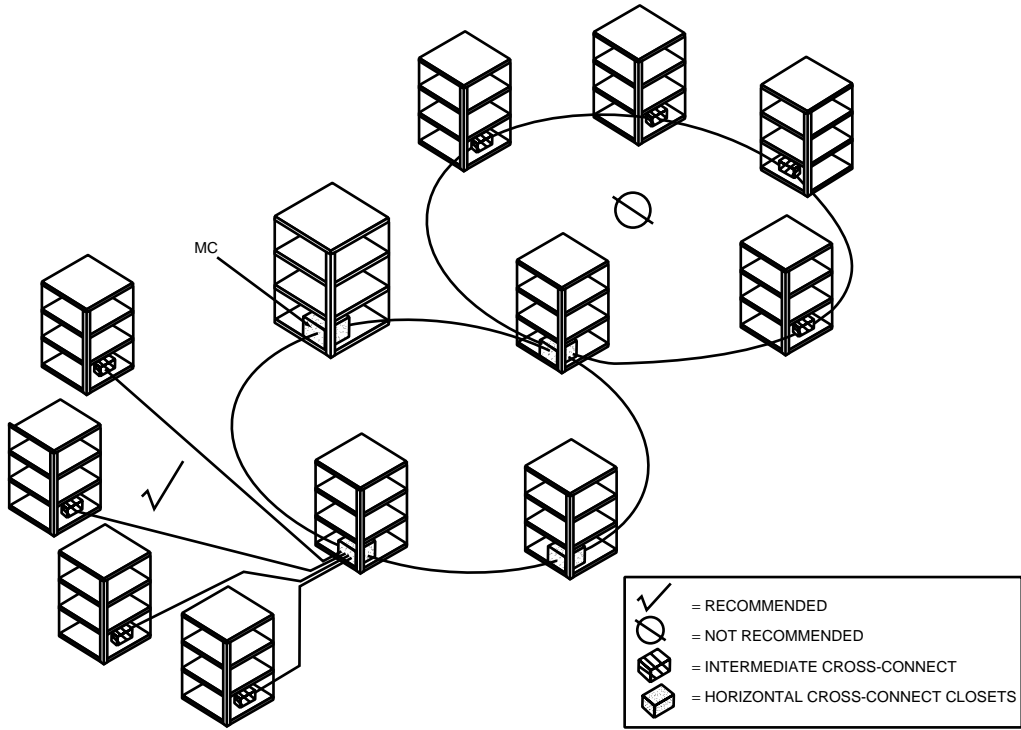

FIGURE 9.92 Interbuilding main backbone ring.

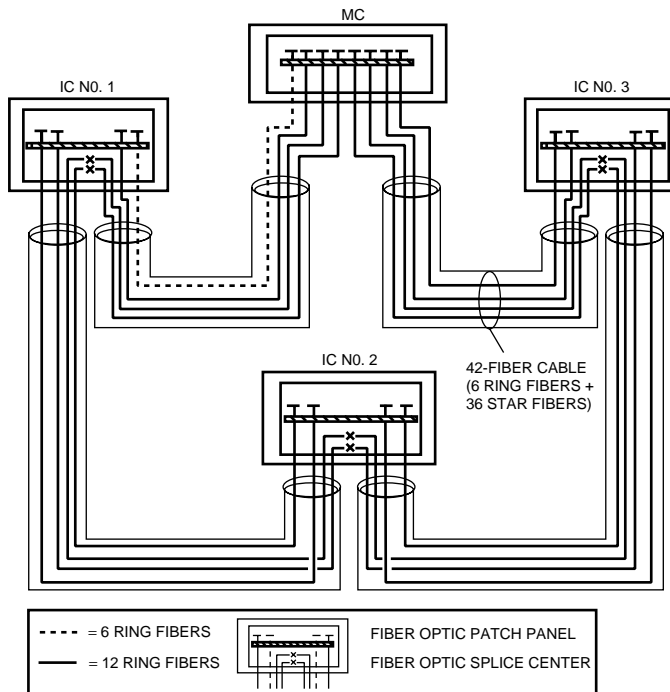

FIGURE 9.93 Main backbone ring and redundant backbone star combined.

addition to IC to HC, especially in buildings with multiple HCs per floor. Only in specific applications should a user design an HC-to-HC link. For example, this pathway might be of value in providing a redundant path between HC and IC, although direct connection between HCs should always be avoided (Fig. 9.96).

Horizontal Cabling

The benefits of fiber optics (high bandwidth, low attenuation, and system operating margin) allow greater flexibility in cabling design. Because of the distance limitations of copper and small operating margin, passing data over UTP requires compliance with stringent design rules. In addition to the traditional horizontal cabling network, optical fiber supports designs specifically addressing the use of open-systems furniture and/or centralized management.

The traditional network consists of an individual outlet for each user within 300 ft of the telecommunications closet. This network typically has data electronics equipment (hub, concentrator, or switch) located in each telecommunications closet within the building. Because electronics are located in each closet, this network is normally implemented with a small fiber-count backbone cable, 12- or 24-fiber count. This network uses a single cable per user in a physical star from the HC to the telecommunications outlet (Fig. 9.97).

For open-systems furniture applications employ a multiuser outlet network. The multiuser outlet calls for a high-fiber-count cable to be placed from the closet to an area in the open office where there is a fairly permanent structure, such as a wiring column or cabinet, in a grid type wiring scheme. At this structure, a multiuser outlet, capable of supporting 6–12 offices, is installed instead of individual outlets (Fig. 9.98). Fiber optic patch cords are then installed through the furniture raceways from the multiuser outlet to the office area. This allows the user to rearrange the furniture without disrupting or relocating the horizontal cabling. This type of network is supported in Annex G of TIA/EIA-568A, (TIA, 1995).

Centralized optical fiber cabling is intended as a cost-effective alternative to the optical horizontal cross connect when deploying 62.5 μm optical fiber cable in the horizontal in support of centralized electronics. Whereas category 5 UTP systems are limited to 100-m total length and require electronics in each closet for high-speed data systems,

FIGURE 9.94 Interbuilding backbone (one-level hierarchy).

FIGURE 9.95 Interbuilding backbone (two-level hierarchy).

fiber optic systems do not require the use of electronics in closets on each floor and, therefore, support a centralized cabling network. This greatly simplifies the management of fiber optic networks, providing for more efficient use of ports on electronic hubs, and allows for easy establishment of work group networks. Centralized cabling provides direct connections from the work areas to the centralized cross connect by allowing the use of pull-through cables, or a splice or interconnect in the telecommunications closet instead of a horizontal cross connect. Although each of these options has its benefits, splicing a low-fiber-count horizontal cable to a higher fiber count intrabuilding cable in the telecommunications closet is often the best choice (Fig. 9.99). This type of network is presently under study and being considered by the committee responsible for TIA/EIA-568A (TIA, 1995).

Equipment Room(s) and Network Interface Cabling

As discussed in the interbuilding backbone section, the MC is ideally colocated in the equipment room with the PBX, data center, security monitoring

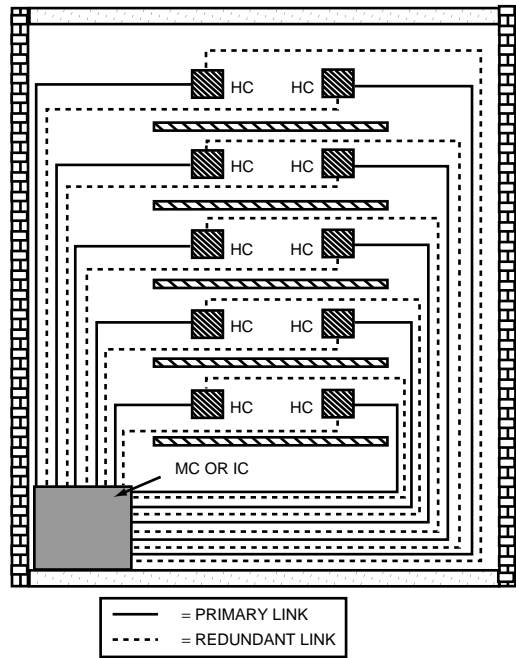

FIGURE 9.96 Intrabuilding backbone (redundant routing).

FIGURE 9.97 Traditional horizontal cabling system.

FIGURE 9.98 Multi-user outlet cabling.

equipment, or other active equipment being served. Although this is ideal, physical constraints sometimes make this impossible, such as when multiple equipment rooms are being served and are not centralized. The MC does not have to be colocated with any equipment room, and its location may be based entirely on geographic and physical constraints, that is, duct space and termination space. There should be only one primary MC. Connection to the equipment room(s) can then be provided either with fibers in separate sheaths or combined with the backbone fiber cables (Fig. 9.100).

For ultimate flexibility, manageability, and versatility of the fiber network all backbone cables and links to equipment room(s) should be terminated at the MC. Fibers can be cross connected to the required equipment room on an as-needed basis with the simple installation of a jumper. If there are link loss concerns, security concerns, or cost issues, selected fibers can be spliced through the MC to specific equipment rooms. Although this forfeits a degree of flexibility, as long as all of the cables come to the MC, the routing can be changed by altering the splice plan.

The same location considerations apply to the MC and network interface when contracted services are provided by a local common carrier, long distance company, or by-pass company. The designer/user should bear in mind that, when these services are provided via optical fibers, the fibers will almost certainly be single mode.

Multiple Sheaths and Splice Points

Multiple Cables

The physical design of the system should minimize splices whenever possible. The small size and long lengths of optical fiber cable allow, in most cases, the use of separate cable sheaths to serve each cross connect, closet, or outlet, providing conduit space allows. This avoids cable splices and results in fewer

FIGURE 9.99 Centralized optical fiber cabling.

different fiber count cables, allowing for an easier installation, and typically avoiding minimum-order requirement issues. In short, the small incremental cost of additional sheaths usually offsets the cost of splicing different fiber count cables together (Fig. 9.101).

Consolidation Splice

When constrained duct or conduit space precludes the use of multiple sheaths, a splice should be used to consolidate the sheaths into one higher fiber count sheath. Combine as many cables as possible at a single splice point, since the incremental cost per additional fiber splice is less than the cost for splicing at different locations. It is important to analyze the entire system when planning splice points. For example, if a planned cross connect is near a manhole that is being considered for a splice point, it might make more sense to route the cables to the cross connect, so that the splice point is combined with the termination point. This can result in substantial labor cost savings (Fig. 9.102).

Splice Points

Splice point locations should be chosen only after considering the requirements for performing optical fiber splicing:

- To effectively perform a splice, the cable ends must reach a satisfactory work surface (preferably a vehicle or table that is clean and stable). The distance can be as much as 30 ft.
- The chosen location should have provisions for storing the slack cable after splicing is completed.

FIGURE 9.100 Equipment room(s) and network interface cabling.

FIGURE 9.101 The use of multiple cables in wiring a facility.

FIGURE 9.102 Consolidation splice point.

- Physical protection of all slack is recommended, although not required.
- Splicing and racking slack should be considered when making cable length calculations. Optical fiber splice closures typically require 8–10 ft of stripped cable inside the closure.

Midspan Access

Special applications exist, such as the combination of a star and ring topology, where access to individual fibers is required without disturbing the remaining fibers. The designer should allow for cable slack, normally 30 ft to allow for easy midspan access. Ideally, the number of fibers being accessed corresponds to the number of fibers in the cable units, buffer tube, or unitized subunit, usually 6 or 12 fibers. Although this is not required, it provides an easier and cleaner installation.

Cable Slack for Repair

A small amount of slack cable (20–30 ft) can be useful in the event cable repair or relocation is needed. If a cable is cut, the slack can be shifted to the damaged point, necessitating only one splice point in the permanent repair, rather than two splices if an additional length of cable is added. This results in reduced labor and hardware costs and link loss budget savings.

Cable Slack for Relocation and Future Drops

Additional cable slack (about 30 ft) stored at planned future cable drop points results in savings in labor and materials when the drop is finally needed. Relocation of terminals or cable plant can also take place without splicing if sufficient cable slack is available.

Installation Considerations

Minimum Bend Radius

Optical fiber cable installation is as simple and, in many cases, much easier than installing coaxial or UTP cable in the horizontal network. The most important factor in optical fiber cable installations is maintaining

		MINIMUM BEND RADIUS ^a			
APPLICATION	FIBER COUNT	LOADED		UNLOADED

FIGURE 9.103 Typical bend radius specifications.

the **cable's minimum bend radius**. Bending the cable tighter than the minimum bend radius may result in increased attenuation and broken fibers. If the elements of the cable, that is, buffer tube or sheath, are not damaged, when the bend is relaxed, the attenuation should return to normal. Cable manufacturers specify a minimum bend radii for cables under tension and for long-term installation (Fig. 9.103).

Maximum Tensile Rating

The cable's maximum tensile rating must not be exceeded during installation. This value is specified by the cable manufacturer (Fig. 9.104). Tension on the cable should be monitored when a mechanical pulling device is used. Hand pulls do not require monitoring. Circuitous pulls can be accomplished through the use of backfeeding or center-pull techniques. For indoor installations, pull boxes can be used to allow cable access for backfeeding at every third 90° bend. No residual tension should remain on the cable after installation except that which is due to the cable's own weight in a vertical rise.

FIGURE 9.105 Typical vertical rise values.

Maximum Vertical Rise

All optical fiber cables have a maximum vertical rise that is a function of the cable’s weight and tensile strength (Fig. 9.105). This represents the maximum vertical distance the cable can be installed without intermediate support points. Some guidelines for vertical installations include:

- All vertical cable must be secured at the top of the run.
- The attachment point should be carefully chosen to comply with the cable’s minimum bend radius while holding the cable securely.
- Long vertical cables should be secured when the maximum rise has been reached.

The use of a split mesh grip is recommended to secure the cable (Fig. 9.106). The optical fiber cables weight should be borne by the split mesh grip. **Riser** cables should be secured with cable ties where the cable is exposed to prevent unintentional movement. However, the cable’s weight should be borne by the split mesh grip, not the cable ties.

Pathways and Spaces

The consideration and design of proper cable pathways (i.e., conduit, cable trays, riser shafts, etc.) and termination spaces (i.e., main/intermediate cross connects, horizontal cross connects, and work area telecommunication outlets) are as important as the design of the cable network. Fortunately, a TIA/EIA standard addresses this area (TIA/EIA). Another useful document is the *Telecommunications Distribution Methods Manual* from the Building Industry Consulting Service International (BICSI). Listed next are just a few items to consider when designing or working with existing pathways and spaces.

Cable Protection

If future cable pulls in the same duct or conduit are a possibility, the use of innerduct to sectionalize the available duct space is recommended. Without this sectionalization, additional cable pulls can entangle an operating cable and could cause an interruption in service. Care should be exercised to ensure the

FIGURE 9.106 Vertical Rise Split Grip.

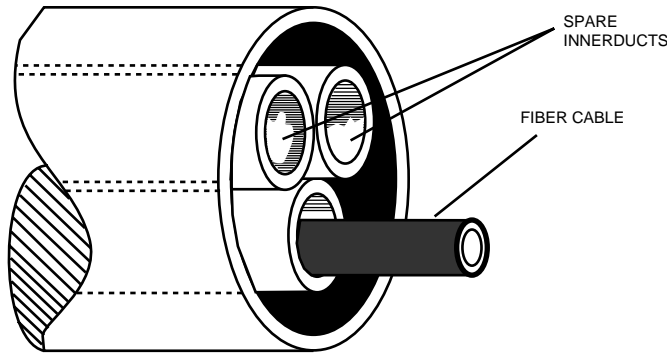

FIGURE 9.107 Proper duct utilization.

innerduct is installed as straight as possible, without twists that could increase the cable pulling tension (Fig. 9.107).

When the cable is installed in raceways, cable trays, or secured to other cables, consideration should be given to movement of the existing cables. Although optical fiber cable can be moved while in service without affecting fiber performance, it may warrant protection with conduit in places exposed to physical damage.

Duct Utilization

When pulling long lengths of cable through a duct or conduit, less than a 50% fill ratio by cross-sectional area is recommended (Fig. 9.108). For one cable, for example, this equates to a 0.71-in outside diameter cable in a 1-in inside diameter duct. Multiple cables can be pulled at once, as long as the tensile load is applied equally to all cables.

Fill ratios may dictate higher fiber counts in anticipation of future needs. One sheath can be more densely packed with fiber than multiple cable sheaths. In short, for customer premises applications, the cost of extra fibers is usually small when these extra fibers are not terminated until needed. For a difficult cable pull, extra fibers installed now but not terminated may be the most cost effective provision for the future.

FIGURE 9.108 Fill ratio guidelines.

Building and Fire Codes

Building and fire codes must be considered not only with intrabuilding telecommunications cabling but also most importantly when interbuilding telecommunications cabling enters the building. One of the most significant documents, while advisory in nature, is the **National Electrical Code (NEC)**. The interbuilding backbone cable is usually not flame retardant. The NEC allows these cables to enter and be routed inside a building for 50 ft without conduit. This should be considered when planning the location of the main/intermediate cross connect in a building. If the unlisted cable must run more than 50 ft, then the designer/installer has two choices:

- To plan a splice point at the building entrance to transition from nonrated outdoor to indoor rated cable designs. The added loss of the splice is small and usually not significant in the link loss budget
- To enclose the outdoor cable in a proper flame-retardant conduit

The use of all-dielectric cable is recommended whenever possible. However, if an optical fiber cable with metallic members must be used, such as steel armoring, follow the NEC and local codes to ensure that the metallic members are properly grounded for safety reasons.

Optical Fiber Termination Spaces

Adequate space and proper location is required for the optical fiber termination hardware throughout a building, from the main cross connect to the **work area telecommunications outlet**. Optical fiber hardware typically is designed for rack and/or wall applications. Not only must space requirements for patch panels be considered, but also space for jumper routing to electronics. Specific guidance is provided in the TIA/EIA-569 and the BICSI manual mentioned earlier.

Other Installation Considerations

Although the typical pathway for the interbuilding backbone is a conduit/duct raceway, sometimes the designer may consider aerial or direct cable placement.

Aerial Cable

Aerial cable is exposed to many external forces. Wind and ice loading can put stresses on cables, and temperature changes are more extreme than in any other installation environment. Furthermore, aerial cables can be damaged by vehicular accidents, rodents, lightning, and even gunshots. Some guidelines follow:

- Aerial pole spans of less than 300 ft can be routinely engineered when a dedicated messenger wire is used.
- In some cases, optical fiber cable can be overlashed to the existing aerial plant.
- Cable is available in self-supporting designs, not requiring the use of a messenger.
- The use of tight-buffered cables in an aerial installation is not recommended. The external factors, specifically ice and wind loading, can place the fibers in tight-buffered cables under constant stress. This can result in fiber failure or significant increases in attenuation over time.

Direct Buried Cable

Direct buried cable experiences fewer environmental extremes than aerial cable. This cable is usually laid into a trench or potentially plowed into the soil. Primary dangers to underground cable are dig ups and rodent damage. Rodent resistance of the cable is provided by a coated steel tape armor. Installation in a duct offers additional protection from rodents, as well as dig ups. Some guidelines follow:

- Cable should be buried as deep as possible, at least 30 in underground, if possible.
- The cable should be located below the frost line to prevent damage due to frost heave.
- When planning a direct buried cable route, locate and avoid existing utilities.
- Plastic duct with an outside diameter greater than 1.5 in will also provide rodent resistance where armor cannot be used.
- A means of locating the cable, especially all-dielectric cable, should be provided.
- The use of tight-buffered cables in direct installations is not recommended. These cables are typically not waterblocked and are susceptible to water penetration and ensuing forces.

9.5.3 Fiber Count

The selection of the fiber count, or number of fibers used in the cable plant, is an extremely important decision that impacts both the current and future capabilities and cost of a communications network. The development and widespread use of fiber in all aspects of the network requires the designer to plan not only for the immediate needs but also for the evolution of future system requirements. Many of the isolated business or campus fiber links installed today will be integrated into the universal communication networks of tomorrow. Because these fiber systems will provide service for a number of different applications later, the number of fibers designed into the network today must be carefully considered.

FIGURE 9.109 One-way (simplex) communications.

FIGURE 9.110 Two-way (duplex) communications.

The number of optical fibers required is dependent upon

- Intended end user application(s) requirements
- Level of electronics integration in the proposed network
- Future growth of the network
- Physical network topology

Application Requirements

Most of today’s fiber optic system applications fall into three categories:

- *Simplex*. One fiber for transmit and receive (Fig. 9.109).
- *Duplex*. Two fibers, one for transmit and one for receive (Fig. 9.110).
- *Redundant duplex*. Four fibers, two for transmit and two for receive using separate duplex routing (Fig. 9.111).

Most of today’s applications are duplex, utilizing two fibers to establish two-way communications—one fiber to transmit and the other fiber to receive. Note: It is possible to transmit and receive simultaneously using the same fiber. This is normally accomplished through the use of optical splitters inside the transceiver.

Video

Today’s video applications employ a one- or two-fiber solution installed in either a point-to-point or physical star topology. The number of fibers depends on the sophistication of the proposed video system. Security video, for example, is a one-way, transmit type of application. However, certain systems require interaction at the camera for movement or voice communication and, thereby, require two fibers.

FIGURE 9.111 Redundant duplex communications.

Interactive video, video conferencing, or educational video typically requires two fibers. Broadcast or community antenna television (CATV) video is rapidly changing from the traditional one-fiber, source broadcast to receiver station interaction and, thus, utilizes two fibers. As this last form of video communication services expands, existing and future video systems will require at least two fibers.

Telemetry/Sensors

Telemetry involves the transmission of sensor data such as fire alarms, emissions, access, etc., to a distant or central monitoring station. This application generally involves one-way transmission and requires only one fiber. Certain types of telemetry, however, may be interactive. Correction signals, based on received data or signals, may be sent to the transmit locations. These applications would employ two fibers, one for transmit and one for receive.

Voice

Voice applications, which are normally multichannel systems, generally employ four fibers (two working and two protection) from the main switch to a remote switch to meet transmission requirements. The most significant factors that determine the number of fibers required are:

- Number of voice channels required between switch locations.
- Level of multiplexing to be employed. The same four 62.5- μ m fibers that support a DS1/1.544 Mb/s (24 voice channels) network can be upgraded to support a DS3/ 44.736 Mb/s (672 voice channels) network or a DS3D/135 + Mb/s (2016 voice channels) network.

The determining factor is the cost of additional fibers vs. increased multiplexing equipment.

Data Communications

Today's data communications systems generally employ two fibers, however, four-fiber systems are also used. The determining factor in most situations will be the type of network application you are working with. Listed in Fig. 9.112 below are several current systems that most system designers are familiar with.

Electronic Integration

Electronics Versus Fiber Count

The diversity and depth of electronic integration in a system impacts the actual fiber count of the network. Simply put, you can use less fiber by increasing the electronics to collect or distribute the signals. In the same manner, you can reduce your dependence on electronics by adding fiber paths. The decision to be

^cSONET AND VIDEO ARE LISTED HERE DUE TO SYSTEM DESIGN REQUIREMENTS TO INCORPORATE THESE APPLICATIONS INTO EXISTING COMMUNICATION NETWORKS.

FIGURE 9.112 Network applications and fibers required.

made is to what level, if at all, bridges, routers, concentrators, or switches will be employed in the network. With the advent of FDDI and ATM, the designer/end user has an increased number of options. In the case of FDDI, this allows multiple networks such as ethernet and token ring to operate and includes voice channels. Add ATM, which accepts voice, data, or video over the same network, to this array and the designers options open up tremendously. The high bandwidth and distance capabilities of optical fiber allow the user the flexibility and ability to grow as requirements demand.

The decision to utilize electronics must be made by considering the cost of additional fibers vs. the cost of sophisticated electronics. It also involves the desirability of keeping networks separated vs. combined. Two networks are depicted in Fig. 9.113. The first network provides connectivity between locations by utilizing fibers. This has the added effect of isolating each **local area network (LAN)** in case of an electronics outage and, typically, providing the lowest electronics cost. The second network utilizes a router to reduce the fiber count. This concentrates all traffic into one system allowing for more efficient use of available fibers and easier management. Users often conclude that the most cost effective networks are those that require more fibers and less sophisticated electronics.

Future Growth

Single-Mode Fiber Planning

One decision that many system designers have been faced with is the inclusion of single mode fibers in the network. With the introduction of new high-speed networks, it has become more important to include single-mode into systems, especially the interbuilding backbone. TIA/ EIA-568A was modified to include single mode as a recognized media for backbone networks (TIA, 1995). A significant planning factor, which must be addressed, is that the design you install today will outlive all the electronics currently used. The standard fiber optic cable plant will have a typical useful lifetime of 20–30 years. This means that you are installing a network system that will be used for applications the designer cannot be aware of. Therefore, an efficient design will seek to include media that will handle any application. Single mode is certainly that media.

The use of hybrid cables containing single-mode and multimode fibers is recommended for interbuilding backbone networks. In a hybrid cable, single-mode and multimode fibers are placed in different buffer tubes or bundles within the same cable. This provides easy identification at splice points and allows termination into separate panels at cross-connect points. Additionally, use of hybrid cables reduces installation costs and duct/conduit congestion.

Backbone Spare Fiber Count Planning

Installing additional (spare) fibers for future use is recommended because of the versatility of fiber and almost certain growth of bandwidth requirements. Users should plan for growth in the backbone network, especially the interbuilding backbone. Extra fibers can be installed and left unterminated until needed. The cost of these unterminated spare fibers to the overall project is minimal. The major expense of cable installation is the labor associated with the actual cable placement and termination, especially in difficult installations with congested or inaccessible raceways. The incremental cost of installing extra fibers now will be much less than the cost if installing a new cable later.

The methods for deciding how many additional fibers to plan for are based on network analysis and percentage rules.

Network Analysis

Spare fiber counts can be determined by examining

- Future growth in existing areas
- Future growth from new construction or acquired areas
- Knowledge of proposed new network systems

For instance, if the designer/end user is aware that the organization will add 300 FDDI workstations within the next two years, then fibers required to network these added stations can be planned.

FIGURE 9.113 Electronics options.

Percentage Rules

Spare fiber counts can also be determined if limited future system information is available. The designer can utilize the 25, 50, or 100% rule.

- 25% Rule. If future network applications are defined and potential demand for unanticipated service is low, add 25–33% to the number of fibers currently required.

- 50% Rule. If the future network applications are defined and potential demand for unanticipated service is high, add 50% to the number of fibers currently required.
- 100% Rule. If the future network applications are uncertain and potential demand for unanticipated service is very high or if the installation of subsequent cable/fiber is extremely difficult, add 100% to the number of fibers currently required.

For example, a proposed system currently requires 24 fibers to service existing and defined future networks. If you employ the 25% rule then you would add 6 fibers to the cable run for a total of 30 fibers.

In the case of single-mode fibers, it is recommended that system designers look at adding either 25 or 50% to the number of fibers to ensure sufficient high-capacity media is available for future demands.

System designers should view the addition of spare fibers as a necessity that permits the system to accommodate the needs of the network as it expands and changes.

Backbone Standard Fiber Counts

Although a user can purchase a cable with almost any number of fibers, cable manufacturers, and cable distributors consider certain fiber counts standard and often stock these cables. Fiber counts in multiples of 6 and 12 are standard for backbone cabling and connecting hardware. For low-fiber counts (< 24), multiples of 6 are common (i.e., 6, 12, 18, and 24). For higher fiber counts (> 24), multiples of 12 are common (i.e., 36, 48, 60, 72, etc.). This should be considered when determining the fiber counts for your system.

Installation Considerations

An important aspect of overall system design is the physical construction of the existing system. Every system will have to be examined to determine if existing conduits, duct banks, and cable trays have sufficient space to handle the proposed cabling. This also includes future additions that may be required due to new service requirements. As previously discussed, the system designer must determine if there are sufficient fibers so that future cable installations are reduced or preferably eliminated.

Before a system design is complete and the fiber counts are determined, check to see if the physical facilities can accommodate additional cable. This includes proposed construction and any future additions that may be unseen.

Physical Network Topology

To better illustrate the approach to fiber count selection, we will review the requirements of an example system and propose a baseline fiber count for each of the three primary cable plant segments: interbuilding backbone, intrabuilding backbone, and horizontal cabling. The reader is advised that the solution to this example is one of many. Fiber counts depend on a number of variables that must be considered on a case-by-case basis.

Network Requirements

For the purpose of this discussion, this system will be

- A campus-type network that employs interbuilding and intrabuilding backbones plus horizontal cabling employed in accordance with UTS and EIA/TIA-568A recommendations.
- The system assumes a multiapplication end user environment consisting of voice, data, and video.
- The system allows for easy migration from separate LANs to an ATM or FDDI backbone network.
- As indicated in Fig. 9.114, the campus is configured in a physical star with a MC, ICs, HCs, and work area telecommunication outlets.

Interbuilding Backbone

Of the various segments of the fiber optic cable plant, the designer/user should spend the greatest effort in determining the proper fiber count for the interbuilding backbone. Not only is this the portion of

FIGURE 9.114 Example fiber network system.

the network that is most influenced by the decisions involving **multiplexing** and the use of bridges and routers, it is also the segment in which the end user must allow for adequate growth and flexibility because of the expense involved in placing interbuilding cables and constructing interbuilding pathways. Listed in Fig. 9.115 are the planning requirements for this example and the resulting fiber counts.

The user initially plans for the coexistence of ethernet, token ring, and FDDI vs. placing these applications onto one single FDDI backbone. This was based on a decision, initially, to use less sophisticated end electronics. This particular user decides to utilize a hybrid 60-fiber cable comprising 48 multimode (62.5- μm) fibers and 12 single-mode fibers. The additional 16 multimode fibers (50% rule) allow for

APPLICATION	NO. MULTIMODE FIBERS	NO. SINGLE-MODE FIBERS	COMMENTS
ATM	2	2	62.5 μm up to 155 Mb/s SM FOR 622 Mb/s

future growth and the 12 single-mode fibers (100% rule) will be utilized for high data rate requirements. Additional growth can also be achieved by more effectively using the high bandwidth of fiber, such as moving from token ring to FDDI or implementing an ATM switch.

This particular example, although while not uncommon, did employ an extensive list of requirements. It is recommended that at least a 24–48 multimode fiber interbuilding backbone be considered, plus an additional 6–12 single-mode fibers. In large campus networks that may utilize an hierarchical star or ring interbuilding backbone, the designer/user should consider the fiber count requirements for the main backbone separate from the secondary backbone.

Intrabuilding Backbone

Traditionally data networks have been implemented with hubs or concentrators distributed to each telecommunications closet. This keeps the fiber count requirements relatively low in the intrabuilding backbone. This section analyzes such a network.

Although the determination of the proper fiber count in the intrabuilding backbone is typically less complicated than the interbuilding backbone, many of the same issues exist. These issues primarily concern establishing the list of requirements, both present and future, and determining the level of use of bridges and routers. Figure 9.116 indicates the example systems fiber count requirements for one of the intrabuilding backbone areas.

This intrabuilding backbone run comprises the fiber optic paths that support applications to the telecommunications closet. This network supports the use of fiber-to-the-desk (FTTD) or copper but requires hubs or switches in the closet. This particular user decides to install a 30-fiber, 62.5- μm cable to each horizontal cross connect. The choice of 30 fibers included sufficient spares to handle expansion and future needs.

This particular example, although not uncommon, did employ an extensive list of requirements. It is recommended to utilize a minimum of a 24-fiber interbuilding backbone cable in support of distributed electronics.

In most cases, the installation of single mode in the intrabuilding backbone is not recommended unless special requirements exist. Cable placement costs for intrabuilding backbone are typically inexpensive when compared to the interbuilding backbone and horizontal wiring. Additionally, 62.5- μm multimode fiber can support extremely high data rates, in excess of 1 Gb/s, for the short distances (typically less than 300 m) found in the intrabuilding backbone.

Centralized Backbone Cabling

Although category 5 UTP systems are limited in total length and require electronics in the closet for high-speed data systems, fiber optic systems do not require the use of electronics in closets on each floor and,

therefore, allow for a totally collapsed or centralized cabling network. This design allows the end user to place all of the data electronics in one closet in the building vs. multiple closets throughout the building, thus greatly simplifying the management of fiber optic networks and providing for more efficient use of ports on electronic hubs.

This design can be implemented in a number of ways: (1) pull-through cables from outlets or multiuser outlets to the single central closet in the building, (2) a splice between the horizontal cabling and a high-fiber-count backbone cable in the closet, or (3) a passive interconnect in each closet. Although each of these three options has its corresponding benefits, most users will choose option 2 because it allows for simpler cable placement and offers an acceptable degree of flexibility for adding users at a reasonable cost.

The intrabuilding backbone cable should be sized with sufficient spare capacity to permit additional horizontal circuits to be routed to the centralized cross connect without the need to pull additional intrabuilding backbone cables. The intrabuilding backbone fiber count should be sized to deliver present and future applications to the maximum work area density within the area served by the TC. If maximum density is not anticipated for a number of years, however, the user may elect to install a backbone based on present density allowing for additional cables in the future as the office area is fully occupied.

Horizontal Cabling

Fiber in the horizontal is a reality because of the recent advances in technology easing installation, reducing the overall system cost, and offering a system that is reliable, flexible, certifiable, and future proofed for the information era. A minimum of a two-fiber, 62.5- μm cable is recommended for data communications and a separate category 3 UTP cable for voice. In determining the fiber count of the horizontal data cables, there are two distinct network possibilities.

For hard-wired offices, a single-user cable will be installed to a single-user outlet. The fiber count of the single-user cable is based on the number of applications that user requires. Typically, it is a 2-fiber, 62.5- μm cable but sometimes a user has a requirement to run two separate networks requiring four fibers.

For open-systems furniture applications, the use of a multiuser cable and outlet can be implemented to ensure the long-term survivability of the horizontal cabling network in this rapidly changing office area. Multiuser cabling calls for a high-fiber count cable to be placed from the closet to an area in the open office where there is a fairly permanent structure, such as a wiring column or cabinet, in a grid type wiring scheme. At this structure, a multiuser outlet, capable of supporting 6–12 offices, is installed instead of individual outlets. Fiber optic patch cords are then installed through the furniture raceways from the multiuser outlet to the office area, allowing the user to rearrange the furniture without disrupting or relocating the horizontal cabling.

Defining Terms

Adapter: A mechanical media termination device designed to align and join fiber optic connectors. Often referred to as a coupling, bulkhead, or interconnect sleeve.

Backbone cabling: The portion of premises telecommunications cabling that provides connections between telecommunications closets, equipment rooms, and entrance facilities. The backbone cabling consists of the transmission media (optical fiber cable), main and intermediate cross connects, and terminations for the horizontal cross connect, equipment rooms, and entrance facilities. The backbone cabling can further be classified as interbuilding backbone (cabling between buildings), or intrabuilding backbone (cabling within a building).

Cable assembly: Optical fiber cable that has connectors installed on one or both ends. General use of these cable assemblies includes the interconnection of optical fiber cable systems and optoelectronic equipment. If connectors are attached to only one end of a cable, it is known as a pigtail. If connectors are attached to both ends, it is known as a jumper or patch cord.

Cable bend radius: Cable bend radius during installation infers that the cable is experiencing a tensile load. Free bend infers a smaller allowable bend radius since it is at a condition of no load.

Centralized cabling: A cabling topology used with centralized electronics connecting the optical horizontal cabling with intrabuilding backbone cabling passively in the telecommunications closet.

- Composite cable:** A cable containing both fiber and copper media per article 770 of the NEC.
- Connecting hardware:** A device used to terminate an optical fiber cable with connectors and adapters that provides an administration point for cross connecting between cabling segments or interconnecting to electronic equipment.
- Entrance facility:** An entrance to a building for both public and private network service cables including the entrance point at the building wall and continuing to the entrance room or space.
- Equipment room:** A centralized space for telecommunications equipment that serves the occupants of a building. An equipment room is considered distinct from a telecommunications closet because of the nature or complexity of the equipment.
- Fiber bend radius:** Radius a fiber can bend before the risk of breakage or increase in attenuation.
- Horizontal cabling:** That portion of the telecommunications cabling that provides connectivity between the horizontal cross connect and the work area telecommunications outlet. The horizontal cabling consists of transmission media, the outlet, the terminations of the horizontal cables, and horizontal cross connect.
- Horizontal cross connect (HC):** A cross connect of horizontal cabling to other cabling, for example, horizontal, backbone, equipment.
- Hybrid cable:** A fiber optic cable containing two or more different types of fiber, such as 62.5- μm multimode and single mode.
- Interbuilding backbone:** The portion of the backbone cabling between buildings. See backbone cabling.
- Intermediate cross connect (IC):** A secondary cross connect in the backbone cabling used to mechanically terminate and administer backbone cabling between the main cross connect and horizontal cross connect.
- Intrabuilding backbone:** The portion of the backbone cabling within a building. See backbone cabling.
- Link:** A telecommunications circuit between any two telecommunications devices, not including the equipment connector.
- Local area network (LAN):** A geographically limited communications network intended for the local transport of voice, data, and video. Often referred to as a customer premises network.
- Main cross connect (MC):** The centralized portion of the backbone cabling used to mechanically terminate and administer the backbone cabling, providing connectivity between equipment rooms, entrance facilities, horizontal cross connects, and intermediate cross connects.
- Multifiber cable:** An optical fiber cable that contains two or more fibers.
- Multiplex:** Combining two or more signals into a single bit stream that can be individually recovered.
- Multiuser outlet:** A telecommunications outlet used to serve more than one work area, typically in open-systems furniture applications.
- National Electrical Code (NEC):** Defines building flammability requirements for indoor cables. Note: Local codes take precedence but may refer to or require compliance to the NEC.
- Plenum:** An air-handling space such as that found above drop-ceiling tiles or in raised floors. Also, a fire-code rating for indoor cable.
- Point-to-point:** A connection established between two specific locations, as between two buildings.
- Repeater:** A device used to regenerate an optical signal to allow an increase in the system length.
- Riser:** Pathways for indoor cables that pass between floors. It is normally a vertical shaft or space. Also a fire-code rating for indoor cable.
- Telecommunications closet (TC):** An enclosed space for housing telecommunications equipment, cable terminations, and cross connects. The closet is the recognized cross connect between the backbone and horizontal cabling.
- Transmitter:** An electronic package used to convert an electrical information-carrying signal to a corresponding optical signal for transmission by fiber. The transmitter is usually a light emitting diode (LED) or laser diode.
- Work area telecommunications outlet:** A connecting device located in a work area at which the horizontal cabling terminates and provides connectivity for work-area patch cords.

10.1 Transformers

Sadrul Ula

10.1.1 Introduction

In the most basic definition, a transformer is a device that magnetically links two or more circuits for time-varying voltage and current. Magnetic coupling has a number of intrinsic advantages, including (1) DC isolation between the circuits, (2) the ability to match the voltage and current capability of a source to a load on the other side, (3) the ability to change the magnitude of the voltage and current from one side of the transformer to the other, and (4) the ability to change the phases of voltage and current from one side of the transformer to the other (three phase).

Transformers permeate nearly every facet of electrical engineering in one form or another. They are used in applications as diverse as power transmission and audio applications. Because the uses for transformers vary over such a wide range, and because the performance of a transformer depends on different critical design parameters for each application, it is essential that the design engineers have an understanding of transformer characteristics.

10.1.2 Electromagnetics of Transformers

In 1830 Faraday and Henry discovered that a voltage was induced in a coil of wire that was in the presence of a time-varying magnetic field. This relationship of the induced voltage to the magnetic flux is called Faraday's law, and is given in Eq. (10.1), where v is the induced voltage, ϕ is the magnetic flux, and N is the number of turns in the coil

$$v = N \frac{d\phi}{dt} \quad (10.1)$$

This fundamental relationship forms the basis for transformer operation. Take the case where two coils are set in close proximity, as illustrated in Fig. 10.1. A voltage, which is introduced on the first coil, produces magnetic flux. Part of this flux passes through, or links, the second coil, ϕ_{12} . As a result, a voltage is produced on the second coil. In the same way, a voltage on the second coil produces a flux, which links the first coil. The amount of flux that passes through both coils determines how tightly they are coupled.

FIGURE 10.1 Linked coils.

Notice that not all of the flux that is produced by the first coil passes through the second coil. The nonlinking flux is called leakage flux, and produces an inductance in the coil, called leakage inductance. In Fig. 10.1, ϕ_{11} is the leakage flux of coil 1, and ϕ_{22} is the leakage flux of coil 2. In many transformers, a ring of magnetic material, called a core, is used to concentrate the flux, so that most of it passes through both coils and the leakage inductance is reduced.

In general, the coil into which power flows is called the *primary* coil, whereas the other coil is called the *secondary*.

Magnetic Cores

The ease with which a flux can be produced in a material is called its *permeability*, μ . More flux will be produced in a material with high permeability than in a one with a low permeability, given the same amount of current and the same number of turns in the coil. Core materials usually have a permeability thousands of times that of free space or air. The ratio of a material's permeability to the permeability of free space, called *relative permeability*, is often used. The actual permeability, which has units of webers per ampere-turn-meter, is found by multiplying the permeability of free space by the relative permeability.

The overall ability of a core to carry flux also depends on its size and shape, and its cross-sectional area. This is described by a quantity called *permeance*. The basic relationship of permeance to permeability in a core is defined in Eq. (10.2), where P is the permeance, μ is the permeability of the material, A is the cross-sectional area of the core, and l is the mean length of the flux path in the core. This equation assumes uniform flux distribution in the core and constant permeability inside the core. It does not take into account the variations in the length of the flux path from the inside of the core to the outside. The reciprocal of permeance is *reluctance*

$$P = \frac{\mu A}{l} = \frac{1}{R} \quad \text{or} \quad R = \frac{l}{\mu A} \quad (10.2)$$

Air Gaps

The technique of putting an air gap in the core is used to prevent saturation in some applications. Since the reluctance of the air gap is much larger than that of the core, the flux density in the core is greatly reduced. The formula for the reluctance of the air gap is the same as that for the core. In Eq. (10.3) l_a is the length of the air gap, μ_a is the permeability of air, and A_a is the cross-sectional area of the air gap. The cross-sectional area of the air gap is not necessarily the same as that of the core, due to the tendency of the flux to spread. This effect is called *fringing*, and it is more prevalent in applications where the air gap length is large compared to the cross-sectional area of the core. In most applications, fringing can be ignored.

$$R_a = \frac{l_a}{\mu_a A_a} \quad (10.3)$$

The total reluctance is the sum of the core reluctance and the air gap reluctance. This reluctance is used to calculate the flux in the core

$$R_{\text{total}} = R_a + R_c \quad (10.4)$$

$$\phi = \frac{N_i}{R_{\text{total}}} \quad (10.5)$$

Example Problem

A core made of iron and nickel has a relative permeability of 100,000, a path length of 30 cm, and a cross-sectional area of 9 cm². An air gap has been placed in the core, which is 5 mm deep. The total reluctance can be found by adding the reluctance of the air gap and the iron core. The core reluctance can be found using Eq. (10.2),

$$\begin{aligned} R_c &= \frac{l_c}{\mu_c A_c} = \frac{l_c}{\mu_{Cr} \mu_{fs} A_c} \\ &= \frac{3 \times 10^{-1} \text{ m}}{(1 \times 10^5)(4\pi \times 10^{-7} \text{ Wb/A} \cdot \text{turn} \cdot \text{m})(9 \times 10^{-4} \text{ m}^2)} = 2.65 \times 10^3 \frac{\text{A} \cdot \text{turns}}{\text{Wb}} \end{aligned}$$

If the effects of fringing are neglected, the cross-sectional area of the air gap is the same as that of the core. The reluctance of the air gap can then be found using Eq. (10.2)

$$R_c = \frac{l_{\text{air}}}{\mu_{\text{air}} A_{\text{air}}} = \frac{l_{\text{air}}}{\mu_{\text{air}} \mu_{fs} A_c}$$

$$= \frac{5 \times 10^{-3} \text{ m}}{(1.0)(4\pi \times 10^{-7} \text{ Wb/A} \cdot \text{turn} \cdot \text{m})(9 \times 10^{-4} \text{ m}^2)} = 4.42 \times 10^6 \frac{\text{A} \cdot \text{turns}}{\text{Wb}}$$

The relationship between the flux passing through the coil and the current in the coil is given in Eq. (10.6), where N is the number of turns in the coil, i is the current, P is the permeance of the core material, and ϕ is the flux. The product of the current and the number of turns in the transformer is called the magnetomotive force (mmf). Notice the similarity of this equation to the one relating voltage and current in a circuit. The voltage is replaced by the mmf, impedance is replaced by the reluctance, and current is replaced by flux. The magnetizing force H is defined as the mmf divided by the length of the flux path for a continuous core.

$$\text{mmf} = N_i = R_\phi \quad (10.6)$$

$$H = \frac{\text{mmf}}{l} \quad (10.7)$$

Although the materials used to make transformer cores have high permeability, their ability to carry flux is not unlimited. The quotient of the flux divided by the area of the core is called the flux density. Equation (10.8) gives the formula for flux density. When the amount of flux density in the core gets too high, the permeability of the core material begins to decrease. This magnetic overloading of the core material is called saturation.

$$B = \frac{\phi}{A} \quad (10.8)$$

Mutual Inductance

The voltage of the second coil is related to the linking flux, ϕ_{12} by Faraday's law:

$$v_2 = \frac{d}{dt}(N_2 \phi_{12}) \quad (10.9)$$

The flux ϕ_{12} is related to the number of turns and the current as shown in Eq. (10.10) giving the relationship between the current in the first coil and the voltage in the second coil shown in Eq. (10.11). The quantity $N_1 N_2 P_{21}$ is called the mutual inductance since it relates the voltage on coil 2 to the differential of the current in coil 1. The mutual inductance between the coils can be increased by increasing the permeance of the core material which links them.

$$\phi_{12} = P_{21} N_1 i_1 \quad (10.10)$$

$$v_2 = N_1 N_2 P_{21} \frac{di_1}{dt} \quad (10.11)$$

Saturation, Hysteresis and Core Losses

Figure 10.2 shows the magnetization curve for a typical ferromagnetic material. Note that the curve follows two different paths, depending on whether the magnetizing force H is increasing or decreasing. This is called a hysteresis curve. It is caused by the fact that the magnetic particles in the core need to be rotated and realigned each time the polarity of the magnetizing force changes. This is why the magnetic force must be reversed to reduce the flux density to zero.

As the magnetizing force H increases, the flux density increases up to a point, then the curve flattens out. In this flattened region, the mmf can increase greatly, and only a small increase in the flux density

FIGURE 10.2 Typical magnetization curve.

will result. The core is said to be saturated in this region. The flattening of the curve indicates that the permeability has decreased from the value it had when there was only a little flux passing through the core.

10.1.3 The Ideal Transformer

Although no transformer is ideal in its characteristics, transformers approach their ideal characteristics in the operating range for which they were designed. The ideal transformer has no coil resistance and no core losses, so that it has no power loss. It also has no leakage inductance, since the permeability of the core is infinite, and the core material is able to carry an infinite amount of flux without saturating. Therefore, the mutual inductance is also infinite. The capacitance in an ideal transformer is negligible. The equations for an ideal transformer are given as follows:

$$v_1 i_1 = v_2 i_2 \tag{10.12}$$

$$\frac{v_1}{v_2} = \frac{N_1}{N_2} \tag{10.13}$$

$$\frac{i_1}{i_2} = \frac{N_2}{N_1} \tag{10.14}$$

$$\frac{Z_1}{Z_2} = \left(\frac{N_1}{N_2} \right)^2 \tag{10.15}$$

Equation (10.15) gives the effect of the transformer on an impedance on the secondary side. It is multiplied by the square of the turns ratio. The magnitude of the impedance as seen on the secondary side is called the reflected impedance.

Dot Convention

To eliminate ambiguity in the voltage and current polarity at the input and output of the transformer symbol, the dot convention is used. In circuit diagrams, a small dot is placed near one end of each coil, as shown in Fig. 10.3. The dot indicates a rise in voltage from the unmarked to the marked terminal on each coil. Under this convention, current into the dot on the primary side is labeled as having positive polarity, whereas current out of the dotted terminal on the other side is assigned positive polarity. This means that the power flow must be into the transformer on one side, and out of the transformer on the other side.

FIGURE 10.3 Dotted schematic symbol for a transformer.

The side of the transformer into which power flows is called the primary; the other side is referred to as the secondary.

FIGURE 10.4 Equivalent circuit.

Transformer Equivalent Circuit

Equivalent circuits are often used to model the performance of transformers with greater accuracy. Although equivalent circuits are not exact replicas of real transformers, they are close enough to realize accurate results for most situations. The complete transformer equivalent circuit is shown in Fig. 10.4.

The leakage inductance of both coils has been modeled by an inductor in series with the load, since the current in the coils also produces leakage flux. These inductances are labeled L_p and L_s , respectively. Notice that the leakage inductance for the secondary side has been divided by the turns ratio n , squared because it was reflected to the primary side. Resistors labeled R_p and R_s have also been placed in series with the load to represent the resistance of the conductors used to wind the coils. Again, the secondary resistance has been divided by the square of the turns ratio, since it was reflected.

The mutual inductance is represented by shunt inductor L_m , since the magnetizing current is not coupled to the load. A resistor R_c is also placed in shunt, to represent the core loss due to hysteresis and eddy currents in the core.

The stray capacitances between turns of the coils are represented by a capacitor placed across the terminals of each coil. This capacitance is larger for coils with more turns. Although the capacitance is actually distributed, it is lumped for the equivalent circuit, in order to simplify the analysis. The capacitance from one coil to the other is represented by another capacitor placed in parallel with the leakage inductance and resistance. The transfer function of the complete equivalent circuit is given in Eq. (10.16),

$$\frac{V_{out}(j\omega)}{V_{in}(j\omega)} = \frac{Z_L(Z_P Z_S + Z_M Z_C + Z_M Z_P + Z_M Z_S)}{Z_P Z_C Z_L + Z_P Z_C Z_M + Z_P Z_C Z_S + Z_P Z_S Z_L + Z_M Z_C Z_L + Z_M Z_C Z_S + Z_P Z_M Z_L + Z_M Z_S Z_L} \tag{10.16}$$

The transfer function of the complete equivalent circuit is quite complex. For this reason, the equivalent circuit is often broken up into several equivalent circuits, each of which is valid only for a certain set of operating conditions. The simplified circuits are then analyzed for their pertinent operating conditions.

Equivalent Circuit for Low Frequency

In the low-frequency range, the transformer acts like a high-pass filter. Above the corner frequency, the output voltage is nearly equal to the input voltage. Below the corner frequency the output voltage is substantially smaller than the input voltage, due to the presence of the shunt inductor L_m . The distributed capacitances and leakage inductances can be neglected. The equivalent circuit for low frequencies shown in Fig. 10.5, and the transfer functions for voltage and current are given in Eq. (10.17) and

FIGURE 10.5 Low-frequency equivalent circuit.

Eq. (10.18), assuming the generator impedance is R_g . The impedance seen at the input of the transformer is given in Eq. (10.18), and the equation for the corner frequency of the transformer is given in Eq. (10.18) assuming a resistive load impedance.

$$\frac{V_{out}}{V_{in}} = \frac{j\omega L_m \cdot \frac{Z_l}{n^2}}{j\omega L_m \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} \right) + (R_p + R_g) \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} + j\omega L_m \right)} \tag{10.17}$$

$$\frac{I_{out}}{I_{in}} = \frac{j\omega L_m}{\frac{Z_l}{n^2} + \frac{R_s}{n^2} + j\omega L_m} \tag{10.18}$$

$$Z_{total} = \frac{j\omega L_m \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} \right) + (R_p + R_g) \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} + j\omega L_m \right)}{\frac{Z_l}{n^2} + \frac{R_s}{n^2} + j\omega L_m} \tag{10.19}$$

$$f_{corner,voltage} = \frac{2\pi L_m \left(\frac{R_l}{n^2} + \frac{R_s}{n^2} + R_p + R_g \right)}{(R_p + R_g) \left(\frac{R_l}{n^2} + \frac{R_s}{n^2} \right)} \tag{10.20}$$

Midband

This is the intended operating range for the transformer. The frequency is high enough that the mutual inductance can be neglected and low enough that the leakage inductance and distributed capacitance are still not a concern. For this reason, the only impedances of concern are the coil resistances and the core loss component. The resulting equivalent circuit is shown in Fig. 10.6, and the transfer functions for both voltage and current are given in Eq. (10.21) and Eq. (10.22). The formula for the input impedance is given by Eq. (10.23).

FIGURE 10.6 Midband equivalent circuit.

$$\frac{V_{out}}{V_{in}} = \frac{R_c \cdot \frac{Z_l}{n^2}}{R_c \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} \right) + (R_p + R_g) \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} + R_c \right)} \tag{10.21}$$

$$\frac{I_{out}}{I_{in}} = \frac{R_c}{\frac{Z_l}{n^2} + \frac{R_s}{n^2} + R_c} \tag{10.22}$$

$$Z_{total} = \frac{R_c \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} \right) + (R_p + R_g) \left(\frac{Z_l}{n^2} + \frac{R_s}{n^2} + R_c \right)}{\frac{Z_l}{n^2} + \frac{R_s}{n^2} + R_c} \tag{10.23}$$

High Frequency

At higher frequencies, the leakage inductance begins to dominate the transformer’s response. The high-frequency equivalent circuit is shown in Fig. 10.7, and transfer functions for voltage and current are given in Eq. (10.23) and Eq. (10.24).

FIGURE 10.7 High-frequency model.

$$\frac{V_{out}}{V_{in}} = \frac{R_c \cdot \frac{Z_l}{n^2}}{R_c \left(\frac{Z_l}{n^2} + \frac{(R_s + j\omega L_s)}{n^2} \right) + (R_p + j\omega L_p + R_g) \left(\frac{Z_l}{n^2} + \frac{(R_s + j\omega L_s)}{n^2} + R_c \right)} \quad (10.24)$$

$$\frac{I_{out}}{I_{in}} = \frac{R_c}{\frac{Z_l}{n^2} + \left(\frac{j\omega L_s + R_s}{n^2} + R_c \right)} \quad (10.25)$$

$$Z_{total} = \frac{R_c \left(\frac{Z_l}{n^2} + \frac{(R_s + j\omega L_s)}{n^2} \right) + (R_p + j\omega L_p + R_g) \left(\frac{Z_l}{n^2} + \frac{(R_s + j\omega L_s)}{n^2} + R_c \right)}{\frac{Z_l}{n^2} + \frac{(R_s + j\omega L_s)}{n^2} + R_c} \quad (10.26)$$

Ultra High Frequency

At extremely high frequencies, the distributed capacitance of each coil begins to play a role, along with the leakage inductance of each coil (see Fig. 10.8).

$$\frac{V_{out}}{V_{in}} = \frac{Z_l}{Z_l + n^2 j\omega L_l (j\omega L_l C_s + 1)} \quad (10.27)$$

$$\frac{I_{out}}{I_{in}} = \frac{n^2}{j\omega C_p Z_l + n^2 (1 - \omega^2 L_l C_p) (j\omega Z_l C_s + 1)} \quad (10.28)$$

$$Z_{in} = \frac{Z_l + n^2 j\omega L_l (Z_l j\omega C_s + 1)}{Z_l j\omega C_p + n^2 \omega^2 L_l C_p (Z_l j\omega C_s + 1) + n^2 (Z_l j\omega C_s + 1)} \quad (10.29)$$

FIGURE 10.8 Ultra-high-frequency model.

FIGURE 10.9 Connections for open-circuit test.

10.1.4 Testing to Determine Transformer Parameters

It is possible to quantify some of the important transformer parameters through testing. Two simple tests, the open-circuit and short-circuit tests, allow the user to identify the leakage inductance, the coil resistance, the core loss, and mutual inductance of the transformer. Since the characteristics of the transformer change with frequency, the tests should be done at the frequency (or frequencies) of interest.

The open-circuit test is done by leaving the terminals on one side of the transformer open, and applying the rated voltage to the coil on the other side. Figure 10.9 shows the equivalent circuit for this test, assuming the test is done at a midband frequency. Since the leakage inductance and core resistance are small compared to the mutual inductance and core loss resistance, they can be neglected for the open-circuit test.

The value of the exciting admittance is then given by Eq. (10.30), where I_ϕ and V_1 are phase values. The conductance component of the admittance is found by dividing the input power by the magnitude of the input voltage, as shown in Eq. (10.31). The susceptance component is then given by Eq. (10.32). The resistance and inductance, which account for the core loss, can then be found by taking the reciprocal of the conductance and susceptance, respectively. The values that are found are referred to the side of the transformer to which the voltage was applied.

$$Y_\phi = Y_{oc} = \frac{\hat{I}_\phi}{\hat{V}_1} \tag{10.30}$$

$$G_c = G_{oc} = \frac{P_1}{|V_1|^2} \tag{10.31}$$

$$B_m = B_{oc} = \sqrt{|Y_{oc}|^2 - G_{oc}^2} \tag{10.32}$$

$$R_{oc} = \frac{1}{G_{oc}} \tag{10.33}$$

$$L_m = \frac{1}{2\pi f B_m} \tag{10.34}$$

The short-circuit test is conducted by shorting one of the transformer’s coils, and applying rated current to the other coil. Only a fraction of the rated voltage is needed to produce the rated current. The input current and power are then measured. Figure 10.10 shows a circuit diagram for this test.

Since the magnetization and core loss impedances are large compared to the leakage inductance and coil resistance, the input current is assumed to be the secondary current. Accordingly, the power input must go toward losses in the coil resistances. The sum of the leakage inductances and coil resistances can

FIGURE 10.10 Short-circuit test setup.

be found using Eq. (10.35–10.37). Note that the impedances are referred to the side of the transformer that the voltage was applied to. If it is necessary to know the magnitudes of the primary and secondary impedances separately, a common approximation is to assume $R_1, R_2 = 0.5 R_{eq}$, and $X_{11} = X_{12} = 0.5 X_{eq}$.

$$\hat{Z}_{eq} = \hat{Z}_{sc} = \frac{\hat{V}_{sc}}{\hat{I}_{sc}} \quad (10.35)$$

$$R_{eq} = R_{sc} = \frac{P_{sc}}{I_{sc}^2} \quad (10.36)$$

$$X_{eq} = X_{sc} = \sqrt{|Z_{sc}|^2 - R_{sc}^2} \quad (10.37)$$

Example Problem: Determining the Core Loss, Mutual Inductance, Leakage Inductance, and Coil Resistance

Open- and short-circuit tests were conducted on a 60-Hz, 500-W 120:6-V transformer. In the short-circuit test, the readings were 10 V, 4.16 A, and 24 W. The combined impedance of the coil resistance and the leakage inductance can be found using Eq. (10.35). The resistance and reactance of the transformer can then be found using Eq. (10.36). The resistance and reactance of the transformer can then be found using Eq. (10.36) and Eq. (10.37).

$$Z_{eq} = Z_{sc} = \frac{|\hat{V}_{sc}|}{|\hat{I}_{sc}|} = \frac{10.0 \text{ V}}{4.16 \text{ A}} = 2.40 \Omega$$

$$R_{eq} = R_{sc} = \frac{P_{sc}}{I_{sc}^2} = \frac{24.0 \text{ W}}{(4.16 \text{ A})^2} = 1.39 \Omega$$

$$X_{eq} = X_{sc} = \sqrt{|Z_{sc}|^2 - R_{sc}^2} = \sqrt{(2.40)^2 - (1.39)^2} = 1.96 \Omega$$

The open-circuit test was done with the low-voltage side energized. The readings were 6.0 V, 1.2 A, and 0.8 W. The exciting admittance is then given by Eq. (10.30), and the conductance and susceptance components can be found using Eq. (10.31) and Eq. (10.32),

$$Y_{\phi} = Y_{oc} = \frac{I_{\phi}}{V_{oc}} = \frac{1.2 \text{ A}}{6.0 \text{ V}} = 0.21 \Omega$$

$$G_c = G_{oc} = \frac{P_{oc}}{|V_{oc}|^2} = \frac{0.8 \text{ W}}{(6.0 \text{ V})^2} = 0.022 \Omega$$

$$B_m = B_{oc} = \sqrt{|Y_{oc}|^2 - G_{oc}^2} = \sqrt{(0.2)^2 - (0.022)^2} = 0.198 \Omega$$

$$R_{oc} = \frac{1}{G_{oc}} = \frac{\Omega}{0.022} = 45.4 \Omega$$

$$L_m = \frac{1}{2\pi f B_m} = \frac{1}{2\pi(60.0)(0.198)} = 13.4 \text{ mH}$$

10.1.5 Applications

Power Transformers

Designers of power transformers are primarily concerned with efficiency and voltage regulation. The efficiency of a transformer is the ratio of the power output to the power input, as shown in Eq. (10.38). Because the power flow through the transformer varies depending on the power factor of the load, Eq. (10.38) is used with the understanding that the power factor of the load be unity. The losses in power transformers are due to the copper losses in the windings and the core losses. The copper losses vary with the square of the current; the core losses vary with the input voltage magnitude and frequency.

Because neither of these quantities depends on the power being consumed by the load, power transformers are rated by the volt-amperes (VA), which flows through them.

$$\%Eff = \frac{P_{out}}{P_{in}} \times 100 \tag{10.38}$$

The regulation of a power transformer is a measure of the transformer’s ability to maintain a constant output voltage for varying loads. The formula for regulation is given in Eq. (10.39). The primary voltage is held constant at the value required to produce rate voltage on the secondary at full load.

$$Regulation\% = \frac{V_{2oc} - V_{2fl}}{V_{2fl}} \times 100\% \tag{10.39}$$

Wide-Band

Wide-band transformers are designed to be used over a frequency range, rather than at a single frequency. They are used in applications where waveforms that consist of a number of frequencies must be passed with a minimum of distortion. Some applications of wide-band transformers include audio, video, and sonar.

The power that is dissipated by the transformer in its midband with a resistive load is called the insertion loss. The formula for insertion loss is given in Eq. (10.40) where P_L is the power transmitted to the load and P_T is the power loss in the transformer due to winding resistance and core loss. Insertion loss is also found by taking the ratio of the load voltage with the actual transformer, E , over the load voltage with an ideal transformer, E' . This method is given in Eq. (10.41).

$$Insertion\ Loss, dB = 10 \log \frac{P_L}{P_L + P_T} \tag{10.40}$$

$$Insertion\ Loss, dB = 20 \log \frac{E}{E'} \tag{10.41}$$

Wide-band transformers are often used to match the load to the source for maximum power transfer and minimum reflection. A frequency used approximation is to select a turns ratio such that the generator resistance R_G is equal to the reflected load resistance, R_L/n^2 . A more exact method is to set the generator resistance equal to the sum of the transformer coil resistances and the load, as shown in Eq. (10.42)

$$R_G = R_p + \frac{R_s}{n^2} + \frac{R_L}{n^2} \tag{10.42}$$

Frequency Response of Wide-band Transformers

The equivalent circuit of Fig. 10.11(a) is used to analyze the low-frequency response of wide-band transformers. The critical element in the low-frequency range is the mutual inductance L_m . The corner frequency is given by Eq. (10.20). The midband response of the transformer can be found using the equivalent circuit of Fig. 10.6.

The high-frequency response of the wide-band transformer can be found using the equivalent circuit shown in Fig. 10.8. This circuit is somewhat complex, however, and a common practice is to include only

FIGURE 10.11 (a) Equivalent for 1:1, (b) equivalent for step up ($n > 1.0$), (c) equivalent for step down ($n < 1.0$).

FIGURE 10.12 Pulse terminology.

one of the distributed capacitances, depending on whether the transformer is a step down, or step up, or 1:1 transformer. Assuming that one of the capacitances is dominant simplifies the equivalent circuit and makes the transfer function easier to analyze. The distributed capacitance will be larger in the coil with more turns, and the reflection of the larger capacitance to the other side of the transformer increases this effect. The equivalent circuits for 1:1, step up, and step down are given in Fig. 10.11(a), Fig. 10.11(b), and Fig. 10.11(c), respectively.

Pulse Transformers

Pulse transformers are used to transform video pulses. Although they are similar in design to wide-band transformers, they are designed with different specifications in mind. The shape of a typical pulse is shown in Fig. 10.12, which demonstrates how the important quantities in the pulse are specified.

Because of the complex nature of the pulse, it is often divided into three stages, which are analyzed separately. The rising edge of the pulse is analyzed using the high-frequency equivalent circuit for step up or step down wide-band transformers due to the high frequencies that are present. The top of the pulse is analyzed using the low-frequency equivalent circuit, since it is a DC voltage. The trailing edge is analyzed using the high-frequency model, with the assumption that the source is an open circuit.

Rising Edge

Because of the high frequencies present in the rising edge of the pulse, the high-frequency equivalent circuit is used to analyze it. For the step up transformer the ratio of the load voltage to the source voltage is given by Eq. (10.43). If $4c < b^2$, then the circuit is overdamped. If $4c > b^2$, then the circuit is underdamped, and the overshoot is larger. The damping factor is defined in Eq. (10.44). The rise time is less for lower damping factors, but the overshoot also increases for lower damping factors. A damping factor of 0.707 is optimum in the sense that it produces the shortest rise time with no overshoot.

$$\frac{V_L}{V_G} = \frac{R_L}{R_L + R_G} \left[1 - \exp\left(-\frac{b}{2}t\right) \left(\frac{b}{\sqrt{b^2 - 4c}} \sinh \frac{\sqrt{b^2 - 4c}}{2}t + \cosh \frac{\sqrt{b^2 - 4c}}{2}t \right) \right] \quad (10.43)$$

$$b = \frac{R_G}{L_L} + \frac{1}{R_L C_D} \quad c = \frac{R_L + R_G}{L_L C_D R_L}$$

$$\text{Damping Coeff} = \frac{b}{2\sqrt{c}} = \frac{R_G R_L C_D + L_L}{2\sqrt{R_L L_L C_D (R_G + R_L)}} \quad (10.44)$$

For the step down transformer, Eq. (10.43) can be used with the following substitutions:

$$b = \frac{R_L}{L_L} + \frac{1}{R_G C_D} \quad c = \frac{R_G + R_L}{L_L C_D R_G}$$

Top of Pulse

The top of the pulse is comparable to a DC input to the transformer. For this reason, the low-frequency equivalent circuit is used. As the pulse continues in the high state, the mutual inductance begins to conduct more current away from the load resistance. The ratio of the load voltage to the input voltage is given by Eq. (10.45). The negative exponential form of Eq. (10.45) indicates that the output voltage decays, or droops with time. The larger the mutual inductance is, the slower the rate of decay. It is necessary to know the source resistance during the top of the pulse in order to accurately estimate the droop.

$$\frac{V_L}{V_G} = \frac{R_L}{R_L + R_G} \exp \left[\frac{R_L R_G}{L_M (R_L + R_G)} t \right] \tag{10.45}$$

Trailing Edge of Pulse

At the trailing edge of the pulse, the high-frequency model is used again. In this case, however, the source is assumed to be an open circuit. The distributed capacitance and the mutual inductance now produce a voltage on the load with stored energy. The equivalent circuit for the trailing edge is shown in Fig. 10.13, where R_T is the total shunt resistance, which include the core loss and the reflected load resistance.

FIGURE 10.13 Equivalent circuit for trailing edge of pulse.

The response of the trailing-edge circuit is then given by Eq. (10.46), which relates the output voltage to the initial voltage at the time the pulse ends.

$$\frac{e(t)}{E_0} = \exp(-2\pi DT) \left(\cosh 2\pi T \sqrt{D^2 - 1} - \frac{D + F}{\sqrt{D^2 - 1}} \sinh 2\pi T \sqrt{1 - D^2} \right) \tag{10.46}$$

$$\text{Damping Factor} = D = \frac{1}{2R_T \sqrt{L_M C_D}}$$

$$\text{Initial current factor} = F = \frac{\tau}{\sqrt{L_M C_D}}$$

$$\text{Normalized Time} = T = \frac{t}{2\pi \sqrt{L_M C_D}}$$

τ = Pulse Width

Further Information

The quarterly journal *IEEE Transactions on Power Delivery* covers the field of transformers mostly at power frequency ranges of 50 and 60 Hz.

The quarterly journal *IEEE Transactions on Magnetics* covers magnetic material aspects of transformers.

Information on transformers for high frequency applications is rather difficult to find. The following publications occasionally covers transformers for high frequency applications:

IEEE Circuits & Devices, the magazine of electronic and photonic systems.

Electronic Design, Penton Publishing Inc., Cleveland, Ohio.

IEE Proceedings Circuits, Devices and Systems (London, UK).

IEEE Transactions on Signals and Systems.

10.2 Rectifier and Filter Circuits

T. S. Kalkur

10.2.1 Rectifier Circuits

One of the most important building blocks in electronic power supplies is the **rectifier**. **Diodes** are used to form rectifiers in electronic power supplies.

Half-Wave Rectifier

The half wave rectifier circuit is shown in Fig. 10.14(a). When the input sinusoid voltage at A goes positive, the diode conducts, resulting in current in the load resistor R . When the input voltage goes negative, the diode is reverse biased and, hence, it does not conduct, resulting in negligible current across R . Therefore, the output voltage is given by

$$V_o = 0, \quad \text{if } V_i < V_{D_o} \quad (10.47)$$

$$V_o = R/(R + r_D)V_i - V_{D_o}R/(R + r_D) \quad (10.48)$$

where

V_i = the input voltage

r_D = diode resistance

V_{D_o} = diode forward voltage $\approx 0.7\text{--}0.8$ V

Figure 10.15(b) shows the output voltage waveform for a sinusoidal input voltage. If $R \gg r_D$, then Eq. (10.48) simplifies to

$$V_o \approx V_i - V_{D_o} \quad (10.49)$$

The following aspects should be considered in designing the diode power supply:

- The current or power handling capability of the diode
- The *peak inverse voltage* (PIV) that the diode must be able to withstand without breakdown

When the input voltage goes negative, the diode is reverse biased, and the input voltage V_i appears across the diode.

FIGURE 10.14 Half-wave rectifier: (a) circuit diagram, (b) input and output waveforms.

The average output DC voltage, neglecting V_{D_o} is given by

$$V_{DC} = \frac{1}{2\pi} \int_0^{2\pi} \frac{V_m R \sin wt d(wt)}{(R + r_D)} \tag{10.50}$$

$$= V_m R / \pi (R + r_D)$$

$$\cong V_m / \pi \quad \text{if } R \gg r_D \tag{10.51}$$

where V_m is the maximum value of V_o . The ripple factor of a half-wave rectifier is given by

$$r = [\pi^2/4 - 1]^{\frac{1}{2}} = 1.21 \tag{10.52}$$

Full-Wave Rectifier

The full-wave rectifier utilizes both halves of the input sinusoid; one possible implementation is shown in Fig. 10.15(a). The full-wave rectifier consists of two half-wave rectifiers connected to a load R . The secondary transformer winding is center tapped to provide two equal voltages V_i for each half-wave rectifier. When the node A is at positive polarity V_i with respect to node B, $D1$ will be forward biased and $D2$ will be reverse biased. Therefore, diode $D1$ will conduct and the current will flow through R back to the center tap of the transformer. When the node B is at positive polarity V_i with respect to node A, $D2$ will be forward biased and diode $D1$ will be reverse biased. The current conducted by $D2$ will flow through R and back to the center tap. The current through R is always in the same direction giving rise to unipolar voltage V_o across R . The input and output voltage waveforms of the full-wave rectifier are shown in Fig. 10.15(b).

FIGURE 10.15 Full wave rectifier: (a) schematic diagram, (b) input and output waveforms.

The output voltage of the full rectifier is given by

$$V_o = \left[\frac{R}{R_t + r_D + R} \right] (V_s - V_{D_o}) \tag{10.53}$$

where R_t is the resistance associated with the transformer. The DC value of the output voltage

$$V_{DC} \cong 2 \left[\frac{R}{R + r_D + R_t} \right] \frac{V_m}{\pi} \tag{10.54}$$

$$\cong 2V_m / \pi, \quad \text{if } R \gg R + r_D + R_t \tag{10.55}$$

where V_m is the peak output voltage. Thus the full-wave rectifier produces double the output voltage of that of a half-wave rectifier. The ripple content of the full-wave rectifier is given by

$$r = (\pi^2/8 - 1)^{1/2} = 0.483 \tag{10.56}$$

The ripple factor for a full-wave rectifier is significantly less than that of a half-wave rectifier.

Another important factor to be considered in the design of full-wave rectifier is the peak inverse voltage of the diode. During the positive half-cycle, diode $D1$ is conducting and $D2$ is cut off. The voltage at the cathode of $D2$ will be at its maximum when V_o is at its peak value of $(V_i - V_{D_o})$ and V_i at its peak value. Therefore, the peak inverse voltage

$$PIV = 2V_i - V_{D_o} \tag{10.57}$$

is approximately twice that of the half-wave rectifier.

The Bridge Rectifier

The full-wave rectifier just discussed requires a center-tapped transformer. An alternative implementation of the full-wave rectifier, as shown in Fig. 10.16(a), is the bridge rectifier. This rectifier has four diodes arranged similar to Wheatstones bridge and does not require a center tapped transformer. Figure 10.16(b) shows the input and output voltage waveforms for the bridge rectifier. During the positive half-cycles of the input voltage, V_i is positive and the current is conducted through diode $D1$, resistor R , and diode $D2$. Meanwhile diodes $D3$ and $D4$ will be reverse biased. During the positive half-cycle, since two diodes are conducting, the output voltage will be $V_i - 2V_{D_o}$. During the negative half-cycle, the voltage V_i will be negative, diodes $D3$ and $D4$ are forward biased, and the current through R follows the same direction as in the case of the positive half-cycle.

FIGURE 10.16 Bridge rectifier: (a) circuit schematic, (b) input and output voltage waveforms.

During the positive half-cycle, the reverse voltage across $D3$ can be determined from the loop formed by $D3$, R , and $D2$ as

$$V_{D3}(\text{reverse}) = V_o + V_{D2}(\text{ forward}) \tag{10.58}$$

The maximum value of V_{D3} occurs at the peak of V_o and is given by

$$\begin{aligned} \text{PIV} &= V_i - 2V_{D_o} + V_{D_o} \\ &= V_i - V_{D_o} \end{aligned} \tag{10.59}$$

The PIV is about half the value for the full-wave rectifier with a center tapped transformer, which is an advantage of the bridge rectifier.

Voltage Multipliers

The DC output voltage V_{DC} in rectifier circuits is limited by the peak value of the AC voltage applied V_i . Figure 10.17(a) shows the voltage doubler circuit composed of a clamp formed by $C1$ and $D1$ and a peak rectifier formed by $D2$ and $C2$. When excited by a sinusoid of amplitude V_p , the output of the clamping section reaches the negative peak value of $-2V_p$ as shown in Fig. 10.17(b). In response to this clamp section output voltage, the output of the peak rectifier reaches $-2V_p$. By connecting additional diode capacitor circuits it is possible to generate rectifier circuits that triple and quadruple the input voltage.

FIGURE 10.17 Voltage doubler circuit: (a) diagram, (b) voltage across diode $D1$.

Precision Half-Wave Rectifiers

The rectifier circuits discussed previously are useful to rectify large input signals, that is, signals with amplitude greater than 0.6 V. Figure 10.18(a) shows a precision half-wave rectifier circuit that can be used to rectify small input signals. If V_i goes positive, the output voltage V_a of the op-amp will go positive and the diode will conduct, thus establishing a closed feedback path between the op-amp output terminal

FIGURE 10.18 A precision rectifier: (a) circuit diagram, (b) an improved version of the precision half-wave rectifier.

and the negative input terminal. Because of the virtual ground, the output voltage $V_o = V_i$ for $V_i > 0$. Therefore, this circuit is useful to rectify very small signals.

When the input voltage goes negative, the op-amp output voltage V_a tends to follow and go negative. This reverse biases the diode with no current flowing through R . Therefore, the output voltage will be zero. The applied voltage V_i will be dropped across the two inputs of the op-amp. If V_i is more than a few volts, the op-amp might be damaged if input overvoltage protection is not provided. Another problem associated with this circuit is speed. When V_i goes negative, because of large reverse resistance of diode, the op-amp goes to saturation. Getting the op-amp out of saturation generally requires more time resulting in speed degradation.

An improved version of half-wave precision rectifier is shown in Fig. 10.18(b). When V_i goes positive, diode $D2$ conducts and closes the negative feedback loop around the op-amp. The diode $D1$ will be off, and no current flows through $R2$ resulting in zero output voltage. When the input voltage V_i goes negative, the output of the op-amp goes positive. This results in reverse bias for diode $D2$ and forward bias for diode $D1$. The output voltage V_o tracks the input voltage and by appropriately selecting $R1$ and $R2$, V_o can be equal to V_i .

In this circuit configuration, the feedback loop for the op-amp is always closed, thus avoiding the chances of the op-amp moving into saturation.

Precision Full-Wave Rectifier

Figure 10.19 shows the circuit diagram of the precision full-wave rectifier. When V_i is positive, V_F goes negative and V_E goes positive. Therefore, diode $D1$ will be in reverse bias and $D2$ will conduct because of forward bias, and the voltage $V_o = V_i$ for appropriate ratio of $R1$ and $R2$. When V_i goes negative, V_F goes positive and V_E goes negative. This results in diode $D2$ being cut off and $D1$ in conduction with $V_i = V_o$.

FIGURE 10.19 Precision full wave rectifier with a diode placed in the feedback loop.

Precision Bridge Rectifier

The precision bridge rectifier is shown in Fig. 10.20. When the input voltage V_i goes positive, diodes $D1$ and $D3$ are forward biased, the current flows through R , and the output voltage $V_o = V_i$. When the input voltage V_i goes negative, diodes $D2$ and $D4$ are forward biased and V_o follows V_i .

FIGURE 10.20 A precision bridge rectifier.

FIGURE 10.21 Half-wave rectifier and RC filter circuit: (a) schematic diagram, (b) input and output waveforms.

10.2.2 Filter Circuits

Resistor Capacitor (RC) Filters

Consider a diode half-wave rectifier with a filter capacitor C and a resistor R as shown in Fig. 10.21(a). When the input voltage V_i is positive, the diode conducts and charges the capacitor C . When the diode moves into cutoff, the capacitor discharges through the rest of the cycle until the time at which V_i exceeds the voltage at the capacitor. The output waveform for the rectifier with a capacitor is shown in Fig. 10.21(b). The **ripple voltage** V_r is given by

$$V_r \cong V_p / fCR \tag{10.60}$$

where V_p is the peak input voltage and f is the frequency of the input AC voltage. To decrease the ripple voltage, it is necessary to increase the value of RC . The average output voltage is

$$V_o \cong V_p - 0.5V_r \tag{10.61}$$

For full-wave rectifiers, the discharge period is half that of a half-wave rectifier. Therefore, the ripple voltage is given by

$$V_r = V_p / 2fCR \tag{10.62}$$

Filter Circuit with LCR

A full wave rectifier with a choke input L type RC filter (as shown in Fig. 10.22(a)) improves the ripple factor and DC regulation. The ripple voltage across R and C for the first harmonic is given by

$$V_r = V_m / \{3(2)^{\frac{1}{2}}\pi\omega^2LC\} \tag{10.63}$$

where ω is the angular frequency of the input waveform. The ripple voltage is independent of load resistance R .

The DC output voltage is given by

$$V_{DC} = V_m / \pi - R'I_{DC} \tag{10.64}$$

where I_{DC} is the direct DC current

$$R' = 1/6(2)^{\frac{1}{2}}\omega^2LC \tag{10.65}$$

R' is the sum of diode, **transformer**, and inductor resistance.

FIGURE 10.22 Filter circuits: (a) full wave rectifier with L -section filter, (b) multiple L -section filter.

Even without load, a resistance is added across the output, and this is called a *bleeder resistance*. The bleeder resistance performs the following functions:

- It bleeds the charge from the filter capacitor when the rectifier is turned off.
- It improves the regulation.
- It acts as a minimum load, preventing excessive voltage development in the filter inductance.

The ripple voltage is inversely proportional to inductance L and capacitance C . This discussion is valid when continuous current flows through the inductor. The current through the inductor is continuous if the inductance is greater than the critical inductance L_C , where L_C is greater than or equal to $R/(3\omega)$.

Filtering can be improved by cascading more energy storing elements L and C as shown in Fig. 10.22(b). The load voltage V_o is reduced due to the DC voltage drop across the inductor. This can be minimized by reducing the resistance associated with the inductors.

Defining Terms

Diode: A semiconductor device made up of a p and n type semiconductor junction.

Filter circuits: The circuits used to filter out AC ripple from DC.

Rectifier: A device that converts AC signals to DC.

Ripple voltage: The AC voltage associated with the DC in a rectifier circuit.

Transformer: A device used to step up or step down the AC voltage and to isolate mains supply from the rectifier circuit.

10.3 Voltage Regulation

Melissa S. Mattmuller

10.3.1 Introduction

An almost universal requirement of electronic systems is a regulated source of DC voltage. Whether the DC power originates with a battery or has been converted from widely available AC power, a voltage regulator is usually required to provide a steady DC voltage for a variety of load conditions. Figure 10.23 illustrates the place of voltage regulation in a typical power supply.

FIGURE 10.23 A typical power supply.

Although one may still find it useful to design and construct voltage regulators with discrete devices, today's precise but robust, bipolar monolithic voltage regulators make design a much easier task. They are available in increasing variety in both high- and low-power products. The low-power products include low voltage output regulators to drive low voltage (3–3.3 V) and very low voltage (sub 3.0 V) digital components.

10.3.2 Types of Voltage Regulators

Voltage regulators can be categorized as *discrete component circuits* or as *ICs*, as illustrated in Fig. 10.24. Examples of simple voltage regulators comprising discrete components open this chapter, but primarily IC regulators will be covered. Today a wide variety of IC regulators is available for almost any application or environment. IC voltage regulators are increasingly available for very low-power, high-power, and low-dropout applications. Also, many desirable features such as high precision and self-protection are common.

FIGURE 10.24 Voltage regulator groupings.

IC voltage regulators are usually divided into two categories, *linear* and *switching*. There are five basic categories of **linear voltage regulators**: positive adjustable, negative adjustable, fixed output, tracking, and floating. Any of these may be available with other attributes such as three-terminal packaging or **low dropout voltage** features. Some of the more popular linear IC regulators are summarized in [Sec. 10.3.3](#) and references will guide the reader to more expansive literature.

Switching regulators have advanced significantly in the areas of size and weight reduction and improved efficiency, and they have the ability to perform voltage step-up, step-down, and voltage-inverting functions. Switching regulators are discussed in the [Sec. 10.3.6](#).

10.3.3 Selecting a Voltage Regulator

In past years designing a power supply could become a tricky matter. Designers usually had to construct their own voltage regulators either of discrete components or using positive fixed regulators as building blocks. But with today's wide variety of IC voltage regulators it is likely that a single device may satisfy most design requirements. This is not just a matter of convenience, but it is important for reliability and maintainability reasons to keep the component count low. The following guidelines may offer some assistance in making the build/buy decision.

- If the load current is very low (50 mA or less) then either build, a simple zener diode may provide sufficient regulation, as shown in [Fig. 10.25](#), or buy, for example, a 79 series in a TO-92 case.
- If the current load is less than one ampere then build. The two discrete voltage regulators (one op amp and the other transistor) discussed in this chapter are useful samples. Note that low-current IC regulators may be available to do the job just as easily.

FIGURE 10.25 Simple zener regulator.

Or

- If a load current level from 50 mA to a few amperes is desired then buy. The designer may want to look for a linear IC regulator. As mentioned in the previous section, there are five basic categories of linear regulators: positive adjustable, negative adjustable, fixed output, tracking, and floating.
- If load currents of more than one ampere range are required then buy. The designer may want to investigate switching regulators, especially if the application requires high-current output at low voltages such as computer applications, or if efficiency, size, and weight are of primary concern. Recognize, however, that they are a source of high-frequency electrical noise. Switching power supplies are discussed extensively in [Sec. 10.3.6](#).

Selecting a Linear IC Voltage Regulator

Generally regulators are chosen for use as their names would indicate: fixed positive regulators are used to generate the specified, rated positive voltage. Negative regulators, however, can be connected to provide positive voltages and positive fixed regulators can be utilized to make variable voltage regulators, or tracking regulators, or switching regulators, or even current regulators. The application notes contained in data books can be very useful for exploring the possible uses for the various regulators.

When the purpose of the regulated output is to provide $+/-$ DC bias voltages as for an op amp, then a *dual, bipolar tracking regulator* is needed. In this way, not only will the positive and negative output voltages be symmetric but the midpoint of the signals will be at ground potential.

Many varieties of linear IC regulators are available with low dropout voltage requirements. The **dropout voltage** is the input-to-output voltage differential below which regulation is not provided. Thus, a low dropout voltage regulator may provide, for example, a regulated output voltage of 5 V for an input voltage of only 5.6 V. This is a considerable improvement from the earlier regulators requiring 2–3 V of headroom. Low dropout voltage regulators are available and are especially useful for battery powered systems where it is desired to extend the useful battery life. Two examples include automotive and laptop computer applications in which memory needs to be maintained for very low battery conditions.

One of the most popular IC regulator products is a *three-terminal regulator*. The output is either fixed or adjustable, and both categories are available in a variety of positive or negative output voltages and current ranges, as well as some with low dropout voltage requirements. Although it is not a difficult matter to make an adjustable voltage regulator from a fixed, three-terminal IC by providing external circuitry, three-terminal adjustable output regulators are readily available and easy to set.

Three-terminal regulators are frequently used as on-card regulators. That is, an unregulated power supply voltage is provided to each printed circuit board in a system, and a three-terminal voltage regulator provides the voltage for the circuits on that card, thereby eliminating coupling effects of a centralized power supply system.

The three-terminal voltage regulator is a popular choice for the following reasons:

- They are easy to use.
- They are robust with regard to their internal overcurrent and thermal protection.

TABLE 10.1 Some Popular IC Voltage Regulators

Output Current, A	Device	Description	V_{out}
5.0	LM338	3-term adj pos	1.2 to 32
3.0	LM350	3-term adj pos	1.2 to 32
1.5	LM317	3-term adj pos	1.2 to 37
0.5	LM317	3-term adj pos	1.2 to 37
3.0	LM333	3-term adj neg	-32 to -1.2
1.5	LM337	3-term adj neg	-32 to -1.2
3.0	LM323	3-term fxd pos	5
1.0	LM340	3-term fxd pos	5, 12, 15
3.0	LM345	3-term fxd neg	-5
1.5	LM320	3-term fxd neg	-5, -12, -15
1.5	LM330	Ldv ^a 0.6 V, 3-term fxd pos	5
0.5	LM2937	Ldv ^a 0.82 V	5, 8, 10, 12, 1, 5
0.5	MC33267	Ldv ^a 0.6 V or lower fxd pos	5 V
0.1	LM2951	Ldv ^a 0.38 V	5, or adj (1.24 to 29)
0.1	MC1468/1568 8	+/-15 V dual tracking	+/-15 V
0.15	MC1723	positive or negative adj	2 to 37

^aLow dropout voltage.

- Fixed output regulators require no external circuitry (except, perhaps, two bypass capacitors) and the adjustable regulators may require as little as two external resistors to set the output.
- A wide variety of output currents and voltages are readily available at a low cost.

IC regulators are very versatile so regulator design can become a complicated matter and is considered to be beyond the scope of this work, but there are a few guidelines that can aid in the decision (Motorola, 1993).

- Determine which type of voltage regulator is best suited for the application of interest, based on the descriptions given previously. For example, negative, variable output, low dropout voltage, etc.
- Determine which products of this description meet or exceed the requirements for **line regulation**, **load regulation**, temperature coefficient of output voltage TC of V_O , and operating ambient temperature range.
- Select application circuits meeting the requirements for output current, output voltage, or any special features desired. From here, the designer may consider size, cost, and complexity.
- Because load current may be altered dramatically with the use of outboard, current-boosting transistors one need not be limited by specified output current. If possible the designer should choose a product whose output current gives plenty of margin, because output current performance will drop off as the temperature rises. This needs to be balanced with the fact that the rated maximum current may be delivered, if only for a time, in the event that the load is shorted.

Other selection criteria relate to individual device specifications. Product specifications and selection criteria are discussed in [Sec. 10.3.6](#). Table 10.1 shows a small subset of the products currently available on the market. It is intended merely to illustrate the variety, not be a representative or complete market description.

10.3.4 Two Discrete Voltage Regulator Examples

Simple Op Amp Regulator

[Figure 10.26](#) shows a stable, relatively simple voltage regulator, this one using a noninverting operational amplifier to provide the negative feedback control (Jacob, 1982, 80). The op amp buffers the voltage from the zener diode, placing a negligible load on the zener, allowing it to operate at a single, fixed point. The

FIGURE 10.26 An op amp voltage regulator.

zener diode voltage then is very stable and the zener is not subjected to large swings in current and so one may select a low-power, highly precise reference diode.

The output voltage is altered by adjusting R_f

$$V_{LOAD} = V_z(1 + R_f/R_i)$$

The peak of the input voltage V_{DC} should be kept below the maximum supply voltage for the op amp (look for an op amp with a high supply voltage rating). Also, V_{DC} must always be at least 2 V above the output (load) voltage. This is necessary to keep the op amp out of saturation and to keep the zener diode in its breakdown region.

Notice that the minimum output voltage is V_z (when R_f is shorted), and so the zener voltage should be chosen to be smaller than the lowest output needed.

The op amp provides the base current that is then multiplied by the β of the **pass transistor** (so called because all of the load current is passed through it) to produce load current. The β of the transistor is determined by

$$\beta \geq \frac{I_{load}}{I_{op\ amp\ max}}$$

Also, the transistor must be able to dissipate the power produced by

$$P_Q = (V_{DC} - V_{load})I_{load}$$

where

V_{DC} = DC output voltage from the filter

V_{load} = load DC voltage

I_{load} = load DC current

A power metal oxide semiconductor field effect transistor (MOSFET) could have been used here. Be sure to carefully review the biasing and headroom requirements.

Second Discrete Voltage Regulator Example

The circuit of Fig. 10.27 shows how the highly stable zener voltage, or reference voltage, can be amplified using a negative-feedback amplifier to get a higher output voltage while retaining the temperature stability provided by the zener diode. A **Darlington pair** is used for the pass transistor for greater current gain. Here a voltage divider (R_1 and R_2 , chosen to draw minimal current from the load) is used to feed a portion of the output voltage back to the base of Q_1 controlling its collector current. This control provides the regulation from the source. Recall that the input to this voltage regulator was an AC voltage source that has been rectified and filtered but probably had considerable **ripple**.

FIGURE 10.27 A discrete voltage regulator.

The closed-loop gain of this circuit A_{CL} , can be expressed as

$$A_{CL} = \frac{R_1}{R_2} + 1$$

and

$$V_{OUT} = A_{CL}(V_z + V_{BE})$$

Once the potentiometer is adjusted for the desired V_{OUT} , this output voltage remains constant despite changes in line voltage or load current.

The designer must check the power dissipated by the pass transistor (the Darlington transistor) to determine the heat sinking requirements.

Discrete Voltage Regulator with Current Limiting

Notice that the two voltage regulators discussed previously provide no short-circuit protection. In the event that the load terminals are shorted together, the pass transistor(s) and possibly other components could be destroyed. For this reason robust designs include some form of **current limiting**. A simple method of current limiting is illustrated in Fig. 10.28 but **fold-back current limiting** is more desirable because it reduces the power dissipated by reducing both the load current and voltage. This technique will be discussed in more detail in the next section.

FIGURE 10.28 A voltage regulator with current limiting.

Notice the resistor marked R_{sense} . It is called a *current sensing* resistor and is very small in value. If the current through it is great enough, it will provide the base emitter of Q_3 with enough voltage to turn it on. Then Q_3 collector current will flow through R_3 and act to decrease the base voltage to Q_2 . Since the transistor Q_2 is an emitter follower, decreasing its base voltage causes a decrease in the output voltage.

Now the maximum current that flows even for a shorted load I_{SL} is

$$I_{\text{SL}} = V_{\text{BE}}/R_{\text{sense}}$$

and the load for which regulation is lost can be estimated by

$$R_{\text{min}} = V_{\text{REG}}/I_{\text{SL}}$$

where V_{REG} is the regulated output voltage of the circuit.

10.3.5 IC Regulator Examples

Four examples are included here, a three-terminal standard application adjustable voltage regulator, a digital-to-analog controlled regulator, a current boosting configuration for a three-terminal positive regulator, and a positive or negative regulator with foldback current limiting.

Figure 10.29 shows a standard configuration for a positive or negative, three-terminal, adjustable voltage regulator.

FIGURE 10.29 Configuration for an adjustable output three-terminal regulator.

The input capacitor (usually on the order of 0.1- μF disc or a 1- μF solid tantalum) is required if the regulator is more than 4 in. from the power supply filter, and the output capacitor is generally used to improve transient response performance, perhaps for stability (frequently 1- μF solid tantalum or 25- μF aluminum electrolytic).

Sometimes a bypass capacitor (10 μF) will be connected between the adjustment terminal and ground to improve **ripple rejection** and noise. Generally solid tantalum capacitors are used because of their low impedance even at high frequencies. If the bypass capacitor is used, then the addition of protection diodes for the bypass and output capacitors is a good idea. The details are left for the databooks.

The output voltage for the positive regulator can be expressed as

$$V_{\text{OUT}} = V_{\text{REG}} \times [(1 + R_2/R_1) + I_{\text{ADJ}}R_2]$$

and for the negative regulator

$$V_{\text{OUT}} = -V_{\text{REG}} \times [(1 + R_2/R_1) + I_{\text{ADJ}}R_2]$$

The $I_{\text{ADJ}}R_2$ term is frequently left out because $I_{\text{ADJ}}R_2$ is on the order of 10 mV.

Digital-to-Analog (D/A) Applications for Voltage Regulator

Figure 10.30 shows a different use of a three-terminal voltage regulator (Jacob, 1982). Here the three-terminal regulator has replaced the transistor of the previous circuits, and the D/A effectively replaces the zener diode. By using high quality but relatively inexpensive parts, the designer can acquire the robust power of a voltage regulator with the accuracy and resolution of a D/A converter.

FIGURE 10.30 D/A controlled voltage regulator.

Notice the regulator in this voltage follower feedback loop. The closed-loop gain of this circuit is still given by

$$A_{CL} = 1 + \frac{R_F}{R_I}$$

thus omitting the feedback resistors R_F and R_I and feeding the regulated V_{OUT} back to the inverting input of the CMOS op amp gives $V_{OUT} = V_{D/A}$.

IC Three-Terminal Voltage Regulator Current Boosting

More current may be required of a power supply than is provided by the chosen IC regulator. Recall that the maximum power dissipated by the IC regulator (only available if appropriate heat sinking is provided) can be expressed as

$$P_{Dmax} = (V_{IN} - V_{REG})I_{Lmax}$$

and is called out in the device specification sheet. If a load is expected to draw close to the maximum, or if the heat sinking is in question, the regulator design should include a current boosting capability to prevent the IC device from entering thermal shutdown.

The output current capability may be increased through the use of a supplementary current boosting transistor. An example is shown in Fig. 10.31. This supplemental transistor will handle the current that the IC is not capable of passing. It is activated by the appropriate choice of a sensing resistor R_s . When the voltage across the sensing resistor is great enough to turn on the supplemental transistor, it acts to supply the additional current required of the load. This particular configuration provides output current to 5.0 A.

FIGURE 10.31 A three-terminal IC regulator with current boosting.

FIGURE 10.32 Current limiting schemes: (a) simple current limiting, (b) foldback current limiting.

IC Regulator Over Current Protection Schemes

Unlike discrete voltage regulators, IC voltage regulators routinely provide internal protection against overpower situations in the way of thermal shutdown. This means the device shuts off current from the internal pass transistor until it cools sufficiently and resets. If the load attempts to draw too much current, thermal shutdown would occur, the device would eventually cool, operation would resume with the uncorrected load, and the cycle would repeat.

Recall that with simple current limiting, discussed in Sec. 10.3.4, the current was held constant at some maximum value as the load resistance fell below R_{min} (the minimum value of load resistance for which regulation is provided). This is illustrated in Fig. 10.32(a). Although this offers some degree of protection for the pass transistor and diodes, it is still dissipating much power unnecessarily. This is especially undesirable because heat is usually responsible for variation and failure in voltage regulator circuits.

A preferable situation would be to design for foldback current limiting. This would prevent the high-power dissipation and cycling and simply cut back the load current and load voltage until the situation could be corrected. Figure 10.32(b) illustrates graphically the effect of foldback current limiting. Notice that foldback current limiting can actually bring the current down to a *fraction* of its maximum value.

Figure 10.33 shows a partial schematic of the 723 positive or negative adjustable voltage regulator, shaded. External circuitry to provide foldback current limiting is shown. Notice that as the load current rises it develops enough voltage across R_{SC} to turn on the current limit transistor Q_2 . When Q_2 is activated it draws current from Q_1 . Q_1 eventually turns off decreasing I_{LOAD} and in turn decreasing V_1 and V_{LOAD} . A difference in potential develops between the base and emitter of Q_2 making Q_2 conduct more; hence

FIGURE 10.33 A 723 voltage regulator configured for foldback current limiting.

Q_1 conducts harder. This continues until the load voltage is almost zero and V_1 is only large enough to maintain V_{sense} (about 0.5 V) across the Q_2 base-emitter junction. Notice both V_1 and $I_{\text{LOAD}} (= I_{\text{SC}})$ have been lowered.

$$I_{\text{SC}} = \frac{(R_3 + R_4)(V_{\text{sense}})}{R_{\text{SC}} \times R_4}$$

and the point at which this foldback begins, called the *knee current*, may be found as

$$I_{\text{knee}} = \frac{(R_3 + R_4)V_{R4}}{R_{\text{SC}} \times R_4} - \frac{V_{\text{LOAD}}}{R_{\text{SC}}}$$

10.3.6 Reading the Voltage Regulator Specification Sheet

This section will be discussed in terms of an example, the LM317. First, it is important to realize that the industry part number or alphanumeric descriptor of the IC regulator is not unique to the manufacturer. The LM317, being a popular three-terminal adjustable regulator is found in several manufacturer's data books. It certainly could be the case, however, that a particular regulator is supplied by only one manufacturer. Some manufacturers provide a cross reference guide in the data book to aid in substitution or replacement decisions.

The regulator specification sheet starts with a general description of the part. Here the designer can quickly determine the applicability of the part to a particular need. Looking, for example, at the Motorola linear/interface ICs databook the following information in the general description of the LM317 can be obtained:

- The only available package is T-suffix Case 221A, a plastic body case with a tab mount.
- The upper limit on output current I_{OUT} is in excess of 1.5 A (assuming proper heat sinking; this is an implicit assumption throughout the specification sheets).
- Additional features are present such as internal thermal overload protection and the fact that short circuit current limiting is constant with temperature
- The adjustable range on output voltage is 1.2–37 V.
- Usually a standard application circuit is provided. This circuit shows exactly what resistors and capacitors are needed to use the regulator in its most basic configuration. This would be the circuit of choice if the part met the requirements of the designer without any kind of special features such as output current boosting or foldback current limiting. Frequently, these variations are detailed in a section on applications.

The maximum ratings include the following:

- Extremes in junction operating temperature T_J are specified as 0–125°C. (This specification sheet shows another IC is available with junction operating temperature range –40–125°C.) See [Sec. 10.3.7](#) for information on how to determine the junction operating temperature.
- Maximum input-output voltage differential, $V_I - V_O$, is the maximum instantaneous difference between the *unregulated* input and the output pin,
- Maximum power dissipation, $P_D = (V_{\text{IN}} - V_{\text{OUT}})I_{\text{OUT}}$ cannot be exceeded without risking damage to the regulator. The allowable combinations of output current and voltage differentials are sometimes referred to as *safe operating area* (SOA).
- Storage temperature range.

Finally, a table of electrical characteristics contains approximately 15 parameters and lists underlying assumptions regarding these characteristics. Of particular interest are as follows:

- Percent line and load regulation, which indicate how well the regulator does its job given changes in line voltage and load current, respectively.

- Minimum and maximum load current. Note that maximum output current may never be achieved if proper heat sinking is not provided.
- Ripple rejection in decibels. This specification is for the line regulation, indicating the regulator's attenuation of the line voltage ripple. It is predicated on particular AC input signal levels and frequencies with a specified value of bypass capacitor.
- Thermal resistance for junction case θ_{JC} and thermal resistance for junction to ambient, θ_{JA} . (This assumes no heat sink is used). These two values are important for determining heat-sink requirements.

10.3.7 Voltage Regulator Packaging and Heat Sinking

Voltage regulators dissipate a significant amount of power as heat. This heat, generated at the IC junction, can, if not carried away, impair performance or destroy the device. (Remember performance specifications assume the use of proper heat sinking.) Data sheets indicate the maximum safe junction temperature (T_J) and the user must verify that it is not exceeded. The following relationship is used for this verification:

$$T_J = T_A + P_D \theta_{JA} \quad (10.66)$$

where

T_J = junction temperature, °C

T_A = ambient air temperature in close proximity to case, °C

P_D = power dissipated by device, W

θ_{JA} = thermal resistance from junction to ambient air, °C/W (see Fig. 10.34)

Note: if no heatsink is used this will come from the specification sheet; otherwise, it is determined as

$$\theta_{JA} = \theta_{JC} + \theta_{CS} + \theta_{SA} \quad (10.67)$$

where

θ_{JC} = thermal resistance from junction to case, °C/W

θ_{CS} = thermal resistance from case to heat sink, °C/W

θ_{SA} = thermal resistance from heat sink to ambient, °C/W

The device data sheets provide information regarding the following parameters: case options, see Fig. 10.35 for case types; maximum operating junction temperature $T_{J(\max)}$ (°C); thermal resistance junction to ambient (no heat sink) θ_{JA} ; and thermal resistance junction to case θ_{JC} .

To quickly check the junction temperature [Eq. (10.66)] use the θ_{JA} value from the data sheet and the calculated power dissipated for the circuit specific regulator application. (Note: the power calculation may be a simple matter, as in the case of a three-terminal voltage regulator [$(V_{IN} - V_{OUT}) \times I_{OUT}$]; or it may be more difficult, as in the case of a pulsed input or highly reactive loads. This is considered to be beyond the scope of this work.) If the maximum ambient temperature is not known, it is best to measure it. If that is not possible, an estimate may be made considering the operating environment. In open air, 50°C is not a bad number; but in a closed encasement with other electronics, 60°C may be more reasonable. Automotive and some plant environments are more severe (70–75°C).

If the calculated junction temperature exceeds the $T_{J(\max)}$ of the data sheet, notice from Eq. (10.66) that it may be lowered by lowering the ambient temperature (T_A), lowering the power dissipated by the IC, or lowering the junction to ambient thermal resistance (θ_{JA}). Although a lower ambient temperature can be

FIGURE 10.34 Contributors to thermal resistance.

FIGURE 10.35 Available regulator package styles. (Source: Courtesy of National Semiconductor.)

realized through the use of ventilation, a fan, or other cooling techniques, these come at the expense of added cost and noise and may be beyond the scope of the designer. Lowering the operating power may not be an option either, but choosing an IC rated for a higher current may offer a lower θ_{JA} . This decision needs to be weighed against circuit requirements and the short-circuit protection offered by a lower rated IC. The first choice should be simply lowering θ_{JA} through use of a heat sink.

Once the need for a heat sink has been established, the designer can use Eqs. (10.66) and (10.67) to determine the maximum value of θ_{SA} . Equation (10.67) indicates that θ_{JA} is the sum of three thermal resistances: θ_{JC} , θ_{CS} , and θ_{SA} . The first, θ_{JC} , is provided in the device data sheet and estimates of θ_{CS} are provided in Table 10.2. Using these two values one may determine the necessary value of θ_{SA} and use this to select one of the commercially available heat sinks available. A sampling of θ_{SA} value is provided in Table 10.3.

A partial summary of heat sink θ_{SA} values is provided for a variety of manufacturers in Table 10.3.

TABLE 10.4 Voltage Regulator Troubleshooting Guidelines

Symptoms	Design Area to Check
Regulator oscillates:	Layout Compensation capacitor too small Input leads not bypassed External pass element parasitically oscillating
Loss of regulation at light loads:	Emitter–base resistor in PNP type boost configuration too large Absence of 1.0-mA minimum load Improper circuit configuration
Loss of regulation at heavy loads:	Input voltage or voltage differential too low External pass element gain too low Current limit too low Line resistance between sense points and load Inadequate heat sinking
IC regulator or pass element fails after warm-up or at high T_A :	Inadequate heat sinking Input voltage transient $V_{in(max)}$, V_{CEO}
Pass element fails during short circuit:	Insufficient pass element ratings SOA, $I_{C(max)}$ Inadequate heat sinking
IC regulator fails during short circuit:	IC current or SOA capability exceeded Inadequate heat sinking
IC regulator fails during power-up:	Input voltage transient $V_{in(max)}$ IC current or SOA capability exceeded as load (capacitor) is charged up
IC regulator fails during power-down:	Regulator reverse bias
Output voltage does not come up during power-up or after short circuit:	Out polarity reversal Load has latched up in some manner (usually seen with op amps, current sources, etc.)
Excessive 60 or 120 Hz output ripple:	Input supply filter capacitor ground loop

Defining Terms

Current limiting: A technique used to provide short-circuit protection. Typically a current sensing resistor is used to turn a transistor on and off that in turn is used to provide negative feedback to hold the output current at a high but safe value.

Darlington pair: A configuration of two transistors, the emitter of one feeding the base of the other, used to increase gain.

Dropout voltage: The input-output voltage differential at which the circuit ceases to regulate against further reductions in input voltage.

Foldback current limiting: A more sophisticated type of short-circuit protection in which the output current is cut dramatically back, not just held constant.

Line regulation: The percent change of output voltage for a change in input supply voltage.

Linear regulator: Voltage regulator using a transistor operating in the linear region.

Load regulation: The percent change of output voltage for a change in output current.

Low dropout voltage: Refers to a class of voltage regulators designed to operate at especially low input-output voltage differentials.

Pass transistor: A transistor used to boost the load current, so-called because all of the load current passes through it.

Quiescent current: That portion of the current not being supplied to the load.

Ripple: The fluctuation on the DC input signal to the voltage regulator, caused by the charging and discharging of the capacitor input filter.

Ripple rejection: A measure of how well the regulator attenuates the input ripple, usually specified in decibels.

Switching regulator: A voltage that operates by using a saturating switching transistor to chop an unregulated DC voltage. This chopped voltage is then filtered. The duty cycle of the switching transistor is varied to provide regulation of the output voltage.

Voltage regulator: That part of a power supply that accepts a filtered DC voltage and reduces, if not eliminates, the ripple, providing a continuous, smooth DC signal.

Circuit Cellar INK BBS @ 203/871-1988.

The trade journal *Power Conversion and Intelligent Motion (PCIM)* is another source of relevant information regarding power supplies.

10.4 Switching Power Supplies

Robert J. Hofinger

10.4.1 Introduction

Efficient conversion of electrical power is becoming a primary concern to electrical product manufacturers and to users alike. Switching supplies not only offer much higher efficiencies to the user but also greater flexibility to the product manufacturer. Recent advances in semiconductor, magnetic, and passive component technologies are making the switching power supply a popular choice in the power conversion arena today.

10.4.2 Linear Versus Switching Power Supplies

Historically, the linear **regulator** was the primary method of creating a fixed, regulated output voltage. It operated on the principal of inserting a power regulating transistor between the input voltage and the output voltage. By comparing the output voltage against a fixed reference voltage, a signal could be produced that would be proportional to the difference between these two inputs and that could then be used to control the power-regulating transistor. The power regulating transistor operated in a continuous conduction mode, dissipating large amounts of power at high-load currents, especially when the input-output voltage difference was large.

The power regulating transistor in a switching power supply operates in either the cutoff or saturated mode of operation. The switching regulator regulates by varying the on-off duty cycle of the power regulating transistor. Therefore, there is relatively little power dissipation in it. Also, because the switching regulator operates at a high frequency (much higher than the line frequency), the filtering elements used in the power supply can be made small, lightweight, low in cost, and very efficient.

Since the input-output voltage difference has very little effect on its operation and efficiency, very poorly filtered DC input voltage sources can be used, thereby eliminating the large and expensive line-frequency filtering elements.

Common Topologies

A **topology** is the arrangement of the power semiconductors, their magnetic storage elements, and the filtering elements used to make up a power supply. Each topology has its own merits and deficiencies. Each application requires that the designer review the needs and peculiarities of the system and choose the topology that most closely meets those requirements. Some of the factors that determine the suitability of a particular topology to those requirements are as follows:

1. Electrical isolation between the input and the output.
2. The ratio of the output voltage to the input voltage.
3. The magnitude of the voltages that are placed across the power semiconductors.
4. The magnitude of the currents that go through the power semiconductors.
5. A single output vs. multiple outputs.

Electrically isolated regulators are generally used in applications where the input comes from the AC mains, whereas nonisolated regulators are typically used for board-level regulation. The ratio of the output voltage to the input voltage determines whether one is to use a step-up or a step-down approach. There is even a topology that reverses the polarity of the output voltage. Multiple output voltages, which come from the addition of a transformer, can minimize the control circuitry. The control, or regulation of the power supply, however, can be related to only one output; therefore, the cross-regulation requirements should be reviewed to ensure the feasibility of this approach.

The input voltage variations and the output power requirements have an effect on the stresses that the regulator topology places on the power semiconductors. Minimizing these system stresses ensures a long product life (high Mean Time Between Failures—MTBF). At reduced DC input voltages and high output

power, for example, large peak currents are experienced with a resultant high level of electromagnetic interference (EMI) radiation.

A few common topologies are as follows:

- Flyback
- Discontinuous
- Continuous
- Push-pull
- Half-bridge
- Full-bridge

Regulation

In the **pulse width modulated (PWM)** switching power supply, the output voltage is regulated by the ratio of either t_{on} to t_{off} or t_{on} to T , the switching period. The ratio of t_{on} to t_{off} can be varied in two ways. The switching period, $T = t_{on} + t_{off}$, may be kept constant and both t_{on} and t_{off} may be varied, or t_{on} may be kept constant and the switching period T varied in order to achieve the desired t_{off} . A constant switching period or frequency is generally preferred. Output ripple is generally easier to filter if the regulator is operated at a fixed frequency. Also, the noise generated by the switching operation is easier to tolerate if it is synchronous with some fundamental system frequency.

10.4.3 The Buck Regulator

The most elementary step-down regulator is the *buck regulator* whose topology can be seen in Fig. 10.36.

The buck regulator's operation can be seen as having two distinct time periods, which occur when the power switch $Q1$ is closed or is open. When the power switch is closed, referred to as the *on time* (denoted by t_{on}), the input voltage V_{in} is connected by the power switch $Q1$ to the left-hand or input side of the inductor. The output voltage V_{out} , which is held at a relatively constant voltage by the presence of the output capacitor $C1$, is connected to the right-hand or output side of inductor $L1$. Since the input side of the inductor is connected to V_{in} , the diode $D1$ is back biased. During the t_{on} period, there is a constant voltage connected across the inductor; hence, the inductor current ramps upward in a linear fashion, and energy is stored within the magnetic core of the inductor, see Fig. 10.37. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(on)} = ((V_{in} - V_{out}) * t_{on}) / L1 \quad (10.68)$$

During the time when the power switch $Q1$ is open, referred to as the *off time* (denoted as t_{off}), the energy stored within the inductor carries the load's energy requirements, and the current through the inductor starts to fall toward zero. Because of the negative

FIGURE 10.36 The buck regulator topology.

FIGURE 10.37 DC waveforms for a buck regulator.

slope of the current, the voltage across the inductor reverses polarity; hence, the input side of the inductor is clamped to one diode drop below ground by the diode $D1$, which is commonly called the *catch* or *free wheeling* diode. In this analysis, we will neglect the diode drop, that is, set it equal to zero. The inductor current now flows through the diode loop, thus maintaining its continuity and removing the stored energy from the inductor. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(\text{off})} = ((V_{\text{out}} - V_{\text{diode}}) * t_{\text{off}}) / L1 \tag{10.69}$$

The off period ends when the power switch is turned on at a predetermined time, that is, a fixed frequency, or when the output voltage drops below a predefined design value and the power switch is turned on by the feedback control circuitry.

Regulation is accomplished by varying the on-to-off duty cycle of the power switch in order to keep $\Delta i_{L1(\text{on})} = \Delta i_{L1(\text{off})}$ (see Fig. 10.38). Combining the two previous equations, and disregarding the diode drop that becomes negligible, the relationship that describes the regulator's operation is

$$V_{\text{out}} = V_{\text{in}} * t_{\text{on}} / (t_{\text{on}} + t_{\text{off}}) \tag{10.70}$$

Inductor $L1$

From Eq. (10.68)

$$L1 = ((V_{\text{in}} - V_{\text{out}}) * t_{\text{on}}) / \Delta i_{L1(\text{on})} \tag{10.71}$$

and from the definition of

$$t_{\text{on}} = \text{duty cycle} * T$$

where the switching period $T = (t_{\text{on}} + t_{\text{off}})$

$$L1 = ((V_{\text{in}} - V_{\text{out}}) / \Delta i_{L1(\text{on})}) * \text{duty cycle} * T \tag{10.72}$$

The following facts now come into play:

1. The average current of the triangular waveshape of the inductor current is equal to the average (or DC) load current.
2. The inductor current should not be allowed to fall to a zero value. If this were to happen, the inductor current would then go into the negative region. The forward biased diode $D1$ would not allow this. Hence, the inductor current would be held at zero. The load current would have to come entirely from the charge stored in the output capacitor $C1$ and the output voltage would drop.
3. The power switch $Q1$ would now be turned back on, due to the output voltage dropping below its regulation value, or the output voltage would go out of regulation until the end of the fixed switching period T . This would depend on the type of switching system used.

For the sake of simplicity, let us assume that $i_{(L1)}$ will not get to zero. Then

$$\Delta i_{L1(\text{on})} = 2 * i_{(\text{min})} \tag{10.73}$$

and

$$L1 = ((V_{\text{in}} - V_{\text{out}}) / (2 * i_{(\text{min})})) * t_{\text{on}} \tag{10.74a}$$

or

$$L1 = ((V_{\text{in}} - V_{\text{out}}) / (2 * i_{(\text{min})})) * \text{duty cycle} * T \tag{10.74b}$$

FIGURE 10.38 AC waveforms for a buck regulator.

At maximum load current, the peak current should be limited so that the inductor will not saturate. A rule of thumb is to limit the peak inductor current to 1.25 times the maximum output load current. Then

$$\Delta i_{L1(on)} = 0.5 i_{(max)} \tag{10.75}$$

and

$$L1 = ((V_{in} - V_{out}) / (0.5 * i_{(max)})) * t_{on} \tag{10.76a}$$

or

$$L1 = 2 * ((V_{in} - V_{out}) / i_{(max)}) * \text{duty cycle} * T \tag{10.76b}$$

This may take a few iterations to arrive at a comfortable compromise between $i_{(min)}$, $i_{(max)}$, duty cycle (or t_{on}), and the operating period T .

Capacitor C1

After the inductor $L1$ has been selected and the operating parameters have been decided, in accordance with Eq. (10.74) and Eq. (10.76), the next design is the selection of capacitor $C1$.

$C1$ is chosen to provide a maximum ripple voltage at the output node at the maximum load current. This ripple voltage is calculated from the average current per cycle that enters and leaves the capacitor. From

$$v_{(out)max} = \Delta Q / C1$$

where ΔQ is the area under the capacitor current triangle

$$\Delta Q = 1/2 * T/2 * \Delta i_{L1(on)} / 2 \tag{10.77}$$

$$\Delta Q = (\Delta i_{L1(on)} / 8) * T \tag{10.77a}$$

or where $T = 1/f$,

$$\Delta Q = \Delta i_{L1(on)} / (8 * f) \tag{10.77b}$$

therefore,

$$C1 = \Delta i_{L1(on)} / (8 * \Delta v_{(out)max} * f) \tag{10.78}$$

from Eq. (10.73)

$$C1_{min} = i_{min} / (4 * \Delta v_{(out)max} * f) \tag{10.79}$$

10.4.4 The Boost Regulator

The most elementary stepup regulator is the *boost regulator* whose topology can be seen in Fig. 10.39.

The boost regulator's operation can also be broken down into two distinct periods, which occur when the power switch $Q1$ is closed or is open. When the power switch $Q1$ is closed, which is referred to as the on time (denoted by t_{on}), the input voltage V_{in} is placed directly across inductor $L1$. This causes the current to ramp upward in a linear

FIGURE 10.39 The boost regulator topology.

fashion from zero to some peak value and have energy stored within the magnetic core of the inductor proportional to this peak value, see Fig. 10.40. Since the right-hand end of the inductor and the anode of the diode $D1$ are effectively connected to ground, the diode is back biased, and no load current passes through the inductor during this period. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(\text{on})} = (V_{\text{in}} * t_{\text{on}}) / L1 \tag{10.80}$$

When the power switch $Q1$ opens, which is referred to as the off time (denoted by t_{off}), the inductor voltage reverses polarity, and the output side (the right-hand end) flies back above the input voltage and is clamped by diode $D1$ at the output voltage. The current then begins to linearly ramp downward until the energy within the core is completely depleted. This is shown as time t_D . Hence, the output voltage V_{out} must be greater than the input voltage. The current waveform during the downward ramping period t_D , which is shown in Fig. 10.40 is described as

$$\Delta i_{L1(\text{off})} = ((V_{\text{out}} - V_{\text{in}}) * t_D) / L1 \tag{10.81}$$

Regulation is again accomplished by varying the on-to-off duty cycle of the power switch. The relationship that approximately describes its operation is

$$V_{\text{out}} = V_{\text{in}} * (1 + t_{\text{on}} / t_D) \tag{10.82}$$

Note that during the on period, the energy required by the load is being supplied by the capacitor $C1$. Therefore, the amount of energy stored in the inductor $L1$ during the on period must be sufficient not only to carry the load during the off period (denoted by t_{off}), but to recharge the capacitor as well.

As with the buck regulator, the output voltage is varied by varying the ratio of the t_{on} / t_D times. Both t_{on} and t_D may be varied, as long as the sum of the t_{on} and t_D times is less than the switching period. This keeps the boost regulator in what is called the *discontinuous mode of operation*. The switching frequency is then constant, which as discussed earlier, is preferred from a system filtering standpoint.

Capacitor C1

During the time that the power switch $Q1$ is closed, the on time, the output capacitor $C1$ must supply the full load current (Fig. 10.41). While the capacitor is supplying the load current, its voltage will be decreasing at the rate of

$$\Delta V_{\text{out}} / \Delta t = I_{\text{out}} / C1 \tag{10.83}$$

with $\Delta t = t_{\text{on}}$ and $\Delta V_{\text{out}} = V_{\text{ripple}}$

$$C1 = I_{\text{out}} * (t_{\text{on}} / V_{\text{ripple}}) \tag{10.84}$$

from Eq. (10.82)

$$t_{\text{off}} = T * (V_{\text{in}} / V_{\text{out}})$$

FIGURE 10.40 DC waveforms for a boost regulator.

FIGURE 10.41 AC waveforms for a boost regulator.

and defining the switching period

$$T = t_{on} + t_{off} = 1/f$$

therefore

$$t_{on} = (V_{out} - V_{in}) / (f * V_{out}) \tag{10.85}$$

substituting into Eq. (10.84), we get

$$C1 = I_{out} * ((V_{out} - V_{in}) / (f * V_{out} * V_{ripple})) \tag{10.86}$$

Inductor L1

For the moment assume the system to be lossless; therefore

$$P_{in} = P_{out}$$

$$V_{in} * I_{in(avg)} = V_{out} * I_{out(avg)} \tag{10.87}$$

$$I_{in(avg)} = (V_{out} / V_{in}) * I_{out(avg)}$$

from Eq. (10.82)

$$(V_{out} / V_{in}) = 1 + t_{on} / t_{off} = T / t_{off} \tag{10.88}$$

therefore

$$I_{in(avg)} = I_{out(avg)} * T / t_{off} \tag{10.89}$$

The input current waveform (t_{on}) is a triangular waveform with the $I_{in(avg)} = 1/2 I_{pk}$ since

$$V_{in} = L \Delta I_L / \Delta t \quad \text{or} \quad L = V_{in} \Delta t / \Delta I_L$$

To keep the I_L waveform continuous

$$I_{in(avg)min} = 1/2 I_{pk(min)} \quad \text{or} \quad \Delta I_{L1} = 2 * I_{in(avg)min} \tag{10.90}$$

therefore

$$L1 = V_{in} * t_{on} / (2 * I_{in(avg)min}) \tag{10.91}$$

from Eq. (10.85)

$$t_{on} = (V_{out} - V_{in}) / (f * V_{out})$$

therefore

$$L1 = 1/2 * (V_{in} / V_{out})^2 * ((V_{out} - V_{in}) / (I_{out} * f)) \tag{10.92}$$

10.4.5 The Buck/Boost Regulator

The buck/boost regulator shown in the topology in Fig. 10.42 accepts a DC voltage input and provides a regulated output voltage of opposite polarity.

The output voltage of this regulator is the reverse polarity of the input voltage. When the power switch Q1 is closed, which is referred to as the on time (denoted by t_{on}), the input voltage V_{in} is connected across the inductor L1, and thus the current

FIGURE 10.42 The buck/boost regulator topology.

FIGURE 10.43 DC waveforms for a buck/boost regulator.

through the inductor ramps upward in a linear fashion, and energy is stored within the magnetic core of the inductor, see Fig. 10.43. The change in inductor current during this time is described by the relationship

$$\Delta I_{L1(\text{on})} = (V_{\text{in}} * t_{\text{on}}) / L1 \quad (10.93)$$

The power switch $Q1$ is then opened, which is referred to as the off time (denoted by t_{off}) and the inductor voltage flies back above the input voltage and is clamped by the diode $D1$ at the output voltage V_{out} . The current then begins to linearly ramp downward for a time t_D , the time that the diode $D1$ conducts, until the energy within the magnetic core is completely depleted. Its waveform is shown in Fig. 10.43. The change in inductor current during this time is described by the relationship

$$\Delta I_{L1(\text{off})} = (V_{\text{out}} * t_D) / L1 \quad (10.94)$$

The relationship between the output voltage V_{out} and the input voltage V_{in} can be obtained by combining Eq. (10.93) and (10.94)

$$V_{\text{out}} = V_{\text{in}} * (t_{\text{on}} / t_D) \quad (10.95)$$

Since the DC output current I_{out} is equal to the average current through the diode $D1$

$$I_{\text{out}} = I_{L1(\text{pk})} / 2 * (t_{\text{on}} + t_D) / T \quad (10.96)$$

therefore

$$I_{L1(\text{pk})} = 2 * I_{\text{out}} * T / (t_{\text{on}} + t_D)$$

From Eq. (10.96), we see that when I_{out} is a maximum, t_D is equal to t_{off} , or

$$T = t_{\text{on}} + t_D \quad (10.97)$$

hence

$$I_{L1(\text{pk})} = 2 * I_{\text{out}(\text{max})} \quad (10.98)$$

The simplest way to regulate the buck/boost system is to establish a fixed peak current $I_{L1(\text{pk})}$, determined by $I_{\text{out}(\text{max})}$, through the inductor, thereby allowing the on time t_{on} to vary inversely with changes in the input voltage and the sum of $t_{\text{on}} + t_D$ to vary directly with changes in the output current (see Fig. 10.44).

FIGURE 10.44 AC waveforms for a buck/boost regulator.

Inductor L1

From Eqs. (10.93), (10.94) and the relationship

$$\Delta I_{L1(on)} = I_{L1(pk)} = 2 * I_{out(max)} \tag{10.99}$$

when

$$t_{on} + t_D = T = 1/f$$

$$L1 = (V_{in} * V_{out}) / (2 * I_{out(max)} * f) \tag{10.100}$$

Capacitor C1

During the time that the diode is not conducting, the output current has to come from the capacitor C1. From

$$\Delta v_{(out)max} = 1/C1 * I * \Delta t$$

where

$$\Delta t = T - t_D$$

$$I = I_{out(max)}$$

$$\Delta v_{(out)max} = V_{ripple} \tag{10.101}$$

$$V_{ripple} = 1/C1 * I_{out(max)} * (T - t_D)$$

or

$$C1 = [I_{out(max)} * (T - t_D)] / V_{ripple} \tag{10.102}$$

10.4.6 The Flyback Regulator

The topology of the *flyback regulator* can be seen in Fig. 10.45.

The operation of the flyback regulator, also called the *transformer coupled boost regulator*, can also be broken down into two distinct periods, where the power switch Q1 is closed or open. When the power switch is closed, which is referred to as the on time (denoted by t_{on}) the input voltage source is placed directly across the primary of the switching transformer. This causes the primary current to linearly ramp upward from zero and is described by

FIGURE 10.45 The flyback regulator topology.

$$\Delta i_{PRI(on)} = (V_{in} * t_{on}) / L_{PRI} \tag{10.103}$$

FIGURE 10.46 DC waveforms for a flyback regulator.

Because the polarity of the output voltage of the secondary winding of the switching transformer reverse biases the diode $D1$, no secondary current can flow. (On transformers are marked with a dot; the winding ends that are similarly marked are all positive at the same time, i.e., of the same polarity.) Therefore, all the energy during the on time is stored within the transformer primary inductance. The amount of energy stored during the t_{on} period is denoted by

$$W = 1/2 * L_{PRI} * I_{PRI(pk)}^2 \tag{10.104}$$

The power switch $Q1$ then turns off and the secondary of the switching transformer flies back above the output voltage and is clamped by diode $D1$ at the output voltage. The energy stored within the transformer is then transferred to the secondary circuit. The secondary current then begins to linearly ramp downward until the energy within the transformer core is completely depleted. This is shown as t_D in Fig. 10.46 (see also Fig. 10.47) and is described as

$$\Delta i_{SEC(on)} = (V_{out} * t_D) / L_{SEC} \tag{10.105}$$

From Faraday's Law

$$v = N \Delta\phi / \Delta t$$

FIGURE 10.47 AC waveforms for a flyback regulator.

When Q1 is closed, t_{on} , the transformer flux builds up an amount $\Delta\phi = (V_{in} * t_{on})/N_P$. Now when Q1 is opened, the voltage across the winding reverses and causes $\Delta\phi/\Delta t$ to reverse. If the desired output voltage across N_S is V_{out} , then the transformer flux decreases an amount $\Delta\phi = (V_{out} * t_D)/N_S$.

In the steady state, the decrease in flux $\Delta\phi$ when Q1 is open must equal the increase in flux when Q1 is closed, for otherwise there would be a net change in flux per cycle and the flux would continue to build up to saturation. Hence

$$(V_{in} * t_{on})/N_P = (V_{out} * t_D)/N_S \quad (10.106)$$

$$V_{out} = V_{in} * (N_S/N_P) * (t_{on}/t_D) \quad (10.107)$$

Regulation is accomplished by varying the on-to-off duty cycle of the power switch. Care must be taken so that the voltage across the transistor Q1 when it is turned off does not exceed its maximum voltage rating. The maximum voltage that Q1 is subjected to is the input DC voltage plus the voltage coupled back from the secondary winding into the primary winding by the transformer turns ratio. The maximum voltage is

$$\begin{aligned} V_{Q1(max)} &= V_{in} + V_{out} * (N_P/N_S) \\ &= V_{in} + V_{in} * [(N_S/N_P) * (t_{on}/t_D) * (N_P/N_S)] \\ V_{Q1(max)} &= V_{in}(1 + (t_{on}/t_D)) \end{aligned} \quad (10.108)$$

Transformer T1

The switching transformer for the flyback regulator is in reality two inductors linked together by a common magnetic core. Therefore, in selecting the transformer, the dominating parameters are the primary and secondary inductances.

For the primary inductance, from Eq. (10.104)

$$W = 1/2 * L_{PRI} * I_{PRI(pk)}^2$$

since energy is equal to power \times time

$$W = P_{out} * T = V_{out} * I_{out} * T$$

where the switching time

$$T = 1/f$$

therefore

$$L_{PRI} = (2 * V_{out} * I_{out}) / (f * I_{PRI(pk)}^2) \quad (10.109)$$

and

$$L_{SEC} = (2 * V_{out} * I_{out}) / (f * I_{SEC(pk)}^2) \quad (10.110)$$

Capacitor C1

The output capacitor C1 can be treated in a similar manner as a capacitive-input type filter. C1 is chosen so that it is large enough to supply the full load current for the entire half-cycle until the time when the half-wave rectified output rises high enough to forward bias diode D1. The secondary current then provides the current to the load as well as replenishing the charge lost by capacitor C1 when it supplied the full load current.

During the portion of the cycle when C1 is supplying load current, that current is considered to be constant. For a constant current out of a capacitor, its rate of change of voltage is given by the expression

$$\Delta V/\Delta T = I/C1 \quad (10.111)$$

since $\Delta T = T - t_{on}$

$$C1 = I * (T - t_{on}) / \Delta V \tag{10.112}$$

10.4.7 The Half-Forward Regulator

The topology for the elementary *half-forward regulator* can be seen in Fig. 10.48.

When the power switch Q1 is closed, which is referred to as the on time (denoted by t_{on}), the voltage across the primary of transformer T1 is V_{in} , and thus the current through the transformer ramps up linearly. Its waveform during the on time, which is shown in Fig. 10.49(b) is described as

FIGURE 10.48 The half-forward regulator topology.

$$i_{PRI(on)} = ((V_{in}/L_{PRI}) * t) + I_{PRI(min)} \tag{10.113}$$

During the on time, the secondary current is also ramping up linearly as

$$i_{SEC(on)} = (N_p/N_s) * i_{PRI(on)}$$

At the end of the on time, when the power switch Q1 opens, the transformer primary and the secondary currents have reached their maximums. The current through the inductor L1 is the same as the transformer secondary current, and energy is thus stored within the magnetic core of the inductor, see Fig. 10.49(c) and Fig. 10.50. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(on)} = ((V_{SEC} - V_{out}) * t_{on}) / L1 \tag{10.114}$$

where

$$V_{SEC} = (N_s/N_p) * V_{in}$$

FIGURE 10.49 DC waveforms for a half-forward regulator.

FIGURE 10.50 AC waveforms for a half-forward regulator.

hence

$$\Delta i_{L1(\text{on})} = ((N_s/N_p) * V_{in} - V_{out}) * t_{on} / L1 \tag{10.115}$$

During the time when the power switch Q1 is open, which is referred to as the off time (denoted as t_{off}), the energy stored within the inductor carries the load's energy requirements, and the current through the inductor starts to fall toward zero. Because of the negative slope of the current, the voltage across the inductor reverses polarity; hence, the input side of the inductor is clamped to one diode drop below ground by the diode D2, which is commonly called the catch or free-wheeling diode. The inductor current now flows through the diode loop, thus maintaining its continuity and removing the stored energy from the inductor. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(\text{off})} = (V_{out} * t_{off}) / L1 \tag{10.116}$$

The off period ends when the power switch is turned on at a predetermined time, that is, a fixed frequency, or when the output voltage drops below a predefined design value and the power switch is turned on by the feedback control circuitry.

Regulation is accomplished by varying the on-to-off duty cycle of the power switch in order to keep $\Delta i_{L1(\text{on})} = \Delta i_{L1(\text{off})}$. Combining the two previous equations, the relationship that describes the regulator's operation is

$$V_{out} = [(N_s/N_p) * V_{in}] * t_{on} / (t_{on} + t_{off}) \tag{10.117}$$

Transformer T1

The switching transformer for the half-forward regulator transfers current, hence, power, in a linear fashion when the power switch is closed. Therefore, in selecting the transformer, the dominating parameters are again the primary and secondary inductances. During t_{on}

$$V_{SEC} = L_{SEC} * (\Delta I / \Delta T) \quad \text{or} \quad L_{SEC} = V_{SEC} * (\Delta T / \Delta I) \tag{10.118}$$

where

$$\begin{aligned} \Delta T &= t_{on} \\ \Delta I &= I_{SEC(\text{max})} - I_{SEC(\text{min})} \\ V_{SEC} &= N_s / N_p * V_{in} \end{aligned}$$

since

$$\begin{aligned} I_{out} &= (I_{SEC(\text{max})} + I_{SEC(\text{min})}) / 2 \\ L_{SEC} &= ((N_s/N_p) * V_{in} * t_{on}) / (2 * (I_{out} - I_{SEC(\text{min})})) \end{aligned} \tag{10.119}$$

in a similar fashion

$$L_{PRI} = (V_{in} * t_{on}) / (2 * (N_p / N_s) * (I_{out} - I_{SEC(min)})) \quad (10.120)$$

The number of turns of the transformer can be calculated from

$$N = (L / A_L)^{\frac{1}{2}} \quad (10.121)$$

where

A_L = inductance index in milli-henry/turns²

L = winding inductance

N = number of turns

Inductor L1

The power inductor $L1$ is chosen in the same manner as is done for the buck regulator, see Sec. 10.4.3. In this case, however, V_{in} is the peak secondary voltage V_{sec} . Since

$$\begin{aligned} V_{sec} &= N_s / N_p * V_{in} \\ L1 &= 2 * \{((N_s / N_p * V_{in}) - V_{out}) / i_{(max)}\} * \text{duty cycle} * T \end{aligned} \quad (10.122)$$

Capacitor C1

The output capacitor is determined in the same manner as is done for the buck regulator, see Sec. 10.4.3. From Eq. (10.79)

$$C1_{min} = i_{min} / (4 * \Delta v_{(out)max} * f) \quad (10.123)$$

10.4.8 The Push-Pull Regulator

The topology for the elementary *push-pull regulator* can be seen in Fig. 10.51.

In the operation of the push-pull regulator each power switch, $Q1$ and $Q2$, operate in the same way but 180° out of phase with each other. Each power switch has its own t_{on} and t_{off} time, see Fig. 10.52. During the time when either power switch is closed, the ramping transformer primary current and the resultant secondary current cause energy to be stored in inductor $L1$. There is also a dead time when both power switches are open. It is during this time that the energy stored in inductor $L1$ is moved to the output load and the current through the inductor starts to fall toward zero.

FIGURE 10.51 The push-pull regulator topology.

FIGURE 10.52 DC waveforms for a push-pull regulator.

Each half of the push-pull regulator thus resembles the half-forward regulator. The waveform of the primary current during the on time, which is shown in Fig. 10.52(c) and Fig. 10.52(d) is described as

$$i_{PRI(on)} = ((V_{in}/L_{PRI}) * t) + I_{PRI(min)} \tag{10.124}$$

During the on time, the secondary current is also ramping up linearly as

$$i_{SEC(on)} = (N_p/N_s) * i_{PRI(on)}$$

At the end of the on time, when the power switch opens, the transformer primary and secondary currents have reached their maximums. The current through the inductor L_1 is the same as the transformer secondary current, and energy is thus stored within the magnetic core of the inductor, see Fig. 10.52(c) and Fig. 10.53. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(on)} = ((V_{SEC} - V_{out}) * t_{on})/L_1 \tag{10.125}$$

where

$$V_{SEC} = (N_s/N_p) * V_{IN}$$

hence

$$\Delta i_{L1(on)} = (((N_s/N_p) * V_{in}) - V_{out}) * t_{on}/L_1 \tag{10.126}$$

During the time when both power switches are open, which is referred to as the off time (denoted as t_{off}), the energy stored within the inductor carries the load's energy requirements, and the current through the inductor starts to fall toward zero. Because of the negative slope of the current, the voltage across the inductor reverses polarity, and the input side of the inductor is clamped by its associated diode to one diode drop below ground. The inductor current now flows through the diode loop, thus maintaining its continuity and removing the stored energy from the inductor. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(off)} = (V_{out} * t_{off})/L_1 \tag{10.127}$$

FIGURE 10.53 AC waveforms for a push-pull regulator.

The off period ends when the other power switch is turned on at a predetermined time, that is, a fixed frequency, or when the output voltage drops below a predefined design value and the other power switch is turned on by the feedback control circuitry.

Regulation is accomplished by varying the on-to-off duty cycle of the each power switch in order to keep $\Delta i_{L1(\text{on})} = \Delta i_{L1(\text{off})}$. Combining the two previous equations, the relationship that describes the regulator's operation is

$$V_{\text{out}} = ((N_s/N_p) * V_{\text{in}}) * t_{\text{on}} / (t_{\text{on}} + t_{\text{off}}) \quad (10.128)$$

where

$$t_{\text{on}} + t_{\text{off}} = \frac{1}{2} T$$

Note that in this configuration, each section of the push-pull regulator switches at twice the control switching frequency.

Transformer T1

The switching transformer for the push-pull regulator is similar in operation to that of the half-forward transformer, see Sec. 10.4.7. In this case, however, each half of the transformer carries the forward current only during its one-half cycle. From Eq. (10.119) and Eq. (10.120)

$$I_{\text{SEC}} = ((N_s/N_p) * V_{\text{in}} * t_{\text{on}}) / (2 * (I_{\text{out}} - I_{\text{SEC}(\text{min})})) \quad (10.129)$$

and

$$I_{\text{PRI}} = (V_{\text{in}} * t_{\text{on}}) / (2 * (N_p/N_s) * (I_{\text{out}} - I_{\text{SEC}(\text{min})})) \quad (10.130)$$

for each half of the center-tapped primary and secondary windings.

The number of turns of the transformer can be calculated from

$$N = (L/A_L)^{\frac{1}{2}} * 2 \quad (10.131)$$

where

A_L = inductance index in milli-henry/turns²

L = winding inductance

N = number of turns (center tapped)

Inductor L1

The power inductor $L1$ is chosen in the same manner as is done for the buck regulator, see Sec. 10.4.3. In this case, however, V_{in} is the peak secondary voltage V_{sec} . Since

$$V_{\text{sec}} = N_s/N_p * V_{\text{in}} \quad (10.132)$$

$$L1 = 2 * \{[(N_s/N_p * V_{\text{in}}) - V_{\text{out}}] / i_{(\text{max})}\} * \text{duty cycle} * T$$

Capacitor C1

The output capacitor is determined in the same manner as is done for the buck regulator, see [Sec. 10.4.3](#). From Eq. (10.79)

$$C1_{\min} = i_{\min}/(4 * \Delta v_{(out)\max} * f) \tag{10.133}$$

10.4.9 The Full-Bridge Regulator

The topology for the elementary *full-bridge regulator* can be seen in Fig. 10.54.

A disadvantage of the push-pull regulator of [Fig. 10.51](#) is that when a power switch is not on, it must be able to withstand $2V_{in}$, that is, twice the DC input voltage. The full-bridge regulator of Fig. 10.54 reduces that requirement to V_{in} .

Each power switch combination, that is, $Q1-Q3$ and $Q2-Q4$, is on for a maximum of half the switching frequency. Hence, each power switch combination has its own t_{on} and t_{off} time, see [Fig. 10.55](#). During the time when a power switch combination is closed, the ramping transformer current and its resultant secondary current cause energy to be stored in the inductor $L1$. The waveform of the primary current during the on time, which is shown in [Fig. 10.55\(c\)](#) and [Fig. 10.55\(d\)](#) (see also [Fig. 10.56](#)), is described as

$$i_{PRI(on)} = ((V_{in}/L_{PRI}) * t) + I_{PRI(min)} \tag{10.134}$$

During the on time, the secondary current is also ramping up linearly as

$$i_{SEC(on)} = (N_p/N_s) * i_{PRI(on)}$$

At the end of the on time, when the power switch opens, the transformer primary and the secondary currents have reached their maximums. The current through the inductor $L1$, which is the same as the transformer secondary current, starts to fall toward zero, and the energy stored in inductor $L1$ is moved to the output. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(on)} = ((V_{SEC} - V_{out}) * t_{on})/L1 \tag{10.135}$$

FIGURE 10.54 The full-bridge regulator topology.

FIGURE 10.55 DC waveforms for a full-bridge regulator.

where

$$V_{SEC} = (N_s / N_p) * V_{IN}$$

hence,

$$\Delta i_{L1(on)} = \{((N_s / N_p) * V_{in}) - V_{out}\} * t_{on} / L1 \tag{10.136}$$

During the time when both power switches are open, which is referred to as the off time (denoted as t_{off}), the energy stored within the inductor carries the load's energy requirements and the current through the inductor starts to fall toward zero. Because of the negative slope of the current, the voltage across the inductor reverses polarity, and the input side of the inductor is clamped by its associated diode to one diode drop below ground. The inductor current now flows through the diode loop, thus maintaining its continuity and removing the stored energy from the inductor. The change in inductor current during this

FIGURE 10.56 AC waveforms for a full-bridge regulator.

time is described by the relationship

$$\Delta i_{L1(\text{off})} = (V_{\text{out}} * t_{\text{off}}) / L1 \quad (10.137)$$

The off period ends when the other power switch combination is turned on at a predetermined time, that is, a fixed frequency, or the output voltage drops below a predefined design value and the other power switch combination is turned on by the feedback control circuitry.

Regulation is accomplished by varying the on-to-off duty cycle of each power switch combination in order to keep $\Delta i_{L1(\text{on})} = \Delta i_{L1(\text{off})}$. Combining the two previous equations, the relationship that describes the regulator's operation is

$$V_{\text{out}} = ((N_s / N_p) * V_{\text{in}}) * t_{\text{on}} / (t_{\text{on}} + t_{\text{off}}) \quad (10.138)$$

where

$$t_{\text{on}} + t_{\text{off}} = \frac{1}{2} T$$

Note that in this configuration also, each section of the full-bridge regulator switches at twice the control switching frequency.

Transformer T1

The switching transformer for the push-pull regulator is similar in operation to that of the half-forward transformer, see [Sec. 10.4.7](#). In this case, however, each half of the transformer carries the forward current only during its one-half cycle. From [Eq. \(10.119\)](#) and [Eq. \(10.120\)](#)

$$L_{\text{SEC}} = ((N_s / N_p) * V_{\text{in}} * t_{\text{on}}) / (2 * (I_{\text{out}} - I_{\text{SEC}(\text{min})})) \quad (10.139)$$

and

$$L_{\text{PRI}} = (V_{\text{in}} * t_{\text{on}}) / (2 * (N_p / N_s) * (I_{\text{out}} - I_{\text{SEC}(\text{min})})) \quad (10.140)$$

for each half of the center-tapped primary and secondary windings.

The number of turns of the transformer can be calculated from

$$N = (L / A_L)^{\frac{1}{2}} * 2 \quad (10.141)$$

where

A_L = inductance index in milli-henry/turns²

L = winding inductance

N = number of turns (center tapped)

Inductor L1

The power inductor $L1$ is chosen in the same manner as is done for the buck regulator, see [Sec. 10.4.3](#). In this case, however, V_{in} is the peak secondary voltage V_{sec} . Since

$$V_{\text{sec}} = N_s / N_p * V_{\text{in}} \quad (10.142)$$

$$L1 = 2 * \{((N_s / N_p * V_{\text{in}}) - V_{\text{out}}) / i_{(\text{max})}\} * \text{duty cycle} * T$$

Capacitor C1

The output capacitor is determined in the same manner as is done for the buck regulator, see [Sec. 10.4.3](#).

From [Eq. \(10.79\)](#)

$$C1_{\text{min}} = i_{\text{min}} / (4 * \Delta v_{(\text{out})\text{max}} * f) \quad (10.143)$$

FIGURE 10.57 The half-bridge regulator topology.

10.4.10 The Half-Bridge Regulator

The topology for the elementary *half-bridge regulator* can be seen in Fig. 10.57.

The advantage of reducing the applied voltage across the inverter transistor from $2V_{in}$ to V_{in} is also offered by the half-bridge regulator of Fig. 10.58. The half-bridge regulator replaces two of the power switch transistors by two resistor/capacitor combinations that could be somewhat more economical. However, with the rapidly falling transistor prices and the fact that the two capacitors occupy a larger volume and footprint area than the two transistors, this advantage may be somewhat nullified.

FIGURE 10.58 DC waveforms for a half-bridge regulator.

FIGURE 10.59 AC waveforms for a half-bridge regulator.

Like the full-bridge regulator, each power switch, that is, Q1 or Q2, is on for a maximum of half the switching frequency. Hence, each power switch has its own t_{on} and t_{off} time, see Fig. 10.58 and Fig. 10.59. During the time when a power switch is closed, the ramping transformer current and its resultant secondary current cause energy to be stored in inductor $L1$. The waveform of the primary current during the on time, which is shown in Fig. 10.58(c), is described as

$$i_{PRI(on)} = \{((V_{in}/2)/L_{PRI}) * t\} + I_{PRI(min)} \tag{10.144}$$

During the on time, the secondary current is also ramping up linearly as

$$i_{SEC(on)} = (N_p/N_s) * i_{PRI(on)}$$

At the end of the on time, when the power switch opens, the transformer primary and the secondary currents have reached their maximums. The current through inductor $L1$, which is the same as the transformer secondary current, starts to fall toward zero, and the energy stored in inductor $L1$ is transferred to the output. Assuming 1 V drops in the secondary circuit rectifier diodes, the change in inductor current during this time is described by the relationship

$$\Delta i_{L1(on)} = ((V_{SEC} - V_{out} - 2) * t_{on})/L1 \tag{10.145}$$

where

$$V_{SEC} = (N_s/N_p) * V_{in}$$

hence

$$\Delta i_{L1(on)} = \{((N_s/N_p)V_{out}\} - * t_{on})/L1 \tag{10.146}$$

During the time when both power switches are open, which is referred to as the off time (denoted as t_{off}), the energy stored within the inductor carries the load's energy requirements, and the current through the inductor starts to fall toward zero. Because of the negative slope of the current, the voltage across the inductor reverses polarity; hence, the input side of the inductor is clamped to one diode drop below ground by its associated diode. The inductor current now flows through the diode loop, thus maintaining its continuity and removing the stored energy from the inductor. The change in inductor current during this time is described by the relationship

$$\Delta i_{L1(off)} = (V_{out} * t_{off})/L1 \tag{10.147}$$

The off period ends when the other power switch is turned on or the output voltage drops below a predefined design value and the other power switch is turned on by the feedback control circuitry.

Regulation is accomplished by varying the on-to-off duty cycle of the each power switch in order to keep $\Delta i_{L1(on)} = \Delta i_{L1(off)}$. Combining the two previous equations, the relationship that describes the regulator's operation is

$$V_{out} = ((N_s/N_p) * V_{in}) * t_{on}/(t_{on} + t_{off}) \tag{10.148}$$

where

$$t_{on} + t_{off} = \frac{1}{2}T$$

Note that, in this configuration also, each section of the full-bridge regulator switches at twice the control switching frequency.

Transformer $T1$

The switching transformer for the push-pull regulator is very similar in operation to that of the half-forward transformer, see [Sec. 10.4.7](#). In this case, however, each half of the transformer carries the forward current only during its one-half cycle. From Eq. (10.119) and Eq. (10.120)

$$L_{\text{SEC}} = ((N_s/N_p) * V_{\text{in}} * t_{\text{on}})/(2 * (I_{\text{out}} - I_{\text{SEC}(\text{min})})) \quad (10.149)$$

and

$$L_{\text{PRI}} = (V_{\text{in}} * t_{\text{on}})/(2 * (N_p/N_s) * (I_{\text{out}} - I_{\text{SEC}(\text{min})})) \quad (10.150)$$

for each half of the center-tapped primary and secondary windings.

The number of turns of the transformer can be calculated from

$$N = (L/A_L)^{\frac{1}{2}} * 2 \quad (10.151)$$

where

A_L = Inductance index in milli-henry/turns²

L = winding Inductance

N = number of turns (center tapped)

Inductor $L1$

The power inductor $L1$ is chosen in the same manner as is done for the buck regulator, see [Sec. 10.4.3](#). In this case, however, V_{in} is the peak secondary voltage V_{sec} . Since

$$\begin{aligned} V_{\text{sec}} &= N_s/N_p * V_{\text{in}} \\ L1 &= 2 * \{[(N_s/N_p * V_{\text{in}}) - V_{\text{out}}]/i_{(\text{max})}\} * \text{duty cycle} * T \end{aligned} \quad (10.152)$$

Capacitor $C1$

The output capacitor is determined in the same manner as is done for the Buck regulator, see [Sec. 10.4.3](#). From Eq. (10.79)

$$C1_{\text{min}} = i_{\text{min}}/(4 * \Delta v_{(\text{out})\text{max}} * f) \quad (10.153)$$

Defining Terms

Flyback regulator: The technique by which the regulated load power is transferred during the *off* time of the switching device.

Forward regulator: The technique by which the regulated load power is transferred during the *on* time of the switching device.

Pulse width modulation (PWM): A modulation technique by which the width of a rectangular waveshape is varied in accordance with a particular error signal. Typically, the overall period is held constant, and the duty cycle is therefore varied.

Regulator: An electronic device that attempts to keep the output signal constant in spite of changes in the other system characteristics.

Topology: The overall design technique, or layout, by which an electronic device, such as a switching power supply regulator, operates.

10.5 Inverters

Ashoka K.S. Bhat

10.5.1 Introduction

The function of an **inverter** is to convert a DC input voltage to an AC output voltage. The output voltage and frequency may be fixed or variable depending on the application. Inverters find several applications, some of them are in variable speed AC motor drives, uninterruptible power supplies (UPS), mobile AC power supplies (operating on a battery), induction heating, etc. They are also used as the front stage in DC-to-DC converters.

Inverters can be broadly classified as: (1) **voltage-source inverters (VSI)**, and (2) **current-source inverters (CSI)**.

10.5.2 Voltage-Source Inverters

In the case of a VSI, input to the inverter is a constant DC voltage. This is usually obtained by connecting large capacitors at the input. There are basically three types of configurations:

- Half-bridge
- Full-bridge
- Push-pull

Half-Bridge

Figure 10.60(a) shows the half-bridge inverter circuit. A center tapped DC source is created by two large capacitors connected across the DC supply. The switch–diode pairs, S_1, D_1 and S_2, D_2 , generate a square-wave voltage across the terminals A and B by connecting the sources V_1 and V_2 ($V_1 = V_2 = V_s/2$) alternately (Fig. 10.60(b)). The switches S_1 and S_2 are switching power devices (e.g., bipolar power transistors, metal oxide semiconductor field effect transistors (MOSFETs), insulated gate bipolar transistor (IGBT), silicon controlled rectifiers (SCRs), gate-turn-off thyristor (GTO)) (Fig. 10.60(d)). If SCRs are used as the switching devices, then a forced commutation circuit is needed unless natural or load commutation takes place. The diodes D_1 and D_2 carry the reactive current. The current flowing through the load depends on the nature of the load circuit. If the load is purely resistive (usually not possible due to wiring inductance), then the current and voltage waveforms are the same and the diodes D_1 , and D_2 will never conduct. In the case of RLC type load (Fig. 10.60(c)), current waveshape depends on whether the load circuit is underdamped or overdamped. Sometimes, an inductor L_s and a capacitor C_s are added in series with R_L , to obtain load commutation or to shape the load current and (in turn, the switch currents)

FIGURE 10.60 The half-bridge inverter configuration: (a) Basic circuit diagram, snubber circuits are not shown. $V_1 = V_2 = E = V_s/2$. (b) Gating pulses and the voltage v_{AB} . (c) RLC load circuit that can be connected across AB. (d) Some of the semiconductor switches that can be used in (a).

sinusoidally. An inverter which uses an RLC type load is usually referred to as a **resonant inverter** since the resonating nature of the RLC circuit is made use of in its operation. Two types of operation are possible.

Case 1: Below Resonance (Leading Power Factor (PF)) Mode of Operation

The inverter operates in this mode when the load is underdamped, and Fig. 10.61(a) shows the typical steady-state operating waveforms. The sequence of device conduction is also shown in the same figure. Assume that the switch S1 is carrying the load current. Since the load circuit is RLC and is underdamped, current is approximately sinusoidal. At $t = t_1$, current goes to zero naturally and tries to reverse. Switch S1 turns off and the diode D1 starts conducting, providing the path for the reverse current. At the end of the half-cycle, that is, at $t = T_s/2$ (where T_s is the period of the waveform equal to $1/f_s$ and f_s is the switching frequency), S2 is turned on. For an ideal switch-diode pair, S2 turns on immediately, applying a reverse voltage across D1. Therefore, D1 turns off, and S2 carries the load current. When the current

FIGURE 10.61 The half-bridge configuration: (a) operating waveforms for below resonance (or leading PF) mode of operation, (b) half-bridge configuration with the di/dt inductors (L_1, L_1) and snubber components. $C_{sn1} = C_{sn2} = C_{sn}$ and $R_{sn1} = R_{sn2} = R_{sn}$. High-frequency transformer is added for isolation and voltage scaling purpose.

through S2 goes to zero, D2 conducts and the cycle is complete when S1 is turned on at the beginning of the next cycle. The following important observations are to be made:

- During the conduction of D1 (or D2), a reverse voltage of a diode drop is applied across S1 (or S2). This time for which the diode conducts must be greater than the turn-off time of the switch for successful operation of the circuit.
- The switches turn off naturally, that is, load commutation takes place. This means thyristors can be employed in this type of operation provided the turn off time condition is satisfied, that is, $t_q > t_{off}$, where t_q is the diode conduction time and t_{off} is the turn off time of the thyristor used.
- Since the switches turn off with zero current, this operation is referred to as *zero current switching* (ZCS) and there are no turn off losses.
- The load current i is leading the voltage across AB, that is why this type of operation is referred to as leading PF mode of operation. In practice, usually the switching frequency is below the resonance frequency of the RLC circuit. Hence, it is also referred to as *operation below resonance*.

In the previous explanation, the turn-on time of the switch and the reverse recovery time of the diode were neglected. But in practice, this is not true, and due to the reverse recovery time of the diode, when a switch in the other arm is turned-on, the conducting diode will not turn off instantly. This means that there is a short interval during which the turned on switch and the reverse conducting diode short circuit the supply voltage. To take care of this, di/dt limiting inductors are connected in series with each switch (Fig. 10.61(b)). To reduce the size of these extra inductors and to reduce the losses, fast recovery diodes are used. If switches having slow recovery internal diodes (e.g., MOSFETs) are used, then the internal diodes must be bypassed by connecting external fast recovery diodes.

A snubber capacitor (C_{sn}) is connected across each switch in order to limit the rate of rise of voltage, dv/dt . When a switch is conducting, the capacitor across the other switch is charged to the supply voltage V_s . This capacitor gets discharged when the switch across it is turned on resulting in a large peak current through the switch. To limit this peak current, a resistor (R_{sn}) is connected in series with each snubber capacitor. These snubber resistors must be of proper power rating ($=C_{sn}V_s^2 f_s$). Losses in these snubber resistors increase if the switching frequency or the supply voltage increases.

Case 2: Above Resonance (Lagging PF) Mode of Operation

The gating signals and the steady-state waveforms for this mode of operation are shown in Fig. 10.62. This mode of operation occurs when the RLC type load is overdamped (Fig. 10.62(a)) or for an RL type load (Fig. 10.62(b)). Assume that D1 is conducting. The current through D1 goes to zero at t_1 . The load current reverses after this. Since the gating signal is already applied to S1, current is transferred to S1. Because the antiparallel diode across S1 was conducting just prior to the turning on of S1, S1 turns on with *zero voltage switching* (ZVS). This means there are no turn on losses. The switch S1 is turned off at $T_s/2$ and the current through the load is transferred to D2. The next half-cycle is similar to the first half-cycle. When S1 or S2 is turned off, during the turn off time of the switch, snubber capacitor across the switch starts charging, whereas the snubber capacitor across the incoming diode starts discharging from the supply voltage. Since C_{sn1} and C_{sn2} are in series and directly across the supply, the sum of the voltages across these two capacitors must be equal to the supply voltage at any time. Therefore, when the voltage across the turned-off switch reaches V_s , the diode across the discharged capacitor starts conducting. The charging and discharging current of the capacitors flow through the load circuit. By properly choosing these snubber capacitors, the turn off losses can be minimized.

The following observations can be made:

- Lossy snubbers and di/dt inductors are not required, that is, only a capacitive snubber is used across the switch.
- Since there is enough time for the diodes to recover, internal diodes of MOSFETs, IGBTs and bipolar transistors can be used.
- Since the switches are turned off forcibly, a forced commutation circuit is required if SCRs are used as the switches.

FIGURE 10.62 Operating waveforms of the half-bridge configuration, Fig. 1 (a) for above resonance (or lagging PF) mode of operation: (a) RLC type overdamped load, (b) RL load.

When the load across AB is an RLC type, then the inverter is called a *series resonant inverter* or *series loaded resonant inverter*. In some applications, the commutating or resonating components are added to form the resonating tank. There are several other resonating tank circuit configurations possible. Other than the series resonant inverter, two more popular configurations are parallel loaded or parallel resonant inverter (Fig. 10.63(a)), and series-parallel (or LCC type) inverter (Fig. 10.63(b)). These resonant inverters are particularly useful in generating high-frequency voltage waveforms. They are used in induction heating, fluorescent lamp electronic ballasts, and other applications. The high-frequency transformer used in the circuits of Fig. 10.63 is for voltage scaling or **isolation**.

FIGURE 10.63 Inverter types: (a) parallel loaded or parallel resonant inverter, (b) series-parallel loaded (or LCC type) resonant inverter.

FIGURE 10.64 Operating waveforms for the discontinuous current mode of operation.

Power control in the case of resonant inverters is achieved either by variable frequency control or with fixed-frequency control. Fixed-frequency control is not applicable to the half-bridge configuration and, therefore, only variable frequency control method is explained here. This type of control can be used when the output frequency is not very important.

Variable Frequency Operation

The inverter operates near resonance frequency at full load and minimum input voltage. In this case the switching frequency is varied for power control. Two possibilities exist.

1. At full load and minimum input voltage, the switching frequency is slightly below resonance but enough turn-off time for the switches is provided. As the load current decreases or the input voltage increases, the inverter operating frequency is decreased below this value. The current can become discontinuous (Fig. 10.64) if the switching frequency is reduced below certain value. In addition to the disadvantages of below resonance operation mentioned earlier, this control method has an additional disadvantage, namely, the magnetics and input/output filters have to be designed for the lowest frequency of operation, increasing the inverter size.
2. At full load and minimum input voltage, the switching frequency is slightly above the resonance frequency. Power control is achieved by increasing the switching frequency above this value. This method has all of the advantages of above resonance operation explained earlier. SCRs cannot be used in this case since forced commutation or gate turn-off capability is required. Also, the switching frequency required may be very high at light load conditions, which increases the magnetic core losses and makes the control circuit design difficult.

Differential Equations (or Time-Domain Analysis) Approach

In this method, differential equations for the load circuit during different intervals are written, and they are solved to obtain the solutions for various state variables. This method is useful when transient response of the inverter has to be predicted. The steady-state solutions are obtained by matching the boundary conditions at the end of various intervals. This approach is complex when the order of the load circuit is higher.

Frequency-Domain Analysis

This approach is useful to analyze the inverter under steady-state conditions. The Fourier series expressions can be written taking into account all of the harmonics or using only the fundamental component in the simplified approximate analysis.

Fourier-Series Approach

In this method, the square-wave voltage across AB is represented by the Fourier series (note: $E = V_s/2$ for half-bridge and $\omega_s = 2\pi f_s$)

$$v_{AB} = \left(\frac{4E}{\pi}\right) \sum_{n=1,3,\dots}^{\infty} \left[\frac{\sin(n\omega_s t)}{n}\right] \tag{10.154}$$

FIGURE 10.65 Phasor circuits for n th harmonic: (a) series-loaded inverter, (b) parallel-loaded inverter, (c) series-parallel resonant inverter. Note: (1) V_{ABn} and V'_{on} are the n th harmonic phasors of voltage v_{AB} and the output voltage referred to primary side of the high-frequency transformer, respectively; I_n is the n th harmonic phasor current at the output of the inverter. (2) $X_{Lsn} = n\omega_s L_s$, $X_{Csn} = 1/(n\omega_s C_s)$, and $X_{Cpn} = 1/(n\omega_s C_p)$ are the n th harmonic reactances of L_s , C_s , and C_p , respectively.

The n th harmonic phasor equivalent circuits across AB are shown in Fig. 10.65 for the three types of resonant inverters presented earlier. Using this circuit, the n th harmonic voltage and current equations can be written. Then the effect of all of the harmonics can be superposed to obtain the total response. In Fig. 10.65, the output voltage and the load resistor are referred to the primary side (using the turns ratio n_t of the transformer) and are denoted by $V'_{on} (= n_t V_{on})$ and $R'_L (= n_t^2 R_L)$, respectively.

The current at the output of the inverter is

$$i = \left(\frac{4E}{\pi}\right) \sum_{n=1,3,\dots}^{\infty} \left[\frac{\sin(n\omega_s t - \phi_n)}{nZ_n} \right] \tag{10.155}$$

where Z_n is the n th harmonic impedance across the terminals A and B. For example, for a series loaded resonant inverter

$$Z_n = [R'_L{}^2 + \{n\omega_s L_s - 1/(n\omega_s C_s)\}^2]^{1/2} \tag{10.156}$$

and

$$\phi_n = \tan^{-1}[\{n\omega_s L_s - 1/(n\omega_s C_s)\}/R'_L] \tag{10.157}$$

The voltage and current through other components can be obtained in a similar way.

Approximate or Complex AC Circuit Analysis Approach

In this method, all of the harmonics except the fundamental are neglected. Although the method is an approximate approach, it can be used to design an inverter in a simple way. The fundamental voltage across AB is

$$v_{AB1} = (4E/\pi)(\sin(\omega_s t)) \tag{10.158}$$

Then the current at the output of the inverter is

$$i = (4E/(\pi Z_1))(\sin(\omega_s t - \phi_1)) \tag{10.159}$$

Depending on the value of ϕ_1 , the inverter operates in lagging or leading PF mode. If ϕ_1 is negative, initial current (i at $t = 0$) is positive, and the inverter is operating in leading PF mode. If ϕ_1 is positive, initial current is negative with the inverter operating in the lagging PF mode, and forced commutation is necessary.

Using the approximate analysis, the gain of resonant inverters can be derived easily. For a series loaded resonant inverter (SLRI), considering only the fundamental component and neglecting all the harmonics (Fig. 10.65(a), with $n = 1$)

$$M(j\omega_s) = \frac{V'_{o1}}{V_{AB1}} = \frac{R'_L}{R'_L + j(\omega_s L_s - (1/\omega_s C_s))} \tag{10.160}$$

$$M = |M(j\omega_s)| = 1/(1 + (Q_s F - Q_s/F)^2)^{1/2} \tag{10.161}$$

FIGURE 10.66 Inverter gain vs. switching frequency ratio, F : for (a) series-loaded inverter, (b) parallel-loaded inverter, (c) series-parallel inverter.

where $Q_s = (L_s/C_s)^{1/2}/R'_L$, $F = \omega_s/\omega_o$, $\omega_s = 2\pi f_s$ and $\omega_o = 1/(L_s C_s)^{1/2}$. Similarly, for a parallel loaded resonant inverter,

$$M = 1/((1 - F^2)^2 + (F/Q_p)^2)^{1/2} \tag{10.162}$$

where $Q_p = R'_L/(L_s/C_p)^{1/2}$, $F = \omega_s/\omega_p$, and $\omega_p = 1/(L_s C_p)^{1/2}$, and for a series-parallel resonant inverter (Q_s and F same as those defined for SLRI)

$$M = 1/(\{1 + (C_p/C_s)(1 - F^2)\}^2 + (Q_s F - Q_s/F)^2)^{1/2} \tag{10.163}$$

Figure 10.66 shows the plots of inverter gains vs. frequency ratio F obtained using the equations derived previously. It can be observed that the frequency variation required for load regulation is very wide for a series-loaded inverter, whereas it is very narrow for a parallel-loaded resonant inverter. But the inverter switch peak current decreases with the load current for a series-loaded inverter, whereas it does not decrease with the load current in the case of a parallel-loaded inverter. The series-parallel resonant inverter combines the advantages of series-loaded and parallel-loaded resonant inverters. Also, with a proper selection of C_s/C_p ratio, a near sine-wave output waveform which is almost load independent can be obtained.

Full-Bridge

Figure 10.67 shows the full-bridge inverter configuration. The basic operating principle is the same as the half-bridge inverter. However, the amplitude of the square-wave voltage across AB is V_s . Therefore, for the same power output, there is twice the output voltage, and the average current rating of the switches is half compared to the half-bridge configuration.

FIGURE 10.67 Basic circuit diagram of a full-bridge inverter.

Power control in a full bridge can be obtained by either variable-frequency control or fixed-frequency **pulse width modulated (PWM)** control. The variable frequency control method used in resonant inverters is same as that explained in [Sec. 10.5.2](#). The fixed-frequency control method is explained in [Sec. 10.5.4](#).

Push-Pull

Figure 10.68 shows the push-pull configuration. This configuration uses only two switches. But the voltage rating of the switch is $2V_s$ and the transformer size is larger (primary winding volt-ampere rating is $\sqrt{2}$ times the secondary winding or the load power) compared to the bridge configurations.

FIGURE 10.68 Push-pull inverter configuration.

10.5.3 Current-Source Inverters (CSI)

This type of inverter is similar to the voltage-source type inverter. The input to the inverter is a current source, which is usually obtained by using a large inductor in series with the voltage source at the input. The voltage source at the input, in some cases (for example, in AC motor drives), is obtained by employing a phase controlled converter (for AC input) or a DC/DC chopper (for DC input). This allows the voltage to be controlled and, in turn, a controlled constant current source. The output of a CSI can be shorted, but cannot be open circuited. The peak current rating of the switches is equal to the DC current source and is lower compared to the VSI case. The disadvantages of a CSI are (1) slower dynamic response and (2) filters are required at the output to suppress the output voltage spikes.

In the case of a CSI (Fig. 10.69(a)), a DC current source is switched to obtain a square-wave current flowing at the output as shown in Fig. 10.69(c). The load used can be a parallel connection of R_L , L_p , and C_p , as shown in Fig. 10.69(b). This configuration is usually referred to as a *parallel resonant inverter*. The switches used in a CSI must be able to block the reverse voltage (similar to the capability of passing reverse

FIGURE 10.69 A current-source inverter: (a) circuit diagram, (b) load circuit used across A and B for parallel resonant inverter, (c) typical operating waveforms.

current for the switches of VSI). Therefore, diodes are connected in series with each switch, if transistors (MOSFETs, IGBTs, and bipolar) are used. The operating principle is similar to the voltage source case. Figure 10.69(c) illustrates operation corresponding to the lagging PF mode explained for a VSI.

The analysis approaches are similar to those explained for the VSI. For example, in the Fourier series approach, the equation for the square-wave current flowing in the output is given by

$$i = \left(\frac{4I}{\pi}\right) \sum_{n=1,3,\dots}^{\infty} \left[\frac{\sin(n\omega_s t)}{n}\right] \quad (10.164)$$

Figure 10.70 shows a single-phase CSI using thyristors. A three-phase version of this type of inverter is widely used in induction motor drives.

FIGURE 10.70 A single-phase current-source inverter using thyristors.

10.5.4 Voltage Control in Inverters

In most applications, output voltage of the inverter must be controlled. This may be to regulate the load voltage with variations in the load current or with variations in the DC (or AC if DC is derived from an AC supply) input voltage. In AC induction motor control applications, output voltage to frequency (V/f) must be kept constant. There are several ways to control the output voltage of an inverter. Some of them are listed next.

- Control the input DC voltage using a DC chopper.
- If the input is AC, use a phase controlled converter.
- Use an extra stage at the output to vary the output voltage.
- Control the inverter itself to vary the ratio of AC output voltage to the DC input voltage ratio.

The first three methods require an extra power stage. This causes additional losses and reduced efficiency. The fourth method involves the design of control electronics to properly vary the gating pulse pattern to obtain the desired output voltage control. This is called pulse width modulation (PWM). There are three methods of PWM possible:

- Single pulse width modulation.
- Multiple pulse width modulation.
- Sinusoidal pulse width modulation.

In many applications, the load voltage required must have low harmonic distortion. In some cases, a sine wave with a frequency equal to the utility line supply (60 Hz in North America) is required. In induction motor control applications, the output voltage, as well as frequency, must be controllable. In this case, it is possible to combine both the voltage control and sine wave generation in the inverter itself using sinusoidal PWM.

Single Pulse Width Modulation

Figure 10.71 shows the typical waveforms for this system. The gating signals G1 and G4 (or G3 and G2) are always 180° apart. The phase shift ϕ between the gating signals G1 and G3 is varied to get an output voltage of variable pulse width δ across the terminals A and B. When fixed-frequency control is used in a bridge converter, voltage waveform v_{AB} can be positive, negative, or zero. Zero voltage across AB is realized by turning on one switch and one diode on the positive side (or negative side), shorting the terminals A and B. The rms voltage across AB is a function of δ (or ϕ). When the inverter operates with minimum input voltage and maximum load power, $\delta = \pi$. As the load power decreases or the input voltage increases, output voltage

FIGURE 10.71 Typical operating waveforms of the bridge inverter when operating with fixed-frequency, phase-shift control.

is regulated by changing ϕ (in turn, δ). The same approach is used if voltage control is required across the load. The current through the load can be lagging or leading the voltage v_{AB} , depending on the load.

Fourier series analysis technique presented in [Sec. 10.5.2](#) can be used for the steady-state analysis in this case also, with

$$v_{AB} = \left(\frac{4V_s}{\pi} \right) \sum_{n=1,3,\dots}^{\infty} \left[\frac{\sin(n\omega_s t)}{n} \right] \left[\sin\left(\frac{n\pi}{2}\right) \right] \left[\sin\left(\frac{n\delta}{2}\right) \right] \quad (10.165)$$

The rms output voltage is given by

$$V_{ac\,rms} = V_s \sqrt{\delta/\pi} \quad (10.166)$$

The amplitudes of output voltage harmonics are high in this control method. Filters can be added at the output to remove the harmonics and to generate the sine-wave of required frequency (such as 60 Hz), but the inverter then becomes bulky. This method can be used for power control in the case of resonant inverters also, and used in applications where the waveform harmonics may not be very important. This control method can further be applied to a CSI ([Fig. 10.69](#)). In the case of a CSI, zero current flow across the terminals A and B is obtained by turning on the switches of the same limb (i.e., S1 and S4 or S3 and S2).

Multiple Pulse Width Modulation

In this case, gating signals are generated by comparing a carrier signal (e.g., triangular wave) with a square wave to generate the output voltage v_{AB} as shown in [Fig. 10.72](#). The number of pulses per half-cycle is $N = f_c/(2f)$, where f_c is carrier frequency and f is output frequency. If A_c and A_r are the amplitudes of the carrier and reference waveforms, respectively, then the modulation index is defined as

$$M = A_r/A_c \quad (10.167)$$

M can be varied by varying A_r . This in turn varies δ^* , the range of variation being $0 < \delta^* < \pi/N$. This variation changes the output voltage from zero to the maximum value. This method reduces the output harmonics compared to single pulse PWM. When $\delta^* = \pi$, the output waveform is a square wave and has the highest distortion.

FIGURE 10.72 Waveforms to illustrate the multiple pulse width modulation technique.

Sinusoidal Pulse Width Modulation

When a sine wave voltage with low harmonic distortion is required across the load terminals, then sinusoidal PWM is used. As shown in Fig. 10.73, the gating signals are generated by comparing a triangular wave with the reference sine wave. Since the pulse widths of the output load voltage (shown for a full bridge) are modulated using a sine wave, the distortion is low and the harmonics of higher frequency can be easily filtered to get the sine wave voltage of required frequency. In this case also, similar to the multiple PWM, output voltage can be varied by changing the modulation index M . For $0 < M < 1$, lower order harmonics are eliminated. When a half-bridge configuration is used, then the output voltage can change only between $+V_s/2$ and $-V_s/2$.

10.5.5 Harmonic Reduction

The harmonics in the output voltage must be reduced to decrease the size of the filters used. If the amplitudes of lower order harmonics are reduced, then the size of the filter can be made smaller. This will also increase the speed of response of the inverter. The sinusoidal PWM technique discussed previously is a popular method. The disadvantages of this method are: (1) reduction of the fundamental component compared to a square-wave results in derating of the inverter by more than 17% and (2) increased switching losses

FIGURE 10.73 Waveforms to illustrate the sinusoidal pulse width modulation technique.

FIGURE 10.74 Typical output voltage waveform for a half-bridge inverter when the third and fifth harmonics are eliminated using harmonic elimination techniques.

are experienced because the switches are turned on and off several times in a cycle. The following two methods are also used for harmonic reduction of inverters.

1. **Harmonic elimination technique:** Selected harmonics can be eliminated by precalculated positioning of gating pulses. For example, for a half-bridge inverter with the output voltage, as shown in Fig. 10.74, third and fifth harmonics can be eliminated if $\alpha_1 = 23.62^\circ$ and $\alpha_2 = 33.3^\circ$. This method suffers from the disadvantages mentioned for sinusoidal PWM, but the number of switchings are less when only the first few lower order harmonics are eliminated.
2. **Phase-shifted inverters or harmonic cancellation technique:** In this case, the outputs of several inverters are phase shifted and combined at the output of the transformers to eliminate the low-order harmonics. For example, Fig. 10.75 shows the schematic to eliminate the third harmonic (in fact, all triple- n harmonics). The derating of each inverter in this case is about 14%. Using two such systems and phase shifting their outputs by 36° , a stepped wave can be generated to eliminate third and fifth harmonics. The same effect can be achieved by adding the outputs of two single pulse width modulated inverters generating the waveforms v_{o1} and v_{o2} .

Another disadvantage of these methods is that the voltage control has to be done at the input of the inverter (or by some other technique).

There are several other modulation techniques available (Rashid, 1993; Sen, 1987; Mohan, Undeland, and Robins, 1995). Among them is the hysteresis control technique.

FIGURE 10.75 Cancelling third harmonic in the output voltage by summing the outputs of two phase-shifted inverters: (a) circuit diagram, (b) output voltage waveforms.

FIGURE 10.76 Hysteresis control technique.

Hysteresis Control

In this method, load current is sensed and compared with a reference sine wave. The inverter switches are controlled such that the output current does not exceed the set hysteresis limits $\pm \Delta I$ of the reference (Fig. 10.76). Although ΔI can be made very small to get almost a sinusoidal current, this will increase the switching frequency to a high value, which increases the switching losses. This method of control is popular in motor drive application.

Phase-Controlled Inverters

A phase-controlled inverter is a special type of inverter working on the utility line. It (shown in Fig. 10.77) can be used as an inverter when the firing angle α is in the range $\pi/2 < \alpha < \pi$, and the source is capable of supplying the energy to the AC source. This inverter requires the line voltage for commutation of the SCRs and, therefore, is referred to as a *line commutated inverter*. For a continuous current mode of operation,

FIGURE 10.77 A single-phase phase-controlled inverter and typical operating waveforms for continuous current mode of operation.

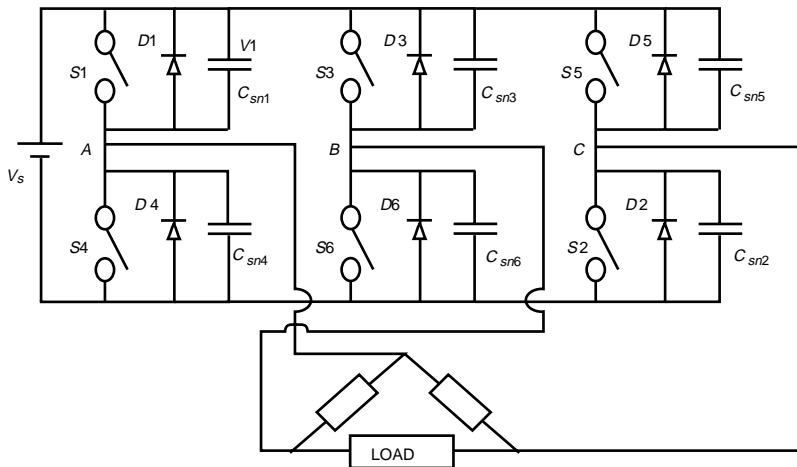

FIGURE 10.78 A three-phase inverter with the loads connected in delta.

the average output voltage is given by

$$V_o = (2\sqrt{2}V/\pi) \cos \alpha \quad (10.168)$$

Since the average output current I_o is always positive and $V_o < 0$ for $\pi/2 < \alpha < \pi$, the output power is negative. Therefore, the converter operates in the inversion mode with the power being fed to the AC supply.

10.5.6 Three-Phase Inverters

For medium to high power applications, three-phase inverters are used. Figure 10.78 shows the basic circuit diagram of a three-phase VSI with the loads connected in delta. The loads can also be Y connected. The control of this inverter can be done by either 180° wide gating pulse control or 120° wide gating pulses.

Defining Terms

Current source inverters: Inverters having a constant DC current input.

Inverter: A power electronic circuit which converts DC input to AC output.

Isolated: A power electronic circuit which has ohmic isolation between the input source and the load circuit.

Pulse width modulated (PWM) inverters: A power electronic inverter which employs square-wave switching waveforms with variation of pulse width for controlling the load voltage.

Resonant inverters: A power electronic inverter which employs LC resonant circuits to obtain sinusoidal switching waveforms.

Voltage source inverters: Inverters having a constant DC voltage input.

10.6 DC-to-DC Conversion

Ashoka K.S. Bhat

10.6.1 Introduction

DC-to-DC converters convert a DC input voltage to a variable or a required fixed DC output voltage. The output can be single or multiple. These converters are used in many applications including industrial, aerospace, telecommunications, and consumer products. Some of the requirements of DC-to-DC converters are small size, light weight, low cost, and high-power conversion efficiency. In addition to these, some applications require electrical isolation between the source and load. Some special applications require controlled direction of power flow.

10.6.2 Linear and Switch-Mode DC-to-DC Converters

DC-to-DC power converters can be mainly classified as: *linear* and *switch-mode* power converters.

In a linear DC-to-DC converter, the output voltage is regulated by dropping the extra input voltage across a series transistor. These regulators have very small output ripple, theoretically zero noise, large holdup time (typically, 1–2 ms), and fast response. The disadvantages of this type of converters are very low efficiency, no electrical isolation between the input and the output, larger volume and weight, and, in general, only single output possible. However, they are still used in very small regulated power supplies and in some special applications (e.g., magnet power supplies). Three terminal linear regulator integrated circuits (ICs) are readily available are easy to use, and have built-in load short-circuit protection.

In a switch-mode DC-to-DC converter, power semiconductors are used as switches to connect or to remove the input DC supply voltage to the output. Since the switches operate in the on and off switching states, power conversion efficiency is very high, reducing the size and weight of heat sinks. With the availability of fast switching devices, high-frequency (HF) magnetics and capacitors, and high-speed

control ICs, switching power converters have become very popular. They can be further classified as: *pulse width modulated (PWM)* converters and *soft-switched* converters.

10.6.3 Pulse Width Modulated Converters

In these converters, square-wave pulse width modulation is used to achieve voltage regulation. The **duty cycle** of the power semiconductor switch is varied to vary the average output voltage. The voltage (and current) waveform across the switch and at the output are square wave in nature, and they generally result in higher switching losses when the switching frequency is increased. Also, the switching stresses are high with the generation of large electromagnetic interference (EMI), which is difficult to filter. However, these converters are easy to control, well understood, and have wide load control range.

The Methods of Control

The PWM converters operate with fixed frequency, variable duty cycle. The three possible control methods (Severns and Bloom, 1988; Hnatek, 1981; Unitrode, 1984; Motorola, 1989; Philips, 1991) are briefly explained next:

1. *Direct duty cycle control*: This is the simplest control method. A fixed-frequency ramp is compared with the control voltage to obtain a variable duty cycle base drive signal for the transistor. Disadvantages of this method are that it provides no voltage feedforward to anticipate the effects of input voltage changes (slow response to sudden input changes, poor audio susceptibility, poor open-loop line regulation, requiring higher loop gain to achieve specifications) and it has poor dynamic response.
2. *Voltage feedforward control*: In this case the ramp amplitude varies in direct proportion to the input voltage. The open loop regulation is very good, and the problems in (1) are overcome.
3. *Current mode control*: In this method, as shown in Fig. 10.79, a second inner control loop compares the peak inductor current with the control voltage, which provides improved open-loop line regulation. All of the problems of the direct duty cycle control method (1) and (2) are corrected with this method. An additional advantage of this method is that the two pole second-order filter is reduced to a single pole (the filter capacitor) first-order filter resulting in simpler compensation networks. There are several current mode control ICs available in the market.

These control methods can be used in all of the PWM converter configurations. The converters can operate in either *continuous current mode (CCM)* or *discontinuous current mode (DCM)*. If the current through the output inductor (e.g., refer to the circuit shown in Fig. 10.80(a)) never reaches zero, then the converter operates in CCM, otherwise DCM occurs.

PWM converters can be classified as: (1) single-ended and (2) double-ended converters. These converters may or may not have a HF transformer for isolation.

Nonisolated Single-Ended PWM Converters

The basic nonisolated single-ended converters are: (1) buck (step-down) (Fig. 10.80(a)), (2) boost (step-up) (Fig. 10.80(b)), (3) buck-boost (step down or up, also referred to as *flyback*) (Fig. 10.80(c)), and

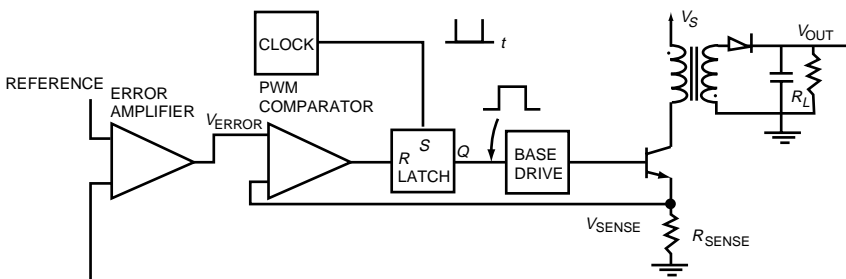

FIGURE 10.79 Current mode control technique illustrated for flyback converter.

Buck converter	$V_o = D V_{in}$
Boost converter	$V_o = V_{in}/(1 - D)$
Buck–boost converter	$V_o = D V_{in}/(1 - D)$
Cuk converter	$V_o = D V_{in}/(1 - D)$

^aNote: duty ratio, $D = t_{on}/T_s$; V_{in} = DC input voltage; V_o = output DC voltage.

FIGURE 10.80 Converter types: (a) buck converter, (b) boost converter, (c) buck–boost converter, (d) nonisolated Cuk converter.

(4) Ćuk converter (Fig. 10.80(d)). The output voltage of a buck converter is always less than the input voltage and the input current is pulsating. In a boost converter, the output voltage is greater than the input voltage and the output current is pulsating. In a buck–boost converter, one can get an output voltage less than or greater than the input voltage and both the input and output currents are pulsating. The Ćuk converter provides the advantage of nonpulsating input–output current ripple requiring smaller size external filters. The output voltage expression is the same as the buck–boost converter. Table 10.5 summarizes the expressions for the output voltage in these converters. There are many variations of the basic nonisolated converters, and most of them use high-frequency transformer for ohmic isolation between the input and the output.

Isolated Single-Ended Topologies

The Flyback Converter

The flyback converter (Fig. 10.81) is an isolated version of the buck–boost converter. In this converter, when the transistor is on, energy is stored in the coupled inductor (not a transformer) and this energy is transferred to the load when the switch is off. Flyback converters are used in the power range of 20–200 W.

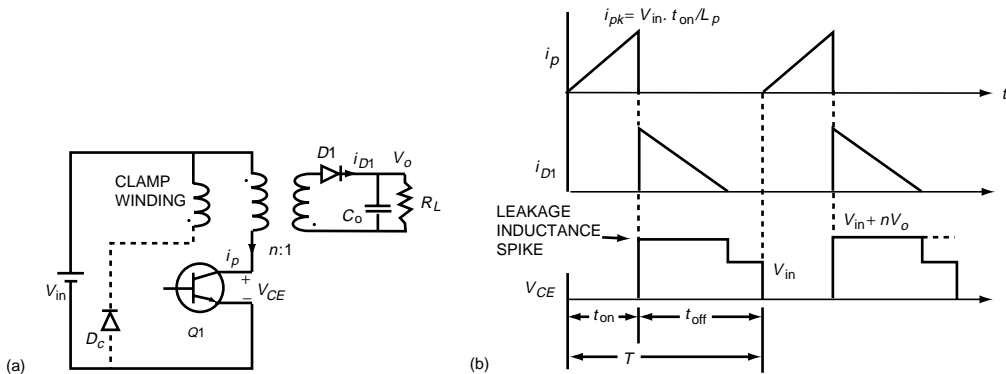

FIGURE 10.81 (a) Flyback converter. The clamp winding shown is optional and is used to clamp the transistor voltage stress to $V_{in} + nV_o$. (b) Flyback converter waveforms without the clamp winding. The leakage inductance spikes vanish with the clamp winding.

Some of the advantages of this converter are the following: (1) The leakage inductance is in series with the output diode when current is delivered to the output and, therefore, no filter inductor is required. (2) Cross regulation for multiple output converters is good. (3) It is ideally suited for high-voltage output applications. (4) It has the lowest cost.

Some of the disadvantages are the following: (1) Large output filter capacitors are required to smooth the pulsating output current. (2) Inductor size is large since air-gaps are to be provided. (3) Because of stability reasons, flyback converters are usually operated in the DCM, which results in increased losses. To avoid the stability problem, flyback converters are operated with current mode control explained in Sec. 10.6.3.

The Forward Converter

The forward converter (Fig. 10.82) is a variation of the buck converter. It is usually operated in the CCM to reduce the peak currents and does not have the stability problem of the flyback converter. The HF transformer transfers energy directly to the output with very small stored energy. The output capacitor size and peak current rating are smaller than they are for the flyback. A *reset winding* is required to remove the stored energy in the transformer. The maximum duty cycle is about 0.45, which limits the control range. This topology is used for power levels up to about 1 kW.

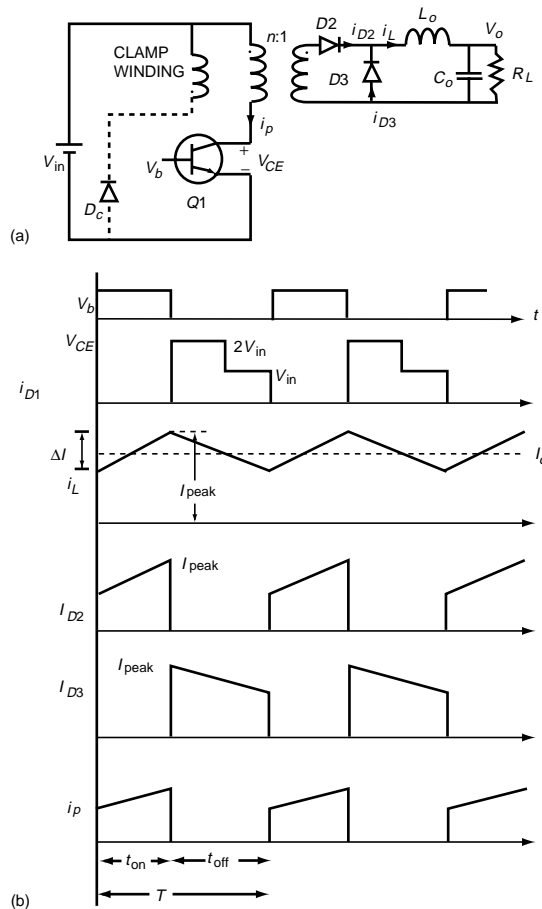

FIGURE 10.82 (a) Forward converter. The clamp winding shown is required for operation. (b) Forward converter waveforms.

FIGURE 10.83 (a) Two transistor single-ended flyback converter, (b) two transistor single-ended forward converter.

The flyback and forward converters require the voltage rating of power transistors to be much higher than the supply voltage. The two transistor flyback and forward converters shown in Fig. 10.83 limit the voltage rating of transistors to the supply voltage.

FIGURE 10.84 Sepic converter.

The Sepic converter shown in Fig. 10.84 is another isolated single-ended PWM converter.

Double-Ended PWM Converters

Usually, for power levels above 300 W, double-ended converters are used. Full-wave rectifiers are used in the double-ended converters and the ripple frequency of the output voltage is twice the switching frequency. Three important double-ended PWM converter configurations are push-pull (Fig. 10.85(a)), half-bridge (Fig. 10.85(b)) and full bridge (Fig. 10.85(c)).

The Push-Pull Converter

The duty ratio of each transistor in a push-pull converter (Fig. 10.85(a)) is less than 0.5. Some of the advantages are the transformer flux swings fully and the size of transformer is much smaller (typically half the size) than single-ended converters, and the output ripple is twice the switching frequency of transistors; therefore, smaller filters are needed.

Some of the disadvantages of this configuration are the transistors must block twice the supply voltage; flux symmetry imbalance can cause transformer saturation and special control circuitry is required to avoid this problem; and the use of a center-tap transformer requires extra copper resulting in a higher VA rating.

Current mode control (for the primary current) can be used to overcome the flux imbalance. This configuration is used in 100–500 W output range.

FIGURE 10.85 (a) Push-pull converter, (b) half-bridge converter, (c) full-bridge converter. Coupling capacitor C_c is used to avoid transformer saturation in (b) and (c).

The Half-Bridge

Two smoothing capacitors (C_{in}) are used to create a center tapped DC source, and this configuration (Fig. 10.85(b)) utilizes the transformer core efficiently. The voltage across each transistor is equal to the supply voltage (half of push-pull) and, therefore, is suitable for high-voltage inputs.

The disadvantage of this configuration is the requirement for large-size input filter capacitors. The half-bridge configuration is used for power levels of the order of 500–1000 W.

The Full Bridge

Only one smoothing capacitor is required at the input for this configuration (Fig. 10.85(c)) and for the same transistor type as that of half-bridge, output power can be doubled. Usually used for power levels above 1 kW, the design is more costly due to increased number of components (uses four transistors compared to two in push-pull and half-bridge converters.)

Using a proper control technique, a full-bridge converter can be operated in a *zero-voltage switching* (ZVS) mode (Dalal, 1990). This type of operation results in negligible switching losses. At reduced load currents, however, the ZVS property is lost. There has been much effort to overcome this problem, but the converter requires additional components to maintain the ZVS.

10.6.4 Soft-Switched Converters

Soft-switched converters can be classified as (a) **resonant converters**, and (b) **resonant** (zero-current or zero-voltage) **transition converters**. Similar to the PWM converters, there are two types in each case, namely, **single-ended** and **double-ended**.

Resonant DC-to-DC Converters

In the PWM converters explained in Sec. 10.6.3, LC (inductor and capacitor) resonating elements are added to generate resonant converter configurations. These converters generate sinusoidally varying voltage and/or current waveforms reducing the switching losses and the switch stresses, enabling the converter to operate at high switching frequencies resulting in reduced size, weight, and cost. Some other advantages of resonant converters are the leakage inductances of the HF transformer and the junction capacitances of semiconductors can be used profitably in the resonant circuit, and reduced EMI. The major disadvantage of resonant converters is increased peak current (or voltage).

Single-Ended Resonant Converters

Single-ended resonant converters generate quasisinusoidal voltage (or current) waveforms and, hence, the name *quasiresonant converters* (QRCs). They can operate with zero-current switching (ZCS) or zero-voltage switching (ZVS) or both. All of the QRC configurations can be generated by replacing the conventional switches by the resonant switches shown in Fig. 10.86 and Fig. 10.87. A number of configurations are realizable.

Zero-Current-Switching QRCs

Figure 10.86(d) shows an example of a ZCS QR buck converter (Kit Sum, 1988; Liu, Oruganti, and Lee, 1985) implemented using a ZC resonant switch. Depending on whether the resonant switch is half-wave type or full-wave type, the resonating current will be only half-wave sinusoidal (Fig. 10.86(e)) or a full sine wave (Fig. 10.86(f)). The device currents are shaped sinusoidally and, therefore, the switching losses are almost negligible with low turn-on and turn-off stresses. ZCS QRCs can operate at frequencies of the order of 2 MHz. The major problems with this type of converter is high peak currents through the switch and capacitive turn-on losses.

Zero-Voltage-Switching QRCs

ZVS QRCs (Kit Sum, 1988; Liu and Lee, 1986) are similar to ZCS QRCs. The auxiliary LC elements are used to shape the switching device's voltage waveform at off time in order to create a zero-voltage condition for the device to turn on. Figure 10.87(d) shows an example of ZVS QR boost converter implemented using ZV resonant switch. The circuit can operate in the half-wave mode (Fig. 10.87(e)) or in the full-wave mode

FIGURE 10.86 (a) Zero current resonant switch (i) L type (ii) M type. (b) half-wave configuration using L type ZC resonant switch. (c) full-wave configuration using L type ZC resonant switch. (d) implementation of ZCS QR buck converter using L type resonant switch. (e) operating waveforms for half-wave mode. (f) operating waveforms for full-wave mode.

FIGURE 10.87 (a) Zero voltage resonant switches. (b) half-wave configuration using ZV resonant switch shown in Fig. 10.87(a)(i). (c) full-wave configuration using ZV resonant switch shown in Fig. 10.87(a)(i). (d) implementation of ZVS QR boost converter using resonant switch shown in Fig. 10.87(a)(i). (e) operating waveforms for half-wave mode. (f) operating waveforms for full-wave mode.

FIGURE 10.88 High-frequency resonant converter (half-bridge version) configurations suitable for operation above resonance. Cn1 and Cn2 are the snubber capacitors: (a) series resonant converter. (b) parallel resonant converter. (c) series-parallel (or LCC type) resonant converter with capacitor C_i placed on the secondary side of the HF transformer. [Note: (1) For operation below resonance, di/dt limiting inductors and RC (Resistor-Capacitor) snubbers are required. For operation above resonance, only capacitive snubbers are required as shown. (2) leakage inductances of the HF transformer can be part of resonant inductance.]

(Fig. 10.87(f)) depending on whether half-wave or full-wave ZV resonant switch is used. The full-wave mode ZVS circuit suffers from capacitive turn-on losses. The ZVS QRCs suffer from increased voltage stress on the switch. However, they can be operated at much higher frequencies compared to ZCS QRCs.

Double-Ended Resonant Converters

These converters (Kit Sum, 1988; Bhat, 1988, 1991; Steigerwald, 1988) use a half-bridge or full-bridge converter with full-wave rectifiers at the output, and are generally referred to as *resonant converters*. A number of resonant converter configurations are realizable by using different resonant tank circuits (Bhat, 1995b) and the three most popular configurations, namely, the *series resonant converter* (SRC), the *parallel resonant converter* (PRC) and the *series-parallel resonant converter* (SPRC) (also called LCC type PRC) are shown in Fig. 10.88(a) to Fig. 10.88(c). Load voltage regulation in such converters for input supply variations and load changes is achieved by either varying the switching frequency or using fixed-frequency (variable pulse width) control.

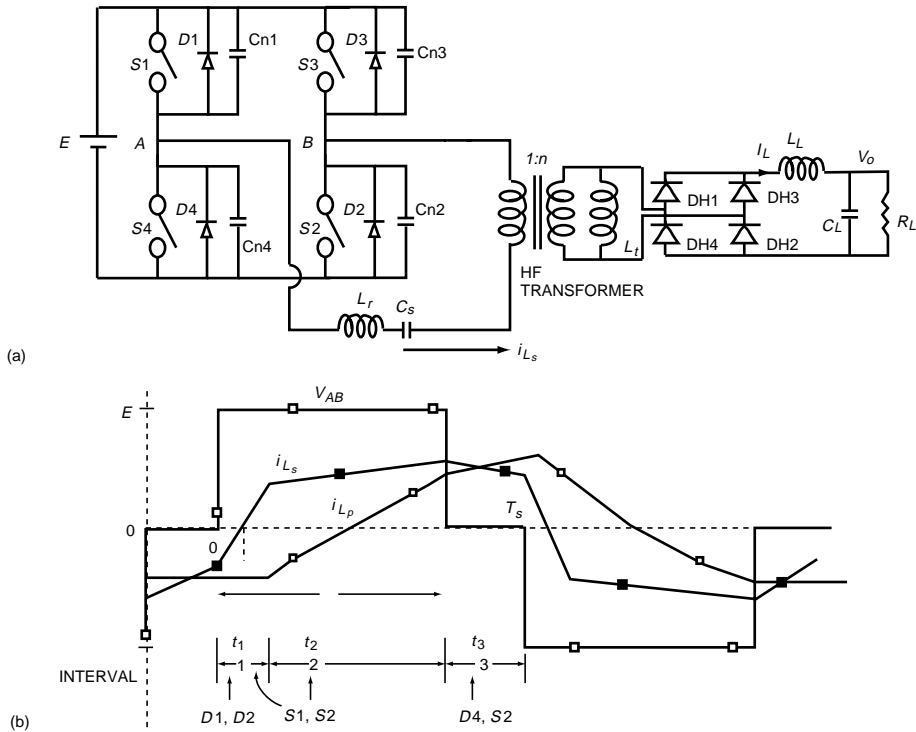

FIGURE 10.89 (a) Basic circuit diagram of a modified series resonant (LCL type) converter suitable for fixed-frequency operation with PWM (clamped-mode) control. This converter uses an inductive output filter. (b) waveforms to illustrate the operation of fixed-frequency PWM LCL type resonant converter working with a pulsewidth δ .

Series resonant converters (Fig. 10.88(a)) have high efficiency from full load to part load. Transformer saturation is avoided due to the series blocking resonating capacitor. The major problems with the SRC are (1) It requires a very wide change in switching frequency to regulate the load voltage and (2) the output filter capacitor must carry high ripple current (a major problem especially in low-output voltage, high-output current applications).

Parallel resonant converters (Fig. 10.88(b)) are suitable for low-output voltage, high-output current applications due to the use of filter inductance at the output with low ripple current requirements for the filter capacitor. The major disadvantage of the PRC is that the device currents do not decrease with the load current resulting in reduced efficiency at reduced load currents. The SPRC (Fig. 10.88(c)) takes the desirable features of SRC and PRC. It is possible to realize higher order resonant converters with improved characteristics and many of them are presented in Bhat (1991). Recently, modified series resonant converters (Bhat, 1994, 1995a) have been proposed. A modified SRC with an inductive output filter is shown in Fig. 10.89(a). The resonant inductor current is clamped approximately to the primary-side reflected load current. This configuration gives almost the same performance as the PWM converter but with reduced losses.

Variable Frequency Operation

Depending on whether the switching frequency is below the natural resonance frequency (ω_r) or above ω_r , the converter can operate in two different operating modes:

- Below resonance (leading PF) mode
- Above resonance (lagging PF) mode

These two modes of operation have been explained in Chapter 69. The operating principles, the advantages, and disadvantages are the same as those explained there.

Some of the problems associated with variable-frequency control technique are: (1) variation in switching frequency required for power control can be wide for some configurations (e.g., SRC), (2) design of filter elements and magnetics is difficult, (3) If operated below resonance, then the size of magnetics becomes large.

Fixed Frequency Operation

To overcome some of the problems associated with the variable frequency control of resonant converters, they are operated at a fixed frequency (Kit Sum, 1988; Bhat, 1988). A number of configurations and control methods for fixed-frequency operation are available in the literature (Bhat (1988) gives a list of papers). One of the most popular methods of control is the phase-shift control (also called clamped mode or PWM operation) method. Figure 10.89(b) illustrates the clamped mode fixed-frequency operation of the modified SRC shown in Fig. 10.89(a). The load power control is achieved by changing the phase-shift angle ϕ between the gating signals to vary the pulse width δ of v_{AB} .

Exact analysis of resonant converters is difficult due to the nonlinear loading on the resonant tanks. The rectifier-filter-load resistor block can be replaced by a square-wave voltage source (for SRC, Fig. 10.89(a)) or a square-wave current source (for PRC and SPRC, Fig. 10.88(b) and 10.88(c)).

Three popular methods of analysis of resonant converters are the following:

1. Differential equations (or **state-space**) approach: This method is difficult for higher order circuits, but gives more exact results. Also, this method is useful for dynamic analysis (**large-signal** (Agarwal and Bhat, 1995) and **small-signal analysis** (Agarwal and Bhat, 1994)) of resonant converters.
2. Fourier-series approach (Bhat, 1995b): In this method, the inverter output voltage and the rectifier input square-wave voltage (or current) are expressed in the Fourier-series form. Bhat (1995b) gives a generalized analysis of resonant converters using two-port model and the Fourier-series approach. The various waveforms for the converter can be predicted more accurately with this method.
3. Approximate analysis: Using fundamental components of the waveforms, an approximate analysis (Bhat, 1991; Steigerwald, 1988) using phasor circuit gives a reasonably good design approach. This analysis approach is illustrated for the SPRC in the next section.

Methods 2 and 3 give only steady-state analysis. The describing function method (Yang, Lee and Jovanovic, 1992) is an approximate but powerful method for the small signal analysis of resonant converters.

Approximate Analysis of SPRC

Using the fundamental waveforms, the rectifier-filter-load block can be replaced by an equivalent AC resistance R_{ac} and Fig. 10.90 shows the equivalent circuit at the output of the inverter. This phasor circuit is used for the analysis. All of the equations are normalized using the base quantities:

- Base voltage, $V_B = E$ where $E = V_s/2$ for half-bridge and V_s for full-bridge.
- Base impedance, $Z_B = R'_L = n^2 R_L$.
- Base current, $I_B = V_B/Z_B$.

FIGURE 10.90 Phasor circuit model used for the analysis of the SPRC converter. $R_{ac} = (\pi^2/8)R'_L$ where $R'_L = n^2 R_L$. For voltage- source load [e.g., SRC of Fig. 10.88(a)] $R_{ac} = (8/\pi^2)R'_L$.

The converter gain (normalized output voltage in per unit (p.u.) referred to the primary-side) for an SPRC is given by (Bhat, 1988, 1991; Steigerwald, 1988)

$$M = \sin(\delta/2) / [(\pi^2/8)^2 \{1 + (C_t/C_s)(1 - F_s^2)\}^2 + Q_s^2 \{F_s - (1/F_s)\}^2]^{1/2} \text{ p.u.} \quad (10.169)$$

where $\delta = \pi$ for variable-frequency operation,

$$Q_s = (L_s/C_s)^{1/2}/R'_L \quad (10.170)$$

$$F_s = f_s/f_r, \quad (10.171)$$

where f_s is the switching frequency, L_s includes leakage inductance of the HF transformer, and f_r is the series resonance frequency,

$$f_r = \omega_r/(2\pi) = 1/(2\pi(L_s C_s)^{1/2}) \quad (10.172)$$

The peak inverter output (same as the resonant inductor and the switch) current is given by

$$I_p = 4/(\pi|Z_{eq}|) \text{ p.u.} \quad (10.173)$$

where Z_{eq} is the equivalent impedance looking into the terminals AB given by

$$Z_{eq} = (B_1 + jB_2)/B_3 \text{ p.u.} \quad (10.174)$$

where

$$B_1 = (8/\pi^2)(C_s/C_t)^2(Q_s/F_s)^2 \quad (10.175)$$

$$B_2 = Q_s(F_s - (1/F_s))(1 + (8/\pi^2)^2(C_s/C_t)^2(Q_s/F_s)^2) - (C_s/C_t)(Q_s/F_s) \quad (10.176)$$

$$B_3 = 1 + (8/\pi^2)^2(C_s/C_t)^2(Q_s/F_s)^2 \quad (10.177)$$

The value of initial current I_0 is given by

$$I_0 = I_p \sin(-\phi) \text{ p.u.} \quad (10.178)$$

where

$$\phi = \tan^{-1}(B_2/B_1) \text{ rad} \quad (10.179)$$

If I_0 is negative, then the converter is operating in the lagging PF mode. The peak voltage across the capacitor C'_t (on the secondary side) is

$$V_{ctp} = (\pi/2)V_o \text{ V} \quad (10.180)$$

The peak voltage across C_s and the peak current through C'_t are given by

$$V_{csp} = (Q_s/F_s) \cdot I_p \text{ p.u.} \quad (10.181)$$

$$I_{ctp} = V_{ctp}/(X_{ctpu} \cdot R_L) \text{ A} \quad (10.182)$$

where

$$X_{ctpu} = (C_s/C_t)(Q_s/F_s) \text{ p.u.} \quad (10.183)$$

The plot of converter gain vs. the switching frequency ratio F_s can be obtained using Eq. (10.169). If the ratio C_s/C_t increases, then the converter takes the characteristics of SRC and the load voltage regulation requires very wide variation in the switching frequency. Lower values of C_s/C_t takes the characteristics of a PRC. Therefore, a compromised value of $C_s/C_t = 1$ is usually chosen in the design of such converters (Bhat, 1988, 1991; Steigerwald, 1988).

The converter gain and other equations just derived can be repeated for the SRC, PRC, and other resonant converters (Bhat, 1991).

Resonant Transition Converters

Major problem with the resonant converters is the high-current (or voltage) stress across the switches due to the generation of sinusoidal currents (and voltages). To overcome this problem, resonant transition converters have been proposed (Hua, Leu, and Lee, 1992; Hua et al., 1993). Basically, these converters use LC elements together with an auxiliary switch (the rating of which is much lower than the main switch) in parallel with the main switching device. Resonant transitions are used only during switching instants. These converters can be viewed as the switches employing active snubbers. There are two types of converters possible:

- *Zero-current-transition PWM converters* (Hua, Leu, and Lee, 1992): Figure 10.91 shows an example of zero-current transition boost converter. This approach is useful in high power converters when **insulated gate bipolar transistors (IGBTs)** or bipolar transistors are used as the switching devices.
- *Zero-voltage transition PWM converters* (Hua et al., 1993): Figure 10.92 shows an example of zero-voltage transition boost converter.

Some of the advantages of these converters are: fixed-frequency ZCS or ZVS PWM operation with characteristics closer to the PWM converters, and operation in ZCS or ZVS for both the switches and rectifier diodes for wide load and line voltage variations. The leakage inductance of the HF transformer, however, must be minimized in the isolated version of the converters. Also, extra components and drive circuits are required.

With the development of digital ICs operating on low voltage (of the order of 3 V) supplies, the use of MOSFETs as synchronous rectifiers with very low voltage drop ($\cong 0.2$ V) has become essential (Motorola, 1989) to increase the efficiency of the DC-to-DC converter.

Defining Terms

DC-to-DC converters: A power electronic circuit that converts DC input to DC output.

Duty cycle: Ratio of on time of the switch to the period of switching.

Insulated gate bipolar transistor (IGBT): A power semiconductor which can be turned on like a MOSFET with a collector to emitter conduction drop similar to a bipolar transistor.

Large signal analysis: Analysis used to study the behavior of a converter for large step changes in an input parameter (e.g., input supply voltage change, load change, etc.).

Resonant-transition-converter: A DC-to-DC converter that employs resonant transitions only during the instants of switching.

Small signal analysis: Analysis used to study the behavior of a converter for small changes in an input parameter (e.g., control voltage).

10.7 Power Distribution and Control

Badrul H. Chowdhury

10.7.1 Introduction

The power distribution system is that part of the power system which is concerned with delivering the power generated at remote generating stations to the consumers. Its place in the entire scheme of the power generation and transmission system is shown in Fig. 10.93. Transmission voltages can range up to 760 kV and subtransmission and distribution voltages are successively lower. Power from bulk sources is stepped down at substations for distribution to different points in a service area. Primary distribution feeders, originating at the substations, carry power at voltages such as 2.4, 4, 16, and 13.8 kV or higher. Distribution transformers are used to step down from these primary voltage levels to 120 or 240 V for distribution over secondary lines to the individual customer's connection point. A generic scheme for distributing power is shown in Fig. 10.94. The primary system consists of the circuit between the distribution **substation** and the distribution **transformers**. A primary **feeder** includes a main feeder; usually a three-phase, four wire circuit; and lateral and sublateral branches tapped from the primary mains. The lateral circuits can be either single phase or three phase. **Fuses** and **reclosers** are freely used on feeders in order to minimize the portion of the circuit removed during faults.

The most common type of primary feeder is of the radial type, wherein the main feeder branches off into several lateral and sublateral branches. The current magnitude is the greatest in the circuit conductors that leave the substation and the smallest in the conductors farthest from the substation. Hence, if the same size of conductors are used in all circuits, then the capacity of those conductors which are far from the substation are underutilized. The reliability of service continuity of radial systems is low since the

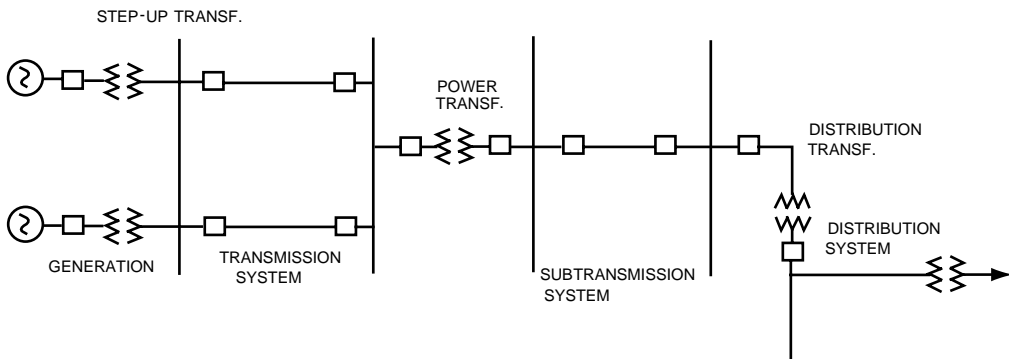

FIGURE 10.93 One-line diagram of a generation-transmission-distribution system.

FIGURE 10.94 A generic primary distribution system.

occurrence of a fault at any location on the radial system causes power outage for all of the customers downstream on the feeder. If a higher service reliability is desired, the primary system could be designed as a loop where the feeder loops through the loads and returns to its origin, the substation. Thus, if a faulted section is isolated, the remaining sections can still be served, irrespective of their location. A specific design, called *primary networking*, is one where adjacent primary feeders emanating from different substations are interconnected together. This system has the capability of serving a load from several different directions, thus providing higher service reliability than the other designs.

The secondary system, as seen in Fig. 10.94, is that part of the distribution system that originates at the distribution transformers and ends at the consumer loads. Each secondary main may supply groups of customers. In some instances where greater service reliability is incorporated into the design, the secondary mains of several adjacent transformers may be connected together through a fuse or a recloser. This is referred to as *secondary banking*. If an even higher service reliability is desired in relation to secondary banking, the secondary mains in an area can all be connected together in a mesh or a network, similar to primary networking.

Single-Phase vs. Three-Phase Primary Systems

Single-phase circuits are mostly found in secondary systems and are typically used for supplying small motor and lighting loads. On the other hand, three-phase systems are used to supply larger industrial loads and are inherently more economical than single-phase systems. The following are the nominal voltage standards for most electric utilities serving residential and commercial customers in the U.S.:

- 120/240-V three-wire single-phase
- 120/240-V four-wire three-phase delta
- 208 Y/120-V four-wire three-phase wye
- 480 Y/277-V four-wire three-phase wye

The single-phase two-wire system, shown in Fig. 10.95(a), consists of a two-conductor circuit with constant voltage available between the conductors. The load is connected across the two lines. For safety reasons, one of the conductors can be grounded to form the neutral line. The single-phase, three-wire system, shown in Fig. 10.95(b), is the equivalent of two, two-wire systems combined so that a single wire serves as one wire of each of the two systems, the neutral. Hence, if one outer wire has a potential of 120 V above the neutral, the other outer wire will be 120 V below the neutral. The voltage between the two outer conductors will be 240 V.

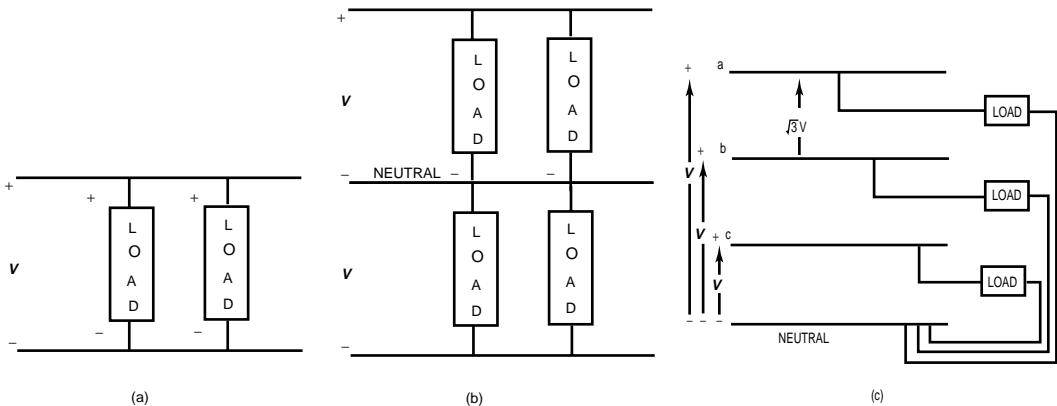

FIGURE 10.95 Distribution line arrangement.

In the three-phase, four-wire system, shown in Fig. 10.95(c), the voltage between each phase conductor and the neutral conductor is equal to 120 V. The individual phase voltages are also 120° out of phase with each other. If the positive sequence is followed, the a-phase leads the b-phase and the b-phase leads the c-phase by 120° . The voltages between the phases are $\sqrt{3}$ times the phase-to-neutral voltages of 120 V. Single-phase loads are connected between each phase and the neutral. If the loads in each phase can be balanced, then the currents in all three lines are also equal in magnitude with the phase angles being 120° out of phase. Under this condition, no current exists in the neutral conductor.

In the next section, the basics of complex algebra are introduced. Complex algebra is required whenever alternating current analysis is desired. Since most distribution systems are of the AC type, this tool is a necessity. In succeeding sections, distribution line equipment and substation equipment are discussed. Voltage analysis in power distribution systems are described at the end.

10.7.2 Basics of AC Analysis

Complex Numbers

A complex number is represented by a real part and an imaginary part. For example, in $A = a + jb$, A is the complex number; a is real part, sometimes written as $\text{Re}(A)$; and b is the imaginary part of A , often written as $\text{Im}(A)$. It is a convention to precede the imaginary component by the letter j (or i). This form of writing the real and imaginary components is called the *Cartesian* form and symbolizes the complex (or s) plane, wherein both the real and imaginary components can be indicated graphically. To illustrate this, consider the same complex number A when represented graphically as shown in Fig. 10.96. A second complex number B is also shown to illustrate the fact that the real and imaginary components can take on both positive and negative values. Figure 10.96 also shows an alternate form of representing complex numbers. When a complex number is represented by its magnitude and angle, for example, $A = r_A \angle \theta_A$, it is called the *polar* representation.

To see the relationship between the Cartesian and the polar forms, the following equations can be used:

$$r_A = \sqrt{a^2 + b^2} \quad (10.184)$$

$$\theta_A = \tan^{-1} \frac{b}{a} \quad (10.185)$$

FIGURE 10.96 The s plane representing two complex numbers.

Conceptually, a better insight can be obtained by investigating the triangle shown in Fig. 10.97, and considering the trigonometric relationships. From this figure, one can see that

$$a = \text{Re}(A) = r_A \cos(\theta_A) \quad (10.186)$$

$$b = \text{Im}(A) = r_A \sin(\theta_A) \quad (10.187)$$

FIGURE 10.97 The relationship between Cartesian and polar forms.

Euler’s Identity

The well-known Euler’s identity is a convenient conversion of the polar and Cartesian forms into an exponential form, given by

$$\exp(j\theta) = \cos \theta + j \sin \theta \quad (10.188)$$

Phasors

AC voltages and currents, appearing in distribution systems, can be represented by **phasors**, a concept useful in obtaining analytical solutions of 1- ϕ and 3- ϕ systems. A phasor is generally defined as a transform of sinusoidal functions from the time domain into the complex-number domain and given by the expression shown in Eq. (10.189) as

$$\mathbf{V} = V \exp(j\theta) = P\{V \cos(\omega t + \theta)\} = V/\underline{\theta} \quad (10.189)$$

where \mathbf{V} is the phasor, V is the magnitude of the phasor, and θ is the angle of the phasor. The convention used here is to use boldface symbols to symbolize phasor quantities. Graphically, in the time domain, the phasor \mathbf{V} would be a simple sinusoidal wave shape as shown in Fig. 10.98. The concept of a phasor *leading* or *lagging* another phasor becomes very apparent from the figure. Phasor diagrams are also another effective medium of understanding the relationships between phasors. Figure 10.99 shows a phasor diagram for the phasors represented in Fig. 10.98. In this diagram, the convention of positive angles being read counterclockwise is used. The other alternative is certainly possible as well. It is quite apparent that a purely capacitive load could result in the phasors shown in Fig. 10.98 and Fig. 10.99.

FIGURE 10.98 Wave forms representing leading/lagging phasors.

FIGURE 10.99 Phasor diagram showing phasor representation and phasor operation.

The Per Unit System

In the per unit system, basic quantities such as voltage, current, etc., are represented as certain percentages of base quantities. When so expressed, these per unit quantities do not need units, thereby making numerical analysis in power systems somewhat more easy to handle. Four quantities, namely, voltage, current, power, and impedance, encompass all variables required to solve a power system problem. Out of these, only two base quantities, corresponding to voltage (V_b) and power (S_b), are required to be defined. The other two base quantities can be derived from these two. Consider the following. Let

V_b = voltage base, kV

S_b = power base, MVA

I_b = current base, A

Z_b = impedance base, Ω

Then

$$Z_b = \frac{V_b^2}{S_b} \quad \Omega \quad (10.190)$$

$$I_b = \frac{V_b 10^3}{Z_b} \quad \text{A} \quad (10.191)$$

Power Calculations

Four different power definitions are encountered in power system calculations. These are (with their symbolic representation in parentheses): real power (P), reactive power (Q), complex power (S), and apparent power (T). Their individual definitions and relationships are discussed next with reference to Example 1.

Example 1

Figure 10.100 shows a single-phase distribution system with a single source supplying a load through a feeder which has a resistance of 0.5Ω and a reactance of 1.2Ω . The load impedance is as shown. Assume that the voltage measured at the load is $V_L = 10/0^\circ$.

FIGURE 10.100 A simple single-phase circuit showing a load being supplied from a single source.

Real Power

This is the amount of power that does the actual work when supplying a customer's load; hence, the name **real power**. It is measured in watts and is the amount that is used for billing customers.

$$P = V_L I \cos \theta \quad \text{W} \quad (10.192)$$

where

V_L = rms value of the voltage at the load

I = rms value of the current into the load

θ = phase angle between the voltage and the current phasors

In Fig. 10.100, $V_L = 10 \text{ V}$, $Z_L = 3 + j4 = 5/53.13^\circ$, $I = V_L/Z_L = 10/0^\circ/5/53.13^\circ \text{ A} = 2/-53.13^\circ \text{ A}$. Hence, $I = 2 \text{ A}$; $\theta = -53.13^\circ$. Therefore, from Eq. (10.192), $P = 12 \text{ W}$.

Reactive Power

Reactive power is the amount of power that travels between the source and the load, without doing real work. It is the amount responsible for changing the power factor of the load. The reactive power is measured in var (or kvar).

$$Q = V_L I \sin \theta \quad \text{vars} \tag{10.193}$$

In Fig. 10.100, $Q = 16 \text{ var}$.

Complex Power

When the real and reactive powers are expressed as the real and imaginary components, respectively, of a complex number expression, the latter form is called complex power, and the unit used is megavoltampere

$$S = P + jQ \quad \text{MVA} \tag{10.194}$$

Apparent Power

The magnitude of the complex power S is called the apparent power. Thus

$$T = |S| = \sqrt{P^2 + Q^2} \tag{10.195}$$

From Eqs. (10.192) and (10.193), one can see that

$$T = VI \tag{10.196}$$

In Fig. 10.100, $S = 20/\underline{53.13^\circ} \text{ MVA}$; $T = 20 \text{ MVA}$.

Often the definition of the power terms can be best understood with the help of a power triangle as shown in Fig. 10.101. Note the relationship of this triangle with that of Fig. 10.97.

FIGURE 10.101 The power triangle.

Power Factor

The **power factor** (pf) of a load is defined as the cosine of the angle between the voltage across and the current through the load. Also, from Eq. (10.192) and Eq. (10.196), it is easy to see that the power factor is also the ratio of the real power and the apparent power. The power factor is further quantified by either a *leading* or a *lagging* label to represent capacitive or inductive loads, respectively. Thus

$$\text{pf} = \cos(\angle V - \angle I) = P/T \tag{10.197}$$

In Example 1, verify that the power factor of the load is 0.6 lagging.

Power Factor Correction

Often, the loads at industrial demand points can cause consumption of large reactive components, causing low power factors. It is easy to see from the power triangle in Fig. 10.101 that the power factor angle is directly related to the reactive power and that this angle can be made to go from lagging to leading by changing the amount of reactive power consumed at the load to reactive power injected into the line at the load. Capacitors are typically used in parallel with the loads in order to produce reactive power for suppressing the reactive power consumption. This reduction in reactive power consumed results in a reduced total current, thereby causing reduced power losses.

To illustrate power factor correction calculations, consider the same load of Example 1. It consumes $P = 12 \text{ W}$ of real power and $Q = 16 \text{ var}$ of reactive power to produce a power factor of 0.6 lagging. Assume that we want to improve the power factor to 0.9 lagging. Thus, we need to size a shunt capacitor to provide the necessary correction. From the power triangle, it is easy to see that the new power factor is given by

$$\cos \left[\tan^{-1} \frac{Q_2}{P} \right] = 0.9 \tag{10.198}$$

FIGURE 10.102 The phasor diagram for the circuit of Fig. 10.100.

where Q_2 represents new reactive power consumption at the load. If Q_c represents the amount of reactive power supplied by the capacitor, then

$$Q_c = Q - Q_2 \quad (10.199)$$

Voltage Regulation

The per cent voltage drop of a line with respect to the receiving-end voltage is termed the voltage regulation. It is defined as

$$\text{voltage regulation} = \frac{|V| - |V_L|}{|V_L|} \quad (10.200)$$

where $|V|$ is the sending-end voltage magnitude and $|V_L|$ is the receiving or load-end voltage magnitude. The higher the voltage drop in the line $|V| - |V_L|$, the higher is the regulation. The voltage at the source end can be found by the following relation:

$$V = V_L + I(r + jx) \quad (10.201)$$

Equation (10.201) can then be used to find the voltage drop in the line. However, an approximate relation can be found for the voltage drop by investigating the phasor diagram for the circuit shown in Fig. 10.100. The phasor diagram is shown in Fig. 10.102.

As seen in the figure, angle θ is the power factor angle. If the angle δ is small, then the approximate voltage drop is given by

$$\text{voltage drop} = |V| - |V_L| = Ir \cos \theta + Ix \sin \theta \quad (10.202)$$

For the problem of Example 1, Eq. (10.200) yields a voltage drop of 2.53 V whereas Eq. (10.202) yields a drop of 2.52 V. The difference in results from the two equations is, therefore, negligible.

Three-Phase Systems

If the 3- ϕ system is balanced, or close to being balanced, then a number of simplifying assumptions can be used to make the problem more tractable. For examples real power can be assumed to be three times the power consumed by a single phase.

Mathematically

$$P_{3\phi} = 3(VI \cos \theta) \quad \text{and} \quad Q_{3\phi} = 3(VI \sin \theta)$$

A significant advantage is achieved since only one phase of the balanced three-phase system can be used to determine voltages and currents in all three phases. This is illustrated by the following example.

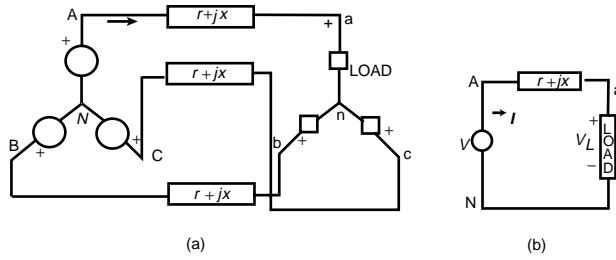

FIGURE 10.103 (a) A three-phase power system with wye-connected source and load. (b) the single-phase equivalent circuit.

Example 2

Consider the three-phase power system shown in Fig. 10.103(a). Assume the following data for the system:

- Phase voltages: $V_{AN} = 150/0^\circ$, $V_{BN} = 150/-120^\circ$, $V_{CN} = 150/120^\circ$.
- Loads connected in wye: $Z_{an} = Z_{bn} = Z_{cn} = 35 + j25 \Omega = 43/35.54^\circ \Omega$.
- Transmission line: identical in each phase; $r = 5 \Omega$, $x = 15 \Omega$.
- Find the line currents and the voltages across the loads.

Since the system is fully balanced, we can use the single-phase equivalent circuit, shown in Fig. 10.103(b), for the analysis. Using Kirchhoff’s circuit laws

$$I_{Aa} = V_{AN}/(r + jx + Z_{an}) = 2.65/-45^\circ \text{ A.}$$

Hence, $V_{an} = I_{Aa} Z_{an} = 114/-9.46^\circ \text{ V}$. Therefore, the desired results are

- Voltages:

$$\begin{aligned} V_{an} &= 114/-9.46^\circ & V_{bn} &= 114/-129.46^\circ \text{ V} & V_{cn} &= 114/110.54^\circ \text{ V} \\ V_{ab} &= 197.5/20.54^\circ & V_{bc} &= 197.5/-99.46^\circ \text{ V} & V_{ca} &= 197.5/140.54^\circ \text{ V} \end{aligned}$$

- Currents:

$$I_{Aa} = 2.65/-45^\circ \text{ A} \quad I_{Bb} = 2.65/-165^\circ \text{ A} \quad I_{Cc} = 2.65/75^\circ \text{ A}$$

The complete phasor diagram is shown in Fig. 10.104.

10.7.3 Distribution Line Equipment

Transformers

Transformers are the most common pieces of equipment found in all substations and distribution lines. Different types of transformers are used for varied purposes, from voltage level changes to phase angle regulation. Since the primary circuit of distribution systems are designed for high voltages in order to increase its load carrying capability, the voltage must be stepped down at the consumer points to ensure proper operation of all devices and equipment connected there. Thus, the most popular use for transformers is to change the voltage level from one side to another.

FIGURE 10.104 The complete phasor diagram for Example 2.

FIGURE 10.105 (a) Equivalent circuit of an ideal transformer. (b) approximate equivalent circuit of a nonideal transformer.

Transformers can be classified as *distribution* transformers and *power* transformers. The former type normally steps down voltages from primary voltage levels, such as 2400, 4160, or 13,800 V to 120 or 240 V. They are almost always located outdoors where they are hung from crossarms, mounted on poles directly, or placed on platforms. Power transformers are larger in size than distribution transformers and usually have auxiliary means for cooling. These transformers are typically installed at distribution substations for stepping down voltages from the subtransmission levels of 34.5 and 69 kV to primary distribution levels of up to 13.8 kV.

Single-Phase Transformers

A transformer consists of two (sometimes three) electrically isolated copper windings wound on an iron core. The choice of a ferromagnetic material for the core is to allow for high permeability so that the magnetic flux can be established easily. The core is usually laminated to reduce losses. Figure 10.105 shows a general representation of a single-phase transformer with the two windings on each side representing the primary and the secondary sides. In the figure subscript 1 denotes the primary quantities and subscript 2 signifies the same on the secondary side. For the ideal transformer of Fig. 10.105(a), the following relationship holds:

$$\frac{V_1}{V_2} = \frac{N_1}{N_2} = \frac{I_2}{I_1} = a \tag{10.203}$$

where N = the number of turns in the windings and a is the transformation ratio.

The nonideal characteristics of a transformer include core and winding losses, presence of leakage fluxes, and finite permeability of the core. Hence, the actual model should include the physical representations of these nonideal characteristics. This is shown in Fig. 10.105(b), where the shunt magnetization and core loss components have been ignored for the sake of convenience. Such approximations are common in transformer analysis and only cause trivial inaccuracies in computation. Figure 10.106 shows the equivalent circuit of Fig. 10.105(b) with the secondary-side impedance referred to the primary side.

FIGURE 10.106 The approximate equivalent circuit as seen by the primary side.

FIGURE 10.107 Single-phase distribution transformer connections.

Thus, the total impedance on the primary side is

$$Z_{eq} = (r_1 + a^2 r_2) + j(x_1 + a^2 x_2) \tag{10.204}$$

To find the voltage regulation of the transformer, one can use the following equations:

$$V_1 = a V_2 + I_1 Z_{eq} \tag{10.205}$$

where $I_1 = I_2/a$.

Single-phase distribution transformers typically have one high-voltage primary winding and two low-voltage secondary windings, which are rated at a nominal 120 V. The secondary coils may be connected in parallel to supply a two-wire 120-V circuit, shown in Fig. 10.107(a), or in series to supply a three-wire 120/240-V single circuit, shown in Fig. 10.107(b). As seen in the figures, one leg of the 120-V, two-wire system, and the middle leg of the 120/240-V, three-wire system is grounded to limit the voltage to ground on the secondary side.

In general, the 120/240-V three-wire connection is preferred since it has twice the load capacity of the 120-V system with only one-and-one-half times the amount of conductor. Each 120-V winding has one-half the total kilovoltampere rating of the transformer. The loads on the secondary side of the transformers are kept as nearly balanced as possible such that maximum transformer capacity can be utilized, as well as the neutral current kept to a minimum.

Three-Phase Transformers

A three-phase transformer bank can be easily created by using three single-phase transformers. The two sides of these three transformers can be either connected as a wye or a delta, thus allowing four possible types of connections: (1) wye-wye, (2) wye-delta, (3) delta-wye, and (4) delta-delta. These possibilities are shown in Fig. 10.108 to Fig. 10.112. As can be observed in the figures, the primary and secondary phase windings are drawn in parallel.

Another possible way of producing a three-phase transformer is to use a three-legged core with the primary and secondary windings of each phase placed on the three legs. Such a construction has an advantage over the bank construction in that a smaller amount of core material is used. However, the three-phase bank has higher versatility since it can operate even with one phase out of operation.

FIGURE 10.108 Y-Y transformer with 0° phase shift between primary and secondary.

FIGURE 10.109 Y-Δ transformer with primary side lagging the secondary side by 30°.

The Wye-Wye Connection

With the wye-wye (Y-Y) connection, the secondary side is in phase with the primary circuit, and the ratio of primary to secondary voltage is the same as the ratio of turns in each of the phases. A possible connection is shown in Fig. 10.108.

Power distribution circuits supplied from a wye-wye bank often create series disturbances in communication circuits (e.g., telephone interference) in their immediate vicinity. However, one of the advantages of this connection is that when a system has changed delta to a four-wire wye to increase system capacity, existing transformers can be used.

The Wye-Delta Connection

In the Y-Δ connection, there is a 30° phase angle shift between the primary and secondary sides. The phase angle difference can be made either lagging or leading depending on the external connections of the transformer bank. The case with the primary side lagging is shown in Fig. 10.109, and the case with the primary side leading is shown in Fig. 10.110. The transformation ratio is $\sqrt{3}$ times the ratio of turns in each of the phases.

The Delta-Wye Connection

With this connection, the neutral of the secondary wye can be grounded and single-phase loads can be connected across the phase and the neutral conductors and three-phase loads can be connected across the phases. The phasor relationship between the primary and the secondary sides is shown in Fig. 10.111. The transformation ratio is $1/\sqrt{3}$ times the ratio of turns in each of the phases.

FIGURE 10.110 Y-Δ transformer with primary side leading the secondary side by 30°.

FIGURE 10.111 Δ-Y transformer with primary side leading the secondary side by 30°.

FIGURE 10.112 Δ–Δ transformer with 0° phase shift between primary and secondary sides.

The Delta-Delta Connection

This connection does not cause a phase shift between the primary and the secondary sides. The phasor relationship of this transformer is shown in Fig. 10.112. The transformation ratio is equal to the ratio of the turns in each of the phases. There is no problem from third-harmonic overvoltage or telephone interference since such disturbances get trapped in the delta and do not pass into the lines.

Other Three-Phase Transformer Connections

Open-Delta Connection

An advantage of the Δ–Δ connection is that if one of the single-phase transformers becomes damaged or removed for maintenance, the remaining two can be operated in the so-called open-delta connection. Since the currents in each of the two remaining transformers is the same as the line current, each transformer therefore carries $\sqrt{3}$ times the current it was carrying in the closed-delta connection. The open-delta bank continues to deliver three-phase currents and voltages in their correct phase relationship. To keep the transformers from being overloaded, however, it would be necessary to reduce the line currents by $1/\sqrt{3}$. Thus, the comparison of the three-phase capacity can be shown as follows:

$$S_{\text{closed}\Delta} = \sqrt{3} V_L I_L \tag{10.206}$$

$$S_{\text{open}\Delta} = \frac{\sqrt{3} V_L I_L}{\sqrt{3}} \tag{10.207}$$

$$\frac{S_{\text{open}\Delta}}{S_{\text{closed}\Delta}} = \frac{1}{\sqrt{3}} \tag{10.208}$$

Hence, even though the open-delta connection constitutes two-thirds or 66.67% of the original Δ–Δ connection, it can only supply 57.7% of the three transformers combined.

Scott or T Connection

The Scott or T connection is used when a two-phase (or a transformed three-phase) supply is needed from a three-phase system. In general, the T connection is used for getting a three-phase transformation, and the Scott connection is mainly used for obtaining a two-phase system. The two connection types are basically similar in design. Either connection requires two specially wound, single-phase transformers. The main transformer has a 50% tap on the primary winding, whereas the other transformer, called the *teaser* transformer, has an 86.6% tap. The main transformer is connected between two primary lines, whereas the teaser transformer is connected from the center tap of the main transformer to the third primary line. The secondary sides of the transformers are connected to serve a two-phase system. A Scott connection is shown in Fig. 10.113.

FIGURE 10.113 The T connection for three-phase to two-phase transformation.

Autotransformer

This is a specific type of transformer wherein the primary and secondary coils are connected in series with each other. The advantages of this connection are that it has lower losses, smaller excitation current

FIGURE 10.114 The autotransformer connection: (a) single phase (b) three phase.

requirement, weighs less, and is cheaper than the equivalent two-winding transformer. However, a specific disadvantage is the absence of electrical isolation between the primary and secondary sides. The single-phase autotransformer connection is shown in Fig. 10.114(a). The series and common windings are indicated in the figure. The corresponding three-phase connection is shown in Fig. 10.114(b).

Tap-Changing Transformers

Often, it becomes necessary to change the voltage in the transformer winding to allow for a varying input voltage on the transformer. Hence, the output voltage is held close to a constant level irrespective of the input voltage level. Changing taps is directly related to changing the transformation ratio. Two specific types of tap changers are available. These are (1) the no-load tap changer and (2) the under-load tap changer (ULTC). A transformer equipped with a no-load tap changer must always be disconnected from the circuit before the tap can be changed. On small distribution transformers, the covers must be removed, and an operating handle is used to make the tap change. For larger transformers, a handle is usually brought out through the cover, and the tap movement is brought about either manually by the use of a wheel or a motor. Under-load tap changers use the autotransformer principle and elaborate switching mechanisms. The ULTC is discussed in the section on voltage regulators.

Capacitors

Capacitors are used in distribution lines to keep line voltages at certain prespecified levels. Under heavy load conditions, the voltage has a tendency to sag. Capacitors can be used effectively in these situations to bring the voltage back up to the desired level. Capacitors also have an added capability of correcting the power factor at close to the load points.

A capacitor consists of two conducting metal plates separated by a dielectric insulating medium, such as an oil-impregnated paper. Capacitor sizes can vary from the 15–25 kvar range to the 200–300 kvar range. Capacitors can also be installed in banks with bank sizes ranging from 300 to 1800 kvar. Typically, provision is made for switching some of the units in the bank on and off as required to maintain a suitable voltage regulation. Distribution capacitors are mounted on crossarms or platforms.

Voltage Regulators

Voltage regulation on distribution lines can also be obtained by devices called voltage regulators. The majority of voltage regulators in use today are of the step type. These regulators can be used both in substations for bus voltage or individual feeder voltage regulation and pole mounted on overhead primary feeders.

The operating principle of the voltage regulator is somewhat similar to tap-changing transformers. Several taps are provided in the series winding. Most regulators are designed to correct the line voltage from 10% boost to 10% buck in 32 equal steps.

A voltage regulator also comes equipped with two other major components, namely, the tap-changing mechanism and the control mechanism. Line voltage sensing is provided through instrument transformers.

TABLE 10.6 Overhead Conductor Characteristics

Conductor	Type	Res, Ω /mi	Diam, in	GMR, ft	Ampere
1,000,000	AA	0.105	1.15	0.03680	698
556,500	ACSR	0.186	0.927	0.03110	730
500,000	AA	0.206	0.813	0.02600	483
336,400	ACSR	0.306	0.721	0.02440	530
4/0	ACSR	0.592	0.563	0.00814	340
2/0	AA	0.769	0.414	0.01250	230
1/0	ACSR	1.120	0.398	0.00446	230
1/0	CU	0.607	0.368	0.01113	310
#2	AA	1.540	0.292	0.00883	156
#2	ACSR	1.690	0.316	0.00418	180
#4	ACSR	2.550	0.257	0.00452	140
#10	CU	5.903	0.102	0.00331	80
#12	CU	9.375	0.081	0.00262	75
#14	CU	14.872	0.064	0.00208	20

The automatic voltage maintenance on the output of voltage regulators is achieved by dial settings (located on the control panel) of the adjustable resistance and reactance elements of a unit called the line drop compensator.

Overhead Conductors

Many different types of conductors are used on overhead distribution lines. They vary both in size and number, depending on the voltage level and the type of circuit. Copper, aluminum, and steel are the most commonly used material for overhead lines. Copper is used in three forms: hard drawn, medium-hard drawn, and soft drawn or annealed. Hard-drawn copper has the greatest strength and is used for circuits of relatively long spans (200 ft or more). However, its inflexibility makes it harder to work with. The soft-drawn variety is the weakest of the copper conductors. Its use is limited to short spans. The medium-hard-drawn copper conductor has found more widespread use in the medium range distribution circuits.

Steel wire is only about one-tenth as good a conductor as copper and, hence, is rarely used alone. However, it offers an economic advantage over the other types of conductors. Also, since steel wire is much stronger than copper, it permits longer spans and requires fewer supports.

Aluminum is only 60–80% as good a conductor as copper and only half as strong as copper. However, its property of lighter weight, as compared to copper and steel, and its relative advantage in transmitting AC power because of reduced skin effect, makes it suitable for overhead lines. Usually the aluminum wires are stranded on a core of steel wire to form what is termed as aluminum conductors steel reinforced (ACSR) conductor. The more strands in the ACSR conductor, the greater is its flexibility. Hence, today's larger conductors are all stranded and twisted in layers concentrically around a central steel wire.

Table 10.6 lists the characteristics of various conductors that are typically used on overhead distribution lines (IEEE, 1991).

Underground Cables

Underground construction of distribution lines is designed mostly in urban areas and is dictated by economics, congestion, and density of population. Although overhead lines have been ordinarily considered to be less expensive and easier to maintain, developments in underground cable and construction technology have narrowed the cost gap to the point where such systems are competitive in many urban and suburban residential installations.

The conductors used underground are different from overhead conductors in that they are insulated for their entire length and several of them may be combined under one protective sheath. The whole assembly

is called an electric cable. These cables are either buried directly in the ground, or they may be installed in ducts buried in the ground.

The conductors in cables are usually made of copper or aluminum and are usually stranded. They are made of soft-drawn copper since they do not have to support any weight. Cables can be either single conductor or multiple conductor enclosed in a single sheath for economy.

Fuses and Fuse Cutouts

To prevent circuit overloads, short pieces of metal having low melting characteristics are installed in circuits. Fuses are designed to melt and disconnect the circuits they are placed on should the current in these circuits increase above the thermal ratings. Fuses designed to be used above 600 V are classified as *fuse cutouts*. Oil-filled cutouts are mainly used in underground installations and contain the fusible elements in an oil-filled tank. Expulsion-type cutouts are the most common type used on overhead primary feeders. In this cutout, the melting of the fusible element causes heating of a fiber fuse tube, which, in turn, produces deionizing gases to extinguish the arc. Expulsion type cutouts are classified as (1) open-fuse cutouts, (2) enclosed-fuse cutouts, and (3) open-link-fuse cutouts.

Automatic Reclosers

The recloser is another overcurrent device that automatically trips and recloses a preset number of times to clear or isolate faults. The concept of reclosing is derived from the fact that most faults are of the temporary type and can be cleared by de-energizing the circuit for a short period. Reclosers can be set for a number of operation sequences depending on the action desired. These typically include instantaneous trip and reclose operation followed by a sequence of time-delayed trip operations prior to lockout of the recloser. The minimum pick-up for most reclosers is typically set to trip instantaneously at two times the current rating.

An automatic line recloser is made of an interrupting chamber and the related contacts that operate in oil, a control mechanism to trigger tripping and reclosing, an operator integrator, and a lockout mechanism. An operating rod is actuated by a solenoid plunger that opens and closes the contacts in oil. Both single-phase and three-phase units are available.

Line Sectionalizer

The **line sectionalizer** is yet another overcurrent device, which is installed with backup circuit breakers or reclosers. It has coordination with the backup interrupting device and is designed to open after a preset number of tripping operations of the backup device. They are installed on poles or crossarms in overhead distribution systems. The standard continuous current rating for sectionalizers range from 10 to 600 A. Sectionalizers also come in both the single-phase and the three-phase variety.

Lightning Arrester

A lightning arrester is a device that protects expensive electrical apparatus from voltage surges caused by lightning. It provides a path over which the surge can pass to ground before it has the opportunity to pass through and damage the equipment.

A standard lightning arrester consists of an air gap in series with a resistive element. The resistive element is usually made of a material that allows a low-resistance path to the voltage surge, but presents a high-resistance path to the flow of line energy during normal operation. This material is known as the *valve* element. A common valve element material is silicon carbide. The voltage surge causes a spark that jumps across the air gap and passes through the resistive element to ground.

One type of arrester consists of a porcelain cylinder filled with some suitable material with electrodes at either end. The series gap assembly is usually at the top. In another type of arrester, called the expulsion type, there are two series gaps, one internal and one external. During a voltage surge, these gaps have to be bridged. Another gap formed between two internal electrodes and placed between two internal electrodes is assembled inside a fiber tube that functions as the valve element and serves to resist the flow of line

energy when it comes through. This tube helps create nonconducting gases, which blow the arc formed through a vent, thus establishing a wall of resistance to the line energy.

10.7.4 Distribution Substation

Distribution substations serve as the source for primary distribution feeders. They receive bulk electric power at high voltages and reduce the voltage to distribution primary values. Also associated with a substation are provisions for protection from faults, for voltage regulation, and for data acquisition and monitoring.

The principle equipment generally installed in a distribution substation are power transformers, oil or air circuit breakers, voltage regulators, protective relays, air break and disconnect switches, surge arresters, measuring instruments, and in some instances, storage batteries and capacitors.

Some substations are entirely enclosed in buildings whereas others are built entirely in the open with all equipment enclosed in a metal-clad unit. The final design of the type of substation depends on economic factors, future load growth, and environmental, legal, and social issues.

Transformers have been discussed in an earlier section. Hence, the discussion in this section will be limited to **circuit breakers** and protection schemes.

Circuit Breakers

The function of circuit breakers is to protect a circuit from the harmful effects of a fault, in addition to energizing and de-energizing the same circuit during normal operation. Breakers are generally installed on both the incoming subtransmission lines and the outgoing primary feeders. These devices are designed to operate as quickly as possible (less than 10 cycles of the power frequency) to limit the impact of a fault on the expensive equipment installed at the substation. At the same time, the arc that forms between opening contacts also has to be quenched rapidly. Several schemes are available to extinguish the arc. The medium of oil is often used in this process. Some circuit breakers have no oil, but quench the arc by a blast of compressed air. These are called *air circuit breakers*. Yet another type encloses the contacts in a vacuum or a gas, such as sulfur hexafluoride, SF₆.

Air circuit breakers are typically used when fault currents are relatively small. These are characteristically simple, low cost and require little maintenance. The fault current flows through coils creating a magnetic field that tends to force the arc into ceramic chutes that stretch the arc, often with the aid of compressed air.

When the arc is extinguished through vacuum, the breaker is called a *vacuum circuit breaker*. Since a vacuum cannot theoretically sustain an arc, it can be an effective medium. However, owing to imperfections present in vacuum, a small arc of short duration can be produced. The construction of vacuum circuit breakers is simple, but the maintenance is more complex.

Breaker Schemes

The breaker schemes used at substations provide for varying degrees of reliability and maintainability on both the input and output sides. Each additional circuit breaker provides greater reliability and flexibility in maintaining the bus energized during fault or maintenance. However, the cost also increases with each circuit breaker. Hence, the selection of a particular substation scheme depends on safety, reliability, economy and simplicity. The most commonly used breaker schemes are (Gonen, 1986): (1) the single-bus, shown in Fig. 10.115(a), (2) the double-bus, double breaker, shown in Fig. 10.115(b), (3) the main-and-transfer bus, shown in Fig. 10.115(c), (4) the breaker-and-a-half, shown in Fig. 10.115(d), and (5) the ring bus, shown in Fig. 10.115(e).

Of these schemes, the single-bus scheme costs the least; however, it possesses a low reliability since the failure of the bus or any circuit breaker results in a total shutdown of the substation. The most expensive arrangement is the double-bus, double-breaker scheme. Each circuit is provided with two circuit breakers, and thus, any breaker can be taken out of service for maintenance without disruption of service at the

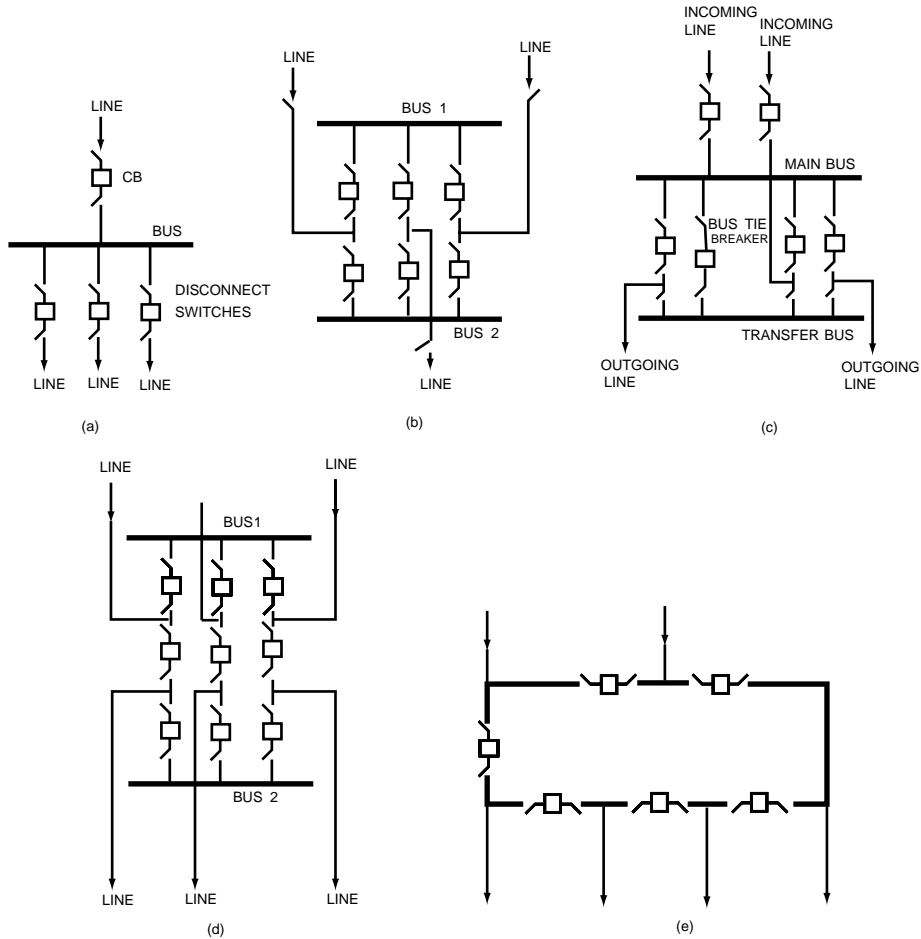

FIGURE 10.115 Substation bus and breaker arrangements.

substation. Also, feeder circuits can be connected to either bus. The main-and-transfer bus requires an extra breaker for the bus tie between the main and the auxiliary buses. The breaker-and-a-half scheme provides the most flexible operation with high reliability. The relaying and automatic reclosing, however, are somewhat complex.

10.7.5 Distribution System Analysis

A number of different mathematical analyses are regularly carried out by distribution planning engineers. Some of the more widely used analytical topics include

- Voltage analysis
- Power loss analysis
- Reactive power analysis
- Peak load analysis
- Motor start analysis
- Protection coordination

Only voltage analysis will be covered here.

Voltage Analysis

Distribution systems are designed to maintain service voltages within specified limits during normal and emergency conditions. Typical voltage limits are

- For service to residential customers, the voltage at the point of delivery shall not exceed 5% above or below the nominal voltage. This is equivalent to the band between 114 and 126 V for most utilities in the U.S.
- For service to commercial or industrial customers, the voltage at the point of delivery shall not exceed 7.5% above or below the nominal voltage.
- The maximum allowable voltage imbalance for a three-phase service should be 2.5%.

The goal of voltage analysis is to determine whether the voltages on different line sections stay within the specified limits under varying load conditions. Thus, voltage analysis facilitates the effective placement of capacitors, voltage regulators, and other voltage regulation devices on the distribution system. Load flow analysis is a computer-aided tool, which is typically used in this planning task. Load flows determine feeder voltages under steady state and at different load conditions.

Voltage analysis starts with a correct representation, or map, of the feeder circuits, starting at the substation. The map generally consists of details and electrical characteristics (e.g., kilovoltampere rating, impedance, etc.) of the conductors and cables on the system, substation and distribution transformers, series and shunt capacitors, voltage regulators, etc.

Before the analysis can begin, feeder loading must be known. Several different methods can be used for this task. If the utility maintains a database on each customer connected to a distribution transformer, it can use the billing data to determine the kilowatt hour supplied by each transformer for a given month. Methods can then be used to convert the kilowatt hour to a noncoincident peak kilovoltampere demand for all distribution transformers connected on the feeder. If this information is not available, the kilovoltampere rating of the transformer and a representative power factor can be used as the load. With the metered demand at the substation, the transformer loads can be allocated, for each phase, such that the allocated loads plus losses will equal the metered substation demand.

Accurately representing the load types or models is an important issue in voltage analysis. Several load models are available. These are

- Spot and distributed loads
- Wye and delta connected loads
- Constant power, constant current, constant impedance, or a combination

In addition, feeder models must also be applied before the analysis can begin. The feeder model can range from the most accurate model, which includes all three phases with exact phasing and spacings of the lines, to an approximate lumped model consisting of lumping the feeder load at the centroid of the feeder area. There are other possible models between the two extremes.

Impedance Calculation

An important step prior to starting voltage analysis is the determination of line impedance. Quite often, impedance tables are used for standard conductors. However, for greater accuracy, *Carson's equations* are recommended (Kersting, 1992).

A modification of Carson's equations is now used widely in calculating self-and mutual impedances in ohm per mile. The equations are

$$Z_{ii} = r_i + 0.0953 + j0.12134(\ln(1/GMR_i) + 7.93402) \quad (10.209)$$

$$Z_{ij} = 0.0953 + j0.12134(\ln(1/D_{ij}) + 7.93402) \quad (10.210)$$

where

- Z_{ii} = self impedance of conductor i
- Z_{ij} = mutual impedance between conductors i and j
- r_i = resistance of conductor i
- GMR_i = geometric mean radius of conductor i , ft
- D_{ij} = distance between conductors i and j , ft

Equations (10.206) and (10.207) are used to compute a square $n \times n$ impedance matrix, where Z_{ii} are the diagonal terms and Z_{ij} are the symmetrical off-diagonal terms. Thus, for a four-wire overhead wye line section, it will result in a 4×4 matrix.

The impedance matrix needs to be reduced to a 3×3 phase frame matrix consisting of the self- and mutual equivalent impedances for the three phases. A standard method of reduction is the Kron reduction where the assumption is made that the line has a multigrounded neutral. Each element of the reduced matrix is determined by the equation

$$Z'_{ij} = Z_{ij} - Z_{in}Z_{nj}/Z_{nn} \quad (10.211)$$

where the subscript n indicates neutral.

Often, the analysis of a feeder uses the positive and zero sequence impedances for the line sections. The 3×3 sequence impedance matrix can be obtained by the following transformation:

$$[Z_{012}] = [A]^{-1}[Z_{abc}][A] \quad (10.212)$$

where

- $[Z_{012}]$ = sequence impedance matrix
- $[Z_{abc}]$ = phase frame impedance matrix
- $[A]$ = symmetrical component transformation matrix

Analysis Methods

Two methods of voltage analysis are discussed briefly. These are

- K factors method
- Ladder network method

K Factors Method

This is an approximate method for finding out the voltage drop in a feeder section. In this method, a K_{drop} factor and a K_{rise} factor are computed for the primary conductors. The K_{drop} factor is defined as the per unit voltage drop per kilovoltampere-mile. A similar definition exists for the K_{rise} factor. The procedure to determine the K_{drop} factor is as follows:

Step 1. Assume a load of 1 kVA, 0.9 lagging power factor located 1 mi from the substation.

Step 2. Find the current by the following equation:

$$I = \frac{1 \text{ kVA}}{\sqrt{3} V_L \text{ kV}} \angle -25.84^\circ \text{ A} \quad (10.213)$$

where V_L is the line-to-line voltage magnitude of the primary feeder.

Step 3. Determine the voltage drop from the substation to the load by

$$VD = \text{re}(Z^+ I) \text{ V} \quad (10.214)$$

where Z^+ is the positive sequence impedance of the primary conductors in ohm per mile.

Step 4. Compute K_{drop} factor as

$$K_{\text{drop}} = (VD/V_{N,\text{rated}}) \text{ per unit drop/kVA-mi} \quad (10.215)$$

where $V_{N,\text{rated}}$ is the rated line-to-neutral voltage.

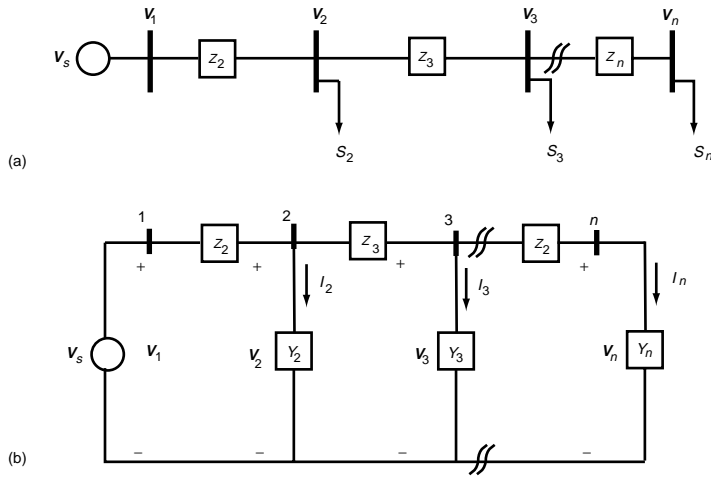

FIGURE 10.116 (a) A radial feeder, (b) its ladder representation.

Thus, if K_{drop} for a specific feeder has been determined to be 0.004%, then, for an actual load of $2500 + j1500 \text{ kVA} = 2915.5\angle 31^\circ$ at a distance of 0.5 mi from the substation, the per cent voltage drop is calculated by

$$VD = (K_{drop}) (\text{kVA})(\text{length pu}) \tag{10.216}$$

On a 120-V base, this represents a voltage drop of

$$VD = (0.0004)(2915.5)(0.5)(120) = 7 \text{ V}$$

Thus, if the goal is to limit the voltage drop to within 5% of the nominal voltage of 120 V, then the drop represents a violation. This situation requires the use of voltage correction devices on the system.

Ladder Network Method of Voltage Analysis

This is an iterative technique used to solve linear electric networks of the ladder type. Since most radial distribution systems can be represented as ladder circuits, this method is effective in voltage analysis. An example of a distribution feeder and its equivalent ladder representation are shown in Fig. 10.116(a) and Fig. 10.116(b), respectively. It should be mentioned that Fig. 10.116(b) is a linear circuit since the loads are modeled as constant admittances. In such a linear circuit, the analysis starts with an initial guess of the voltage at node n . The current I_n is calculated as

$$I_n = V_n Y_n \tag{10.217}$$

With I_n known, the voltage drop in the line section can be calculated, and in turn, the preceding node $(n - 1)$ voltage can be found from Eq. (10.201). Consequently, the load current at node $n - 1$ can be found and the entire procedure repeats thereafter until one reaches node 1 where the source voltage V_1 is calculated. The calculated voltage V_1 is then compared with the known source voltage V_s and a correction factor is found by

$$\gamma = \frac{V_s}{V_1} \tag{10.218}$$

All calculated voltages are multiplied by this correction factor in order to reach the final solution.

In reality, a distribution system is nonlinear since loads are modeled as constant power. Hence, the exact ladder theory cannot be applied. A modification of the linear ladder network solution is used.

In this procedure, the loads are assumed to be constant power instead of constant admittances. Thus, the loads are S_n , S_{n-1} , S_{n-2} , and so on. An initial guess is again made at node n . This time, the current I_n is calculated as

$$I_n = \left(\frac{S_n}{V_n} \right)^* \quad (10.219)$$

where, superscript asterisk represents the conjugate of the complex number. As in the linear case, the analysis proceeds backward and calculates all nodal voltages. Subsequently, when the calculated voltage V_1 is compared with the known source voltage V_s , an error voltage is computed instead of a correction factor. This is given by

$$\Delta V = V_s - V_1 \quad (10.220)$$

The error is added to the assumed voltage at node n using

$$V_{n,\text{new}} = V_{n,\text{old}} + \Delta V \quad (10.221)$$

The entire set of calculations is then repeated by working backward from node n to the source. The procedure is iterated until the calculated voltage V_1 is within a prespecified tolerance of the known source voltage V_s .

Defining Terms

Circuit breaker: Devices that protect a circuit from the harmful effects of a fault, in addition to energizing and de-energizing the same circuit during normal operation.

Feeder: Lines that carry power from substations to distribution transformers.

Fuse: An overcurrent protection device that interrupts the line flow. Cannot be used repeatedly.

Line sectionalizer: An overcurrent protection device that interrupts the line flow. Used with backup protection devices.

Phasor: A form of representing sinusoids in the complex domain.

Power factor: Defined as the cosine of the angle between the voltage across and the current through the load.

Reactive power: The component of power that does no real work, but is responsible for changing the power factor.

Real power: The component of power that does the actual work.

Recloser: An overcurrent protection device that interrupts the line flow. Can be used repeatedly.

Substation: It serves as the source for primary distribution feeders. Receives bulk electric power at high voltages and reduces the voltage to distribution primary values.

Transformer: Equipment used to change the voltage level. Also used for phase angle regulation.

10.8 Power System Protection Alternatives

Jerry C. Whitaker

10.8.1 Introduction

Utility companies make a good-faith attempt to deliver clean, well-regulated power to their customers. Most disturbances on the AC line are beyond the control of the utility company. Large load changes imposed by customers on a random basis, PF correction switching, lightning, and accident-related system faults all combine to produce an environment in which tight control over AC power quality is difficult to maintain. Therefore, the responsibility for ensuring AC power quality must rest with the users of sensitive equipment.

The selection of a protection method for a given facility is as much an economic question as it is a technical one. A wide range of power-line conditioning and isolation equipment is available. A logical decision about how to proceed can be made only with accurate, documented data on the types of disturbances typically found on the AC power service to the facility. The protection equipment chosen must be matched to the problems that exist on the line. Using inexpensive basic protectors may not be much better than operating directly from the AC line. Conversely, the use of a sophisticated protector designed to shield the plant from every conceivable power disturbance may not be economically justifiable.

Purchasing transient-suppression equipment is only one element in the selection equation. Consider the costs associated with site preparation, installation, and maintenance. Also consider the operating efficiency of the system. Protection units that are placed in series with the load consume a certain amount of power and, therefore, generate heat. These considerations may not be significant, but they should be taken into account. Prepare a complete life-cycle cost analysis of the protection methods proposed. The study may reveal that the long-term operating expense of one system outweighs the lower purchase price of another.

The amount of money a facility manager is willing to spend on protection from utility company disturbances generally depends on the engineering budget and how much the plant has to lose. Spending \$225,000 on system-wide protection for a highly computerized manufacturing center is easily justified. At smaller operations, justification may not be so easy.

The Key Tolerance Envelope

The susceptibility of electronic equipment to failure because of disturbances on the AC power line has been studied by many organizations. The benchmark study was conducted by the Naval Facilities Engineering Command (Washington, D.C.). The far-reaching program, directed from 1968 to 1978 by Lt. Thomas Key, identified three distinct categories of recurring disturbances on utility company power systems. As shown in Table 10.7, it is not the magnitude of the voltage, but the duration of the disturbance that determines the classification.

TABLE 10.7 Types of Voltage Disturbances Identified in the Key Report

Parameter	Type 1	Type 2	Type 3
Definition	Transient and oscillatory overvoltage	Momentary undervoltage or overvoltage	Power outage
Causes	Lightning, power network switching, operation of other loads	Power system faults, large load changes, utility company equipment malfunctions	Power system faults, unacceptable load changes, utility equipment malfunctions
Threshold ^a	200–400% of rated rms voltage or higher (peak instantaneous above or below rated rms)	Below 80–85% and above 110% of rated rms voltage	Below 80–85% of rated rms voltage
Duration	Transients 0.5–200 μ s wide and oscillatory up to 16.7 ms at frequencies of 200 Hz to 5 kHz and higher	From 4–6 cycles, depending on the type of power system distribution equipment	From 2–60 s if correction is automatic; from 15 min to 4 h if manual

(After [1].)

^a The approximate limits beyond which the disturbance is considered to be harmful to the load equipment.

TABLE 10.8 Causes of Power-Related Computer Failures, Northern Virginia, 1976

Recorded Cause	Disturbance		Number of Computer Failures
	Undervoltage	Outage	
Wind and lightning	37	14	51
Utility equipment failure	8	0	8
Construction or traffic accident	8	2	10
Animals	5	1	6
Tree limbs	1	1	2
Unknown	21	2	23
Totals	80	20	100

(After [1].)

In the study, Key found that most data processing (DP) equipment failure caused by AC line disturbances occurred during bad weather, as shown in Table 10.8. According to a report on the findings, the incidence of thunderstorms in an area can be used to predict the number of failures. The type of power-transmission system used by the utility company was also found to affect the number of disturbances observed on power company lines (Table 10.9). For example, an analysis of utility system problems in Washington, D.C., Norfolk, VA, and Charleston, SC, demonstrated that underground power-distribution systems experienced one-third fewer failures than overhead lines in the same areas. Based on his research, Key developed the “recommended voltage tolerance envelope” shown in Fig. 10.117. The design goals illustrated are recommendations to computer manufacturers for implementation in new equipment.

Assessing the Lightning Hazard

As identified by Key in his Naval Facilities study, the extent of lightning activity in an area significantly affects the probability of equipment failure caused by transient activity. The threat of a lightning flash to a facility is determined, in large part, by the type of installation and its geographic location. The type and character of the lightning flash are also important factors.

The *Keraunic number* of a geographic location describes the likelihood of lightning activity in that area. Figure 10.118 shows the Isokeraunic map of the U.S., which estimates the number of lightning days per year across the country. On average, 30 storm days occur per year across the continental U.S. This number does not fully describe the lightning threat because many individual lightning flashes occur during a single storm.

The structure of a facility has a significant effect on the exposure of equipment to potential lightning damage. Higher structures tend to collect and even trigger localized lightning flashes. Because storm clouds tend to travel at specific heights above the earth, conductive structures in mountainous areas more readily attract lightning activity. The *plant exposure factor* is a function of the size of the facility and the Isokeraunic rating of the area. The larger the physical size of an installation, the more likely it is to be hit by

TABLE 10.9 Effects of Power-System Configuration on Incidence of Computer Failures

Configuration	Number of Disturbances		Recorded Failures
	Undervoltage	Outage	
Overhead radial	12	6	18
Overhead spot network	22	1	23
Combined overhead (weighted ^a)	16	4	20
Underground radial	6	4	10
Underground network	5	0	5
Combined underground (weighted ^a)	5	2	7

lightning during a storm. The longer a transmission line (AC or RF), the more lightning flashes it is likely to receive.

The relative frequency of power problems is seasonal in nature. As shown in Fig. 10.119, most problems are noted during June, July, and August. These high problem rates primarily can be traced to increased thunderstorm activity.

FIPS Publication 94

In 1983, the U.S. Department of Commerce published a guideline summarizing the fundamentals of powering, grounding, and protecting sensitive electronic devices [2]. The document, known as Federal Information Processing Standards (FIPS) Publication 94, was first reviewed by governmental agencies and then was sent to the Computer Business Equipment Manufacturers Association (CBEMA) for review. When the CBEMA group put its stamp of approval on the document, the data processing industry finally had an overarching guideline for power quality.

FIPS Pub. 94 was written to cover *automatic data processing equipment* (ADP), which at that time constituted the principal equipment that was experiencing difficulty running on normal utility-supplied power. Since then, IEEE standard P1100 was issued, which applies to all sensitive electronic equipment. FIPS Pub. 94 is a guideline intended to provide a cost/benefit course of action. As a result, it can be relied upon to give the best solution to typical problems that will be encountered, for the least amount of money.

In addition to approving the FIPS Pub. 94 document, the CBEMA group provided a curve that had been used as a guideline for their members in designing power supplies for modern electronic equipment. The CBEMA curve from the FIPS document is shown in Fig. 10.120. Note the similarity to the Key tolerance envelope shown in Fig. 10.117.

The curve is a susceptibility profile. In order to better explain its meaning, the curve has been simplified and redrawn in Fig. 10.130. The vertical axis of the graph is the percent of voltage that is applied to the power circuit, and the horizontal axis is the time factor involved (in μs to s). In the center of the chart is the acceptable operating area, and on the outside of that area is a danger area on top and bottom. The danger zone at the top is a function of the tolerance of equipment to excessive voltage levels. The danger zone on the bottom sets the tolerance of equipment to a loss or reduction in applied power. The CBEMA guideline states that if the voltage supply stays within the acceptable area given by the curve, the sensitive load equipment will operate as intended.

Transient Protection Alternatives

A facility can be protected from transient disturbances in two basic ways: the *systems* approach or the *discrete device* approach. Table 10.10 outlines the major alternatives available:

- UPS (uninterruptible power system) and standby generator
- UPS stand-alone system
- Secondary AC spot network
- Secondary selective AC network

FIGURE 10.120 The CBEMA curve from FIPS Pub. 94. (From [2]. Used with permission.)

- Motor-generator set
- Shielded isolation transformer
- Suppressors, filters, and lightning arrestors
- Solid-state line-voltage regulator/filter

Table 10.11 lists the relative benefits of each protection method. Because each installation is unique, a thorough investigation of facility needs should be conducted before purchasing any equipment. The

TABLE 10.10 Types of Systemwide Protection Equipment Available to Facility Managers and the AC Line Abnormalities That Each Approach Can Handle

System	Type 1	Type 2	Type 3
UPS system and standby generator	All source transients; no load transients	All	All
UPS system	All source transients; no load transients	All	All outages shorter than the battery supply discharge time
Secondary spot network ^a	None	None	Most, depending on the type of outage
Secondary selective network ^b	None	Most	Most, depending on the type of outage
Motor-generator set	All source transients; no load transients	Most	Only brown-out conditions
Shielded isolation transformer	Most source transients; no load transients	None	None
Suppressors, filters, lightning arrestors	Most transients	None	None
Solid-state line voltage regulator/filter	Most source transients; no load transients	Some, depending on the response time of the system	Only brown-out conditions

^bDual power feeder network using a static (solid-state) transfer switch.

TABLE 10.11 Relative Merits of Systemwide Protection Equipment

System	Strong Points	Weak Points	Technical Profile
UPS system and standby generator	Full protection from power outage failures and transient disturbances; ideal for critical DP and life-safety loads	Hardware is expensive and may require special construction; electrically and mechanically complex; noise may be a problem; high annual maintenance costs	Efficiency 80–90%; typical high impedance presented to the load may be a consideration; frequency stability good; harmonic distortion determined by UPS system design
UPS system	Completely eliminates transient disturbances; eliminates surge and sag conditions; provides power outage protection up to the limits of the battery supply; ideal for critical load applications	Hardware is expensive; depending on battery supply requirements, special construction may be required; noise may be a problem; periodic maintenance required	Efficiency 80–90%; typical high impedance presented to the load may be a consideration; frequency stability good; harmonic content determined by inverter type
Secondary spot network ^a	Simple; inexpensive when available in a given area; protects against local power interruptions; no maintenance required by user	Not available in all locations; provides no protection from area-wide utility failures; provides no protection against transient disturbances or surge/sag conditions	Virtually no loss, 100% efficient; presents low impedance to the load; no effect on frequency or harmonic content
Secondary selective network ^b	Same as above; provides faster transfer from one utility line to the other	Same as above	Same as above
Motor-generator set	Electrically simple; reliable power source; provides up to 0.5 s power-fail ride-through in basic form; completely eliminates transient and surge/sag conditions	Mechanical system requires regular maintenance; noise may be a consideration; hardware is expensive; depending upon m-g set design, power-fail ride-through may be less than typically quoted by manufacturer	Efficiency 80–90%; typical high impedance presented to the load may be a consideration; frequency stability may be a consideration, especially during momentary power-fail conditions; low harmonic content
Shielded isolation transformer	Electrically simple; provides protection against most types of transients and noise; moderate hardware cost; no maintenance required	Provides no protection from brown-out or outage conditions	No significant loss, essentially 100% efficient; presents low impedance to the load; no effect on frequency stability; usually low harmonic content
Suppressors, filters, lightning arrestors	Components inexpensive; units can be staged to provide transient protection exactly where needed in a plant; no periodic maintenance required	No protection from Type 2 or 3 disturbances; transient protection only as good as the installation job	No loss, 100% efficient; some units subject to power-follow conditions; no effect on impedance presented to the load; no effect on frequency or harmonic content
Solid-state line voltage regulator/filter	Moderate hardware cost; uses a combination of technologies to provide transient suppression and voltage regulation; no periodic maintenance required	No protection against power outage conditions; slow response time may be experienced with some designs	Efficiency 92–98%; most units present low impedance to the load; usually no effect on frequency; harmonic distortion content may be a consideration

^a Dual power feeder network.^b Dual power feeder network using a static (solid state) transfer switch.

systems approach offers the advantages of protection engineered to a particular application and need, and (usually) high-level factory support during equipment design and installation. The systems approach also means higher costs for the end-user.

Specifying System-Protection Hardware

Developing specifications for systemwide power-conditioning/backup hardware requires careful analysis of various factors before a particular technology or a specific vendor is selected. Key factors in this process relate to the load hardware and load application. The electrical power required by a sensitive load may vary widely, depending on the configuration of the system. The principal factors that apply to system specification include the following:

- Power requirements, including voltage, current, power factor, harmonic content, and transformer configuration.
- Voltage-regulation requirements of the load.
- Frequency stability required by the load, and the maximum permissible *slew rate* (the rate of change of frequency per second).
- Effects of unbalanced loading.
- Overload and inrush current capacity.
- Bypass capability.
- Primary/standby path transfer time.
- Maximum standby power reserve time.
- System reliability and maintainability.
- Operating efficiency.

An accurate definition of *critical applications* will aid in the specification process for a given site. The potential for future expansion also must be considered in all plans.

Power requirements can be determined either by measuring the actual installed hardware or by checking the nameplate ratings. Most nameplate ratings include significant safety margins. Moreover, the load will normally include a *diversity factor*; all individual elements of the load will not necessarily be operating at the same time.

Every load has a limited tolerance to noise and harmonic distortion. Total harmonic distortion (THD) is a measure of the quality of the waveform applied to the load. It is calculated by taking the geometric sum of the harmonic voltages present in the waveform, and expressing that value as a percentage of the fundamental voltage. Critical DP loads typically can withstand 5% THD, where no single harmonic exceeds 3%. The power-conditioning system must provide this high-quality output waveform to the load, regardless of the level of noise and/or distortion present at the AC input terminals.

If a power-conditioning/standby system does not operate with high reliability, the results can often be disastrous. In addition to threats to health and safety, there is a danger of lost revenue or inventory, and hardware damage. Reliability must be considered from three different viewpoints:

- Reliability of utility AC power in the area.
- Impact of line-voltage disturbances on DP loads.
- Ability of the protection system to maintain reliable operation when subjected to expected and unexpected external disturbances.

The environment in which the power-conditioning system operates will have a significant effect on reliability. Extremes of temperature, altitude, humidity, and vibration can be encountered in various applications. Extreme conditions can precipitate premature component failure and unexpected system shutdown. Most power-protection equipment is rated for operation from 0 to 40°C. During a commercial power failure, however, the ambient temperature of the equipment room can easily exceed either value, depending on the exterior temperature. Operating temperature derating typically is required for altitudes in excess of 1000 ft.

TABLE 10.12 Power-Quality Attributes for Data Processing Hardware

Environmental Attribute	Typical Environment	Acceptable Limits for DP Systems	
		Normal	Critical
Line frequency	± 0.1 to $\pm 3\%$	$\pm 1\%$	$\pm 0.3\%$
Rate of frequency change	0.5 to 20 Hz/s	1.5 Hz/s	0.3 Hz/s
Over- and under-voltage	$\pm 5\%$ to $+6$, -13.3%	$+5\%$ to -10%	$\pm 3\%$
Phase imbalance	2 to 10%	5% max	3% max
Tolerance to low power factor	0.85 to 0.6 lagging	0.8 lagging	less than 0.6 lagging, or 0.9 leading
Tolerance to high steady state peak current	1.3 to 1.6 peak, rms	1.0 to 2.5 peak, rms	Greater than 2.5 peak, rms
Harmonic voltages	0 to 20% total rms	10 to 20% total, 5 to 10% largest	5% max total, 3% largest
Voltage deviation from sine wave	5 to 50%	5 to 10%	3 to 5%
Voltage modulation	Negligible to 10%	3% max	1% max
Surge/sag conditions	$+10\%$, -15%	$+20\%$, -30%	$+5\%$, -5%
Transient impulses	2 to 3 times nominal peak value (0 to 130% Vs)	Varies; 1.0 to 1.5 kV typical	Varies; 200 to 500 V typical
RFI/EMI normal and common modes	10 V up to 20 kHz, less at high freq.	Varies widely, 3 V is typical	Varies widely, 0.3 V typical
Ground currents	0 to 10 A plus impulse noise current	0.001 to 0.5 A or more	0.0035 A or less

(After [2].)

Table 10.12 lists key power-quality attributes that should be considered when assessing the need for power-conditioning hardware. The limits of acceptable power input are shown in graphical form in Fig. 10.121.

10.8.2 Motor-Generator Set

As the name implies, a motor-generator (m-g) set consists of a motor powered by the AC utility supply that is mechanically tied to a generator, which feeds the load (see Fig. 10.122.). Transients on the utility line will have no effect on the load when this arrangement is used. Adding a flywheel to the motor-to-generator shaft will protect against brief power dips (up to 0.5 s on many models). Figure 10.123 shows the construction of a typical m-g set. The attributes of an m-g include the following:

- An independently generated source of voltage can be regulated without interaction with line-voltage changes on the power source. Utility line changes of $\pm 20\%$ commonly can be held to within $\pm 1\%$ at the load.
- The rotational speed and inertial momentum of the rotating mass represents a substantial amount of stored rotational energy, preventing sudden changes in voltage output when the input is momentarily interrupted.
- The input and output windings are separated electrically, preventing transient disturbances from propagating from the utility company AC line to the load.
- Stable electrical characteristics for the load: (1) output voltage and frequency regulation, (2) ideal sine wave output, and (3) true 120° phase shift for three-phase models.
- Reduced problems relating to the power factor presented to the utility company power source.

The efficiency of a typical m-g ranges from 65 to 89%, depending on the size of the unit and the load. Motor-generator sets have been used widely to supply 415 Hz power to mainframe computers that require this frequency.

FIGURE 10.121 A simplified version of the CBEMA curve. Voltage levels outside the *acceptable zone* results in potential system shutdown and hardware and software loss. (From [2]. Used with permission.)

FIGURE 10.122 Two-machine motor-generator set with an optional flywheel to increase inertia and carry-through capability.

FIGURE 10.123 Construction of a typical m-g set. (Courtesy of Computer Power Protection.)

FIGURE 10.124 Simplified schematic diagram of an m-g set with automatic and secondary bypass capability. (After [2].)

System Configuration

There are a number of types of m-g sets, each having its own characteristics, advantages, and disadvantages. A simplified schematic diagram of an m-g is shown in Fig. 10.124. The type of motor that drives the set is an important design element. Direct-current motor drives can be controlled in speed independently of the frequency of the AC power source from which the DC is derived. Use of a DC motor, thereby, gives the m-g set the capability to produce power at the desired output frequency, regardless of variations in input frequency. The requirement for rectifier conversion hardware, control equipment, and commutator maintenance are drawbacks to this approach that must be considered.

The simplest and least expensive approach to rotary power conditioning involves the use of an induction motor as the mechanical source. Unfortunately, the rotor of an induction motor turns slightly slower than the rotating field produced by the power source. This results in the generator being unable to produce 60 Hz output power if the motor is operated at 60 Hz and the machines are directly coupled end-to-end at their shafts, or are belted in a 1:1 ratio. Furthermore, the shaft speed and output frequency of the generator decreases as the load on the generator is increased. This potential for varying output frequency may be acceptable where the m-g set is used solely as the input to a power supply in which the AC is rectified and converted to DC. However, certain loads cannot tolerate frequency changes greater than 1 Hz/s and frequency deviations of more than 0.5 Hz from the nominal 60 Hz value.

Low-slip induction motor-driven generators are available that can produce 59.7 Hz at full load, assuming 60 Hz input. During power interruptions, the output frequency will drop further, depending upon the length of the interruption. The capability of the induction motor to restart after a momentary power interruption is valuable. Various systems of variable-speed belts have been tried successfully. Magnetically controlled slipping clutches have been found to be largely unsatisfactory. Other approaches to make the induction motor drive the load at constant speed have produced mixed results.

Using a synchronous motor with direct coupling or a cogged 1:1 ratio belt drive guarantees that the output frequency will be equal to the motor input frequency. Although the synchronous motor is more expensive, it is more efficient and can be adjusted to provide a unity PF load to the AC source. The starting characteristics and the mechanical disturbance following a short line-voltage interruption depends, to a large extent, on motor design. Many synchronous motors that are not required to start under load have weak starting torque, and may use a *pony motor* to aid in starting. This approach is shown in Fig. 10.125. Those motors designed to start with a load have starting pole face windings that provide starting torque comparable to that of an induction motor. Such motors can be brought into synchronism while under load with proper selection of the motor and automatic starter system. Typical utility company AC interruptions are a minimum of six cycles (0.1 s). Depending upon the design and size of the flywheel used, the ride-through period can be as much as 0.5 s or more. The generator will continue to produce output power for a longer duration, but the frequency and rate of frequency change will most likely fall outside of the acceptable range of most DP loads after 0.5 s.

FIGURE 10.125 Use of a pony motor for an m-g set to aid in system starting and restarting. (After [2].)

If input power is interrupted and does not return before the output voltage and frequency begin to fall outside acceptable limits, the generator output controller can be programmed to disconnect the load. Before this event, a warning signal is sent to the DP control circuitry to warn of impending shutdown and to initiate an orderly interruption of active computer programs. This facilitates easy restart of the computer after the power interruption has passed.

It is important for users to accurately estimate the length of time that the m-g set will continue to deliver acceptable power without input to the motor from the utility company. This data facilitates accurate power-fail shutdown routines. It is also important to ensure that the m-g system can handle the return of power without operating overcurrent protection devices because of high inrush currents that may be required to accelerate and synchronize the motor with the line frequency. Protection against the latter problem requires proper programming of the synchronous motor controller to correctly disconnect and then reconnect the field current supply. It may be worthwhile to delay an impending shutdown for 100 ms or so. This would give the computer time to prepare for the event through an orderly interruption. It also would be useful if the computer were able to resume operation without shutdown, in case utility power returns within the ride-through period. Control signals from the m-g controller should be configured to identify these conditions and events to the DP system.

Generators typically used in m-g sets have substantially higher internal impedance than equivalent kVA-rated transformers. Because of this situation, m-g sets are sometimes supplied with an oversized generator that will be lightly loaded, coupled with a smaller motor that is adequate to drive the actual load. This approach reduces the initial cost of the system, decreases losses in the motor, and provides a lower operating impedance for the load.

Motor-generator sets can be configured for either horizontal installation, as shown previously, or for vertical installation, as illustrated in Fig. 10.126.

The most common utility supply voltage used to drive the input of an m-g set is 480 V. The generator output for systems rated at about 75 kVA or less is typically 208 Y/120 V. For larger DP systems, the most economical generator output is typically 480 V. A 480-208 Y/120 V three-phase isolating transformer usually is included to provide 208 Y/120 V power to the computer equipment.

FIGURE 10.126 Vertical m-g set with an enclosed flywheel. (After [2].)

Motor-Design Considerations

Both synchronous and induction motors have been used successfully to drive m-g sets, and each has advantages and disadvantages. The major advantage of the synchronous motor is that while running normally, it is synchronized with the supply frequency. An 1800 rpm motor rotates at exactly 1800 rpm

for a supply frequency of exactly 60 Hz. The generator output, therefore, will be exactly 60 Hz. Utility frequencies *average* 60 Hz; utilities vary the frequency slowly to maintain this average value under changing load conditions. Research has shown that utility operating frequencies typically vary from 58.7 to 60.7 Hz. Although frequency tolerances permitted by most computer manufacturers are usually given as ± 0.5 Hz on a nominal 60 Hz system, these utility variations are spread over a 24-hour period or longer, and generally do not result in problems for the load.

The major disadvantage of a synchronous motor is that the device is difficult to start. A synchronous motor must be started and brought up to *pull-in* speed by an auxiliary winding on the armature, known as the *armortisseur* winding. The pull-in speed is the minimum speed (close to synchronous speed) at which the motor will pull into synchronization if excitation is applied to the field. The *armortisseur* winding is usually a squirrel-cage design, although it may be of the wound-rotor type in some cases. This winding allows the synchronous motor to start and come up to speed as an induction motor. When pull-in speed is achieved, automatic sensing equipment applies field excitation, and the motor locks in and runs as a synchronous machine. As discussed previously, some large synchronous motors are brought up to speed by an auxiliary pony motor.

The *armortisseur* winding can produce only limited torque, so synchronous motors usually are brought up to speed without a load. This requirement presents no problem for DP systems upon initial startup. However, in the event of a momentary power outage, problems can develop. When the utility AC fails, the synchronous motor must be disconnected from the input immediately, or it will act as a generator and feed power back into the line, thus rapidly depleting its stored (kinetic) rotational energy. During a power failure, the speed of the motor rapidly drops below the pull-in speed, and when the AC supply returns, the *armortisseur* winding must reaccelerate the motor under load until the field can be applied again. This requires a large winding and a sophisticated control system. When the speed of the m-g set is below synchronous operation, the generator output frequency may be too low for proper computer operation.

The induction motor has no startup problems, but it does have *slip*. To produce torque, the rotor must rotate at a slightly lower speed than the stator field. For a nominal 1800 rpm motor, the actual speed will be about 1750 rpm, varying slightly with the load and the applied input voltage. This represents a slip of about 2.8%. The generator, if driven directly or on a common shaft, will have an output frequency of about 58.3 Hz. This is below the minimum permissible operating frequency for most computer hardware. Special precision-built low-slip induction motors are available with a slip of approximately 0.5% at a nominal motor voltage of 480 V. With 0.5% slip, speed at full load will be about 1791 rpm, and the directly driven or common-shaft generator will have an output frequency of 59.7 Hz. This frequency is within tolerance, but close to the minimum permissible frequency.

A belt-and-pulley system adjustable-speed drive is a common solution to this problem. By making the pulley on the motor slightly larger in diameter than the pulley on the generator (with the actual diameters adjustable) the generator can be driven at synchronous speed.

Voltage sags have no effect on the output frequency of a synchronous motor-driven m-g set until the voltage gets so low that the torque is reduced to a point at which the machine pulls out of synchronization. Resynchronization then becomes a problem. On an induction motor, when the voltage sags, slip increases and the machine slows down. The result is a drop in generator output frequency. The adjustable-speed drive between an induction motor and the generator solves the problem for separate machines. If severe voltage sags are anticipated at a site, the system can be set so that nominal input voltage from the utility company produces a frequency of 60.5 Hz, 0.5 Hz on the high side of nominal frequency. Figure 10.127 charts frequency vs. motor voltage for three operating conditions:

- Slip compensation set high (curve A)
- Slip compensation set for 60 Hz (curve B)
- No slip compensation (curve C)

Through proper adjustment of slip compensation, considerable input-voltage margins can be achieved.

FIGURE 10.127 Generator output frequency vs. motor input voltage for an induction-motor-based m-g set.

Single-Shaft Systems

There are two basic m-g set machine mechanical designs used for DP applications: (1) separate motor-generator systems, and (2) single-shaft, single-housing units. Both designs can use either a synchronous or induction motor. In each case, there are advantages and disadvantages. The separate machine design (discussed previously) uses a motor driving a physically separate generator by means of a coupling shaft or pulley. In an effort to improve efficiency and reduce costs, manufacturers also have produced various types of single-shaft systems.

The basic concept of a single-shaft system is to combine the motor and generator elements into a single unit. A common stator eliminates a number of individual components, making the machine less expensive to produce and mechanically more efficient. The common-stator set substantially reduces mechanical energy losses associated with traditional m-g designs, and it improves system reliability as well. In one design, the stator is constructed so that alternate slots are wound with input and output windings. When it is fed with a three-phase supply, a rotating magnetic field is created, causing the DC-excited rotor to spin at a synchronous speed. By controlling the electrical characteristics of the rotor, control of the output at the secondary stator windings is accomplished.

Common-stator machines offer lower working impedance for the load than a comparable two-machine system. For example, a typical 400-kVA machine has approximately an 800-kVA frame size. The larger frame size yields a relatively low-impedance power source capable of clearing subcircuit fuses under fault conditions. The output of the unit typically can supply up to seven times the full-load current under fault conditions. Despite the increase in frame size, the set is smaller and lighter than comparable systems because of the reduced number of mechanical parts.

Flywheel Considerations

In an effort to achieve higher energy and power densities, m-g set designers have devoted considerable attention to the flywheel element itself. New composite materials and power electronics technologies have resulted in compact flywheel “batteries” capable of high linear velocity at the outside radius of the flywheel (*tip speed*) [3]. The rotational speed of the flywheel is important because the stored energy in a flywheel is proportional to the square of its rotational speed. Therefore, an obvious method for maximizing stored energy is to increase the speed of the flywheel. All practical designs, however, have a limiting speed, which is determined by the stresses developed within the wheel resulting from inertial loads. These loads are also proportional to the square of rotational speed. Flywheels built of composite materials weigh less, and hence develop lower inertial loads at a given speed. In addition, composites are often stronger than conventional engineering metals, such as steel. This combination of high strength and low weight enables extremely high tip speeds, relative to conventional wheels.

TABLE 10.13 Specific Strength of Selected Materials

Material	Specific Strength (in. ³)
Graphite/epoxy	3,509,000
Boron/epoxy	2,740,000
Titanium and alloys	1,043,000
Wrought stainless steel	982,000
Wrought high-strength steel	931,000
7000 series aluminum alloys	892,000

(After [4].)

For a given geometry, the limiting *energy density* (energy per unit mass) of a flywheel is proportional to the ratio of material strength to weight density, otherwise known as the *specific strength*. Table 10.13 illustrates the advantage that composite materials offer in this respect.

Recent advances in composite materials technology may allow nearly an order of magnitude advantage in the specific strength of composites when compared to even the best common engineering metals. The result of this continuous research in composites has been flywheels capable of operation at rotational speeds in excess of 100,000 rpm, with tip speeds in excess of 1000 m/s.

These high speeds bring with them new challenges. The ultrahigh rotational speeds that are required to store significant kinetic energy in these systems virtually rule out the use of conventional mechanical bearings. Instead, most systems run on magnetic bearings. This relatively recent innovation uses magnetic forces to “levitate” a rotor, eliminating the frictional losses inherent in rolling element and fluid film bearings. Unfortunately, aerodynamic drag losses force most high-speed flywheels to operate in a partial vacuum, which complicates the task of dissipating the heat generated by ohmic losses in the bearing electromagnets and rotor. In addition, active magnetic bearings are inherently unstable, and require sophisticated control systems to maintain proper levitation.

The integrated generator of these systems is usually a rotating-field design, with the magnetic field supplied by rare-earth permanent magnets. Because the specific strength of these magnets is typically just fractions of that of the composite flywheel, they must spin at much lower tip speeds; in other words, they must be placed very near the hub of the flywheel. This compromises the power density of the generator. An alternative is to mount them closer to the outer radius of the wheel, but contain their inertial loads with the composite wheel itself. Obviously, this forces the designer to either derate the machine speed, or operate closer to the stress limits of the system.

Maintenance Considerations

Because m-g sets require some maintenance that necessitates shutdown, most systems provide bypass capability so the maintenance work can be performed without having to take the computer out of service. If the automatic bypass contactor, solid-state switch, and control hardware are in the same cabinet as other devices that also need to be de-energized for maintenance, a secondary bypass is recommended. After the automatic bypass path has been established, transfer switching to the secondary bypass can be enabled, taking the m-g set and its automatic bypass system out of the circuit completely. Some automatic bypass control arrangements are designed to transfer the load of the generator to the bypass route with minimum disturbance. This requires the generator output to be synchronized with the bypass power before closing the switch and opening the generator output breaker. However, with the load taken off the generator, bypass power no longer will be synchronized with it. Consequently, retransfer of the load back to the generator may occur with some disturbance. Adjustment for minimum disturbance in either direction requires a compromise in phase settings, or a means to shift the phase before and after the transfer.

The use of rotating field exciters has eliminated the need for slip rings in most m-g designs. Brush inspection and replacement, therefore, are no longer needed. However, as with any rotating machinery, bearings must be inspected and periodically replaced.

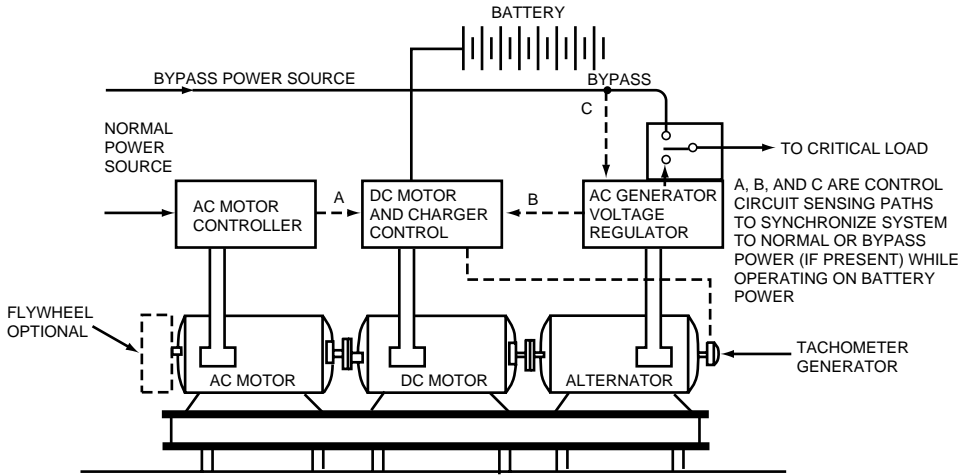

FIGURE 10.128 Uninterruptible m-g set with AC and DC motor drives. (After [2].)

Motor-Generator UPS

Critical DP applications that cannot tolerate even brief AC power interruptions can use the m-g set as the basis for an uninterruptible source of power through the addition of a battery-backed DC motor to the line-driven AC motor shaft. This concept is illustrated in Fig. 10.128. The AC motor normally supplies power to drive the system from the utility company line. The shafts of the three devices are all interconnected, as shown in the figure. When AC power is present, the DC motor serves as a generator to charge the battery bank. When line voltage is interrupted, the DC motor is powered by the batteries. Figure 10.129 shows a modified version of this basic m-g UPS using only a DC motor as the mechanical power source. This configuration eliminates the inefficiency involved in having two motors in the system. Power from the utility source is rectified to provide energy for the DC motor, plus power for charging the batteries. A complex control system to switch the AC motor off and the DC motor on in the event of a utility power failure is not needed in this design.

The m-g UPS also can be built around a synchronous AC motor, as illustrated in Fig. 10.130. Utility AC energy is rectified and used to drive an inverter, which provides a regulated frequency source to power the synchronous motor. The output from the DC-to-AC inverter need not be a well-formed sine wave, nor a

FIGURE 10.129 Uninterruptible m-g set using a single DC drive motor. (After [2].)

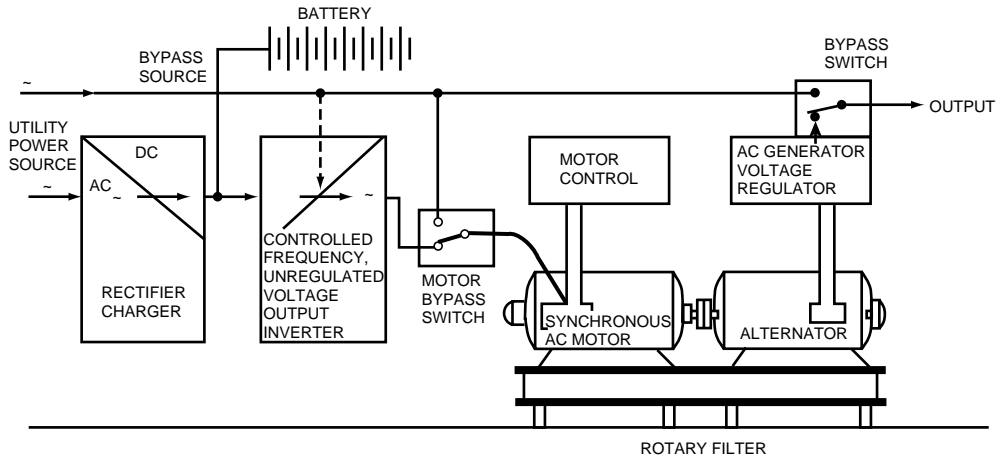

FIGURE 10.130 Uninterruptible m-g set using a synchronous AC motor. (After [2].)

well-regulated source. The output from the generator will provide a well-regulated sine wave for the load. The m-g set also can be operated in a bypass mode that eliminates the rectifier, batteries, and inverter from the current path, operating the synchronous motor directly from the AC line.

An m-g UPS set using a common stator machine is illustrated in Fig. 10.131. A feedback control circuit adjusts the firing angle of the inverter to compensate for changes in input power. This concept is taken a step further in the system shown in Fig. 10.132. A solid-state inverter bypass switch is added to improve efficiency. During normal operation, the bypass route is enabled, eliminating losses across the rectifier diodes. When the control circuitry senses a drop in utility voltage, the inverter is switched on, and the bypass switch is deactivated. A simplified installation diagram of the inverter/bypass system is shown in Fig. 10.133. Magnetic circuit breakers and chokes are included as shown. An isolation transformer is inserted between the utility input and the rectifier bank. The static inverter is an inherently simple design; commutation is achieved via the windings. Six thyristors are used. Under normal operating conditions, 95% of the AC power passes through the static switch; 5% passes through the inverter. This arrangement affords maximum efficiency, while keeping the battery bank charged and the rectifiers and inverter thyristors preheated. Preheating extends the life of the components by reducing the extent of thermal cycling that occurs when the load suddenly switches to the battery backup supply. The static switch allows for fast disconnect of the input AC when the utility power fails.

FIGURE 10.131 Common-stator UPS m-g set. The firing angle of the SCR inverters is determined by a feedback voltage from the generator output.

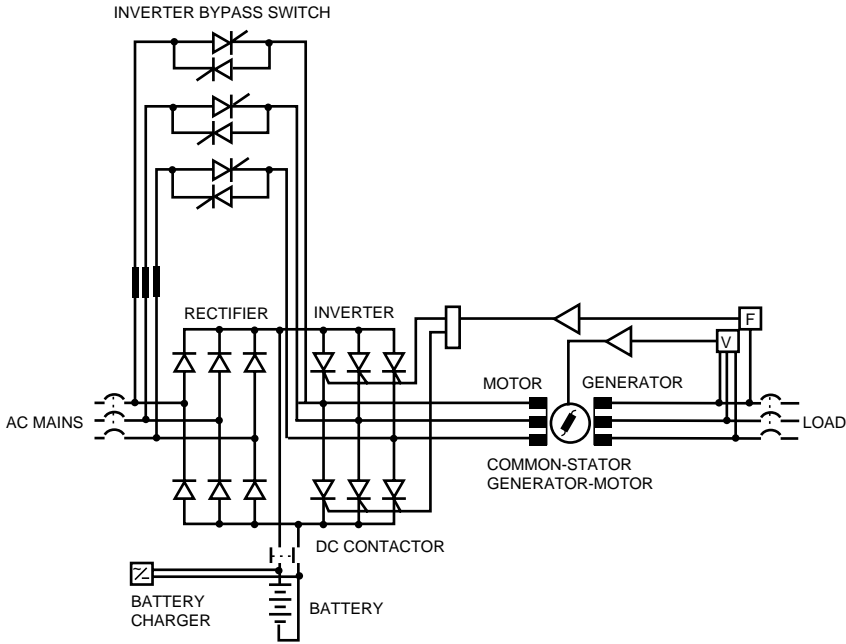

FIGURE 10.132 Common-stator UPS m-g set with a solid-state inverter bypass switch.

Kinetic Battery Storage System

As outlined previously, one of the parameters that limits the ride-through period of an m-g set is the speed decay of the flywheel/generator combination. As the flywheel slows down, the output frequency drops. This limits the useful ride-through period to 0.5 s or so. Figure 10.134 shows an ingenious modification of the classic power conditioning template that extends the potential ride-through considerably. As shown

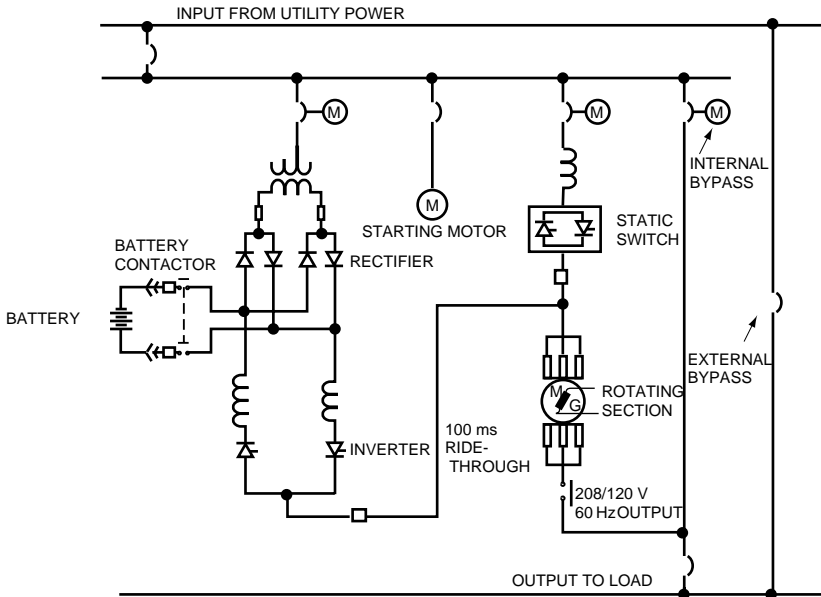

FIGURE 10.133 Power flow diagram of a full-featured UPS m-g set.

FIGURE 10.134 Functional block diagram of a kinetic battery m-g system for powering a UPS. (After [5].)

in the figure, an m-g set is used in a UPS-based system as an element of the DC supply grid. The major components of the system include

- Steel flywheel for energy storage
- Small drive motor, sized at 15 to 20% of the rated system output, to start the flywheel and maintain its normal operating speed
- Variable speed drive (VSD) to slowly ramp the flywheel up to speed and maintain it at the desired rpm
- Generator to convert the kinetic energy stored in the flywheel into electrical energy
- Diode bridge rectifier to convert the AC generator output to DC for use by the UPS bus, which continues to draw usable energy essentially independent of flywheel rpm.

Because the AC output of the generator is converted to DC, frequency is no longer a limiting factor, which allows the DC voltage output to be maintained over a much greater range of the flywheel's rpm envelope.

In operation, the small drive motor spins the flywheel while the variable speed drive maintains the proper motor speed [5]. Because the amount of stored kinetic energy increases by the square of the flywheel rpm, it is possible to greatly increase stored energy, and thus ride-through, by widening the flywheel's usable energy output range. These factors permit typical ride-through times from 10 s to several minutes, depending on loading and other operating conditions. Among the benefits of this approach include the reduced cycling of battery supplies and engine-generators systems.

10.8.3 Uninterruptible Power Systems

Uninterruptible power systems have become a virtual necessity for powering large or small computer systems where the application serves a critical need. Computers and data communications systems are no more reliable than the power from which they operate. The difference between UPS and *emergency standby power* is that the UPS is always in operation. It reverts to an alternative power source, such as the utility company, only if the UPS fails or needs to be deactivated for maintenance. Even then, the transfer of power occurs so quickly (within milliseconds) that it does not interrupt proper operation of the load.

Emergency standby power is normally off and does not start (manually or automatically) until the utility AC feed fails. A diesel generator can be started within 10 to 30 s if the system has been maintained properly. Such an interruption, however, is far too long for DP hardware. Most DP systems cannot ride through more than 8 to 22 ms of power interruption. Systems that can successfully ride through short-duration power breaks, as far as energy continuity is concerned, still may enter a fault condition because of electrical noise created by the disturbance.

FIGURE 10.135 Forward-transfer UPS system.

FIGURE 10.136 Reverse-transfer UPS system.

UPS hardware is available in a number of different configurations. All systems, however, are variations of two basic designs:

- *Forward-transfer mode:* The load normally is powered by the utility power line, and the inverter is idle. If a commercial power failure occurs, the inverter is started and the load is switched. This configuration is illustrated in Fig. 10.135. The primary drawback of this approach is the lack of load protection from power-line disturbances during normal (utility-powered) operation.
- *Reverse-transfer mode:* The load normally is powered by the inverter. In the event of an inverter failure, the load is switched directly to the utility line. This configuration is illustrated in Fig. 10.136. The reverse-transfer mode is, by far, the most popular type of UPS system in use for large-scale systems.

The type of load-transfer switch used in the UPS system is another critical design parameter. The continuity of AC power service to the load is determined by the type of switching circuit used. An electromechanical transfer switch, shown in Fig. 10.137, is limited to switch times of 20 to 50 ms. This time delay can cause sensitive load equipment to malfunction, and perhaps shut down. A control circuit actuates the relay when the sensed output voltage falls below a preset value, such as 94% of nominal. A static transfer switch, shown in Fig. 10.138, can sense a failure and switch the load in about 4 ms. Most

FIGURE 10.137 Electromechanical load-transfer switch.

FIGURE 10.138 Static load-transfer switch.

FIGURE 10.139 Block diagram of an uninterruptible power system using AC rectification to float the battery supply. A closed-loop inverter draws on this supply and delivers clean AC power to the protected load.

loads will ride through this short delay without any malfunction. To accomplish a smooth transition, the inverter output must be synchronized with the power line.

UPS Configuration

The basic uninterruptible power system is built around a battery-driven inverter, with the batteries recharged by the utility AC line. As shown in Fig. 10.139, AC from the utility feed is rectified and applied to recharge or *float* a bank of batteries. This DC power drives a single- or multiphase closed-loop inverter, which regulates output voltage and frequency. The output of the inverter is generally a sine wave, or pseudo sine wave (a stepped square wave). If the utility voltage drops or disappears, current is drawn from the batteries. When AC power is restored, the batteries are recharged. Many UPS systems incorporate a standby diesel generator that starts as soon as the utility company feed is interrupted. With this arrangement, the batteries are called upon to supply operating current for only 30 s or so, until the generator gets up to speed. A UPS system intended to power a computer center is illustrated in Fig. 10.140.

FIGURE 10.140 Installation details for a computer-room UPS power conditioner.

FIGURE 10.141 Simplified diagram of a static UPS system based on a ferroresonant transformer. (After [2].)

Power-Conversion Methods

Solid-state UPS systems that do not employ rotating machinery utilize one of several basic concepts. The design of an inverter is determined primarily by the operating power level. The most common circuit configurations include

- Ferroresonant inverter
- Delta magnetic inverter
- Inverter-fed L/C tank
- Quasi-square wave inverter
- Step wave inverter
- Pulse-width modulation inverter
- Phase modulation inverter

Ferroresonant Inverter

Illustrated in Fig. 10.141, the ferroresonant inverter is popular for low- to medium-power applications. A ferroresonant transformer can be driven with a distorted, unregulated input voltage and deliver a regulated, sinusoidal output when filtered properly. The ferroresonant transformer core is designed so that the secondary section is magnetically saturated at the desired output voltage. As a result, the output level remains relatively constant over a wide range of input voltages and loads. Capacitors, connected across the secondary, help drive the core into saturation and, in conjunction with inductive coupling, provide harmonic filtering. Regulated, sinusoidal three-phase output voltages are derived from two inverters operating into ferroresonant transformers in a *Scott-T* configuration. The basic ferroresonant inverter circuit, shown in Fig. 10.142, consists of an oscillator that controls SCR switches, which feed a ferroresonant transformer and harmonic filter. The saturated operating mode produces a regulated output voltage and inherent current limiting. Efficiency varies from 50 to 83%, depending on the load. Response time of the ferroresonant inverter is about 20 ms.

Although ferroresonant inverters are rugged, simple, and reliable, they do have disadvantages. First, such systems tend to be larger and heavier than electronically controlled inverters. Second, there is a phase shift between the inverter square wave and the output sine wave. This phase shift varies with load magnitude and power factor. When an unbalanced load is applied to a three-phase ferroresonant inverter, the output phases can shift from their normal 120° relationships. This results in a change in line-to-line voltages, even if individual line-to-neutral voltages are regulated perfectly. This voltage imbalance cannot be tolerated by some loads.

FIGURE 10.142 Simplified schematic diagram of a ferroresonant inverter. (After [2].)

Delta Magnetic Inverter

While most multiphase inverters are single-phase systems adapted to three-phase operation, the delta magnetic inverter is inherently a three-phase system. A simplified circuit diagram of a delta magnetic inverter is shown in Fig. 10.143. Inverter modules A1, B1, and C1 produce square wave outputs that are phase-shifted relative to each other by 120° . The waveforms are coupled to the primaries of transformer T1 through linear inductors. T1 is a conventional three-phase isolation transformer. The primaries of the device are connected in a delta configuration, reducing the third harmonic and all other harmonics that are odd-order multiples of the third. The secondaries of T1 are connected in a wye configuration to provide a four-wire three-phase output. Inductors L4–L9 form a network connected in a delta configuration to high-voltage taps on the secondary windings of T1. Inductors L4–L6 are single-winding saturating reactors, and L7–L9 are double-winding saturating reactors. Current drawn by this saturating reactor network is nearly sinusoidal and varies in magnitude, in a nonlinear manner, with voltage variations. For example, if an increase in load tended to pull the inverter output voltages down, the reduced voltage applied to the reactor network would result in a relatively large decrease in current drawn by the network. This, in turn, would decrease the voltage drop across inductors L1–L3 to keep the inverter output voltage at the proper level. The delta magnetic regulation technique is essentially a three-phase shunt regulator. Capacitors C1–C3 help drive the reactor network into saturation, as well as provide harmonic filtering in conjunction with the primary inductors.

Inverter-Fed L/C Tank

An inductor/capacitor tank is driven by a DC-to-AC inverter, as illustrated in Fig. 10.144. The tank circuit acts to reconstruct the sine wave at the output of the system. Regulation is accomplished by varying the capacitance or the inductance to control partial resonance and/or power factor. Some systems of this

FIGURE 10.143 Simplified schematic diagram of the delta magnetic regulation system.

type use a saturable reactor in which electronic voltage-regulator circuits control the DC current in the reactor. Other systems, shown in Fig. 10.145, use a DC-to-variable-DC inverter/converter to control the UPS output through adjustment of the boost voltage. This feature permits compensation for changes in battery level.

Quasi-Square Wave Inverter

Shown in Fig. 10.146, the quasi-square wave inverter produces a variable-duty waveshape that must be filtered by tuned series and parallel inductive-capacitive networks to reduce harmonics and form a sinusoidal output. Because of the filter networks present in this design, the inverter responds slowly to load changes; response time in the range of 150 to 200 ms is common. Efficiency is about 80%. This type of inverter requires voltage-regulating and current-limiting networks, which increase circuit complexity and make it relatively expensive.

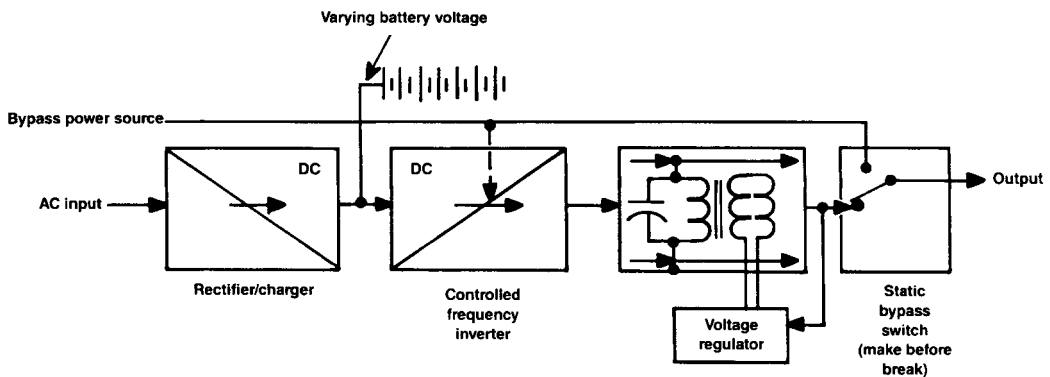

FIGURE 10.144 Static UPS system using saturable reactor voltage control. (After [2].)

FIGURE 10.145 Static UPS system with DC boost voltage control. (After [2].)

Step Wave Inverter

A multistep inverter drives a combining transformer, which feeds the load. The general concept is illustrated in Fig. 10.147. The purity of the output sine wave is a function of the number of discrete steps produced by the inverter. Voltage regulation is achieved by a boost DC-to-DC power supply in series with the battery. Figure 10.148 and Figure 10.149 show two different implementations of single-phase units. Each system uses a number of individual inverter circuits, typically three or multiples of three. The inverters are

FIGURE 10.146 Simplified schematic diagram of a quasi-square wave inverter.

FIGURE 10.147 Static UPS system using a stepped wave output. (After [2].)

controlled by a master oscillator; their outputs are added in a manner that reduces harmonics, producing a near-sinusoidal output. These types of systems require either a separate voltage regulator on the DC bus or a phase shifter. Response time is about 20 ms. Little waveform filtering is required, and efficiency can be as high as 85%. The step wave inverter, however, is complex and expensive. It is usually found in large three-phase UPS systems only.

Pulse-Width Modulation Inverter

Illustrated in Fig. 10.150, the pulse-width modulation (PWM) circuit incorporates two inverters, which regulate the output voltage by varying the pulse width. The output closely resembles a sine wave. Reduced filtering requirements result in good voltage-regulation characteristics. Response times close to 100 ms are typical. The extra inverter and feedback networks make the PWM inverter complex and expensive. Such systems usually are found at power levels greater than 50 kVA.

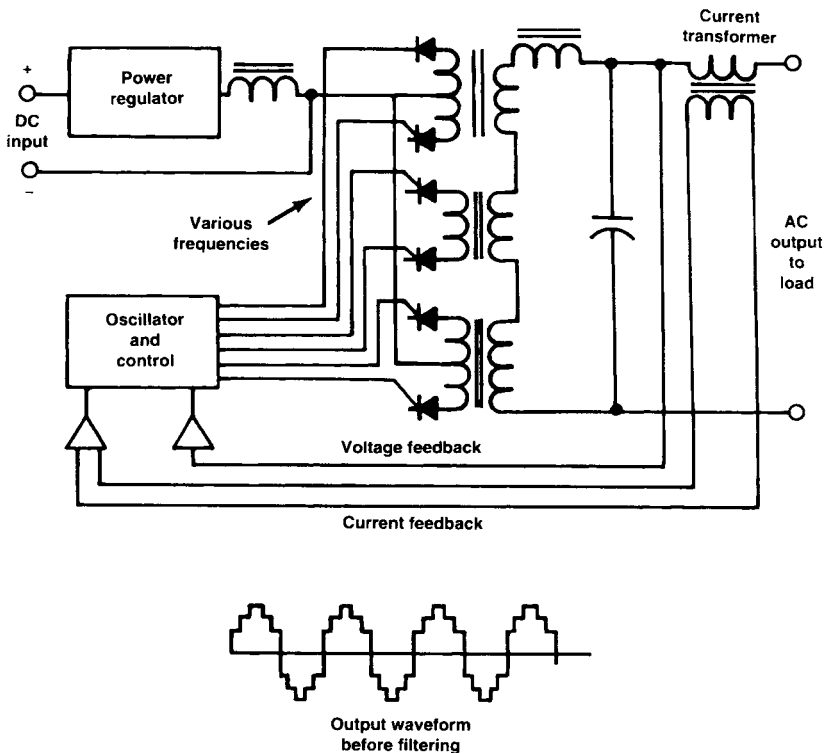

FIGURE 10.148 Step wave inverter schematic diagram.

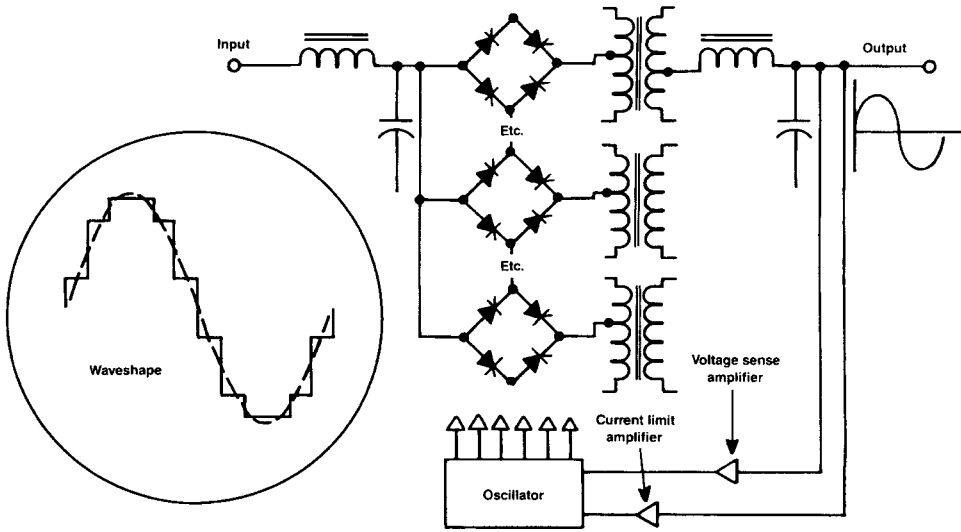

FIGURE 10.149 Step wave inverter and output waveform.

Phase Modulation Inverter

Illustrated in Fig. 10.151, this system uses DC-to-AC conversion through phase modulation of two square wave high-frequency signals to create an output waveform. The waveform then is filtered to remove the carrier signal and feed the load.

FIGURE 10.150 Simplified diagram of a pulse-width modulation inverter.

FIGURE 10.151 Static UPS using a phase-demodulated carrier. (After [2].)

Redundant Operation

UPS systems can be configured as either a single, large power-conditioning/backup unit, or as several smaller systems arranged in a *parallel redundant* or *isolated redundant* mode. In the parallel redundant mode, the UPS outputs are connected together and share the total load. See Fig. 10.152. The power-output ratings of the individual UPS systems are selected to provide for operation of the entire load with any one UPS unit out of commission. In the event of expansion of the DP facility, additional UPS units can be added to carry the load. The parallel system provides the ability to cope with the failure of any single unit.

An isolated redundant system, illustrated in Fig. 10.153, divides the load among several UPS units. If one of the active systems fails, a static bypass switch will connect the affected load to a standby UPS system dedicated to that purpose. The isolated redundant system does not permit the unused capacity of one UPS unit to be utilized on a DP system that is loading another UPS to full capacity. The benefit of the isolated configuration is its immunity to systemwide failures.

Output Transfer Switch

Fault conditions, maintenance operations, and system reconfiguration require the load to be switched from one power source to another. This work is accomplished with an output transfer switch. As discussed previously, most UPS systems use electronic (static) switching. Electromechanical or motor-driven relays

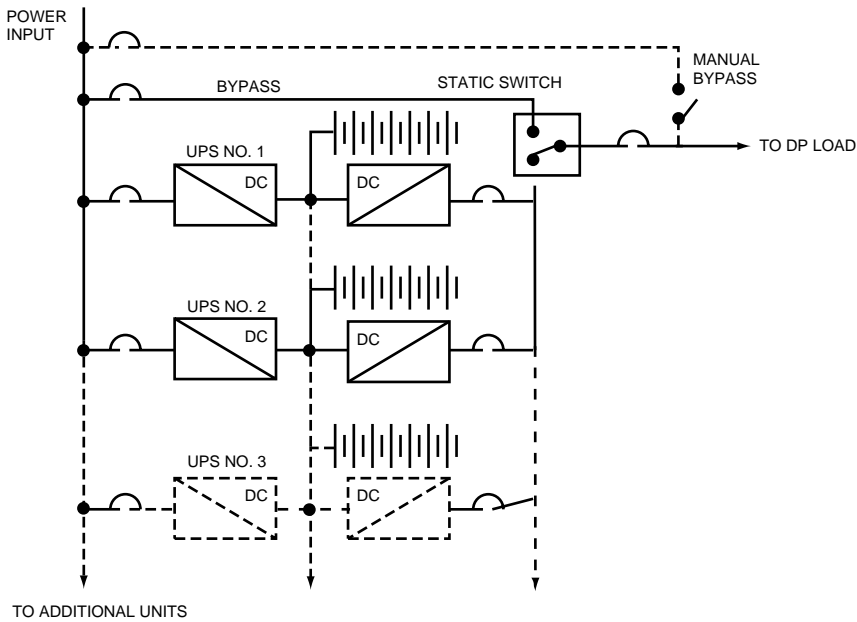

FIGURE 10.152 Configuration of a parallel redundant UPS system. (After [2].)

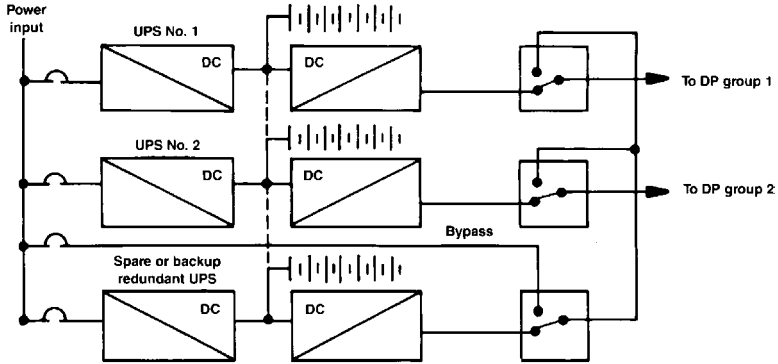

FIGURE 10.153 Configuration of an isolated redundant UPS system. (After [2].)

operate too slowly for most DP loads. Static transfer switches can be configured as either of the following:

- *Break-before-make*: Power output is interrupted before transfer is made to the new source.
- *Make-before-break*: The two power sources are overlapped briefly so as to prevent any interruption in AC power to the load.

Figure 10.154 illustrates each approach to load switching.

For critical-load applications, a make-before-break transfer is necessary. For the switchover to be accomplished with minimum disturbance to the load, both power sources must be synchronized. The UPS

FIGURE 10.154 Static transfer switch modes.

system must, therefore, be capable of synchronizing to the utility AC power line (or other appropriate power source).

Battery Supply

UPS systems typically are supplied with sufficient battery capacity to carry a DP load for periods ranging from 5 min to 1 h. Long backup time periods usually are handled by a standby diesel generator. Batteries require special precautions. For large installations, they almost always are placed in a room dedicated to that purpose. Proper temperature control is important for long life and maximum discharge capacity.

Most rectifier/charger circuits operate in a *constant-current* mode during the initial charge period, and automatically switch to a *constant-voltage* mode near the end of the charge cycle. This provides maximum battery life consistent with rapid recharge. It also prevents excessive battery outgassing and water consumption. The charger provides a *float voltage level* for maintaining the normal battery charge, and sometimes a higher voltage to equalize certain devices.

Four battery types typically are found in UPS systems:

- *Semissealed lead calcium*. A gel-type electrolyte is used that does not require the addition of water. There is no outgassing or corrosion. This type of battery is used when the devices are integral to small UPS units, or when the batteries must be placed in occupied areas. The life span of a semissealed lead calcium battery, under ideal conditions, is about 5 years.
- *Conventional lead calcium*. The most common battery type for UPS installations, these units require watering and terminal cleaning about every 6 months. Expected lifetime ranges up to 20 years. Conventional lead-calcium batteries outgas hydrogen under charge conditions and must be located in a secure, ventilated area.
- *Lead-antimony*. The traditional lead-acid batteries, these devices are equivalent in performance to lead-calcium batteries. Maintenance is required every 3 months. Expected lifetime is about 10 years. To retain their capacity, lead-antimony batteries require a monthly equalizing charge.
- *Nickel-cadmium*. Advantages of the nickel-cadmium battery include small size and low weight for a given capacity. These devices offer excellent high- and low-temperature properties. Life expectancy is nearly that of a conventional lead-calcium battery. Nickel-cadmium batteries require a monthly equalizing charge, as well as periodic discharge cycles to retain their capacity. Nickel-cadmium batteries are the most expensive of the devices typically used for UPS applications.

10.8.4 Dedicated Protection Systems

A wide variety of power-protection technologies are available to solve specific problems at a facility. The method chosen depends upon a number of factors, not the least of which is cost. Although UPS units and m-g sets provide a high level of protection against AC line disturbances, the costs of such systems are high. Many times, adequate protection can be provided using other technologies at a fraction of the cost of a full-featured, facility-wide system. The applicable technologies include:

- Ferroresonant transformer
- Isolation transformer
- Tap-changing regulator
- Line conditioner

Ferroresonant Transformer

Ferroresonant transformers exhibit unique voltage-regulation characteristics that have proved valuable in a wide variety of applications. Voltage output is fixed by the size of the core, which saturates each half cycle, and by the turns ratio of the windings. Voltage output is determined at the time of manufacture and cannot be adjusted. The secondary circuit resonance depends upon capacitors, which work with the saturating inductance of the device to keep the resonance active. A single-phase ferroresonant transformer is shown in Fig. 10.155.

FIGURE 10.155 Basic design of a ferroresonant transformer. (After [2]).

Load currents tend to demagnetize the core, so output current is automatically limited. A ferroresonant transformer typically cannot deliver more than 125 to 150% of its full-load rated output without going into a current-limiting mode. Such transformers cannot support the normal starting loads of motors without a significant dip in output voltage.

Three-phase versions consisting of single-phase units connected in delta-delta, delta-wye, or wye-wye can be unstable when working into unbalanced loads. Increased stability for three-phase operation can be achieved with zigzag and other special winding configurations.

Shortcomings of the basic ferroresonant transformer have been overcome in advanced designs intended for low-power (2 kVA and below) voltage-regulator applications for DP equipment. Figure 10.156 illustrates one of the more common regulator designs. Two additional windings are included:

- *Compensating winding* W_c , which corrects for minor flux changes that occur after saturation has been reached.

FIGURE 10.156 Improved ferroresonant transformer design incorporating a compensating winding and a neutralizing winding.

FIGURE 10.157 Clipping characteristics of a ferroresonant transformer.

- *Neutralizing winding* (W_n), which cancels out most of the harmonic content of the output voltage. Without some form of harmonic reduction, the basic ferroresonant transformer would be unsuitable for sensitive DP loads.

A unique characteristic of the ferroresonant regulator is its ability to reduce normal-mode impulses. Because the regulating capability of the device is based on driving the secondary winding into saturation, transients and noise bursts are clipped, as illustrated in Fig. 10.157.

The typical ferroresonant regulator has a response time of about 25 ms. Because of the tuned circuit at the output, the ferroresonant regulator is sensitive to frequency changes. A 1% frequency change will result (typically) in a 1.5% change in output voltage. Efficiency of the device is about 90% at full rated load, and efficiency declines as the load is reduced. The ferroresonant regulator is sensitive to leading and lagging power factors, and exhibits a relatively high output impedance.

Magnetic-Coupling-Controlled Voltage Regulator

An electronic magnetic regulator uses DC to adjust the output voltage through magnetic saturation of the core. The direct-current fed winding changes the saturation point of the transformer. This action, in turn, controls the AC flux paths through boost or buck coils to raise or lower the output voltage in response to an electronic circuit that monitors the output of the device. A block diagram of the magnetic-coupling-controlled voltage regulator is shown in Fig. 10.158. Changes in output voltage are smooth, although the typical response time of 5 to 10 cycles is too slow to prevent surge and sag conditions from reaching the load.

Figure 10.159 illustrates an electromechanical version of a saturable regulating transformer. Output voltage is controlled by varying the impedance of the saturable reactor winding in series with a step-up autotransformer. Response to sag and surge conditions is 5 to 10 cycles. Such devices usually exhibit high output impedance and are sensitive to lagging load power factor.

Isolation Transformer

Transients, as well as noise (RF and low-level spikes) can pass through transformers, not only by way of the magnetic lines of flux between the primary and the secondary, but through resistive and capacitive paths

FIGURE 10.158 Block diagram of an electronic magnetic regulator. (After [2].)

between the windings as well. There are two basic types of noise signals with which transformer designers must cope:

- *Common-mode* noise. Unwanted signals in the form of voltages appearing between the local ground reference and each of the power conductors, including neutral and the equipment ground.
- *Normal-mode* noise. Unwanted signals in the form of voltages appearing in line-to-line and line-to-neutral signals.

Increasing the physical separation of the primary and secondary windings will reduce the resistive and capacitive coupling. However, it will also reduce the inductive coupling and decrease power transfer.

A better solution involves shielding the primary and secondary windings from each other to divert most of the primary noise current to ground. This leaves the inductive coupling basically unchanged. The concept can be carried a step further by placing the primary winding in a shielding box that shunts noise currents to ground and reduces the capacitive coupling between the windings.

One application of this technology is shown in Fig. 10.160, in which transformer noise decoupling is taken a step further by placing the primary and secondary windings in their own wrapped foil box shields. The windings are separated physically as much as possible for the particular power rating and are placed between Faraday shields. This gives the transformer high noise attenuation from the primary to the secondary, and from the secondary to the primary. Figure 10.161 illustrates the mechanisms involved. Capacitances between the windings, and between the windings and the frame, are broken into smaller

FIGURE 10.159 Autotransformer/saturable reactor voltage regulator.

FIGURE 10.160 The shielding arrangement used in a high-performance isolation transformer. The design goal of this mechanical design is high common-mode and normal-mode noise attenuation.

FIGURE 10.161 The elements involved in a noise-suppression isolation transformer: (a) conventional transformer with capacitive coupling as shown; (b) the addition of an electrostatic shield between the primary and the secondary; (c) transformer with electrostatic box shields surrounding the primary and secondary windings.

FIGURE 10.162 How the normal-mode noise attenuation of an isolation transformer combines with the filtering characteristics of the AC-to-DC power supply to prevent noise propagation to the load.

capacitances and shunted to ground, thus minimizing the overall coupling. The interwinding capacitance of a typical transformer using this technique ranges from 0.001 to 0.0005 pF. Common-mode noise attenuation is generally in excess of 100 dB. This high level of attenuation prevents common-mode impulses on the power line from reaching the load. Figure 10.162 illustrates how an isolation transformer combines with the AC-to-DC power supply to prevent normal-mode noise impulses from affecting the load.

A 7.5-kVA noise-suppression isolation transformer is shown in Fig. 10.163. High-quality isolation transformers are available in sizes ranging from 125 VA single-phase to 125 kVA (or more) three-phase. Usually, the input winding is tapped at 2.5% intervals to provide the rated output voltage, despite high

FIGURE 10.163 A 7.5-kVA noise-suppression isolation transformer. (Courtesy of Topaz.)

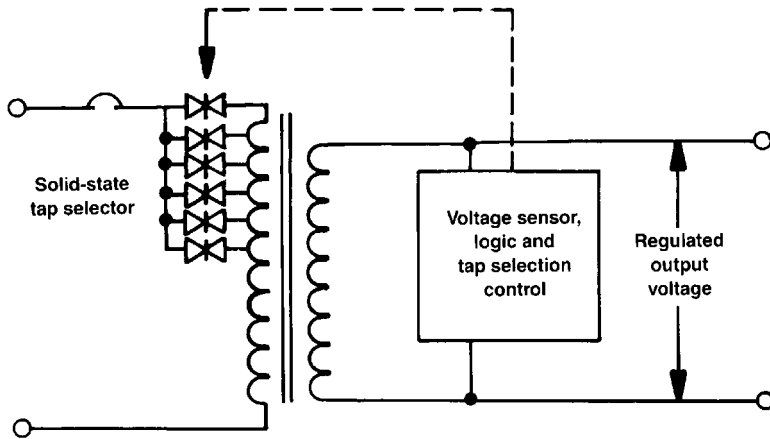

FIGURE 10.164 Simplified schematic diagram of a tap-changing voltage regulator. (After [2].)

or low average input voltages. The total tap adjustment range is typically from 5% above nominal to 10% below nominal. For three-phase devices, typical input-voltage nominal ratings are 600, 480, 240, and 208 V line-to-line for 15 kVA and larger.

Tap-Changing Regulator

The concept behind a tap-changing regulator is simple: adjust the transformer input voltage to compensate for AC line-voltage variations. A tap-changing regulator is shown in Fig. 10.164. Although simple in concept, the actual implementation of the system can become complex because of the timing waveforms and pulses necessary to control the SCR banks. Because of the rapid response time of SCRs, voltage adjustment can be made on a cycle-by-cycle basis in response to changes in both the utility input and the load. Tap steps are typically 2 to 3%. Such systems create no objectionable switching transients in unity power factor loads. For low-PF loads, however, small but observable transients can be generated in the output voltage at the moment the current is switched. This noise usually has no significant effect on DP loads. Other operating characteristics include:

- Low-internal impedance (similar to an equivalent transformer)
- High efficiency from full load to 25% or less
- Rapid response time (typically one to three cycles) to changes in the input AC voltage or load current
- Low acoustic noise level

An autotransformer version of the tap-changing regulator is shown in Fig. 10.165.

FIGURE 10.165 Tap-changing voltage regulator using an autotransformer as the power-control element.

FIGURE 10.166 Variable ratio voltage regulator. (After [2].)

Variable Ratio Regulator

Functionally, the variable ratio regulator is a modified version of the tap-changer. Rather than adjusting output voltage in steps, the motor-driven regulator provides a continuously variable range of voltages. The basic concept is shown in Fig. 10.166. The system is slow, but generally reliable. It is excellent for keeping DP hardware input voltages within the optimum operating range. Motor-driven regulators usually are able to follow the steady rise and fall of line voltages that typically are experienced on utility company lines. Efficiency is normally good, approaching that of a good transformer. The internal impedance is low, making it possible to handle a sudden increase or decrease in load current without excessive undervoltages and/or overvoltages. Primary disadvantages of the variable ratio regulator are limited current ratings, determined by the moving brush assembly, and the need for periodic maintenance.

Variations on the basic design have been marketed, including the system illustrated in Fig. 10.167. A motor-driven brush moves across the exposed windings of an autotransformer, causing the series transformer to buck or boost voltage to the load. The correction motor is controlled by a voltage-sensing circuit at the output of the device.

The induction regulator, shown in Fig. 10.168, is still another variation on the variable ratio transformer. Rotation of the rotor in one direction or the other varies the magnetic coupling and raises or lowers the output voltage. Like the variable ratio transformer, the induction regulator is slow, but it has no brushes and requires little maintenance. The induction regulator has higher inductive reactance and is slightly less efficient than the variable ratio transformer.

Variable Voltage Transformer

Because of their application in voltage control systems, it is worthwhile to discuss the operation of variable voltage transformers in greater detail. A number of conventional transformers can have—to a limited

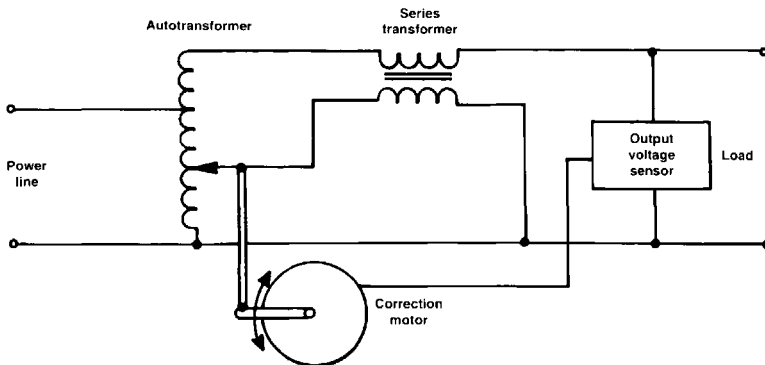

FIGURE 10.167 Motor-driven line-voltage regulator using an autotransformer with a buck/boost series transformer.

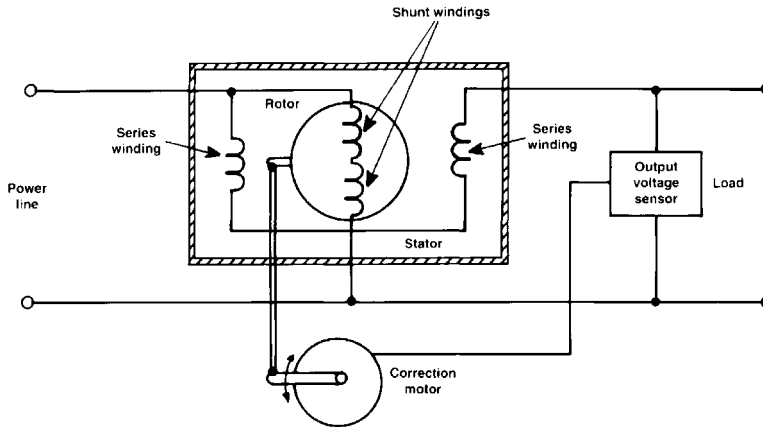

FIGURE 10.168 Rotary induction voltage regulator.

degree—their primary/secondary ratio changed through the use of taps located (usually) on the primary windings [6]. To obtain a greater degree of flexibility in changing the ratio between the primary and secondary coils, and thus allow greater secondary voltage changes, a variable voltage transformer is used. The amount of voltage change depends upon the basic construction of the device, which typically divides into one of two categories

- Brush type
- Induction type

Brush Type

To achieve a variable output voltage, one tap on the transformer secondary is fixed and the other tap is connected to a brush that slides along an uninsulated section of the transformer coil [6]. One way of accomplishing this objective is to have the coil wrapped around a toroidal shaped core. The voltage ratio relates to the location of the brush as it rides against the coil and depends upon where on the coil the brush is allowed to make contact. *Limited ratio* variable transformers are available, as well as full range units that can adjust the output voltage from 0 to about 120% of the incoming line voltage. When the output voltage exceeds the input voltage, it means that there are extra turns on the coil that extend beyond the windings that lie between the incoming power terminals (in effect, the unit becomes a step-up transformer).

Ratings start at less than 1 kVA for a 120 V, single-phase variable transformer. Basic units are wired in parallel and/or in series to obtain higher power capacity. Two units in parallel have double the current and kVA rating. The individual units are stacked on top of each other, bolted together, and operated from a common shaft that rotates the brushes. Operating in a configuration that combines parallel and series connections, with several units stacked together, this type of variable voltage transformer, at 480 V, can have a rating exceeding 200 kVA. Sometimes, a control mechanism is attached to the rotor that turns the brushes, allowing automatic adjustment of the output voltage.

An important characteristic of this type of transformer relates to brush contact and the amount of current flowing through the carbon brush. A rating based solely on output kVA can cause serious operational problems because, for a given kVA load, the current drawn depends on the output voltage. Because the output voltage is variable, a load of a given kVA value can draw a safe current at 100% voltage, but at 25% voltage, the current required to serve a load of the same kVA value would require four times as much current, which could cause the brush to overheat.

Induction Type

The induction type variable transformer does not use brushes [6]. The usual voltage change for these units is $\pm 10\%$, but it can be greater. The device is essentially a variable-ratio autotransformer that uses

two separate windings, a primary and a secondary. There is a laminated steel stator on which is wound a winding that serves as a secondary coil. This winding is connected in series with the load. The primary coil is connected across the supply line. The shunt winding is wound around a rotor. Construction is similar to that of a motor except that in this case, the rotor can only turn 180 mechanical and electrical degrees.

As the primary core is rotated, the amount of primary flux passing through the secondary winding is decreased until the core reaches a position at right angles to the secondary winding. In this position, no primary flux passes through the secondary windings and the induced voltage in the coil is zero. The continued rotation of the core in the same direction again increases the amount of flux passing through the secondary, but it is now in the opposite direction and so reverses the direction of the induced voltage. Thus, the output voltage can be varied by adding or subtracting from it the voltage induced in the secondary winding.

Both single and 3-phase transformers are available. Ratings of these types of transformers vary from 8 kVA, 120 V single-phase to 1500 kVA, 480V 3-phase.

Line Conditioner

A line conditioner combines the functions of an isolation transformer and a voltage regulator in one unit. The three basic types of line conditioners for DP applications are:

- *Linear amplifier correction system.* As illustrated in Fig. 10.169, correction circuitry compares the AC power output to a reference source, derived from a 60-Hz sine wave generator. A correction voltage is developed and applied to the secondary power winding to cancel noise and voltage fluctuations. A box shield around the primary winding provides common-mode impulse rejection (80 to 100 dB typical). The linear amplifier correction system is effective and fast, but the overall regulating range is limited.
- *Hybrid ferroresonant transformer.* As shown in Fig. 10.170, this system consists of a ferroresonant transformer constructed using the isolation techniques discussed in the section titled "Isolation Transformer." The box and Faraday shields around the primary and compensating windings give the transformer essentially the characteristics of a noise-attenuating device, while preserving the voltage-regulating characteristics of a ferroresonant transformer.

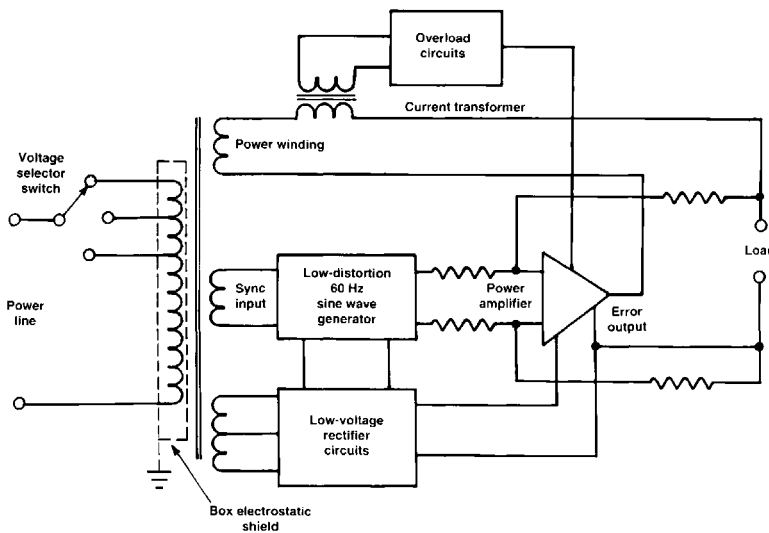

FIGURE 10.169 Power-line conditioner using linear amplifier correction.

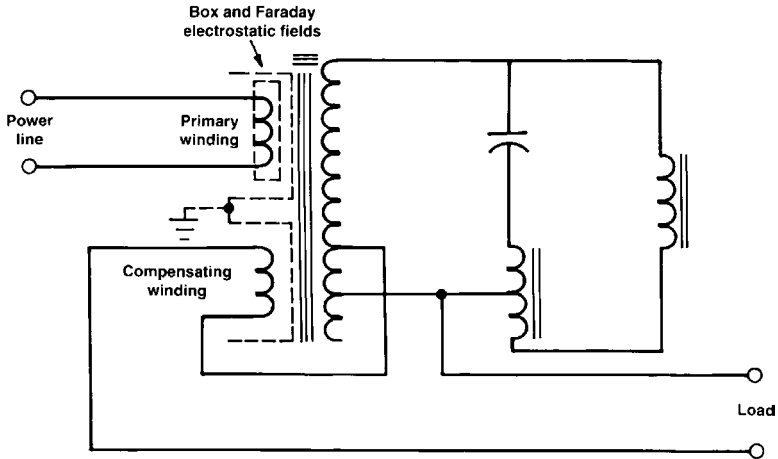

FIGURE 10.170 Line conditioner built around a shielded-winding ferroresonant transformer.

- *Electronic tap-changing, high-isolation transformer.* This system is built around a high-attenuation isolation transformer with a number of primary winding taps. SCR pairs control voltage input to each tap, as in a normal tap-changing regulator. Tap changing can also be applied to the secondary, as shown in Fig. 10.171. The electronic tap-changing, high-isolation transformer is an efficient design that effectively regulates voltage output and prevents noise propagation to the DP load.

Hybrid Transient Suppressor

A wide variety of AC power-conditioning systems are available, based on a combination of solid-state technologies. Most incorporate a combination of series and parallel elements to shunt transient energy. One such system is pictured in Fig. 10.172.

FIGURE 10.171 Secondary-side synchronous tap-changing transformer.

FIGURE 10.172 Interior view of a high-capacity hybrid power conditioner. (Courtesy of Control Concepts.)

Active Power Line Conditioner

The *active power line conditioner* (APLC) provides an adaptive solution to many power quality problems [7]. The major features of APLC include

- Near-instantaneous voltage regulation
- Source voltage harmonic compensation
- Load current harmonic cancellation
- Distortion power factor correction

The basic concept of the APLC can be expressed in mathematical terms. Figure 10.173 shows a block diagram of the APLC in a simplified power system. As shown, the system has two primary components

- A component in series with the harmonic sensitive load, which controls the voltage sine wave being supplied by the power system.
- A component in parallel with the harmonic sensitive load, which controls the harmonic current going to the load.

The voltage that is supplied by the power distribution system (V_{in}) contains two components: (1) the fundamental 60 Hz frequency component represented by V_f and (2) the harmonic component of the source voltage represented by V_h . By definition, V_h is any portion of the source voltage that is not of the 60 Hz fundamental frequency. The APLC modifies this incoming voltage by adding two more voltage components

- The V_h component, which is always equal to the V_h component of V_{in} but of the opposite polarity
- The V_r component, which is the amount of buck or boost required to provide regulation of the output voltage.

- Z = source and line impedance
- NLL= non-linear load(s)
- V_h = harmonic voltage across Z
- V_g = generator voltage
- V_r = voltage required to regulate V_{out}
- V_f = fundamental input voltage
- I_h = harmonic load current
- I_f = fundamental load current
- I_L = load current
- HSL = harmonic sensitive load(s)

FIGURE 10.173 Basic conceptual diagram of the active power line conditioner. (After [7].)

Because the two V_h components cancel, the load receives a regulated sinusoidal voltage at the fundamental frequency with no harmonic components.

The load uses current (I_L) in a nonlinear fashion. The harmonic portion of the current I_h is—by definition—everything that is not the fundamental frequency component. The APLC becomes the source of I_h for the load circuit, leaving only the fundamental frequency portion (I_f) to be supplied by the power system. Because the harmonic portion of the load current is supplied locally by the APLC, the distortion power factor of the load is near unity.

A digital signal processor (DSP) is used to monitor the input and output parameters of the APLC. The DSP then makes any needed adjustment in the amount of voltage compensation and current injection by modifying the switching characteristics of the insulated-gate bipolar transistors (IGBTs) in the APLC.

A simplified schematic of the APLC power circuitry is given in Fig. 10.174. The DC bus (V_{dc}) is the energy storage device that supplies the power required for voltage compensation and current injection. The parallel “filter” serves two purposes. First, the IGBTs in this portion of the APLC keep the DC link capacitor

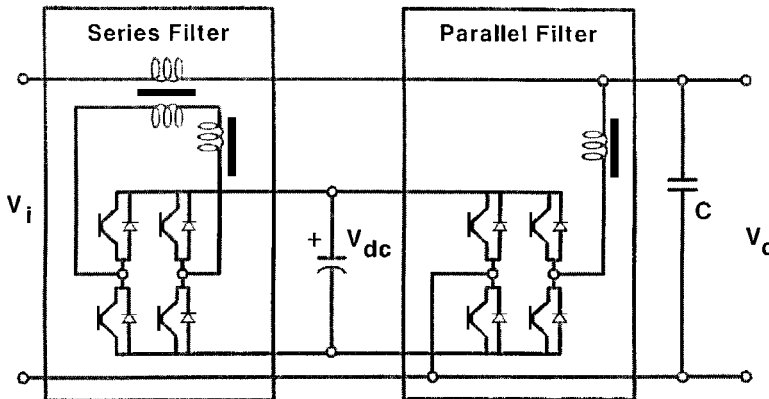

FIGURE 10.174 Series/parallel active power line conditioner power control circuit. (After [7].)

charged. Second, it is used as the source for the harmonic currents needed by the load. By using power from the DC link, the series “filter” compensates for input voltage fluctuations through the buck/boost transformer.

Application Considerations

In a conventional power control system, voltage regulation is performed by using either ferroresonant transformers or tap switching transformers. The fastest response times for either of these solutions is about 1/2 cycle (8 ms). This response time is the result of the tap switching transformer's need for a zero crossing of the waveform to make a change. The use of IGBTs in the APLC allows full power to be switched at any point on the sine wave. Combining these high-speed power transistors with a fast digital signal processor, the voltage can be regulated in less than 1 ms [7]. Furthermore, the input voltage can exhibit up to 10% total harmonic distortion (THD), but output of the APLC to the load will typically see a voltage waveform with less than 1.0% THD [7].

As discussed previously, a switching power supply requires current in a nonlinear fashion. These load currents may have significant harmonic components. The APLC can cancel up to 100% load current THD at full load. The source current being supplied by the power distribution system will see a purely linear load with no more than 3% current THD [7].

10.9 Standby Power Systems

Jerry C. Whitaker

10.9.1 Introduction

When utility company power problems are discussed, most people immediately think of blackouts. The lights go out, and everything stops. With the facility down and in the dark, there is nothing to do but sit and wait until the utility company finds the problem and corrects it. This process generally takes only a few minutes. There are times, however, when it can take hours. In some remote locations, it can take even days.

Blackouts are, without a doubt, the most troublesome utility company problem that facility will have to deal with. Statistics show that power failures are, generally speaking, a rare occurrence in most areas of the country. They are also short in duration. Studies have shown that 50% of blackouts last 6 s or less, and 35% are less than 11 min long. These failure rates usually are not cause for concern to commercial users, except where computer-based operations, transportation control systems, medical facilities, and communications sites are concerned.

When continuity of operation is critical, redundancy must be carried throughout the system. The site never should depend on one critical path for AC power. For example, if the facility is fed by a single step-down transformer, a lightning flash or other catastrophic event could result in a transformer failure that would bring down the entire site. A replacement could take days or even weeks.

10.9.2 Blackout Effects

A facility that is down for even 5 min can suffer a significant loss of productivity or data that may take hours or days to rebuild. A blackout affecting a transportation or medical center could be life threatening. Coupled with this threat is the possibility of extended power-service loss due to severe storm conditions. Many broadcast and communications relay sites are located in remote, rural areas, or on mountaintops. Neither of these kinds of locations are well known for their power reliability. It is not uncommon in mountainous areas for utility company service to be out for days after a major storm. Few operators are willing to take such risks with their businesses. Most choose to install standby power systems at appropriate points in the equipment chain.

The cost of standby power for a facility can be substantial, and an examination of the possible alternatives should be conducted before any decision on equipment is made. Management must clearly define the direct and indirect costs and weigh them appropriately. Include the following items in the cost-vs.-risk analysis:

- Standby power-system equipment purchase and installation cost
- Exposure of the system to utility company power failure
- Alternative operating methods available to the facility
- Direct and indirect costs of lost uptime because of blackout conditions

A distinction must be made between **emergency** and **standby power sources**. Strictly speaking, emergency systems supply circuits legally designated as being essential for safety to life and property. Standby power systems are used to protect a facility against the loss of productivity resulting from a utility company power outage.

10.9.3 Standby Power Options

To ensure the continuity of AC power, many commercial/industrial facilities depend on either two separate utility services or one utility service plus on-site generation. Because of the growing complexity of electrical systems, attention must be given to power-supply reliability.

The engine-generator shown in Fig. 10.175 is the classic standby power system. An automatic transfer switch monitors the AC voltage coming from the utility company line for power failure conditions.

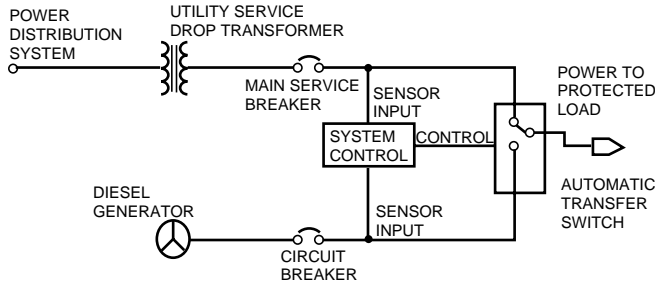

FIGURE 10.175 The classic standby power system using an engine-generator set. This system protects a facility from prolonged utility company power failures.

Upon detection of an outage for a predetermined period of time (generally 1–10 s), the standby generator is started; after the generator is up to speed, the load is transferred from the utility to the local generator. Upon return of the utility feed, the load is switched back after some predetermined safety time, and the generator is stopped. This basic type of system is used widely in industry and provides economical protection against prolonged power outages (5 min or more).

Dual Feeder System

In some areas, usually metropolitan centers, two utility company power drops can be brought into a facility as a means of providing a source of standby power. As shown in Fig. 10.176, two separate utility service drops—from separate power-distribution systems—are brought into the plant, and an automatic transfer switch changes the load to the backup line in the event of a mainline failure. The dual feeder system provides an advantage over the auxiliary diesel arrangement in that power transfer from main to standby can be made in a fraction of a second if a static transfer switch is used. Time delays are involved in the diesel generator system that limit its usefulness to power failures lasting more than several minutes.

The dual feeder system of protection is based on the assumption that each of the service drops brought into the facility is routed via different paths. This being the case, the likelihood of a failure on both power lines simultaneously is remote. The dual feeder system will not, however, protect against areawide power failures, which may occur from time to time.

The dual feeder system is limited primarily to urban areas. Rural or mountainous regions generally are not equipped for dual redundant utility company operation. Even in urban areas, the cost of bringing a second power line into a facility can be high, particularly if special lines must be installed for the feed. If two separate utility services are available at or near the site, redundant feeds generally will be less expensive than engine-driven generators of equivalent capacity.

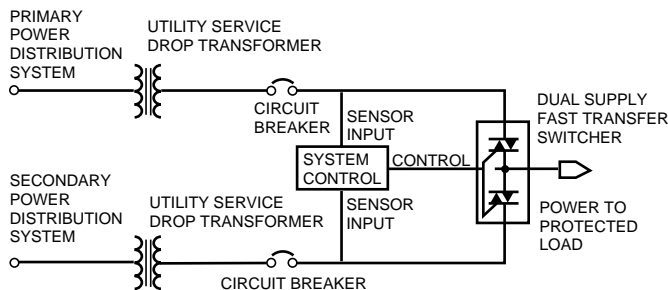

FIGURE 10.176 The dual utility feeder system of AC power loss protection. An automatic transfer switch changes the load from the main utility line to the standby line in the event of a power interruption.

Figure 10.177 illustrates a dual feeder system that utilizes both utility inputs simultaneously at the facility. Notice that during normal operation, both AC lines feed loads, and the tie circuit breaker is open. In the event of a loss of either line, the circuit-breaker switches reconfigure the load to place the entire facility on the single remaining AC feed. Switching is performed automatically; manual control is provided in the event of a planned shutdown on one of the lines.

FIGURE 10.177 A dual utility feeder system with interlocked circuit breakers.

Peak Power Shaving

Figure 10.178 illustrates the use of a backup diesel generator for both standby power and *peak power shaving* applications. Commercial power customers often can realize substantial savings on utility company bills by reducing their energy demand during certain hours of the day. An automatic overlap transfer switch is used to change the load from the utility company system to the local diesel generator. The changeover is accomplished by a static transfer switch that does not disturb the operation of load equipment. This application of a standby generator can provide financial return to the facility, whether or not the unit is ever needed to carry the load through a commercial power failure.

Advanced System Protection

A more sophisticated power-control system is shown in Fig. 10.179, where a dual feeder supply is coupled with a **motor-generator (m-g) set** to provide clean, undisturbed AC power to the load. The m-g set will smooth over the transition from the main utility feed to the standby, often making a commercial power failure unnoticed by on-site personnel. An m-g typically will give up to $\frac{1}{2}$ s of power fail ride-through, more than enough to accomplish a transfer from one utility feed to the other. This standby power system is further refined in the application illustrated in Fig. 10.180, where a diesel generator has been added to the system. With the automatic overlap transfer switch shown at the generator output, this arrangement also can be used for peak demand power shaving.

Application Example

Figure 10.181 shows a simplified schematic diagram of a 220-kW **uninterruptible power system (UPS)** utilizing dual utility company feed lines, a 750-kVA gas engine generator, and five DC-driven

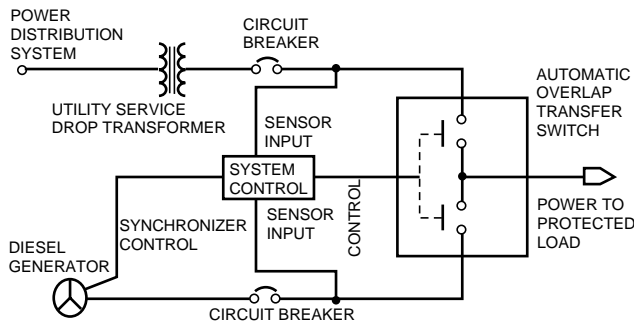

FIGURE 10.178 The use of a diesel generator for standby power and peak power shaving applications. The automatic overlap (*static*) transfer switch changes the load from the utility feed to the generator with sufficient speed that no disruption of normal operation is encountered.

FIGURE 10.179 A dual feeder standby power system using a motor-generator set to provide power fail ride-through and transient-disturbance protection. Switching circuits allow the m-g set to be bypassed, if necessary.

motor-generator sets with a 20-min battery supply at full load. The five m-g sets operate in parallel. Each is rated for 100-kW output. Only three are needed to power the load, but four are on-line at any given time. The fifth machine provides redundancy in the event of a failure or for scheduled maintenance work. The batteries are always on-line under a slight charge across the 270-V DC bus. Two separate natural-gas lines, buried along different land routes, supply the gas engine. Local gas storage capacity also is provided.

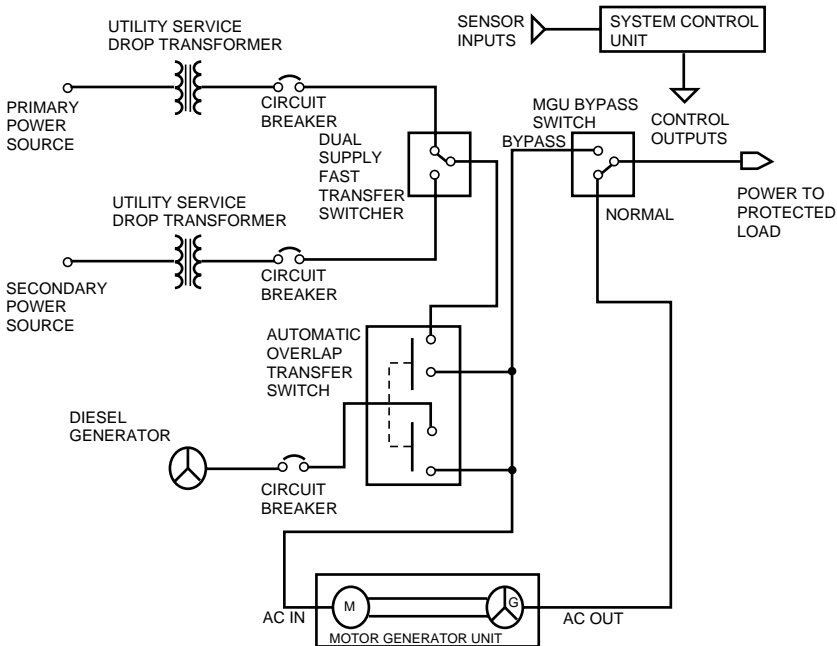

FIGURE 10.180 A premium power-supply backup and conditioning system using dual utility company feeds, a diesel generator, and a motor-generator set. An arrangement such as this would be used for critical loads that require a steady supply of clean AC.

FIGURE 10.181 Simplified installation diagram of a high-reliability power system incorporating dual utility feeds, a standby gas-engine generator, and five battery-backed DC m-g sets.

Motor-Generator Set Operation

As the name implies, a motor-generator set consists of a motor powered by the AC utility supply that is mechanically tied to a generator, which feeds the load (see Fig. 10.182). Transients on the utility line will have no effect on the load when this arrangement is used. Adding a flywheel to the motor-to-generator shaft will protect against brief power dips. Figure 10.183 shows the construction of a typical m-g set. The attributes of an m-g include the following:

- An independently generated source of voltage can be regulated without interaction with line-voltage changes on the power source. Utility line changes of $\pm 20\%$ commonly can be held to within $\pm 1\%$ at the load.
- The rotational speed and inertial momentum of the rotating mass represents a substantial amount of stored rotational energy, preventing sudden changes in voltage output when the input is momentarily interrupted.
- The input and output windings are separated electrically, preventing transient disturbances from propagating from the utility company AC line to the load.

FIGURE 10.182 Two-machine motor-generator set with an optional flywheel to increase inertia and carry-through capability.

FIGURE 10.183 Construction of a typical m-g set. (Source: Computer Power Protection.)

- There are stable electrical characteristics for the load: (1) output voltage and frequency regulation, (2) ideal sine wave output, and (3) true 120° phase shift for three-phase models.
- There are reduced problems relating to the power factor presented to the utility company power source.

The efficiency of a typical m-g ranges from 65 to 89%, depending on the size of the unit and the load. Motor-generator sets have been used widely to supply 415-Hz power to mainframe computers that require this frequency.

System Configuration

There are a number of types of motor-generator sets, each having its own characteristics, advantages, and disadvantages. A simplified schematic diagram of an m-g is shown in Fig. 10.184. The type of motor that drives the set is an important design element. Direct-current motor drives can be controlled in speed independently of the frequency of the AC power source from which the DC is derived. Use of a DC motor, thereby, gives the m-g set the capability to produce power at the desired output frequency, regardless of variations in input frequency. The requirement for rectifier conversion hardware, control equipment, and commutator maintenance are drawbacks to this approach that must be considered.

The simplest and least expensive approach to rotary power conditioning involves the use of an induction motor as the mechanical source. Unfortunately, the rotor of an induction motor turns slower than the

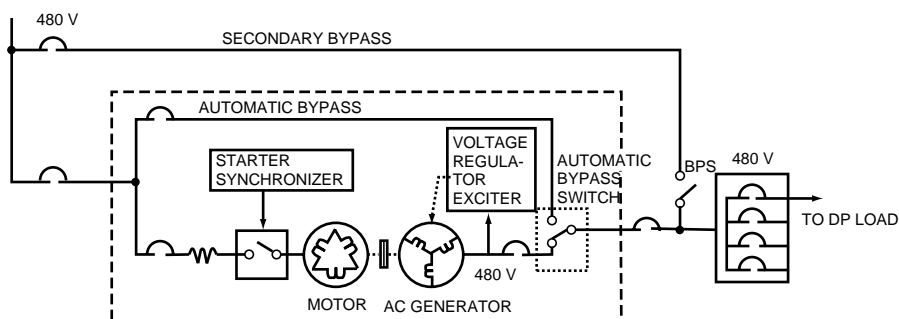

FIGURE 10.184 Simplified schematic diagram of an m-g set with automatic and secondary bypass capability.

FIGURE 10.185 Use of a pony motor for an m-g set to aid in system starting and restarting.

rotating field produced by the power source. This results in the generator being unable to produce 60-Hz output power if the motor is operated at 60 Hz and the machines are directly coupled end-to-end at their shafts, or are belted in a 1:1 ratio. Furthermore, the shaft speed and output frequency of the generator decreases as the load on the generator is increased. This potential for varying output frequency may be acceptable where the m-g set is used solely as the input to a power supply in which the AC is rectified and converted to DC. However, certain loads cannot tolerate frequency changes greater than 1 Hz/s and frequency deviations of more than 0.5 Hz from the nominal 60-Hz value.

Low-slip induction motor-driven generators are available that can produce 59.7 Hz at full load, assuming 60-Hz input. During power interruptions, the output frequency will drop further depending on the length of the interruption. The capability of the induction motor to restart after a momentary power interruption is a valuable attribute. Various systems of variable-speed belts have been tried successfully. Magnetically controlled slipping clutches have been found to be generally unsatisfactory. Other approaches to make the induction motor drive the load at constant speed have produced mixed results.

Using a synchronous motor with direct coupling or a cogged 1:1 ratio belt drive guarantees that the output frequency will be equal to the motor input frequency. Although the synchronous motor is more expensive, it is more efficient and can be adjusted to provide a unity **power factor (PF)** load to the AC source. The starting characteristics and the mechanical disturbance following a brief line-voltage interruption depends, to a large extent, on motor design. Many synchronous motors that are not required to start under load have weak starting torque, and may use a *pony motor* to aid in starting. This approach is shown in Fig. 10.185. Those motors designed to start with a load have starting pole face windings that provide starting torque comparable to that of an induction motor. Such motors can be brought into synchronism while under load with proper selection of the motor and automatic starter system. Typical utility company AC interruptions are a minimum of six cycles (0.1 s). Depending on the design and size of the flywheel used, the ride-through period can be as much as 0.5 s or more. The generator will continue to produce output power for a longer duration, but the frequency and rate of frequency change will most likely fall outside of the acceptable range of most data processing (DP) loads after 0.5 s.

If input power is interrupted and does not return before the output voltage and frequency begin to fall outside acceptable limits, the generator output controller can be programmed to disconnect the load. Before this event, a warning signal is sent to the DP control circuitry to warn of impending shutdown and to initiate an orderly interruption of active computer programs. This facilitates easy restart of the computer after the power interruption has passed.

It is important for designers to accurately estimate the length of time that the m-g set will continue to deliver acceptable power without input to the motor from the utility company. These data facilitate accurate power-fail shutdown routines. It is also important to ensure that the m-g system can handle the return of power without operating overcurrent protection as a result of high inrush currents that may be required to accelerate and synchronize the motor with the line frequency. Protection against the latter problem requires proper programming of the synchronous motor controller to correctly disconnect and then reconnect the field current supply. It may be worthwhile to delay an impending shutdown for 100 ms or so. This would give the computer time to prepare for the event through an orderly interruption. It also would be useful if the computer were able to resume operation without shutdown, in case utility power

returns within the ride-through period. Control signals from the m-g controller are often configured to identify these conditions and events to the DP system.

Generators typically used in m-g sets have substantially higher internal impedance than equivalent kilovolt-ampere-rated transformers. Because of this situation, m-g sets sometimes are supplied with an oversize generator that will be lightly loaded, coupled with a smaller motor that is adequate to drive the actual load. This approach reduces the initial cost of the system, decreases losses in the motor, and provides a lower operating impedance for the load.

Motor-generator sets may be configured for either horizontal installation, as shown previously, or for vertical installation.

The most common utility supply voltage used to drive the input of an m-g set is 480 V. The generator output for systems rated at about 75 kVA or less is typically 208 Y/120 V. For larger DP systems, the most economical generator output is typically 480 V. A 480-208 Y/120 V three-phase isolating transformer usually is included to provide 208 Y/120 V power to the computer equipment.

Motor-Design Considerations

Both synchronous and induction motors have been used successfully to drive m-g sets. Each has advantages and disadvantages. The major advantage of the synchronous motor is that while running normally, it is synchronized with the supply frequency. An 1800-r/min motor rotates at exactly 1800 r/min for a supply frequency of exactly 60 Hz. The generator output, therefore, will be exactly 60 Hz. Utility frequencies *average* 60 Hz; utilities vary the frequency slowly to maintain this average value under changing load conditions. Research has shown that utility operating frequencies typically vary from 58.7 to 60.7 Hz. Although frequency tolerances permitted by most computer manufacturers are usually given as ± 0.5 Hz on a nominal 60-Hz system, these utility variations are spread over a 24-h period or longer, and generally do not result in problems for the load.

The major disadvantage of a synchronous motor is that the device is difficult to start. A synchronous motor must be started and brought up to **pull-in speed** by an auxiliary winding on the armature (the *armortisseur* winding). The pull-in speed is the minimum speed (close to synchronous speed) at which the motor will pull into synchronization if excitation is applied to the field. The *armortisseur* winding is usually a squirrel-cage design, although it may be of the wound-rotor type in some cases. This winding allows the synchronous motor to start and come up to speed as an induction motor. When pull-in speed is achieved, automatic sensing equipment applies field excitation, and the motor locks in and runs as a synchronous machine. As discussed previously, some large synchronous motors are brought up to speed by an auxiliary pony motor.

The *armortisseur* winding can produce only limited torque, so synchronous motors usually are brought up to speed without a load. This requirement presents no problem for DP systems upon initial startup. However, in the event of a momentary power outage, problems can develop. When the utility AC fails, the synchronous motor must be disconnected from the input immediately, or it will act as a generator and feed power back into the line, thus rapidly depleting its stored (kinetic) rotational energy. During a power failure, the speed of the motor rapidly drops below the pull-in speed, and when the AC supply returns, the *armortisseur* winding must reaccelerate the motor under load until the field can be applied again. This requires a large winding and a sophisticated control system. While the speed of the m-g set is below synchronous operation, the generator output frequency may be too low for proper computer operation.

The induction motor has no startup problems, but it does have *slip*. To produce torque, the rotor must rotate at slightly lower speed than the stator field. For a nominal 1800-r/min motor, the actual speed will be about 1750 r/min, varying slightly with the load and the applied input voltage. This represents a slip of about 2.8%. The generator, if driven directly or on a common shaft, will have an output frequency of approximately 58.3 Hz. This is below the minimum permissible operating frequency for most computer hardware. Special precision-built low-slip induction motors are available with a slip of approximately 0.5% at a nominal motor voltage of 480 V. With 0.5% slip, speed at full load will be about 1791 r/min, and the directly driven or common-shaft generator will have an output frequency of 59.7 Hz. This frequency is within tolerance, but close to the minimum permissible frequency.

FIGURE 10.186 Generator output frequency vs. motor input voltage for an induction-motor-based m-g set.

A belt-and-pulley system adjustable-speed drive is a common solution to this problem. By making the pulley on the motor slightly larger in diameter than the pulley on the generator (with the actual diameters adjustable) the generator can be driven at synchronous speed.

Voltage sags have no effect on the output frequency of a synchronous motor-driven m-g set until the voltage gets so low that the torque is reduced to a point at which the machine pulls out of synchronization. Resynchronization then becomes a problem. On an induction motor, when the voltage sags, slip increases and the machine slows down. The result is a drop in generator output frequency. The adjustable-speed drive between an induction motor and the generator solves the problem for separate machines. If severe voltage sags are anticipated at a site, the system can be set so that nominal input voltage from the utility company produces a frequency of 60.5 Hz, 0.5 Hz on the high side of nominal frequency. Figure 10.186 charts frequency vs. motor voltage for three operating conditions:

- Slip compensation set high (curve A)
- Slip compensation set for 60 Hz (curve B)
- No slip compensation (curve C)

Through proper adjustment of slip compensation, considerable input-voltage margins can be achieved.

Single-Shaft Systems

There are two basic m-g set machine designs used for DP applications: (1) separate motor-generator systems and (2) single-shaft, single-housing units. Both designs can use either a synchronous or induction motor. In each case, there are advantages and disadvantages. The separate machine design (discussed previously) uses a motor driving a physically separate generator by means of a coupling shaft or pulley. In an effort to improve efficiency and reduce costs, manufacturers also have produced various types of single-shaft systems.

The basic concept of a single-shaft system is to combine the motor and generator elements into a single unit. A common stator eliminates a number of individual components, making the machine less expensive to produce and mechanically more efficient. The common-stator set substantially reduces mechanical energy losses associated with traditional m-g designs, and it improves system reliability as well. In one design, the stator is constructed so that alternate slots are wound with input and output windings. When it is fed with a three-phase supply, a rotating magnetic field is created, causing the DC-excited rotor to spin at a synchronous speed. By controlling the electrical characteristics of the rotor, control of the output at the secondary stator windings is accomplished.

Common-stator machines offer lower working impedance for the load than a comparable two-machine system. For example, a typical 400-kVA machine has approximately an 800-kVA frame size. The larger frame size yields a relatively low-impedance power source capable of clearing subcircuit fuses under fault

FIGURE 10.187 Uninterruptible m-g set with AC and DC motor drives.

conditions. The output of the unit typically can supply up to seven times the full-load current under fault conditions. Despite the increase in frame size, the set is smaller and lighter than comparable systems because of the reduced number of mechanical parts.

Motor-Generator UPS

Critical DP applications that cannot tolerate even brief AC power interruptions can use the m-g set as the basis for an uninterruptible source of power through the addition of a battery-backed DC motor to the line-driven AC motor shaft. This concept is illustrated in Fig. 10.187. The AC motor normally supplies power to drive the system from the utility company line. The shafts of the three devices all are interconnected, as shown in the figure. When AC power is present, the DC motor serves as a generator to charge the battery bank. When line voltage is interrupted, the DC motor is powered by the batteries. Figure 10.188 shows a modified version of this basic m-g UPS using only a DC motor as the mechanical power source. This configuration eliminates the inefficiency involved in having two motors in the system. Power from the utility source is rectified to provide energy for the DC motor, plus power for charging the

FIGURE 10.188 Uninterruptible m-g set using a single DC drive motor.

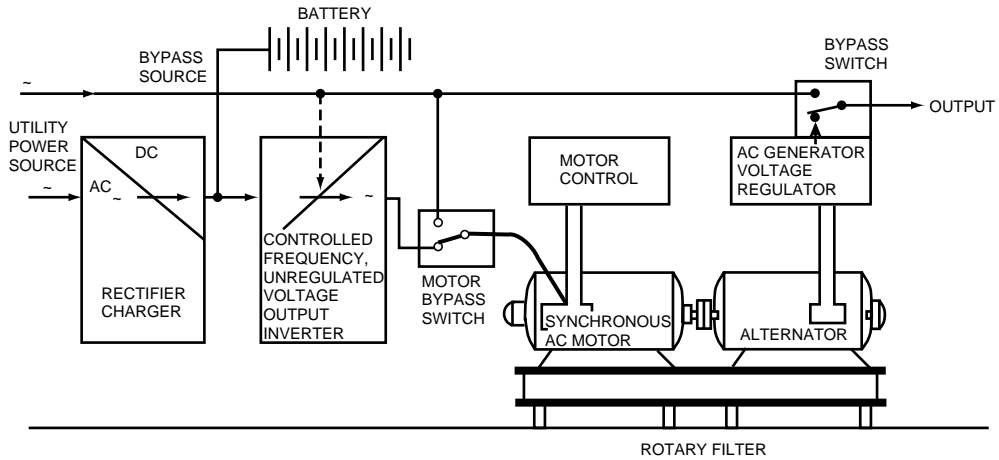

FIGURE 10.189 Uninterruptible m-g set using a synchronous AC motor.

batteries. A complex control system to switch the AC motor off and the DC motor on in the event of a utility power failure is not needed in this design.

The m-g UPS also can be built around a synchronous AC motor, as illustrated in Fig. 10.189. Utility AC energy is rectified and used to drive an inverter, which provides a regulated frequency source to power the synchronous motor. The output from the DC-to-AC inverter need not be a well-formed sine wave, nor a well-regulated source. The output from the generator will provide a well-regulated sine wave for the load. The m-g set also can be operated in a bypass mode that eliminates the rectifier, batteries, and inverter from the current path, operating the synchronous motor directly from the AC line.

An m-g UPS set using a common stator machine is illustrated in Fig. 10.190. A feedback control circuit adjusts the firing angle of the inverter to compensate for changes in input power. This concept is taken a step further in the system shown in Fig. 10.191. A solid-state inverter bypass switch is added to improve efficiency. During normal operation, the bypass route is enabled, eliminating losses across the rectifier diodes. When the control circuitry senses a drop in utility voltage, the inverter is switched on, and the bypass switch is deactivated. A simplified installation diagram of the inverter/bypass system is shown in Fig. 10.192. Magnetic circuit breakers and chokes are included as shown. An isolation transformer is inserted between the utility input and the rectifier bank. The static inverter is an inherently simple design; commutation is achieved via the windings. Six thyristors are used. Under normal operating conditions, 95% of the

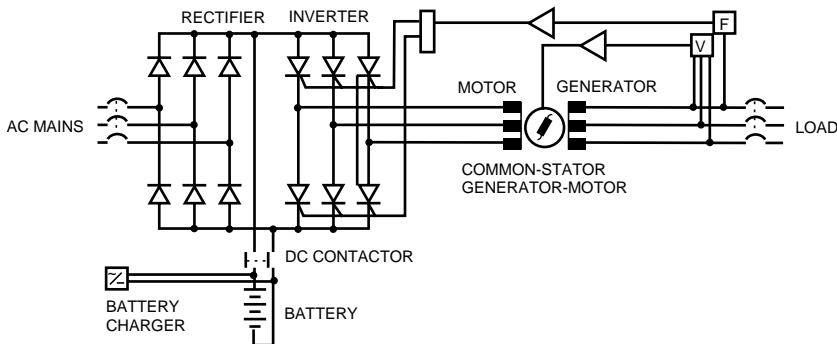

FIGURE 10.190 Common-stator UPS m-g set. The firing angle of the SCR inverters is determined by a feedback voltage from the generator output.

FIGURE 10.191 Common-stator UPS m-g set with a solid-state inverter bypass switch.

AC power passes through the static switch; 5% passes through the inverter. This arrangement affords maximum efficiency, while keeping the battery bank charged and the rectifiers and inverter thyristors preheated. Preheating extends the life of the components by reducing the extent of thermal cycling that occurs when the load suddenly switches to the battery backup supply. The static switch allows for fast disconnect of the input AC when the utility power fails.

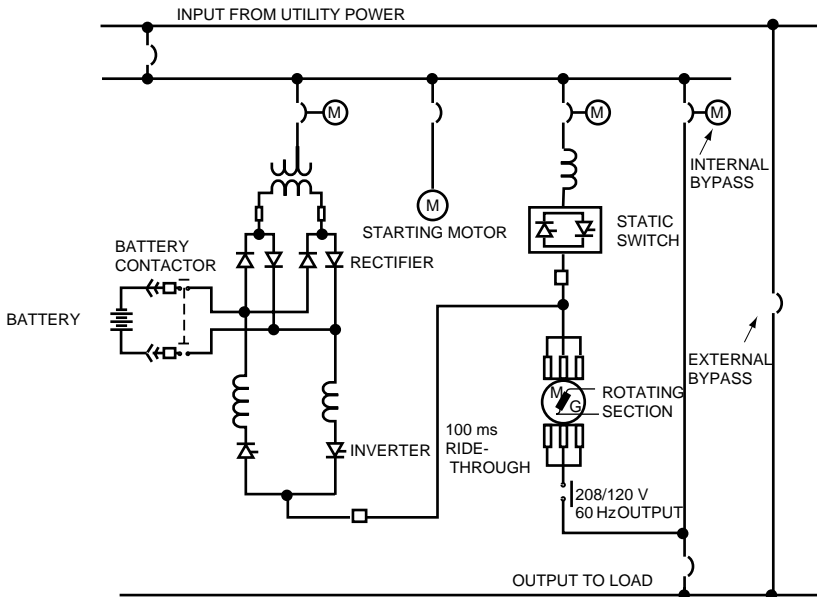

FIGURE 10.192 Power flow diagram of a full-featured UPS m-g set.

Maintenance Considerations

Because m-g sets require some maintenance that necessitates shutdown, most systems provide bypass capability so the maintenance work can be performed without having to take the computer out of service. If the automatic bypass contactor, solid-state switch, and control hardware are in the same cabinet as other devices that also need to be de-energized for maintenance, a secondary bypass is recommended. After the automatic bypass path has been established, transfer switching to the secondary bypass can be enabled, taking the m-g set and its automatic bypass system out of the circuit completely. Some automatic bypass control arrangements are designed to transfer the load of the generator to the bypass route with minimum disturbance. This requires the generator output to be synchronized with the bypass power before closing the switch and opening the generator output breaker. With the load taken off the generator, however, bypass power no longer is synchronized with it. Consequently, retransfer of the load back to the generator may occur with some disturbance. Adjustment for minimum disturbance in either direction requires a compromise in phase settings, or a means to shift the phase before and after the transfer.

The use of rotating field exciters has eliminated the need for slip rings in most m-g designs. Brush inspection and replacement, therefore, are no longer needed. However, as with any rotating machinery, bearings must be inspected and periodically replaced.

Generator System Options

Engine-generator sets are available for power levels ranging from less than 1 kVA to several thousand kilovolt-ampere or more. Machines also may be paralleled to provide greater capacity. Engine-generator sets typically are divided by the type of power plant used:

- *Diesel*. Advantages: rugged and dependable, low-fuel costs, low fire and/or explosion hazard. Disadvantages: somewhat more costly than other engines, heavier in smaller sizes.
- *Natural and liquefied-petroleum gas*. Advantages: quick starting after long shutdown periods, long life, low maintenance. Disadvantage: availability of natural gas during areawide power failure subject to question.
- *Gasoline*. Advantages: rapid starting, low initial cost. Disadvantages: greater hazard associated with storing and handling gasoline, generally shorter mean time between overhaul.
- *Gas turbine*. Advantages: smaller and lighter than piston engines of comparable horsepower, rooftop installations practical, rapid response to load changes. Disadvantages: longer time required to start and reach operating speed, sensitive to high input air temperature.

The type of power plant chosen usually is determined primarily by the environment in which the system will be operated and by the cost of ownership. For example, a standby generator located in an urban area office complex may be best suited to the use of an engine powered by natural gas, because of the problems inherent in storing large amounts of fuel. State or local building codes may place expensive restrictions on fuel-storage tanks and make the use of a gasoline- or diesel-powered engine impractical. The use of propane usually is restricted to rural areas. The availability of propane during periods of bad weather (when most power failures occur) also must be considered.

The generator rating for a standby power system should be chosen carefully and should take into consideration the anticipated future growth of the plant. It is good practice to install a standby power system rated for at least 50% greater output than the current peak facility load. This headroom gives a margin of safety for the standby equipment and allows for future expansion of the facility without overloading the system.

An engine-driven standby generator typically incorporates automatic starting controls, a battery charger, and automatic transfer switch. Control circuits monitor the utility supply and start the engine when there is a failure or a sustained voltage drop on the AC supply. The switch transfers the load as soon as the generator reaches operating voltage and frequency. Upon restoration of the utility supply, the switch returns the load

after a preset delay and initiates engine shutdown. The automatic transfer switch must meet demanding requirements, including

- The ability to carry the full rated current continuously
- Ability to withstand fault currents without contact separation
- Ability to handle high inrush currents
- Ability to withstand repeated interruptions at full load without damage

The nature of most power outages requires a sophisticated monitoring system for the engine-generator set. Most power failures occur during periods of bad weather. Most standby generators are unattended. More often than not, the standby system starts, runs, and shuts down without any human intervention or supervision. For reliable operation, the monitoring system must check the status of the machine continually to ensure that all parameters are within normal limits. Time-delay periods usually are provided by the controller that require an outage to last from 5 to 10 s before the generator is started and the load is transferred. This prevents false starts that needlessly exercise the system. A time delay of 5–30 min usually is allowed between the restoration of utility power and return of the load. This delay permits the utility AC lines to stabilize before the load is reapplied.

The transfer of motor loads may require special consideration, depending on the size and type of motors used at a plant. If the residual voltage of the motor is out of phase with the power source to which the motor is being transferred, serious damage may result to the motor. Excessive current draw also may trip overcurrent protective devices. Motors above 50 hp with relatively high load inertia in relation to torque requirements, such as flywheels and fans, may require special controls. Restart time delays are a common solution.

Automatic starting and synchronizing controls are used for multiple-engine-generator installations. The output of two or three smaller units can be combined to feed the load. This capability offers additional protection for the facility in the event of a failure in any one machine. As the load at the facility increases, additional engine-generator systems can be installed on the standby power bus.

UPS System Options

An uninterruptible power system is an elegant solution to power outage concerns. The output of the UPS inverter may be a sine wave or pseudosine wave. The following design considerations are important:

- Power reserve capacity for future growth of the facility.
- Inverter current surge capability (if the system will be driving inductive loads, such as motors).
- Output voltage and frequency stability over time and with varying loads.
- Required battery supply voltage and current. Battery costs vary greatly, depending on the type of units needed.
- Type of UPS system (*forward-transfer* type or *reverse-transfer* type) required by the particular application. Some sensitive loads may not tolerate even brief interruptions of the AC power source.
- Inverter efficiency at typical load levels. Some inverters have good efficiency ratings when loaded at 90% of capacity, but poor efficiency when lightly loaded.
- Size and environmental requirements of the UPS system. High-power UPS equipment requires a large amount of space for the inverter/control equipment and batteries. Battery banks often require special ventilation and ambient temperature control.

Uninterruptible Power System Design

Uninterruptible power systems have become a virtual necessity for powering large or small computer systems where the application serves a critical need. Computers and data communications systems are no more reliable than the power from which they operate. The difference between UPS and emergency standby power is that the UPS is always in operation. It reverts to an alternative power source, such as the utility company, only if the UPS fails or needs to be deactivated for maintenance. Even then, the transfer of power occurs so quickly (within milliseconds) that it does not interrupt proper operation of the load.

FIGURE 10.193 Forward-transfer UPS system.

FIGURE 10.194 Reverse-transfer UPS system.

UPS hardware is available in a number of different configurations. All systems, however, are variations of two basic designs:

- **Forward-transfer mode.** The load normally is powered by the utility power line, and the inverter is idle. If a commercial power failure occurs, the inverter is started and the load is switched. This configuration is illustrated in Fig. 10.193. The primary drawback of this approach is the lack of load protection from power-line disturbances during normal (utility-powered) operation.
- **Reverse-transfer mode.** The load normally is powered by the inverter. In the event of an inverter failure, the load is switched directly to the utility line. This configuration is illustrated in Fig. 10.194. The reverse-transfer mode is, by far, the most popular type of UPS system in use.

The type of load-transfer switch used in the UPS system is a critical design parameter. The continuity of AC power service to the load is determined by the type of switching circuit used. An electromechanical transfer switch, shown in Fig. 10.195, is limited to switch times of 20–50 ms. This time delay may cause sensitive load equipment to malfunction, and perhaps shut down. A control circuit actuates the relay when the sensed output voltage falls below a preset value, such as 94% of nominal. A static transfer switch, shown in Fig. 10.196, can sense a failure and switch the load in about 4 ms. Most loads will ride through this short delay without any malfunction. To accomplish a smooth transition, the inverter output must be synchronized with the power line.

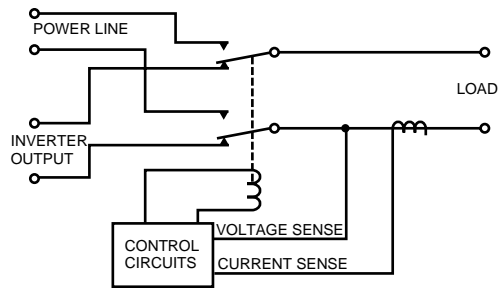

FIGURE 10.195 Electromechanical load-transfer switch.

UPS Configuration

The basic uninterruptible power system is built around a battery-driven inverter, with the batteries recharged by the utility AC line. As shown in Fig. 10.197, AC from the utility feed is rectified and applied to recharge or *float* a bank of batteries. This DC power drives a single- or multiphase closed-loop inverter, which regulates output voltage and frequency. The output of the inverter is generally a sine wave,

FIGURE 10.196 Static load-transfer switch.

or pseudosine wave (a stepped square wave). If the utility voltage drops or disappears, current is drawn from the batteries. When AC power is restored, the batteries are recharged. Many UPS systems incorporate a standby diesel generator that starts as soon as the utility company feed is interrupted. With this arrangement, the batteries are called upon to supply operating current for only 30 s or so, until the generator gets up to speed.

Power-Conversion Methods

Solid-state UPS systems that do not employ rotating machinery utilize one of several basic concepts. The design of an inverter is determined primarily by the operating power level. The most common circuit configurations include

- Ferroresonant inverter
- Delta magnetic inverter
- Inverter-fed L/C tank
- Quasisquare wave inverter
- Step wave inverter
- Pulse-width modulation inverter
- Phase modulation inverter

These and other types of inverters are discussed in Section 6.9.

Redundant Operation

UPS systems can be configured as either a single, large power-conditioning/backup unit, or as several smaller systems arranged in a *parallel redundant* or *isolated redundant* mode. In the parallel redundant mode, the UPS outputs are connected together and share the total load (see Fig. 10.198). The power-output ratings of the individual UPS systems are selected to provide for operation of the entire load with any one UPS unit out of commission. In the event of expansion of the DP facility, additional UPS units can be added to carry the load. The parallel system provides the ability to cope with the failure of any single unit.

FIGURE 10.197 Block diagram of an uninterruptible power system using AC rectification to float the battery supply. A closed-loop inverter draws on this supply and delivers clean AC power to the protected load.

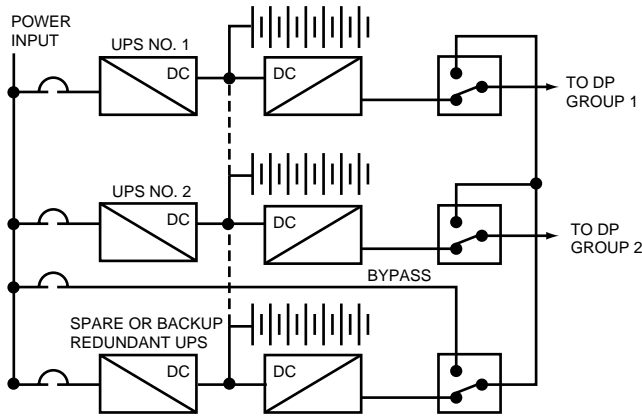

FIGURE 10.198 Configuration of a parallel redundant UPS system.

An isolated redundant system, illustrated in Fig. 10.199, divides the load among several UPS units. If one of the active systems fails, a static bypass switch will connect the affected load to a standby UPS system dedicated to that purpose. The isolated redundant system does not permit the unused capacity of one UPS unit to be utilized on a DP system that is loading another UPS to full capacity. The benefit of the isolated configuration is its immunity to system-wide failures.

Output Transfer Switch

Fault conditions, maintenance operations, and system reconfiguration require the load to be switched from one power source to another. This work is accomplished with an output transfer switch. As discussed previously, most UPS systems use electronic (static) switching. Electromechanical or motor-driven

FIGURE 10.199 Configuration of an isolated redundant UPS system.

FIGURE 10.200 Static transfer switch modes.

relays operate too slowly for most DP loads. Static transfer switches can be configured as either of the following:

- *Break-before-make*. Power output is interrupted before transfer is made to the new source.
- *Make-before-break*. The two power sources are overlapped briefly so as to prevent any interruption in AC power to the load.

Figure 10.200 illustrates each approach to load switching.

For critical-load applications, a make-before-break transfer is necessary. For the switchover to be accomplished with minimum disturbance to the load, both power sources must be synchronized. The UPS system must, therefore, be capable of synchronizing to the utility AC power line (or other appropriate power source).

Battery Supply

UPS systems typically are supplied with sufficient battery capacity to carry a DP load for periods ranging from 5 min to 1 h. Long backup time periods usually are handled by a standby diesel generator. Batteries require special precautions. For large installations, they almost always are placed in a room dedicated to that purpose. Proper temperature control is important for long life and maximum discharge capacity.

Most rectifier/charger circuits operate in a *constant-current* mode during the initial charge period, and automatically switch to a *constant-voltage* mode near the end of the charge cycle. This provides maximum battery life consistent with rapid recharge. It also prevents excessive battery outgassing and water consumption. The charger provides a *float voltage level* for maintaining the normal battery charge, and sometimes a higher voltage to equalize certain devices.

Four battery types typically are found in UPS systems:

- *Semissealed lead calcium*. A gel-type electrolyte is used that does not require the addition of water. There is no outgassing or corrosion. This type of battery is used when the devices are integral to small UPS units, or when the batteries must be placed in occupied areas. The lifespan of a semissealed lead calcium battery, under ideal conditions, is about 5 years.

- *Conventional lead calcium.* The most common battery type for UPS installations, these units require watering and terminal cleaning about every 6 months. Expected lifetime ranges up to 20 years. Conventional lead-calcium batteries outgas hydrogen under charge conditions and must be located in a secure, ventilated area.
- *Lead-antimony.* The traditional lead-acid batteries, these devices are equivalent in performance to lead-calcium batteries. Maintenance is required every 3 months. Expected lifetime is about 10 years. To retain their capacity, lead-antimony batteries require a monthly equalizing charge.
- *Nickel-cadmium.* Advantages of the nickel-cadmium battery includes small size and low weight for a given capacity. These devices offer excellent high- and low-temperature properties. Life expectancy is nearly that of a conventional lead-calcium battery. Nickel-cadmium batteries require a monthly equalizing charge, as well as periodic discharge cycles to retain their capacity. Nickel-cadmium batteries are the most expensive of the devices typically used for UPS applications.

The operation and care of specific battery types is discussed in Section 10.11.

Standby Power-System Noise

Noise produced by backup power systems can be a serious problem if not addressed properly. Standby generators, motor-generator sets, and UPS systems produce noise that can disturb building occupants and irritate neighbors or landlords.

The noise associated with electrical generation usually is related to the drive mechanism, most commonly an internal combustion engine. The amplitude of the noise produced is directly related to the size of the engine-generator set. First consider whether noise reduction is a necessity. Many building owners have elected to tolerate the noise produced by a standby power generator because its use is limited to emergency situations. During a crisis, when the normal source of power is unavailable, most people will tolerate noise associated with a standby generator.

If the decision is made that building occupants can live with the noise of the generator, care must be taken in scheduling the required testing and exercising of the unit. Whether testing occurs monthly or weekly, it should be done on a regular schedule.

If it has been determined that the noise should be controlled, or at least minimized, the easiest way to achieve this objective is to physically separate the machine from occupied areas. This may be easier said than done. Because engine noise is predominantly low-frequency in character, walls and floor/ceiling construction used to contain the noise must be massive. Lightweight construction, even though it may involve several layers of resiliently mounted drywall, is ineffective in reducing low-frequency noise. Exhaust noise is a major component of engine noise but, fortunately, it is easier to control. When selecting an engine-generator set, select the highest quality exhaust muffler available. Such units often are identified as hospital-grade mufflers.

Engine-generator sets also produce significant vibration. The machine should be mounted securely to a slab-on-grade or an isolated basement floor, or it should be installed on vibration isolation mounts. Such mounts usually are specified by the manufacturer.

Because a UPS system or motor-generator set is a source of continuous power, it must run continuously. Noise must be adequately controlled. Physical separation is the easiest and most effective method of shielding occupied areas from noise. Enclosure of UPS equipment usually is required, but noise control is significantly easier than for an engine-generator because of the lower noise levels involved. Nevertheless, the low-frequency 120-Hz fundamental of a UPS system is difficult to contain adequately; massive constructions may be necessary. Vibration control also is required for most UPS and m-gear.

Critical System Bus

Many facilities do not require the operation of all equipment during a power outage. Rather than use one large standby power system, key pieces of equipment can be protected with small, dedicated, uninterruptible power systems. Small UPS units are available with built-in battery supplies for computer systems and other

FIGURE 10.201 An application of the critical-load power bus concept. In the event of a power failure, all equipment necessary for continued operation is powered by the UPS equipment. Noncritical loads are dropped until commercial AC returns.

hardware. If cost prohibits the installation of a system-wide standby power supply (using generator or solid-state UPS technology), consider establishing a *critical load bus* that is connected to a UPS system or generator via an automatic transfer switch. This separate power supply is used to provide AC to critical loads, thus keeping the protected systems up and running. The concept is illustrated in Fig. 10.201. Unnecessary loads are dropped in the event of a power failure.

A standby system built on the critical load principle can be a cost-effective answer to the power-failure threat. The first step in implementing a critical load bus is to accurately determine the power requirements for the most important equipment. Typical power consumption figures can be found in most equipment instruction manuals. If the data is not listed or available from the manufacturer, it can be measured using a wattmeter.

When planning a critical load bus, be certain to identify accurately which loads are critical, and which can be dropped in the event of a commercial power failure. If air conditioning is interrupted but the computer equipment at a large DP center continues to run, temperatures will rise quickly to the point at which system components may be damaged or the hardware automatically shuts down. It may not be necessary to require cooling fans, chillers, and heat-exchange pumps to run without interruption. However,

any outage should be less than 1–2 min in duration. Typically, liquid-cooled DP systems can withstand 1 min of cooling interruption. Air-cooled DP systems may tolerate 5–10 min of cooling interruption.

10.9.4 The Efficient Use of Energy

Utility company power bills are becoming an increasingly large part of the operating budgets of many facilities. To reduce the amount of money spent each month on electricity, engineers must understand the billing methods used by the utility. Saving energy is more complicated than simply turning off unnecessary loads. The amount of money that can be saved through a well-planned energy conservation effort is often substantial. Reductions of 20% are not uncommon, depending on the facility layout and extent of energy conservation efforts already under way. Regardless of any monetary savings that might be realized from a power-use-reduction program, the items discussed here should be considered for any well-run facility.

The rate structures of utility companies vary widely from one area of the country to another. Some generalizations can be made, however, with respect to the basic rate-determining factors. The four primary parameters used to determine a customer's bill are

- Energy usage
- Peak demand
- Load factor
- Power factor

These items often can be controlled, to some extent, by the customer.

Energy Usage

The kilowatt-hour (kWh) usage of a facility can be reduced by turning off loads such as heating and air conditioning systems, lights, and office equipment when they are not needed. The installation of timers, photocells, or sophisticated computer-controlled energy-management systems can make substantial reductions in facility kilowatt-hour demand each month. Common sense will dictate the conservation measures applicable to a particular situation. Obvious items include reducing the length of time high-power equipment is in operation, setting heating and cooling thermostats for reasonable levels, keeping office equipment turned off during the night, and avoiding excessive amounts of indoor or outdoor lighting.

Although energy conservation measures should be taken in every area of facility operation, the greatest savings generally can be found where the largest energy users are located. Transmitter plants, large machinery, and process drying equipment consume a large amount of power, and so particular attention should be given to such hardware. Consider the following:

- Use the waste heat from equipment at the site for other purposes, if practical. In the case of high-power RF generators, room heating can be accomplished with a logic-controlled power amplifier exhaust-air recycling system.
- Have a knowledgeable consultant plan the air conditioning and heating system at the facility for efficient operation.
- Check thermostat settings on a regular basis, and consider installing time-controlled thermostats.
- Inspect outdoor-lighting photocells regularly for proper operation.
- Examine carefully the efficiency of high-power equipment used at the facility. New designs may offer substantial savings in energy costs.

The efficiency of large-power loads, such as mainframe computers, transmitters, or industrial RF heaters, is an item of critical importance to energy conservation efforts. Most systems available today are significantly more efficient than their counterparts of just 10 years ago. Plant management often can find economic justification for updating or replacing an older system on the power savings alone. In virtually any facility, energy conservation can best be accomplished through careful selection of equipment, thoughtful system design, and conscientious maintenance practices.

Peak Demand

Conserving energy is a big part of the power bill reduction equation, but it is not the whole story. The *peak demand* of the customer load is an important criterion in the utility company’s calculation of rate structures. The peak demand figure is a measure of the maximum load placed on the utility company system by a customer during a predetermined billing cycle. The measured quantities may be kilowatts, kilovolt-amperes, or both. Time intervals used for this measurement range from 15 to 60 min. Billing cycles may be annual or semiannual. Figure 10.202 shows an example of varying peak demand.

FIGURE 10.202 The charted power consumption of a facility not practicing energy-management techniques. Note the inefficiency that the utility company must absorb when faced with a load such as this.

If a facility operated at basically the same power consumption level from one hour to the next and one day to the next, the utility company could predict accurately the demand of the load, then size its equipment (including the allocation of energy reserves) for only the amount of power actually needed. For the example shown in the figure, however, the utility company must size its equipment (including allocated energy reserves) for the peak demand. The area between the peak demand and the actual usage is the margin of inefficiency that the customer forces upon the utility. The peak demand factor is a method used by utility companies to assess penalties for such operation, thereby encouraging the customer to approach a more efficient state of operation (from the utility’s viewpoint).

Load shedding is a term used to describe the practice of trimming peak power demand to reduce high-demand penalties. The goal of load shedding is to schedule the operation of nonessential equipment so as to provide a more uniform power load from the utility company, and thereby a better kilowatthour rate. Nearly any operation has certain electric loads that can be rescheduled on a permanent basis or deferred as power demand increases during the day. Figure 10.203 illustrates the results of a load-shedding program. This more efficient operation has a lower overall peak demand and a higher average demand.

Peak demand reduction efforts can cover a wide range of possibilities. It would be unwise from an energy standpoint, for example, to test high-power standby equipment on a summer afternoon, when air conditioning units may be in full operation. Morning or evening hours would be a better choice, when

FIGURE 10.203 An example of the successful application of a load-shedding program. Energy usage has been spread more evenly throughout the day, resulting in reduced demand and, consequently, a better rate from the utility company.

the air conditioning is off and the demand of office equipment is reduced. Each operation is unique and requires an individual assessment of load-shedding options.

A computerized power-demand controller provides an effective method of managing peak demand. A controller can analyze the options available and switch loads as needed to maintain a relatively constant power demand from the utility company. Such systems are programmed to recognize which loads have priority and which loads are nonessential. Power demand then is automatically adjusted by the computer, based on the rate schedule of the utility company.

Load Factor

The load factor on an electric utility company bill is a product of the peak demand and energy usage. It usually is calculated and applied to the customer's bill each month. Reducing either the peak demand or energy usage levels, or both, will decrease this added cost factor. Reducing power factor penalties also will help to reduce load factor charges.

Power Factor

Power factor charges are the result of heavy inductive loading of the utility company system. A poor PF will result in excessive losses along utility company feeder lines because more current is required to supply a particular load with a low PF than would be demanded if the load had a PF close to unity. The power factor charge is a penalty that customers pay for the extra current needed to magnetize motors and other inductive loads. This magnetizing current does not show up on the service drop wattmeter. It is, instead, measured separately or prorated as an additional charge to the customer. The power factor penalty sometimes can be reduced through the addition of on-site **power factor correction** capacitors.

Power factor meters are available for measurement of a given load. It is usually less expensive in the long run, however, to hire a local electrical contractor to conduct a PF survey and recommend correction methods. Possible sources of PF problems include transmitters, blowers, air conditioners, heating equipment, and fluorescent and high-intensity discharge lighting-fixture ballasts.

Power Factor Fundamentals

Power factor is an important, but often misunderstood, characteristic of AC power systems. It is defined as the ratio of *true power* to *apparent power*, generally expressed as a percentage. (PF also may be expressed as a decimal value.) Reactive loads (inductive or capacitive) act on power systems to shift the current out of phase with the voltage. The cosine of the resulting angle between the current and voltage is the power factor.

A utility line that is feeding an inductive load (which is most often the case) is said to have a *lagging* power factor, whereas a line feeding a capacitive load has a *leading* power factor. See Fig. 10.204. A poor power factor will result in excessive losses along utility company feeder lines because more current is required to supply a given load with a low power factor than the same load with a power factor close to unity.

For example, a motor requiring 5 kW from the line is connected to the utility service entrance. If it has a power factor of 86%, the apparent power demanded by the load will be 5 kW divided by 86%, or more than 5.8 kW. The true power is 5 kW, and the apparent power is 5.8 kW. The same amount of work is being done by the motor, but the closer the power factor is to unity, the more efficient the system. To expand on this example, for a single-phase electric motor the actual power is the sum of several components, namely

- The work performed by the system, specifically lifting, moving, or otherwise controlling an object
- Heat developed by the power lost in the motor winding resistance
- Heat developed in the motor iron through eddy-current and hysteresis losses
- Frictional losses in the motor bearings
- Air friction losses in turning the motor rotor

All of these values are expressed in watts or kilowatts, and can be measured. They represent the actual power. The apparent power is determined by measuring the current and voltage with an ammeter and a

FIGURE 10.204 The mathematical relationships of an inductive circuit as they apply to power factor (PF) measurements. Reducing the kVAR component of the circuit causes θ to diminish, improving the PF. When kW is equal to kVA, the phase angle is zero and the power factor is unity (100%).

FIGURE 10.205 The effects of inductance in a circuit: (a) waveforms for resistive and inductive loads, (b) vector diagrams of inductive loads.

voltmeter, then calculating the product of the two. In the single-phase motor example, the apparent power thus obtained is greater than the actual power. The reason for this is the power factor.

The PF reflects the differences that exist between different types of loads. A soldering iron is a purely resistive load that converts current directly into heat. The current is called *actual current* because it contributes directly to the production of actual power. On the other hand, the single-phase electric motor represents a partially inductive load. The motor current consists of actual current that is converted into actual power, and a magnetizing current that is used to generate the magnetic field required for operation of the device. This magnetizing current corresponds to an exchange of energy between the power source and the motor, but it is not converted into actual power. This current is identified as the *reactive current* in the circuit.

As illustrated in Fig. 10.205, in a resistive circuit, the current is in phase with the voltage. In a purely inductive circuit, the current lags the voltage by 90° . This relationship can be represented graphically by vectors, as shown in the figure. For a circuit with both inductive and resistive components, as in the motor example, the two conditions exist simultaneously. The distribution between the actual power and the reactive power is illustrated in Fig. 10.206.

FIGURE 10.206 Vector diagram showing that apparent power is the vector sum of the actual and reactive power in a circuit.

FIGURE 10.207 Changes in power factor for an induction motor as a function of motor loading.

The power factor, which has been defined previously as the ratio between actual power and apparent power, is also the cosine of the angle θ . The greater the angle θ becomes, the lower the power factor.

Determining the power factor for a given element of a power-distribution system is complicated by the wide variety of loads typically connected. Different loads present different PF components:

- Lighting. The PF for most incandescent lamps is unity. Fluorescent lamps usually have a low power factor; 50% is typical. Fluorescent lamps sometimes are supplied with compensation devices to correct for low power factor. Mercury vapor lamps have a low PF; 40–60% is typical. Again, such devices may be supplied with compensation devices.
- Electric motors. The PF of an induction motor varies with the load, as shown in Fig. 10.207. Unloaded or lightly loaded motors exhibit a low PF. Figure 10.208 illustrates the variation of PF and reactive power for varying loads on a three-phase induction motor. Synchronous motors provide good PF when their excitation is adjusted properly. Synchronous motors also can be overexcited to exhibit a leading power factor and, therefore, may be used to improve the power factor of a facility.
- Heating systems. Most heating systems used in ovens or dryers present a PF of close to unity.
- Welding equipment. Electric arc welders usually have a low PF; 60% is typical.
- Distribution transformers. The PF of a transformer varies considerably as a function of the load applied to the device, as well as the design of the transformer. An unloaded transformer would be highly inductive and, therefore, would exhibit a low PF.

To keep the power factor as close as possible to 100%, utility companies place capacitor banks at various locations in the distribution system, offsetting the inductive loading (lagging power factor) of most user equipment. The goal is to create an equal amount of leading PF in the system to match the lagging PF of the load. When balanced, the power factor is 100%. In practice, this is seldom attainable because loads are switched on and off at random times, but utilities routinely maintain an overall power factor of approximately 99%. To accomplish this, capacitor banks are switched automatically to compensate for changing load conditions.

FIGURE 10.208 The relationship of reactive power and power factor to percentage of load for a 100-kW, three-phase induction motor.

Static capacitors are used commonly for power factor correction. These devices are similar to conventional oil-filled high-voltage capacitors. Operating voltages range from 230 V to 13.8 kV for pole-mounted applications. The PF correction capacitors are connected in parallel with the utility lines as close as practical to the low-PF loads. The primary disadvantage of static PF correction capacitors is that they cannot be adjusted for changing power factor conditions. Remotely operated relays may be used, however, to switch capacitor banks in and out of the circuit as required. Power factor correction also can be accomplished by using *synchronous capacitors* connected across utility lines. Synchronous capacitors may be adjusted

to provide varying capacitance to correct for varying PF loads. The capacitive effect of a synchronous capacitor is changed by varying the DC excitation voltage applied to the rotor of the device.

Utilities usually pass on to customers the costs of operating low-PF loads. Power factor may be billed as one, or a combination, of the following:

- A penalty for PF below a predetermined value, or a credit for PF above a predetermined value
- An increasing penalty for decreasing PF
- A charge on monthly kilovolt-ampere reactive (kVAR) hours
- A straight charge for the maximum value of kilovoltampere used during the month

Aside from direct costs from utility companies for low-PF operation, the end-user experiences a number of indirect costs as well. When a facility operates with a low overall PF, the amount of useful electrical energy available inside the plant at the distribution transformer is reduced considerably because of the amount of reactive energy that the transformer(s) must carry. Figure 10.209 illustrates the reduction in available power from a distribution transformer when presented with varying PF loads. Figure 10.210 illustrates the increase in I^2R losses in feeder and branch circuits with varying PF loads. These conditions result in the need for oversized cables, transformers, switchgear, and protection circuits.

FIGURE 10.209 The effects of power factor on output of a transformer.

On-Site Power Factor Correction

The first step in correcting for low PF is to determine the current situation at a given facility. Clamp-on power factor meters are available for this purpose. Power factor can be improved in two ways:

- Reduce the amount of reactive energy by eliminating unloaded motors and transformers.
- Apply external compensation capacitors to correct the low-PF condition.

PF correction capacitors perform the function of an energy-storage device. Instead of transferring reactive energy back and forth between the load and the power source, the magnetizing current reactive energy is stored in a capacitor at the load. Capacitors are rated in kVARs, and are available for single- and multiphase loads. Usually more than one capacitor is required to yield the desired degree of PF correction. The capacitor rating required in a given application may be determined by using lookup tables provided by PF capacitor manufacturers. Installation options include

- Individual capacitors placed at each machine
- A group or bank installation for an entire area of the plant
- A combination of the two approaches

When rectifier loads creating harmonic load current are the cause of a low-PF condition, the addition of PF correcting capacitors will not necessarily provide the desired improvement. The capacitors, in some

FIGURE 10.210 The relationship between power factor and percentage losses in system feeder and branch circuits.

cases, may actually raise the line current and fail to improve the power factor. Harmonic currents generally are most apparent in the neutral of three-phase circuits. Conductors supplying three-phase rectifiers using a neutral conductor require a neutral conductor that is as large as the phase conductors. A reduced neutral should not be permitted. When adding capacitors for PF correction, be careful to avoid any unwanted voltage resonances that might be excited by harmonic load currents.

If a delta/wye connected power transformer is installed between the power source and the load, the power factor at the transformer input generally will reflect the average PF of the loads on the secondary. This conclusion works on the assumption that the low PF is caused by inductive and capacitive reactances in the loads. However, if the load current is rich in harmonics from rectifiers and switching regulators, some of the harmonic currents will flow no farther toward the power source than the transformer delta winding. The third harmonic and multiples of three will flow in the delta winding and will be significantly reduced in amplitude. By this means, the transformer will provide some improvement in the PF of the total load.

An economic evaluation of the cost vs. benefits, plus a review of any mandatory utility company limits that must be observed for PF correction, will determine how much power factor correction, if any, may be advisable at a given facility. Correction to 85% will satisfy most requirements. No economic advantage is likely to result from correcting to 95% or greater. Overcorrecting a load by placing too many PF correction capacitors may reduce the power factor after reaching unity, and may cause uncontrollable overvoltages in low-kVA-capacity power sources.

PF correcting capacitors usually offer some benefits in absorbing line-voltage impulse-type noise spikes. However, if the capacitors are switched on and off, they will create significant impulses of their own. Switching may be accomplished with acceptably low disturbance through the use of soft-start or preinsertion resistors. Such resistors are connected momentarily in series with the capacitors. After a brief delay (0.5 s or less) the resistors are short circuited, connecting the capacitors directly across the line.

Installation of PF correction capacitors at a facility is a complicated process that requires a knowledgeable consultant and licensed electrician. The local utility company should be contacted before any effort is made to improve the PF of a facility.

Defining Terms

Critical system bus: A circuit in an AC power distribution system designated as feeding critical loads that must continue to operate in the event of a utility company power failure.

Emergency power source: A supply circuit or system designated as being essential for safety to life and property.

Forward-transfer mode: An operational state of an uninterruptible power system in which the load is normally powered by the utility line, and the inverter is idle.

Motor-generator set (m-g): A power processing machine consisting of a motor powered by the AC utility supply that is mechanically connected to a generator, which feeds the load.

Power factor: The ratio of *true power* to *apparent power*, generally expressed as a percentage (see the text).

Power factor correction: The practice of placing or connecting one or more devices (usually capacitors) onto an AC power circuit in order to improve its operating power factor.

Power shaving: The practice of a utility customer reducing its demand from the system during peak periods in order to enjoy a more attractive energy rate from the utility.

Pull-in speed: The minimum speed (close to the synchronous speed) at which a motor will pull into synchronization if excitation is applied to the field.

Reverse-transfer mode: An operational state of an uninterruptible power system in which the load is normally powered by the inverter. In the event of an inverter failure, the load is switched directly to the utility line.

Standby power source: A supply circuit or system used to protect a facility against the loss of productivity resulting from a utility company power outage.

Uninterruptible power system (UPS): A power processing device used to protect a sensitive load from disturbances on the utility AC line. A UPS system typically consists of a battery bank that drives an inverter to produce power for the load, line switching hardware, and supervisory control circuitry.

10.10 Facility Grounding

Jerry C. Whitaker

10.10.1 Introduction

The attention given to the design and installation of a facility ground system is a key element in the day-to-day reliability of the plant. A well-designed and -installed ground network is invisible to the engineering staff. A marginal ground system, however, will cause problems on a regular basis. Grounding schemes can

range from simple to complex, but any system serves three primary purposes:

- Provides for operator safety.
- Protects electronic equipment from damage caused by transient disturbances.
- Diverts stray radio frequency energy from sensitive audio, video, control, and computer equipment.

Most engineers view grounding mainly as a method to protect equipment from damage or malfunction. However, the most important element is operator safety. The 120 V or 208 V AC line current that powers most equipment can be dangerous, even deadly, if handled improperly. Grounding of equipment and structures provides protection against wiring errors or faults that could endanger human life.

Proper grounding is basic to protection against AC line disturbances. This applies if the source of the disturbance is lightning, power-system switching activities, or faults in the distribution network. Proper grounding is also a key element in preventing radio frequency interference in transmission or computer equipment. A facility with a poor ground system can experience RFI problems on a regular basis. Implementing an effective ground network is not an easy task. It requires planning, quality components, and skilled installers. It is not inexpensive. However, proper grounding is an investment that will pay dividends for the life of the facility.

Any ground system consists of two key elements: (1) the earth-to-grounding electrode interface outside the facility, and (2) the AC power and signal-wiring systems inside the facility.

Terms and Codes

A *facility* can be defined as something that is built, installed, or established to serve a particular purpose [1]. A facility is usually thought of as a single building or group of buildings. The National Electrical Code (NEC) uses the term *premises* to refer to a facility when it defines premises wiring as the interior and exterior (facility) wiring, such as power, lighting, control, and signal systems. Premises wiring includes the service and all permanent and temporary wiring between the service and the load equipment. Premises wiring does not include wiring internal to any load equipment.

The Need for Grounding

The Institute of Electrical and Electronic Engineers (IEEE) defines grounding as a conducting connection, whether intentional or accidental, by which an electric circuit or equipment is connected to the earth, or to some conducting body of relatively large extent that serves in place of the earth. It is used for establishing and maintaining the potential of the earth (or of the conducting body) or approximately that potential, on conductors connected to it, and for conducting ground current to and from the earth (or the conducting body) [2]. Based on this definition, the reasons for grounding can be identified as

- Personnel safety by limiting potentials between all non-current-carrying metal parts of an electrical distribution system.
- Personnel safety and control of electrostatic discharge (ESD) by limiting potentials between all non-current-carrying metal parts of an electrical distribution system and the earth.
- Fault isolation and equipment safety by providing a low-impedance fault return path to the power source to facilitate the operation of overcurrent devices during a ground fault.

The IEEE definition makes an important distinction between *ground* and *earth*. *Earth* refers to mother earth, and *ground* refers to the equipment grounding system, which includes equipment grounding conductors, metallic raceways, cable armor, enclosures, cabinets, frames, building steel, and all other non-current-carrying metal parts of the electrical distribution system.

There are other reasons for grounding not implicit in the IEEE definition. Overvoltage control has long been a benefit of proper power system grounding, and is described in IEEE Standard 142, also known as the *Green Book* [3]. With the increasing use of electronic computer systems, noise control has become associated with the subject of grounding, and is described in IEEE Standard 1100, the *Emerald Book* [4].

FIGURE 10.211 Equipment grounding and system grounding. (Courtesy of Intertec Publishing. After [5].)

Equipment Grounding

Personnel safety is achieved by interconnecting all non-current-carrying metal parts of an electrical distribution system, and then connecting the interconnected metal parts to the earth [5]. This process of interconnecting metal parts is called equipment grounding and is illustrated in Fig. 10.211, where the equipment grounding conductor is used to interconnect the metal enclosures. Equipment grounding ensures that there is no difference of potential, and thus no shock hazard between non-current-carrying metal parts anywhere in the electrical distribution system. Connecting the equipment grounding system to earth ensures that there is no difference of potential between the earth and the equipment grounding system. It also prevents static charge buildup.

System Grounding

System grounding, which is also illustrated in Fig. 10.211, is the process of intentionally connecting one of the current-carrying conductors of the electrical distribution system to ground [5]. The figure shows the neutral conductor intentionally connected to ground and the earth. This conductor is called the *grounded* conductor because it is intentionally grounded. The purpose of system grounding is overvoltage control and equipment safety through fault isolation. An ungrounded system is subject to serious overvoltages under conditions such as intermittent ground faults, resonant conditions, and contact with higher voltage systems. Fault isolation is achieved by providing a low-impedance return path from the load back to the source, which will ensure operation of overcurrent devices in the event of a ground fault. The system ground connection makes this possible by connecting the equipment grounding system to the low side of the voltage source. Methods of system grounding include solidly grounded, ungrounded, and impedance-grounded.

Solidly grounded means that an intentional zero-impedance connection is made between a current-carrying conductor and ground. The single-phase (1ϕ) system shown in Fig. 10.211 is solidly grounded. A solidly grounded, three-phase, four-wire, wye system is illustrated in Fig. 10.212 The neutral is connected directly to ground with no impedance installed in the neutral circuit. The NEC permits this connection to be made at the service entrance only [6]. The advantages of a solidly grounded wye system include

FIGURE 10.212 Solidly grounded wye power system. (Courtesy of Intertec Publishing. After [5].)

reduced magnitude of transient overvoltages, improved fault protection, and faster location of ground faults. There is one disadvantage of the solidly grounded wye system. For low-level arcing ground faults, the application of sensitive, properly coordinated, ground fault protection (GFP) devices is necessary to prevent equipment damage from arcing ground faults. The NEC requires arcing ground fault protection at 480Y/277V services, and a maximum sensitivity limit of 1200 A is permitted. Severe damage is less frequent at the lower voltage 208 V systems, where the arc may be self-extinguishing.

Ungrounded means that there is no intentional connection between a current-carrying conductor and ground. However, charging capacitance will create unintentional capacitive coupling from each phase to ground, making the system essentially a capacitance-grounded system. A three-phase, three-wire system from an ungrounded delta source is illustrated in Fig. 10.213. The most important advantage of an ungrounded system is that an accidental ground fault in one phase does not require immediate removal of power. This allows for continuity of service, which made the ungrounded delta system popular in the past. However, ungrounded systems have serious disadvantages. Because there is no fixed system ground point, it is difficult to locate the first ground fault and to sense the magnitude of fault current. As a result, the fault is often permitted to remain on the system for an extended period of time. If a second fault should

FIGURE 10.213 Ungrounded delta power system. (Courtesy of Intertec Publishing. After [5].)

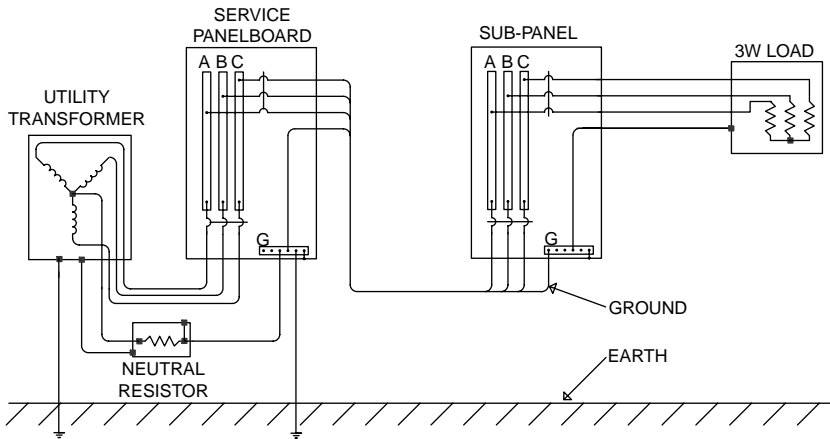

FIGURE 10.214 High-resistance grounded wye power system. (Courtesy of Intertec Publishing. After [5].)

occur before the first one is removed, and the second fault is on a different phase, the result will be a double line-to-ground fault causing serious arcing damage. Another problem with the ungrounded delta system is the occurrence of high transient overvoltages from phase-to-ground. Transient overvoltages can be caused by intermittent ground faults, with overvoltages capable of reaching a phase-to-ground voltage of from six to eight times the phase-to-neutral voltage. Sustained overvoltages can ultimately result in insulation failure and thus more ground faults.

Impedance-grounded means that an intentional impedance connection is made between a current-carrying conductor and ground. The high-resistance grounded wye system, illustrated in Fig. 10.214, is an alternative to solidly grounded and ungrounded systems. High-resistance grounding will limit ground fault current to a few amperes, thus removing the potential for arcing damage inherent in solidly grounded systems. The ground reference point is fixed, and relaying methods can locate first faults before damages from second faults occur. Internally generated transient overvoltages are reduced because the neutral to ground resistor dissipates any charge that may build up on the system charging capacitances.

Table 10.14 compares the three most common methods of system grounding. There is no one *best* system grounding method for all applications. In choosing among the various options, the designer must consider the requirements for safety, continuity of service, and cost. Generally, low-voltage systems should be operated solidly grounded. For applications involving continuous processes in industrial plants or where shutdown might create a hazard, a high-resistance grounded wye system, or a solidly grounded wye system with an alternate power supply, may be used. The high-resistance grounded wye system combines many of

TABLE 10.14 Comparison of System Grounding Methods

Characteristic Assuming No Fault Escalation	System Grounding Method		
	Solidly Grounded	Ungrounded	High Resistance
Operation of overcurrent device on first ground fault	Yes	No	No
Control of internally generated transient overvoltages	Yes	No	Yes
Control of steady-state overvoltages	Yes	No	Yes

the advantages of the ungrounded delta system and the solidly grounded wye system. IEEE Standard 142 recommends that medium-voltage systems less than 15 kV be low-resistance grounded to limit ground fault damage yet permit sufficient current for detection and isolation of ground faults. Standard 142 also recommends that medium-voltage systems over 15 kV be solidly grounded. Solid grounding should include sensitive ground fault relaying in accordance with the NEC.

The Grounding Electrode

The process of connecting the grounding system to earth is called *earthing*, and consists of immersing a metal electrode or system of electrodes into the earth [5]. The conductor that connects the grounding system to earth is called the *grounding electrode conductor*. The function of the grounding electrode conductor is to keep the entire grounding system at earth potential (i.e., voltage equalization during lightning and other transients) rather than for conducting ground-fault current. Therefore, the NEC allows reduced sizing requirements for the grounding electrode conductor when connected to *made* electrodes.

The basic measure of effectiveness of an earth electrode system is called *earth electrode resistance*. Earth electrode resistance is the resistance, in ohms, between the point of connection and a distant point on the earth called *remote earth*. Remote earth, about 25 ft from the driven electrode, is the point where earth electrode resistance does not increase appreciably when this distance is increased. Earth electrode resistance consists of the sum of the resistance of the metal electrode (negligible) plus the contact resistance between the electrode and the soil (negligible) plus the soil resistance itself. Thus, for all practical purposes, earth electrode resistance equals the soil resistance. The soil resistance is nonlinear, with most of the earth resistance contained within several feet of the electrode. Furthermore, current flows only through the electrolyte portion of the soil, not the soil itself. Thus, soil resistance varies as the electrolyte content (moisture and salts) of the soil varies. Without electrolyte, soil resistance would be infinite.

Soil resistance is a function of soil resistivity. A 1 m³ sample of soil with a resistivity ρ of 1 Ω m will present a resistance R of 1 Ω between opposite faces. A broad variation of soil resistivity occurs as a function of soil types, and soil resistivity can be estimated or measured directly. Soil resistivity is usually measured by injecting a known current into a given volume of soil and measuring the resulting voltage drop. When soil resistivity is known, the earth electrode resistance of any given configuration (single rod, multiple rods, or ground ring) can be determined by using standard equations developed by Sunde [6], Schwarz [7], and others.

Earth resistance values should be as low as practicable, but are a function of the application. The NEC approves the use of a single *made* electrode if the earth resistance does not exceed 25 Ω . IEEE Standard 1100 reports that the very low earth resistance values specified for computer systems in the past are not necessary. Methods of reducing earth resistance values include the use of multiple electrodes in parallel, the use of ground rings, increased ground rod lengths, installation of ground rods to the permanent water level, increased area of coverage of ground rings, and the use of concrete-encased electrodes, ground wells, and electrolytic electrodes.

Earth Electrode

Earth electrodes may be *made* electrodes, *natural* electrodes, or *special-purpose* electrodes [5]. Made electrodes include driven rods, buried conductors, ground mats, buried plates, and ground rings. The electrode selected is a function of the type of soil and the available depth. Driven electrodes are used where bedrock is 10 ft or more below the surface. Mats or buried conductors are used for lesser depths. Buried plates are not widely used because of the higher cost when compared to rods. Ground rings employ equally spaced driven electrodes interconnected with buried conductors. Ground rings are used around large buildings, around small unit substations, and in areas having high soil resistivity.

Natural electrodes include buried water pipe electrodes and concrete-encased electrodes. The NEC lists underground metal water piping, available on the premises and not less than 10 ft in length, as part of a preferred grounding electrode system. Because the use of plastic pipe in new water systems will impair the effectiveness of water pipe electrodes, the NEC requires that metal underground water piping be supplemented by an additional approved electrode. Concrete below ground level is a good electrical

conductor. Thus, metal electrodes encased in such concrete will function as excellent grounding electrodes. The application of concrete-encased electrodes is covered in IEEE Standard 142.

10.10.2 Establishing an Earth Ground

The grounding electrode is the primary element of any ground system. The electrode can take many forms. In all cases, its purpose is to interface the electrode (a conductor) with the earth (a semiconductor). Grounding principles have been refined to a science. Still, however, many misconceptions exist regarding grounding. An understanding of proper grounding procedures begins with the basic earth-interface mechanism.

Grounding Interface

The grounding electrode (or ground rod) interacts with the earth to create a hemisphere-shaped volume, as illustrated in Fig. 10.215. The size of this volume is related to the size of the grounding electrode. The length of the electrode has a much greater effect than the diameter. Studies have demonstrated that the earth-to-electrode resistance from a driven ground rod increases exponentially with the distance from that rod. At a given point, the change becomes insignificant. It has been found that for maximum effectiveness of the earth-to-electrode interface, each ground rod requires a hemisphere-shaped volume with a diameter that is approximately 2.2 times the rod length [9].

The constraints of economics and available real estate place practical limitations on the installation of a ground system. It is important, however, to keep the 2.2 rule in mind because it allows the facility design engineer to use the available resources to the best advantage. Figure 10.216 illustrates the effects of locating ground rods too close (less than 2.2 times the rod length). An overlap area is created that effectively wastes some of the earth-to-electrode capabilities of the two ground rods. Research has shown, for example, that two 10-ft ground rods driven only 1 ft apart provide about the same resistivity as a single 10-ft rod.

There are three schools of thought with regard to ground-rod length. The first approach states that extending ground-rod length beyond about 10 ft is of little value for most types of soil. The reasoning behind this conclusion is presented in Fig. 10.217a, where ground resistance is plotted as a function of ground-rod length. Beyond 10 ft in length, a point of diminishing returns is reached.

The second school of thought concludes that optimum earth-to-electrode interface is achieved with long (40 ft or greater) rods, driven to penetrate the local water table. When planning this type of installation,

FIGURE 10.215 The effective earth-interface hemisphere resulting from a single driven ground rod. The 90% effective area of the rod extends to a radius of approximately 1.1 times the length of the rod. (After [10].)

FIGURE 10.216 The effect of overlapping earth interface hemispheres by placing two ground rods at a spacing less than 2.2 times the length of either rod. The overlap area represents wasted earth-to-electrode interface capability. (After [10].)

FIGURE 10.217 Charted grounding resistance as a function of ground-rod length: (a) data demonstrating that ground-rod length in excess of 10 ft produces diminishing returns (1-in.-diameter rod) [10], (b) data demonstrating that ground system performance continues to improve as depth increases. (Chart b courtesy of Intertec Publishing. After [12].)

consider the difficulty that may be encountered when attempting to drive long ground rods. The foregoing discussion assumes that the soil around the grounding electrode is reasonably uniform in composition. Depending upon the location, however, this assumption may not hold true.

The third school of thought concludes that the optimum ground rod installation is achieved by using the longest possible rod depth (length). Data to support this conclusion is given in Fig. 10.217b, which plots ground rod performance as a function of depth in soil of uniform resistivity. This curve does not take into account seasonal moisture content, changing chemical composition at different soil layers, and frozen soil conditions.

Given these three conflicting approaches, the benefits of hiring an experienced, licensed professional engineer to design the ground system can be readily appreciated.

Horizontal grounding electrodes provide essentially the same resistivity as an equivalent-length vertical electrode, given uniform soil conditions. As Fig. 10.218 demonstrates, the difference between a 10-ft vertical and a 10-ft horizontal ground rod is negligible (275 Ω vs. 250 Ω). This comparison includes the effects of the vertical connection element from the surface of the ground to the horizontal rod. Taken by itself, the horizontal ground rod provides an earth-interface resistivity of approximately 308 Ω when buried at a depth of 36 in.

Ground rods come in many sizes and lengths. The more popular sizes are 1/2, 5/8, 3/4, and 1 in. The 1/2-in. size is available in steel with stainless-clad, galvanized, or copper-clad rods. All-stainless-steel rods also are available. Ground rods can be purchased in unthreaded or threaded (sectional) lengths. The sectional sizes are typically 9/16-in. or 1/2-in. rolled threads. Couplers are made from the same materials as the rods.

FIGURE 10.218 The effectiveness of vertical ground rods compared with horizontal ground rods. (After [10].)

Couplers can be used to join 8- or 10-ft length rods together. A 40-ft ground rod, for example, is driven one 10-ft section at a time.

The type and size of ground rod used is determined by how many sections are to be connected and how hard or rocky the soil is. Copper-clad $\frac{5}{8}$ -in. \times 10-ft rods are probably the most popular. Copper cladding is designed to prevent rust. The copper is not primarily to provide better conductivity. Although the copper certainly provides a better conductor interface to earth, the steel that it covers is also an excellent conductor when compared with ground conductivity. The thickness of the cladding is important only insofar as rust protection is concerned.

Wide variations in soil resistivity can be found within a given geographic area, as documented in Table 10.15. The wide range of values shown results from differences in moisture content, mineral content, and temperature.

Temperature is a major concern in shallow grounding systems because it has a significant effect on soil resistivity [11]. During winter months, the ground system resistance can rise to unacceptable levels because of freezing of liquid water in the soil. The same shallow grounding system can also suffer from high resistance in the summer as moisture is evaporated from soil. It is advisable to determine the natural frost line and moisture profile for an area before attempting design of a ground system.

Figure 10.219 describes a four-point method for in-place measurement of soil resistivity. Four uniformly spaced probes are placed in a linear arrangement and connected to a ground resistance test meter. An alternating current (at a frequency other than 60 Hz) is passed between the two most distant probes, resulting in a potential difference between the center potential probes. The meter display in ohms of resistance can then be applied to determine the average soil resistivity in ohm-centimeters for the hemispherical area between the C1 and P2 probes.

Soil resistivity measurements should be repeated at a number of locations to establish a resistivity profile for the site. The depth of measurement can be controlled by varying the spacing between the probes. In no case should the probe length exceed 20% of the spacing between probes.

After the soil resistivity for a site is known, calculations can be made to determine the effectiveness of a variety of ground system configurations. Equations for several driven rod and radial cable configurations are given in [11], which, after the solid resistivity is known, can be used for the purpose of estimating total

TABLE 10.15 Typical Resistivity of Common Soil Types

Type of Soil Resistivity in Ω/cm	Average	Minimum	Maximum
Filled land, ashes, salt marsh	2,400	600	7,000
Top soils, loam	4,100	340	16,000
Hybrid soils	6,000	1,000	135,000
Sand and gravel	90,000	60,000	460,000

FIGURE 10.219 The four-point method for soil resistivity measurement. (After [11].)

system resistance. Generally, driven rod systems are appropriate where soil resistivity continues to improve with depth or where temperature extremes indicate seasonal frozen or dry soil conditions. Figure 15.220 shows a typical soil resistivity map for the U.S.

Ground Electrode Testing

Testing of all ground electrodes before they are connected to form a complex network is a fairly simple process that is well described in the documentation included with all ground electrode meters. This instructional process, therefore, will not be described here. Also, the system as a whole should be tested after all interconnections are made, providing a benchmark for future tests.

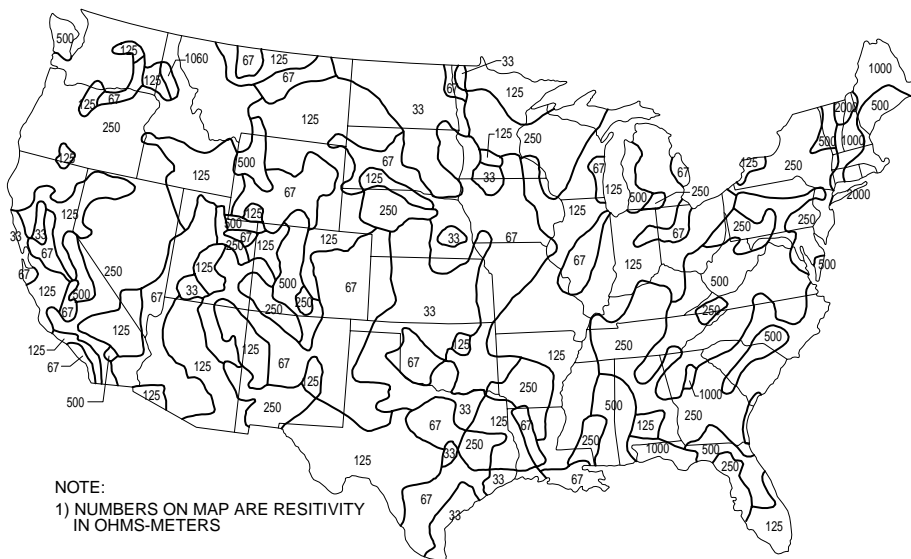

FIGURE 10.220 Typical soil resistivity map for the U.S. (After [11].)

At a new site, it is often advisable to perform ground system tests before the power company ground/neutral conductor is attached to the system. Conduct a before-and-after test with probes in the same position to determine the influence of the power company attachment [11]. It is also worthwhile to install permanent electrodes and marker monuments at the original P2 and C2 probe positions to ensure the repeatability of future tests.

Chemical Ground Rods

A chemically activated ground system is an alternative to the conventional ground rod. The idea behind the chemical ground rod is to increase the earth-to-electrode interface by conditioning the soil surrounding the rod. Experts have known for many years that the addition of ordinary table salt (NaCl) to soil will reduce the resistivity of the earth-to-ground electrode interface. With the proper soil moisture level (4 to 12%), *salting* can reduce soil resistivity from perhaps 10,000 Ω/m to less than 100 Ω/m . Salting the area surrounding a ground rod (or group of rods) follows a predictable life-cycle pattern, as illustrated in Fig. 10.221. Subsequent salt applications are rarely as effective as the initial salting.

Various approaches have been tried over the years to solve this problem. One such product is shown in Fig. 10.222. This chemically activated grounding electrode consists of a 2- $\frac{1}{2}$ -in.-diameter copper pipe filled with rock salt. Breathing holes are provided on the top of the assembly, and seepage holes are located at the bottom. The theory of operation is simple. Moisture is absorbed from the air (when available) and is then absorbed by the salt. This creates a solution that seeps out of the base of the device and conditions the soil in the immediate vicinity of the rod.

Another approach is shown in Fig. 10.223. This device incorporates a number of ports (holes) in the assembly. Moisture from the soil (and rain) is absorbed through the ports. The metallic salts subsequently absorb the moisture, forming a saturated solution that seeps out of the ports and into the earth-to-electrode hemisphere. Tests have shown that if the moisture content is within the required range, earth resistivity can be reduced by as much as 100:1. Figure 15.224 shows the measured performance of a typical chemical ground rod in three types of soil.

Implementations of chemical ground-rod systems vary depending on the application. Figure 10.225 illustrates a counterpoise ground consisting of multiple leaching apertures connected in a spoke fashion to a central hub. The system is serviceable in that additional salt compound can be added to the hub at

FIGURE 10.221 The effect of soil salting on ground-rod resistance with time. The expected resalting period, shown here as 2 years, varies depending on the local soil conditions and the amount of moisture present. (After [10].)

FIGURE 10.222 An air-breathing chemically activated ground rod: (a) breather holes at the top of the device permit moisture penetration into the chemical charge section of the rod; (b) a salt solution seeps out of the bottom of the unit to form a conductive shell. (After [10].)

required intervals to maintain the effectiveness of the ground. Figure 10.226 shows a counterpoise system made up of individual chemical ground rods interconnected with radial wires buried below the surface.

Ufer Ground System

Driving ground rods is not the only method of achieving a good earth-to-electrode interface [9]. The concept of the *Ufer* ground has gained interest because of its simplicity and effectiveness. The Ufer approach (named for its developer), however, must be designed into a new structure. It cannot be added on later. The Ufer ground takes advantage of the natural chemical- and water-retention properties of concrete to provide an earth ground. Concrete typically retains moisture for 15 to 30 days after a rain. The material has a ready supply of ions to conduct current because of its moisture-retention properties, mineral content, and inherent pH. The large mass of any concrete foundation provides a good interface to ground.

FIGURE 10.223 An alternative approach to the chemically activated ground rod. Multiple holes are provided on the ground-rod assembly to increase the effective earth-to-electrode interface. Note that chemical rods can be produced in a variety of configurations. (After [10].)

FIGURE 10.224 Measured performance of a chemical ground rod. (After [10].)

A Ufer system, in its simplest form, is made by routing a solid-copper wire (no. 4 gauge or larger) within the foundation footing forms before concrete is poured. Figure 10.227 shows one such installation. The length of the conductor run within the concrete is important. Typically a 20-ft run (10 ft in each direction) provides a 5 Ω ground in 1000 Ω/m soil.

As an alternative, steel reinforcement bars (rebar) can be welded together to provide a rigid, conductive structure. A ground lug is provided to tie equipment to the ground system in the foundation. The rebar must be welded, not tied, together. If it is only tied, the resulting poor connections between rods can result in arcing during a current surge. This can lead to deterioration of the concrete in the affected areas.

The design of a Ufer ground is not to be taken lightly. Improper installation can result in a ground system that is subject to problems. The grounding electrodes must be kept a minimum of 3 in. from the

FIGURE 10.225 Hub and spoke counterpoise ground system. (After [10].)

FIGURE 10.226 Tower grounding scheme using buried copper radials and chemical ground rods. (After [10].)

bottom and sides of the concrete to avoid the possibility of foundation damage during a large lightning surge. If an electrode is placed too near the edge of the concrete, a surge could turn the water inside the concrete to steam and break the foundation apart.

The Ufer approach also can be applied to guy-anchor points or a tower base, as illustrated in Fig. 10.228. Welded rebar or ground rods sledged in place after the rebar cage is in position can be used. By protruding

FIGURE 10.227 The basic concept of a Ufer ground system, which relies on the moisture-retentive properties of concrete to provide a large earth-to-electrode interface. Design of such a system is critical. Do not attempt to build a Ufer ground without the assistance of an experienced contractor. (After [9].)

FIGURE 10.228 The Ufer ground system as applied to a transmission-tower base or guy-wire anchor point. When using this type of ground system, bond all rebar securely to prevent arcing in the presence of large surge currents. (After [9].)

below the bottom concrete surface, the ground rods add to the overall electrode length to help avoid thermal effects that can crack the concrete. The maximum length necessary to avoid breaking the concrete under a lightning discharge is determined by the following:

- Type of concrete (density, resistivity, and other factors)
- Water content of the concrete
- How much of the buried concrete surface area is in contact with the ground
- Ground resistivity
- Ground water content
- Size and length of the ground rod
- Size of lightning flash

The last variable is a bit of a gamble. The 50% mean occurrence of lightning strikes is 18 A, but superstrikes can occur that approach 100 to 200 kA.

Before implementing a Ufer ground system, consult a qualified contractor. Because the Ufer ground system will be the primary grounding element for the facility, it must be done correctly.

Bonding Ground-System Elements

A ground system is only as good as the methods used to interconnect the component parts [9]. Do not use soldered-only connections outside the equipment building. Crimped/brazed and *exothermic* (*Cadwelded*) connections are preferred. (Cadweld is a registered trademark of Erico Corp.) To make a proper bond, all metal surfaces must be cleaned, any finish removed to bare metal, and surface preparation compound applied. Protect all connections from moisture by appropriate means, usually sealing compound and heat-shrink tubing.

It is not uncommon for an untrained installer to use soft solder to connect the elements of a ground system. Such a system is doomed from the start. Soft-soldered connections cannot stand up to the acid

FIGURE 10.229 The exothermic bonding process. (After [9].)

and mechanical stress imposed by the soil. The most common method of connecting the components of a ground system is silver soldering. The process requires the use of brazing equipment, which may be unfamiliar to many facility engineers. The process uses a high-temperature/high-conductivity solder to complete the bonding process. For most grounding systems, however, the best approach to bonding is the exothermic process.

Exothermic Bonding

Exothermic bonding is the preferred method of connecting the elements of a ground system [9]. Molten copper is used to melt connections together, forming a permanent bond. This process is particularly useful in joining dissimilar metals. In fact, if copper and galvanized cable must be joined, exothermic bonding is the only acceptable means. The completed connection will not loosen or corrode and will carry as much current as the cable connected to it. Figure 10.229 illustrates the bonding that results from the exothermic process.

The bond is accomplished by dumping powdered metals (copper oxide and aluminum) from a container into a graphite crucible and igniting the material by means of a flint lighter. Reduction of the copper oxide by the aluminum produces molten copper and aluminum oxide slag. The molten copper flows over the conductors, bonding them together. The process is illustrated in Fig. 10.230. Figure 10.231 shows a

FIGURE 10.230 Exothermic bonding is the preferred method of joining the elements of a ground system. This photo sequence illustrates the procedure: (a) the powdered copper oxide and aluminum compound are added to the mold after the conductors have been mechanically joined; (b) final preparation of the bond before igniting; (c) the chemical reaction that bonds the materials together.

FIGURE 10.231 Typical exothermic bonding mold for connecting a cable to a ground rod. (After [9].)

typical mold. A variety of special-purpose molds are available to join different-size cables and copper strap. Figure 10.232 shows the bonding process for a copper-strap-to-ground-rod interface.

Ground-System Inductance

Conductors interconnecting sections or components of an earth ground system must be kept as short as possible to be effective [9]. The inductance of a conductor is a major factor in its characteristic impedance to surge energy. For example, consider a no. 6 AWG copper wire 10 m in length. The wire has a DC resistance of 0.013Ω and an inductance of $10 \mu\text{H}$. For a 1000-A lightning surge with a $1 \mu\text{s}$ rise time, the resistive voltage drop will be 13 V, but the reactive voltage drop will be 10 kV. Furthermore, any bends in the conductor will increase its inductance and further decrease the effectiveness of the wire. Bends in ground conductors should be gradual. A 90° -bend is electrically equivalent to a $1/4$ -turn coil. The sharper the bend, the greater the inductance.

Because of the fast rise time of most lightning discharges and power-line transients, the *skin effect* plays an important role in ground-conductor selection. When planning a facility ground system, view the project from an RF standpoint.

The effective resistance offered by a conductor to radio frequencies is considerably higher than the ohmic resistance measured with direct currents. This is because of an action known as the skin effect, which causes the currents to be concentrated in certain parts of the conductor and leaves the remainder of the cross-section to contribute little or nothing toward carrying the applied current.

FIGURE 10.232 Cadweld mold for connecting a copper strap to a ground rod. (After [9].)

When a conductor carries an alternating current, a magnetic field is produced that surrounds the wire. This field continually is expanding and contracting as the AC current wave increases from zero to its maximum positive value and back to zero, then through its negative half-cycle. The changing magnetic lines of force cutting the conductor induce a voltage in the conductor in a direction that tends to retard the normal flow of current in the wire. This effect is more pronounced at the center of the conductor. Thus, current within the conductor tends to flow more easily toward the surface of the wire. The higher the frequency, or the faster the rise time of the applied waveform, the greater the tendency for current to flow at the surface. Figure 10.233 shows the distribution of current in a radial conductor.

FIGURE 10.233 Skin effect on an isolated round conductor carrying a moderately high-frequency signal.

When a circuit is operating at high frequencies, the skin effect causes the current to be redistributed over the conductor cross-section in such a way as to make most of the current flow where it is encircled by the smallest number of flux lines. This general principle controls the distribution of current regardless of the shape of the conductor involved. With a flat-strip conductor, the current flows primarily along the edges, where it is surrounded by the smallest amount of flux.

Grounding Tower Elements

Guyed towers are better than self-supporting towers at dissipating lightning surge currents [9]. This is true, however, only if the guy anchors are grounded properly. Use of the Ufer technique is one way of effectively grounding the anchors. For anchors not provided with a Ufer ground during construction, other, more conventional, techniques can be used. For guyed towers whose guy lines are not electrically continuous between the tower and the base, such as sectionalized towers (certain FM and TV broadcast towers and AM broadcast towers), surge current dissipation is essentially equivalent to a self-supporting tower.

Never rely on the turnbuckles of a guy anchor as a path for lightning energy. The current resulting from a large flash can weld the turnbuckles in position. If the turnbuckles are provided with a safety loop of guy cable (as they should be), the loop can be damaged where it contacts the guys and turnbuckle. Figure 10.234 shows the preferred method of grounding guy wires: tie them together above the loop and turnbuckles. Do not make these connections with copper wire, even if they are Cadwelded. During periods of precipitation, water shed from the top copper wire will carry ions that may react with the lower galvanized (zinc) guy wires. This reaction washes off the zinc coating, allowing rust to develop.

The best way to make the connection is with all-galvanized materials. This includes the grounding wire, clamps, and ground rods. It may not be possible to use all galvanized materials because, at some point, a connection to copper conductors will be required. *Battery action* caused by the dissimilar metal junction may allow the zinc to act as a sacrificial anode. The zinc eventually will disappear into the soil, leaving a bare steel conductor that can fall victim to rust.

Ruling out an all-galvanized system, the next best scheme uses galvanized wire (guy-wire material) to tie the guy wires together. Just above the soil, Cadweld the galvanized wire to a copper conductor that

FIGURE 10.234 Recommended guy-anchor grounding procedure. (After [9].)

FIGURE 10.235 Ground-conductor dressing for the base of a guyed tower. (After [9].)

penetrates below grade to the perimeter ground system. The height above grade for the connection is determined by the local snowfall or flood level. The electric conductivity of snow, although low, can cause battery action from the copper through the snow to the zinc. The Cadwelded joint should be positioned above the usual snow or flood level.

Ground-Wire Dressing

Figure 10.235 illustrates the proper way to bond the tower base ground leads to the buried ground system [9]. Dress the leads close to the tower from the lowest practical structural element at the base. Keep the conductors as straight and short as possible. Avoid any sharp bends. Attach the ground wires to the tower only at one or more existing bolts (or holes). Do not drill any holes into the tower. Do not loosen any

FIGURE 10.236 Top view of proper guy-anchor grounding techniques. A properly dressed and installed ground wire prevents surge currents from welding turnbuckles and damaging safety loops. The perimeter ground connects to the tower base by way of a radial wire. (After [9].)

bolts to make the ground-wire attachment. Use at least two 3- to 4-in copper straps between the base of the tower and the buried ground system. Position the straps next to the concrete pier of the tower base. For towers more than 200 ft in height, use four copper straps, one on each side of the pier.

Figure 10.236 illustrates the proper way to bond guy wires to the buried ground system. The lead is dressed straight down from the topmost to the lowest guy. It should conform as close to vertical as possible, and be dressed downward from the lower side of each guy wire after connecting to each wire (Fig. 10.234). To ensure that no arcing will occur through the turnbuckle, a connection from the anchor plate to the perimeter ground circle is recommended. No. 2 gauge copper wire is recommended. This helps minimize the unavoidable inductance created by the conductor being in the air. Interconnect leads that are suspended in air must be dressed so that no bending radius is less than 8 in.

A *perimeter* ground, a circle of wire connected at several points to ground rods driven into the earth, should be installed around each guy-anchor point. The perimeter system provides a good ground for the anchor, and when tied together with the tower base radials, acts to rapidly dissipate lightning energy in the event of a flash. Tower base radials are buried wires interconnected with the tower base ground that extend away from the center point of the structure.

The required depth of the perimeter ground and the radials depends upon soil conductivity. Generally speaking, however, about 8 in. below grade is sufficient. In soil with good conductivity, the perimeter wire may be as small as no. 10 gauge. Because no. 2 gauge is required for the segment of conductor suspended in air, it may be easier to use no. 2 throughout. An added advantage is that the same size Cadweld molds may be used for all bonds.

Facility Ground Interconnection

Any radial that comes within 2 ft of a conductive structure must be tied into the ground system [9]. Bury the interconnecting wire, if possible, and approach the radial at a 45° angle, pointing toward the expected surge origin (usually the tower). Cadweld the conductor to the radial and to the structure.

For large-base, self-supporting towers, the radials should be split among each leg pad, as shown in Fig. 10.237. The radials may be brought up out of the soil (in air) and each attached at spaced locations

FIGURE 10.237 Interconnecting a self-supporting tower to the buried ground system.

around the foot pad. Some radials may have to be tied together first and then joined to the foot pad. Remember, if space between the radial lines can be maintained, less mutual inductance (coupling) will exist, and the system surge impedance will be lower.

It is desirable to have a continuous one-piece ring with rods around the equipment building. Connect this ring to one, and only one, of the tower radials, thus forming no radial loops. See Fig. 10.238. Bury the ring to the same depth as the radials to which it interconnects. Connect power-line neutral to the ring. *Warning:* Substantial current may flow when the power-line neutral is connected to the ring. Follow safety procedures when making this connection.

Install a ground rod (if the utility company has not installed one) immediately outside the generator or utility company vault, and connect this rod to the equipment building perimeter ground ring. Route a no. 1/0 insulated copper cable from the main power panel inside the generator vault to the ground rod outside the vault. Cut the cable to length, strip both ends, and tie one end to the power-line neutral at

FIGURE 10.238 Interconnecting the metal structures of a facility to the ground system. (After [9].)

the main power panel in the generator vault. Connect the other end to the ground rod. *Warning:* Use care when making this connection. Hazardous voltage may exist between the power-line neutral and any point at earth potential.

Do not remove any existing earth ground connections to power-line neutral, particularly if they are installed by the power company. To do so may violate the local electrical code. The goal of this interconnection is to minimize noise that may be present on the neutral, and to conduct this noise as directly as possible outside to earth ground.

Personnel Protection

The threat to personnel during a lightning strike ranges from the obvious danger of direct contact with a lightning strike to the more obscure effects of *step* and *touch voltages* [11]. Protection from a direct strike when near or within structures is accomplished with traditional rolling sphere concept methods. Step and touch potentials, however, are created as a lightning current passes through resistive soil and other available paths as it dissipates into the earth. A person in contact with only one point of the gradient will simply rise and fall in potential with the gradient without injury. A person in contact with multiple points on the earth or objects at different potentials along the gradient, however, will become part of the current path and may sustain injury or death.

Figure 10.239 [13, 14] indicates a number of methods for protecting personnel from the direct and secondary effects of lightning. A typical tower/transmitter site is used as an example. A technician responding to a service problem during a thunderstorm would likely exit his or her vehicle outside the gate, unlock and open the gate, and move the vehicle into the inside yard. The technician would then leave the vehicle, and enter the building.

The threat of a direct lightning strike to the technician has been minimized by establishing a protective zone over the areas to be traversed. This zone is created by the tower and air terminals mounted atop light poles.

Step potentials are minimized through the use of a ground mat buried just below the surface of the area where the technician is expected to be outside the vehicle. Ground mats are commercially available, fabricated in a 6-in. \times 6-in. square pattern using no. 8 AWG bare copper wire. Each intersection is welded,

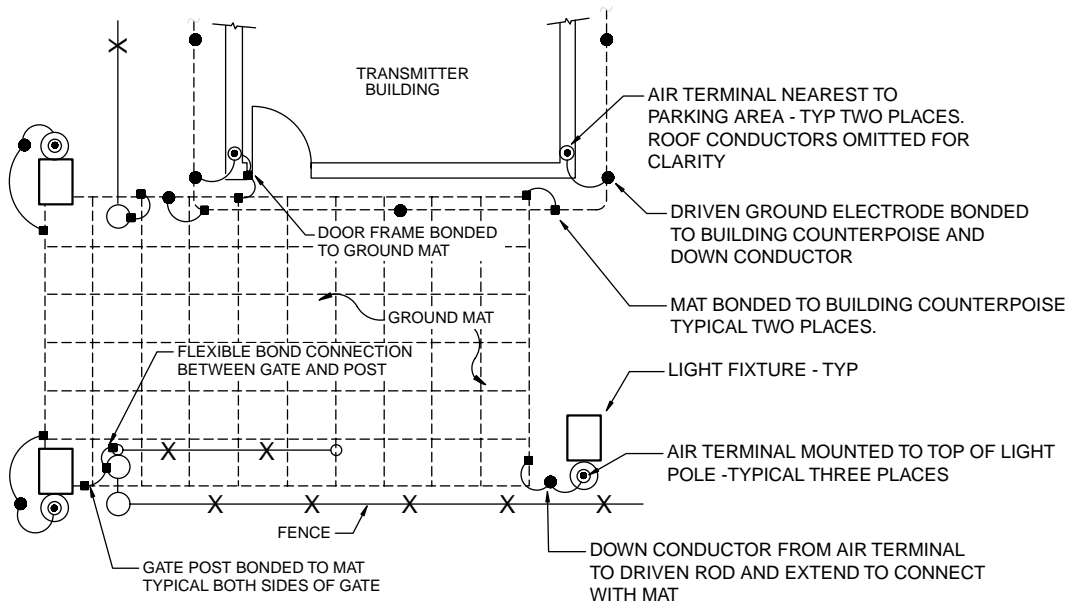

FIGURE 10.239 Protection methods for personnel at an exposed site. (After [11].)

creating, for all practical purposes, an *equipotential area* that short-circuits the step potential gradient in the area above the mat. The mat, as a whole, will rise and fall in potential as a result of the lightning current discharges; however, there will be very little difference in potential between the technician's feet. Mats should be covered with six in. of crushed stone or pavement.

The threat of dangerous touch potentials is minimized by bonding the following elements to the ground system:

- Personnel ground mat
- Fence at each side of the gate opening
- Door frame of the transmitter building
- Flexible bonding connection between the swing gate and its terminal post

Such bonding will ensure that the object being touched by the technician is at or near the same potential as his or her feet.

Bonding both sides of the gate opening to the mat helps to ensure that the technician and both sides of the gate are at approximately the same potential while the gate is being handled. The flexible bond between the gate and its support post can be accomplished using a commercially available kit or by Cadwelding a short length of flexible 2/0 AWG welding cable between the two elements.

Grounding on Bare Rock

A bare rock mountaintop location provides special challenges to the facility design engineer [9]. There is no soil, thus there are no ground rods. Radials are the only means to develop a ground system. Install a large number of radials, laid straight, but not too taut. The portions not in contact with the rock are in air and form an inductance that will choke the surge current. Because rock is not conductive when it is dry, keep the radials short. Only a test measurement will determine how short the radials should be. A conventional earth-resistance tester will tell only half the story (besides, ground rods cannot be placed in rock for such a measurement). A dynamic ground tester offers the only way to obtain the true surge impedance of the system.

Rock-Based Radial Elements

On bare rock, a radial counterpoise will conduct and spread the surge charge over a large area. In essence, it forms a leaky capacitor with the more conductive earth on or under the mountain [9]. The conductivity of the rock will be poor when dry, but quite good when wet. If the site experiences significant rainfall before a lightning flash, protection will be enhanced. The worst case, however, must be assumed: an early strike under dry conditions.

The surge impedance, measured by a dynamic ground tester, should be 25ω or less. This upper-limit number is chosen so that less stress will be placed on the equipment and its surge protectors. With an 18-kA strike to a 25Ω ground system, the entire system will rise 450 kV above the rest of the world at peak current. This voltage has the potential to jump almost 15.750 in. (0.35 in./10 kV at standard atmospheric conditions of 25°C , 30 in. of mercury and 50% relative humidity).

For nonsoil conditions, tower anchor points should have their own radial systems or be encapsulated in concrete. Configure the encapsulation to provide at least 3 in. of concrete on all sides around the embedded conductor. The length will depend on the size of the embedded conductor. Rebar should extend as far as possible into the concrete. The dynamic ground impedance measurements of the anchor grounds should each be less than 25Ω .

The size of the bare conductor for each tower radial (or for an interconnecting wire) will vary, depending on soil conditions. On rock, a bare no. 1/0 or larger wire is recommended. Flat, solid-copper strap would be better, but may be blown or ripped if not covered with soil. If some amount of soil is available, no. 6 cable should be sufficient. Make the interconnecting radial wires continuous, and bury them as deep as possible; however, the first 6 to 10 in. will have the most benefit. Going below 18 in. will not be cost-effective, unless in a dry, sandy soil where the water table can be reached and ground-rod penetration is shallow. If only a small amount of soil exists, use it to cover the radials to the extent possible. It is more important to cover radials in the area near the tower than at greater distances. If, however, soil exists only at the outer distances and cannot be transported to the inner locations, use the soil to cover the outer portions of the radials.

If soil is present, install ground rods along the radial lengths. Spacing between ground rods is affected by the depth that each rod is driven; the shallower the rod, the closer the allowed spacing. Because the ultimate depth a rod can be driven cannot always be predicted by the first rod driven, use a maximum spacing of 15 ft when selecting a location for each additional rod. Drive rods at building corners first (within 24 in. but not closer than 6 in. to a concrete footer unless that footer has an encapsulated Ufer ground), then fill in the space between the corners with additional rods.

Drive the ground rods in place. Do not auger; set in place, then back-fill. The soil compactness is never as great on augured-hole rods when compared with driven rods. The only exception is when a hole is augured or blasted for a ground rod or rebar and then back-filled in concrete. Because concrete contains lime (alkali base) and is porous, it absorbs moisture readily, giving it up slowly. Electron carriers are almost always present, making the substance a good conductor.

If a Ufer ground is not being implemented, the radials may be Cadwelded to a subterranean ring, with the ring interconnected to the tower foot pad via a minimum of three no. 1/0 wires spaced at 120° angles and Cadwelded to the radial ring.

10.10.3 Transmission-System Grounding

Nature can devastate a communications site. Lightning can seriously damage an unprotected facility with little or no warning, leaving an expensive and time-consuming repair job. The first line of defense is proper grounding of the communications system.

Transmission Line

All coax and waveguide lines must include grounding kits for bonding the transmission line at the antenna [9]. On conductive structures, this can be accomplished by bonding the tail of the grounding kit to the structure itself. Remove all nonconductive paint and corrosion before attachment. Do not drill holes, and do not loosen any existing tower member bolts. Antenna clamping hardware can be used, or an

all-stainless-steel hose clamp of the appropriate size can be substituted. The location of the tower-top ground is not as critical as the bottom grounding kit.

On nonconductive structures, a no. 1/0 or larger wire must be run down the tower [9]. Bond the transmission-line grounding kit to this down-run. Keep the wire as far away from all other conductive runs (aviation lights, coax, and waveguide) as possible. Separation of 2 ft is preferred; 18 in. is the minimum. If any other ground lines, conduit, or grounded metallic-structure members must be traversed that are closer than 18 in., they too must be grounded to the down-lead ground line to prevent flashover.

At the point where the coax or waveguide separates from the conductive structure (metal tower), a coax or waveguide grounding kit must be installed. Secure the connection to a large vertical structure member with a small number of joints. Attach to a structural member as low as possible on the tower.

Dress the grounding kit tails in a nearly straight 45° downward angle to the tower member. On non-conductive structures, a metal busbar must be used. Ground the bar to one or more of the vertical downconductors, and as close to ground level as possible.

Coaxial cables, lighting conduit, and other lines on the tower must be secured properly to the structure. Figure 10.240 illustrates several common attachment methods.

FIGURE 10.240 Transmission-line mounting and grounding procedures for a communications site.

Cable Considerations

Ground-strap connections must withstand weathering and maintain low electrical resistance between the grounded component and earth [9]. Corrosion impairs ground-strap performance. Braided-wire ground straps should not be used in outside installations. Through capillary action resembling that of a wick, the braid conveys water, which accelerates corrosion. Eventually, advancing corrosion erodes the ground-strap cable. Braid also can act as a duct that concentrates water at the bond point. This water speeds corrosion, which increases the electrical resistance of the bond. A jacketed, seven-strand copper wire strap (no. 6 to no. 2) is recommended for transmission-line grounding at the tower.

Satellite Antenna Grounding

Most satellite receiving/transmitting antenna piers are encapsulated in concrete [9]. Consideration should be given, therefore, to implementing a Ufer ground for the satellite dish. A 4-in.-diameter pipe, submerged 4 to 5 ft in an 18-in.-diameter (augered) hole will provide a good start for a Ufer-based ground system. It should be noted that an augered hole is preferred because digging and repacking the soil around the pier will create higher ground resistance. In areas of good soil conductivity (100 Ω /m or less), this basic Ufer system may be adequate for the antenna ground.

Figure 10.241 shows the preferred method: a hybrid Ufer/ground-rod and radial system. A cable connects the mounting pipe (Ufer ground) to a separate driven ground rod. The cable then is connected to the facility ground system. In areas of poor soil conductivity, additional ground rods are driven at increments (2.2 times the rod length) between the satellite dish and the facility ground system. Run all cables underground

FIGURE 10.241 Grounding a satellite receiving antenna. (After [9].)

FIGURE 10.242 Addition of a lightning rod to a satellite antenna ground system. (After [9].)

for best performance. Make the interconnecting copper wire no. 10 size or larger; bury the wire at least 8 in. below finished grade. Figure 10.242 shows the addition of a lightning rod to the satellite dish.

10.10.4 Designing a Building Ground System

After the required grounding elements have been determined, they must be connected into a unified system [9]. Many different approaches can be taken, but the goal is the same: establish a low-resistance, low-inductance path to surge energy. Figure 10.243 shows a building ground system using a combination of ground rods and buried bare-copper radial wires. This design is appropriate when the building is large or located in an urban area. This approach also can be used when the facility is located in a highrise building that requires a separate ground system. Most newer office buildings have ground systems designed into them. If a comprehensive building ground system is provided, use it. For older structures (constructed of wood or brick), a separate ground system will be needed.

Figure 10.244 shows another approach in which a perimeter ground strap is buried around the building and ground rods are driven into the earth at regular intervals (2.2 times the rod length). The ground ring consists of a one-piece copper conductor that is bonded to each ground rod.

If a transmission or microwave tower is located at the site, connect the tower ground system to the main ground point via a copper strap. The width of the strap must be at least 1% of the length and, in any

FIGURE 10.243 A facility ground system using the hub-and-spoke approach. The available real estate at the site will dictate the exact configuration of the ground system. If a tower is located at the site, the tower ground system is connected to the building ground as shown.

FIGURE 10.244 Facility ground using a perimeter ground-rod system. This approach works well for buildings with limited available real estate.

FIGURE 10.245 A typical guy-anchor and tower-radial grounding scheme. The radial ground is no. 6 copper wire. The ground rods are $\frac{5}{8}$ in. \times 10 ft. (After [9].)

event, not less than 3 in. wide. The building ground system is not a substitute for a tower ground system, no matter what the size of the tower. The two systems are treated as independent elements, except for the point at which they interconnect.

Connect the utility company power-system ground rod to the main facility ground point as required by the local electrical code. Do not consider the building ground system to be a substitute for the utility company ground rod. The utility rod is important for safety reasons and must not be disconnected or moved. Do not remove any existing earth ground connections to the power-line neutral connection. To do so may violate local electrical code.

Bury all elements of the ground system to reduce the inductance of the overall network. Do not make sharp turns or bends in the interconnecting wires. Straight, direct wiring practices will reduce the overall inductance of the system and increase its effectiveness in shunting fast-rise-time surges to earth. Figure 10.245 illustrates the interconnection of a tower and building ground system. In most areas, soil conductivity is high enough to permit rods to be connected with no. 6 bare-copper wire or larger. In areas of sandy soil, use copper strap. A wire buried in low-conductivity, sandy soil tends to be inductive and less effective in dealing with fast-rise-time current surges. As stated previously, make the width of the ground strap at least 1% of its overall length. Connect buried elements of the system as shown in Fig. 10.246.

For small installations with a low physical profile, a simplified grounding system can be implemented, as shown in Fig. 10.247. A grounding plate is buried below grade level, and a ground wire ties the plate to the microwave tower mounted on the building.

FIGURE 10.246 Preferred bonding method for below-grade elements of the ground system. (After [9].)

Bulkhead Panel

The bulkhead panel is the cornerstone of an effective facility grounding system [9]. The concept of the bulkhead is simple: establish one reference point to which all cables entering and leaving the equipment building are grounded and to which all transient-suppression devices are mounted. Figure 10.248 shows a typical bulkhead installation for a broadcast or communications facility. The panel size depends on the spacing, number, and dimensions of the coaxial lines, power cables, and other conduit entering or leaving the building.

To provide a weatherproof point for mounting transient-suppression devices, the bulkhead can be modified to accept a subpanel, as shown in Fig. 10.249. The subpanel is attached so that it protrudes through an opening in the wall and creates a secondary plate on which transient suppressors are mounted and grounded. A typical cable/suppressor-mounting arrangement for a communications site is shown in Fig. 10.250. To handle the currents that may be experienced during a lightning strike or large transient on the utility company AC line, the bottommost subpanel flange (which joins the subpanel to the main bulkhead) must have a total surface-contact area of at least 0.75 in.^2 per transient suppressor.

Because the bulkhead panel will carry significant current during a lightning strike or AC line disturbance, it must be constructed of heavy material. The recommended material is 1/8-in. C110 (solid copper) 1/2-hard. This type of copper stock weighs nearly $5\text{-}1/2 \text{ lb/ft}^2$ and is rather expensive. Installing a bulkhead, while sometimes difficult and costly, will pay dividends for the life of the facility. Use 18-8 stainless-steel mounting hardware to secure the subpanel to the bulkhead.

Because the bulkhead panel establishes the central grounding point for all equipment within the building, it must be tied to a low-resistance (and low-inductance) perimeter ground system. The bulkhead establishes the *main facility ground point*, from which all grounds inside the building are referenced. A typical bulkhead installation for a small communications site is shown in Fig. 10.251.

Bulkhead Grounding

A properly installed bulkhead panel will exhibit lower impedance and resistance to ground than any other equipment or cable grounding point at the facility [9]. Waveguide and coax line grounding kits should be installed at the bulkhead panel as well as at the tower. Dress the kit tails downward at a straight 45° angle using 3/8-in. stainless-steel hardware to the panel. Position the stainless-steel lug at the tail end, flat

FIGURE 10.247 Grounding a small microwave transmission tower.

against a cleaned spot on the panel. Joint compound will be needed for aluminum and is recommended for copper panels.

Because the bulkhead panel will be used as the central grounding point for all the equipment inside the building, the lower the inductance to the perimeter ground system, the better. The best arrangement is to simply extend the bulkhead panel down the outside of the building, below grade, to the perimeter ground system. This will give the lowest resistance and the smallest inductive voltage drop. This approach is illustrated in Fig. 10.252.

If cables are used to ground the bulkhead panel, secure the interconnection to the outside ground system along the bottom section of the panel. Use multiple no. 1/0 or larger copper wire or several solid-copper straps. If using strap, attach with stainless-steel hardware, and apply joint compound for aluminum bulkhead panels. Clamp and Cadweld, or silver-solder for copper/brass panels. If no. 1/0 or larger wire is used, employ crimp lug and stainless-steel hardware. Measure the DC resistance. It should be less than 0.01 Ω between the ground system and the panel. Repeat this measurement on an annual basis.

FIGURE 10.248 The basic design of a bulkhead panel for a facility. The bulkhead establishes the grounding reference point for the plant.

FIGURE 10.249 The addition of a subpanel to a bulkhead as a means of providing a mounting surface for transient-suppression components. To ensure that the bulkhead is capable of handling high surge currents, use the hardware shown. (After [9].)

FIGURE 10.250 Mounting-hole layout for a communications site bulkhead subpanel.

FIGURE 10.251 Bulkhead installation at a small communications site. (After [9].)

FIGURE 10.252 The proper way to ground a bulkhead panel and provide a low-inductance path for surge currents stripped from cables entering and leaving the facility. The panel extends along the building exterior to below grade. It is silver-soldered to a no. 2/0 copper wire that interconnects with the outside ground system. (After [9].)

If the antenna feed lines do not enter the equipment building via a bulkhead panel, treat them in the following manner:

- Mount a feed-line ground bar on the wall of the building approximately 4 in. below the feed-line entry point.
- Connect the outer conductor of each feed line to the feed-line ground bar using an appropriate grounding kit.
- Connect a no. 1/0 cable or 3- to 6-in.-wide copper strap between the feed-line ground bar and the external ground system. Make the joint a Cadweld or silver-solder connection.
- Mount coaxial arrestors on the edge of the bar.
- Weatherproof all connections.

Lightning Protectors

A variety of lightning arrestors are available for use on coaxial transmission lines, utility AC feeds, and telephone cables. The protector chosen must be carefully matched to the requirements of the application. Do not use air gap protectors because these types are susceptible to air pollution, corrosion, temperature, humidity, and manufacturing tolerances. The turn-on speed of an air gap device is a function of all of the foregoing elements. A simple gas-tube-type arrestor is an improvement, but neither of these devices will operate reliably to protect shunt-fed cavities, isolators, or receivers that include static drain inductors to ground (which most have). Such voltage-sensitive crowbar devices are short-circuited by the DC path to ground found in these circuits. The inductive change in current per unit time ($\Delta di/dt$) voltage drop is usually not enough to fire the protector, but it can be sufficient to destroy the inductor and then the receiver front end. Instead, select a protector that does not have DC continuity on the coaxial center pin from input to output. Such units have a series capacitor between the gas tube and the equipment center pin that will allow the voltage to build up so that the arrestor can fire properly.

FIGURE 10.253 A common, but not ideal, grounding arrangement for a transmission facility using a grounded tower. A better configuration involves the use of a bulkhead panel through which all cables pass into and out of the equipment building.

Typical Installation

Figure 10.253 illustrates a common grounding arrangement for a remotely located grounded-tower (FM, TV, or microwave radio) transmitter plant. The tower and guy wires are grounded using 10-ft-long copper-clad ground rods. The antenna is bonded to the tower, and the transmission line is bonded to the tower at the point where it leaves the structure and begins the horizontal run into the transmitter building. Before entering the structure, the line is bonded to a ground rod through a connecting cable. The transmitter itself is grounded to the transmission line and to the AC power-distribution system ground. This, in turn, is bonded to a ground rod where the utility feed enters the building. The goal of this arrangement is to strip all incoming lines of damaging overvoltages before they enter the facility. One or more lightning rods are mounted at the top of the tower structure. The rods extend at least 10 ft above the highest part of the antenna assembly.

Such a grounding configuration, however, has built-in problems that can make it impossible to provide adequate transient protection to equipment at the site. Look again at the example. To equipment inside the transmitter building, two grounds actually exist: the utility company ground and the antenna ground. One ground will have a lower resistance to earth, and one will have a lower inductance in the connecting cable or copper strap from the equipment to the ground system.

Using the Fig. 10.253 example, assume that a transient overvoltage enters the utility company meter panel from the AC service line. The overvoltage is clamped by a protection device at the meter panel, and the current surge is directed to ground. But *which ground*, the utility ground or the antenna ground?

The utility ground surely will have a lower inductance to the current surge than the antenna ground, but the antenna probably will exhibit a lower resistance to ground than the utility side of the circuit. Therefore, the surge current will be divided between the two grounds, placing the transmission equipment in series with the surge suppressor and the antenna ground system. A transient of sufficient potential will damage the transmission equipment.

Transients generated on the antenna side because of a lightning discharge are no less troublesome. The tower is a conductor, and any conductor is also an inductor. A typical 150-ft self-supporting tower may exhibit as much as 40 μH inductance. During a fast-rise-time lightning strike, an instantaneous voltage drop of 360 kV between the top of the tower and the base is not unlikely. If the coax shield is bonded to

FIGURE 10.254 The equivalent circuit of the facility shown in Fig. 10.253. Note the discharge current path through the electronic equipment.

the tower 15 ft above the earth (as shown in the previous figure), 10% of the tower voltage drop (36 kV) will exist at that point during a flash. Figure 10.254 illustrates the mechanisms involved.

The only way to ensure that damaging voltages are stripped off all incoming cables (coax, AC power, and telephone lines) is to install a bulkhead entrance panel and tie all transient-suppression hardware to it. Configuring the system as shown in Fig. 10.255 strips away all transient voltages through the use of a single-point ground. The bulkhead panel is the ground reference for the facility. With such a design, secondary surge current paths do not exist, as illustrated in Fig. 10.256.

Protecting the building itself is another important element of lightning surge protection. Figure 10.257 shows a common system using multiple lightning rods. As specified by NFPA 78, the dimensions given in the figure are as follows:

- A = 50-ft maximum spacing between air terminals
- B = 150-ft maximum length of a coursing conductor permitted without connection to a main perimeter or downlead conductor
- C = 20- or 25-ft maximum spacing between air terminals along an edge

Checklist for Proper Grounding

A methodical approach is necessary in the design of a facility ground system. Consider the following points:

1. Install a bulkhead panel to provide mechanical support, electric grounding, and lightning protection for coaxial cables, power feeds, and telephone lines entering the equipment building.
2. Install an internal ground bus using no. 2 or larger solid-copper wire. (At transmission facilities, use copper strap that is at least 3 in. wide.) Form a *star* grounding system. At larger installations, form a *star-of-stars* configuration. Do not allow ground loops to exist in the internal ground bus. Connect the following items to the building internal ground system:
 - Chassis racks and cabinets of all hardware
 - All auxiliary equipment
 - Battery charger
 - Switchboard
 - Conduit
 - Metal raceway and cable tray

FIGURE 10.255 The preferred grounding arrangement for a transmission facility using a bulkhead panel. With this configuration, all damaging transient overvoltages are stripped off the coax, power, and telephone lines before they can enter the equipment building.

FIGURE 10.256 The equivalent circuit of the facility shown in Fig. 10.255. Discharge currents are prevented from entering the equipment building.

FIGURE 10.257 Conduction lightning-protection system for a large building. (After [12].)

3. Install a tower earth ground array by driving ground rods and laying radials as required to achieve a low earth ground impedance at the site.
4. Connect outside metal structures to the earth ground array (towers, metal fences, metal buildings, and guy-anchor points).
5. Connect the power-line ground to the array. Follow local electrical code to the letter.
6. Connect the bulkhead to the ground array through a low-inductance, low-resistance bond.
7. Do not use soldered-only connections outside the equipment building. Crimped, brazed, and exothermic (Cadwelded) connections are preferable. For a proper bond, all metal surfaces must be cleaned, any finish removed to bare metal, and surface preparation compound applied (where necessary). Protect all connections from moisture by appropriate means (sealing compound and heat sink tubing).

10.10.5 AC System Grounding Practices

Installing an effective ground system to achieve a good earth-to-grounding-electrode interface is only half the battle for a facility designer. The second, and equally important, element of any ground system is the configuration of grounding conductors inside the building. Many different methods can be used to implement a ground system, but some conventions always should be followed to ensure a low-resistance (and low-inductance) layout that will perform as required. Proper grounding is important whether or not the facility is located in a high-RF field.

Building Codes

As outlined previously in this chapter, the primary purpose of grounding electronic hardware is to prevent electric shock hazard. The National Electrical Code (NEC) and local building codes are designed to provide for the safety of the workplace. Local codes should always be followed. Occasionally, code sections are open to some interpretation. When in doubt, consult a field inspector. Codes constantly are being changed or

FIGURE 10.258 Typical facility grounding system. The *main facility ground point* is the reference from which all grounding is done at the plant. If a bulkhead entrance panel is used, it will function as the main ground point.

expanded because new situations arise that were not anticipated when the codes were written. Sometimes, an interpretation will depend upon whether the governing safety standard applies to building wiring or to a factory-assembled product to be installed in a building. Underwriters Laboratories (UL) and other qualified testing organizations examine products at the request and expense of manufacturers or purchasers, and list products if the examination reveals that the device or system presents no significant safety hazard when installed and used properly.

Municipal and county safety inspectors generally accept UL and other qualified testing laboratory certification listings as evidence that a product is safe to install. Without a listing, the end-user might not be able to obtain the necessary wiring permits and inspection sign-off. On-site wiring must conform with local wiring codes. Most codes are based on the NEC. Electrical codes specify wiring materials, wiring devices, circuit protection, and wiring methods.

Single-Point Ground

Single-point grounding is the basis of any properly designed facility ground network. Fault currents and noise should have only one path to the facility ground. Single-point grounds can be described as *star* systems in which radial elements circle out from a central hub. A star system is illustrated in Fig. 10.258. Note that all equipment grounds are connected to a *main ground point*, which is then tied to the facility ground system. Multiple ground systems of this type can be cascaded as needed to form a *star-of-stars* facility ground system. The key element in a single-point ground is that each piece of equipment has one ground reference. Fault energy and noise are then efficiently drained to the outside earth ground system. The single-point ground is basically an extension of the bulkhead panel discussed previously.

Isolated Grounding

Isolated grounding schemes, where the signal reference plane is *isolated* from equipment ground but connected to an *isolated* electrode in the earth, do not work, are unsafe, and violate the NEC [5]. It is thought by some people that the isolated earth connection is *clean* because there is no connection between it and the *dirty* system ground connection at the service entrance. The clean, isolated earth connection is also viewed (incorrectly) as a point where noise currents can flow into the earth and be dissipated. Kirchoff's current law teaches that any current flowing into the isolated ground must return to the source through another earth connection. Current cannot be dissipated. It must always return to its source. Even lightning current is not dissipated into the earth. It must have a return path (i.e., the electrostatic and electromagnetic fields that created the charge build-up and the lightning strike in the first place).

Consider what might happen if such a system were subjected to a lightning strike. Assume that a transient current of 2000 A flows into the earth and through an earth resistance of 5 Ω between the system ground electrode and the isolated electrode. A more realistic resistance might be even higher, perhaps 25 Ω ; 2000 A flowing through 5 Ω results in a voltage drop or transient potential of 10,000 V

between the two electrodes. Because this potential is impressed between the equipment frame (system ground electrode) and the signal reference plane (isolated electrode), it could result in equipment damage and personnel hazard. Dangerous potential differences between grounding subsystems can be reduced by bonding together all earth electrodes at a facility. Fine print note (FPN) No. 2, in NEC 250-86, states that the bonding together of separate grounding electrodes will limit potential differences between them and their associated wiring systems [6].

A facility ground system, then, can be defined as an electrically interconnected system of multiple conducting paths to the earth electrode or system of electrodes. The facility grounding system includes all electrically interconnected grounding subsystems such as

- The equipment grounding subsystem
- Signal reference subsystem
- Fault protection subsystem
- Lightning protection subsystem

Isolated ground (IG) receptacles, which are a version of single-point grounding, are permitted by the NEC. Proper application of IG receptacles is very important. They must be used with an insulated equipment grounding conductor, not a bare conductor. Also, only metallic conduit should be used.

Separately Derived Systems

A separately derived system is a premises wiring system that derives its power from generator, transformer, or converter windings and that has no direct electrical connection, including a solidly connected grounded circuit conductor, to supply conductors originating in another system [6]. Solidly grounded, wye-connected, isolation transformers used to supply power to computer room equipment are examples of separately derived systems [5]. Figure 10.259 illustrates the bonding and grounding requirements of separately derived systems. NEC 250-26 permits the bonding and grounding connections to be made at the source of the separately derived system or at the first disconnecting means. Other examples of separately derived systems include generators and UPS systems. Note that all earth electrodes are bonded together via the equipment grounding conductor system. This is consistent with the recommendations listed in NEC 250-86.

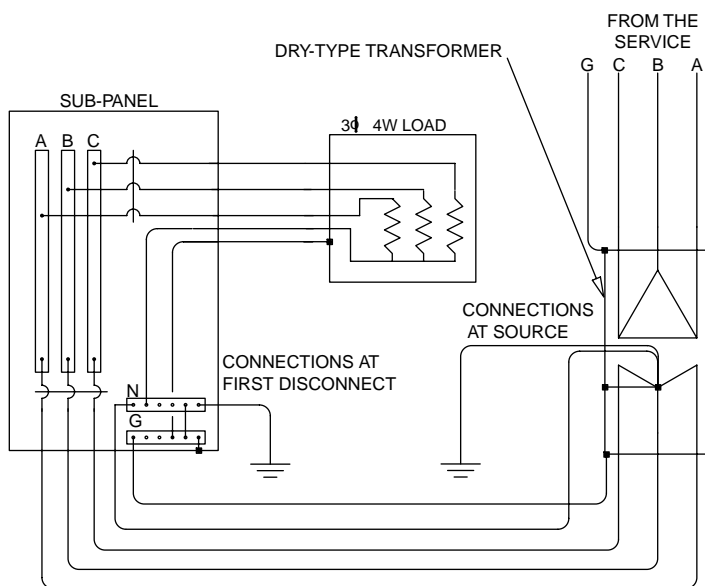

FIGURE 10.259 Basic scheme of the separately derived power system. (Courtesy of Intertec Publishing. After [5].)

Grounding Terminology

- *Grounded conductor.* A system or circuit conductor that is intentionally grounded [6].
- *Equipment grounding conductor.* The conductor used to connect the noncurrent-carrying metal parts of equipment, raceways, and other enclosures to the system grounded conductor, the grounding electrode conductor, or both, at the service equipment or at the source of a separately derived system [6].
- *Main bonding jumper.* The connection between the grounded circuit conductor and the equipment grounding conductor at the service [6].
- *Grounding electrode conductor.* The conductor used to connect the grounding electrode to the equipment grounding conductor, to the grounded conductor, or to both, of the circuit at the service equipment or at the source of a separately derived system [6].
- *Service.* The conductors and equipment for delivering energy from the electricity supply system to the wiring system of the premises served [6].
- *Service conductors.* The supply conductors that extend from the street main or from transformers to the service equipment of the premises supplied [6].
- *Service equipment.* The necessary equipment, usually consisting of a circuit breaker or switch and fuses, and their accessories, located near the point of entrance of supply conductors to a building or other structure, or an otherwise defined area, and intended to constitute the main control and means of cutoff of the supply [6].
- *Equipotential plane.* A mass of conducting material that offers a negligible impedance to current flow, thus producing zero volts (equipotential) between points on the plane.
- *Floating signal grounding.* A non-grounding system in which all electronic signal references are isolated from ground.
- *Single-point grounding.* A grounding system in which all electronic signal references are bonded together and grounded at a single point.
- *Multipoint grounding.* A grounding system in which all electronic signal references are grounded at multiple points.

Facility Ground System

Figure 10.260 illustrates a star grounding system as applied to an AC power-distribution transformer and circuit-breaker panel. Note that a central ground point is established for each section of the system: one in the transformer vault and one in the circuit-breaker box. The breaker ground ties to the transformer vault ground, which is connected to the building ground system. Figure 10.261 shows single-point grounding

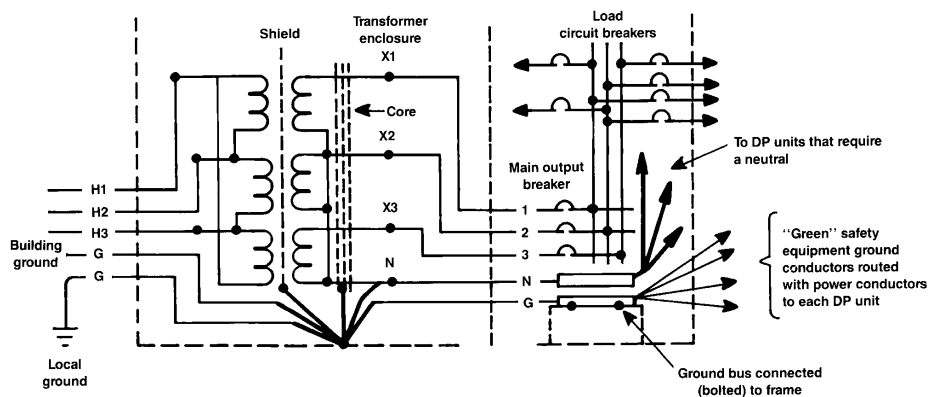

FIGURE 10.260 Single-point grounding applied to a power-distribution system. (After [15].)

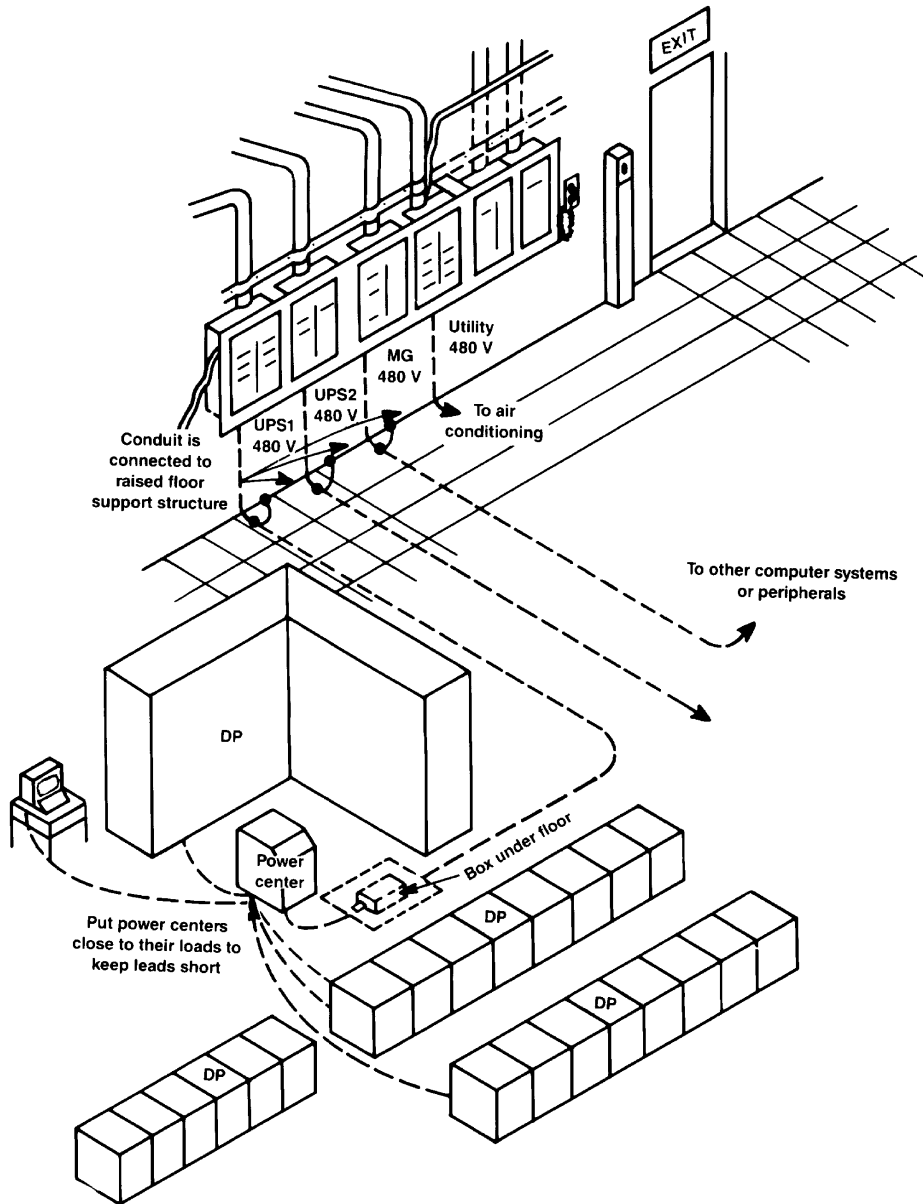

FIGURE 10.261 Configuration of a star-of-stars grounding system at a data processing facility. (After [15].)

applied to a data processing center. Note how individual equipment groups are formed into a star grounding system, and how different groups are formed into a star-of-stars configuration. A similar approach can be taken for a data processing center using multiple modular power center (MPC) units, as shown in Fig. 10.262. The terminal mounting wall is the reference ground point for the room.

Grounding extends to all conductive elements of the data processing center. As illustrated in Fig. 10.263, the raised-floor supports are integrated into the ground system, in addition to the metal work of the building. The flooring is bonded to form a mesh grounding plane that is tied to the central ground reference point of the room. This is another natural extension of the bulkhead concept discussed previously. Figure 10.264 shows connection detail for the raised-floor supports. Make sure to use a flooring system that can be bolted together to form secure electrical—as well as mechanical—connections.

FIGURE 10.262 Establishing a star-based, single-point ground system using multiple modular power centers. (After [15].)

FIGURE 10.263 Grounding plan for a raised-floor support system.

FIGURE 10.264 Bonding detail for the raised-floor support system.

Figure 10.265 shows the recommended grounding arrangement for a typical broadcast or audio/video production facility. The building ground system is constructed using heavy-gauge copper wire (no. 4 or larger) if the studio is not located in an RF field, or a wide copper strap (3-in. minimum) if the facility is located near an RF energy source. Figure 10.266 gives a functional view of the plan shown in Fig. 10.265. Note the bulkhead approach.

Run the strap or cable from the perimeter ground to the main facility ground point. Branch out from the main ground point to each major piece of equipment and to the various equipment rooms. Establish a local *ground point* in each room or group of racks. Use a separate ground cable for each piece of equipment

FIGURE 10.265 Typical grounding arrangement for individual equipment rooms at a communications facility. The ground strap from the main ground point establishes a local *ground point* in each room, to which all electronic equipment is bonded.

FIGURE 10.266 Physical implementation of the facility shown in Fig. 10.265.

(no. 12 gauge or larger). Figure 10.267 shows the grounding plan for a communications facility. Equipment grounding is handled by separate conductors tied to the bulkhead panel (entry plate). A “halo” ground is constructed around the perimeter of the room. Cable trays are tied into the halo. All electronic equipment is grounded to the bulkhead to prevent ground-loop paths. In this application, the halo serves essentially the same function as the raised-floor ground plane in the data processing center.

FIGURE 10.267 Bulkhead-based ground system including a grounding halo.

The AC line ground connection for individual pieces of equipment often presents a built-in problem for the system designer. If the equipment is grounded through the chassis to the equipment-room ground point, a ground loop can be created through the green-wire ground connection when the equipment is plugged in. The solution to this problem involves careful design and installation of the AC power-distribution system to minimize ground-loop currents, while at the same time providing the required protection against ground faults. Some equipment manufacturers provide a convenient solution to the ground-loop problem by isolating the signal ground from the AC and chassis ground. This feature offers the user the best of both worlds: the ability to create a signal ground system and AC ground system that are essentially free of interaction and ground loops. Do not confuse this isolated signal ground with the isolated ground system described in the section entitled "Noise Control." In this context, "isolated" refers only to the equipment input/output (signal) connections, not the equipment chassis; there is still only one integrated ground system for the facility, and all equipment is tied to it.

It should be emphasized that the design of a ground system must be considered as an integrated package. Proper procedures must be used at all points in the system. It takes only one improperly connected piece of equipment to upset an otherwise perfect ground system. The problems generated by a single grounding error can vary from trivial to significant, depending upon where in the system the error exists. This consideration leads, naturally, to the concept of ground-system maintenance for a facility. Check the ground network from time to time to ensure that no faults or errors have occurred. Any time new equipment is installed, or old equipment is removed from service, careful attention must be given to the possible effects that such work will have on the ground system.

Grounding Conductor Size

The NEC and local electrical codes specify the minimum wire size for grounding conductors. The size varies, depending upon the rating of the current-carrying conductors. Code typically permits a smaller ground conductor than hot conductors. It is recommended, however, that the same size wire be used for both ground lines and hot lines. The additional cost involved in the larger ground wire often is offset by the use of a single size of cable. Furthermore, better control over noise and fault currents is achieved with a larger ground wire.

It is recommended that separate insulated ground wires be used throughout the AC distribution system. Do not rely on conduit or raceways to carry the ground connection. A raceway interface that appears to be mechanically sound may not provide the necessary current-carrying capability in the event of a phase-to-ground fault. Significant damage can result if a fault occurs in the system. When the electrical integrity of a breaker panel, conduit run, or raceway junction is in doubt, fix it. Back up the mechanical connection with a separate ground conductor of the same size as the current-carrying conductors. Loose joints have been known to shower sprays of sparks during phase-to-ground faults, creating a fire hazard. Secure the ground cable using appropriate hardware. Clean attachment points of any paint or dirt accumulation. Properly label all cables.

Structural steel, compared with copper, is a poor conductor at any frequency. At DC, steel has a resistivity 10 times that of copper. As frequency rises, the skin effect is more pronounced because of the magnetic effects involved. A no. 6 copper wire can have less RF impedance than a 12-in steel "I" beam. Furthermore, because of their bolted, piecemeal construction, steel racks and building members should not be depended upon alone for circuit returns.

High-Frequency Effects

A significant amount of research has been conducted into why the 60-Hz power grounding system is incapable of conducting RF signals to the common reference point, thereby equalizing existing differences in potential [16]. A properly designed power grounding system is of sufficiently low impedance at 60 Hz to equalize any potential differences so that enclosures, raceways, and all grounded metal elements are at the same reference (ground) potential. However, at higher frequencies, equalization is prevented because of increased impedance.

The impedance of a conductor consists of three basic components: resistance, capacitive reactance, and inductive reactance. Although the inductance L (in Henrys) will be constant for a conductor of a given

length and cross-sectional area, the inductive reactance X_L will vary according to the frequency f of the applied voltage as follows:

$$X_L = 2\pi fL \quad (10.222)$$

Therefore, at 60 Hz, the inductive reactance will be $377 \times L$; and at 30 MHz, it will be $(188.5 \times 10^6) \times L$. It is evident, then, that at 60 Hz the equipment grounding conductor is a short-circuit, but at 30 MHz, it is effectively an open circuit.

In addition to increased inductive reactance at higher frequencies, there is also stray capacitance and stray inductance between adjacent conductors and/or between conductors and adjacent grounded metal, as well as resonance effects. These factors combine to yield an increase in apparent conductor impedance at higher frequencies.

If conductors are connected in a mesh or grid to form a multitude of low-impedance loops in parallel, there will be little voltage difference between any two points on the grid at all frequencies from 60 Hz up to a frequency where the length of one side of the square represents about $\frac{1}{10}$ wavelength. A grid made up of 2-ft squares (such as a raised computer floor) will at any point provide an effective equipotential ground reference point for signals up to perhaps 30 MHz.

Power-Center Grounding

A modular power center, commonly found in computer-room installations, provides a comprehensive solution to AC power-distribution and ground-noise considerations. Such equipment is available from several manufacturers, with various options and features. A computer power-distribution center generally includes an isolation transformer designed for noise suppression, distribution circuit breakers, power-supply cables, and a status-monitoring unit. The system concept is shown in Fig. 10.268. Input power is fed to an isolation transformer with primary taps to match the AC voltage required at the facility. A bank of circuit breakers is included in the chassis, and individual preassembled and terminated cables supply AC power to the various loads. A status-monitoring circuit signals the operator if any condition is detected outside normal parameters.

The ground system is an important component of the MPC. A unified approach, designed to prevent noise or circulating currents, is taken to grounding for the entire facility. This results in a clean ground connection for all equipment on-line.

The use of a modular power center can eliminate the inconvenience associated with rigid conduit installations. Distribution systems also are expandable to meet future facility growth. If the plant is ever relocated, the power center can move with it. MPC units usually are expensive. However, considering the costs of installing circuit-breaker boxes, conduit, outlets, and other hardware on-site by a licensed electrician, the power-center approach may be economically viable. The use of a power center also will make it easier to design a standby power system for the facility. Many computer-based operations do not have a standby generator on site. Depending on the location of the facility, it might be difficult or even impossible to install a generator to provide standby power in the event of a utility company outage. However, by using the power-center approach to AC distribution for computer and other critical load equipment, an uninterruptible power system can be installed easily to power only the loads that are required to keep the facility operating. With a conventional power-distribution system—where all AC power to the building, or a floor of the building, is provided by a single large circuit-breaker panel—separating the critical loads from other nonessential loads (such as office equipment, lights, and heating equipment) can be an expensive detail.

Isolation Transformers

One important aspect of an MPC is the isolation transformer. The transformer serves to

- Attenuate transient disturbances on the AC supply lines.
- Provide voltage correction through primary-side taps.
- Permit the establishment of a local ground reference for the facility served.

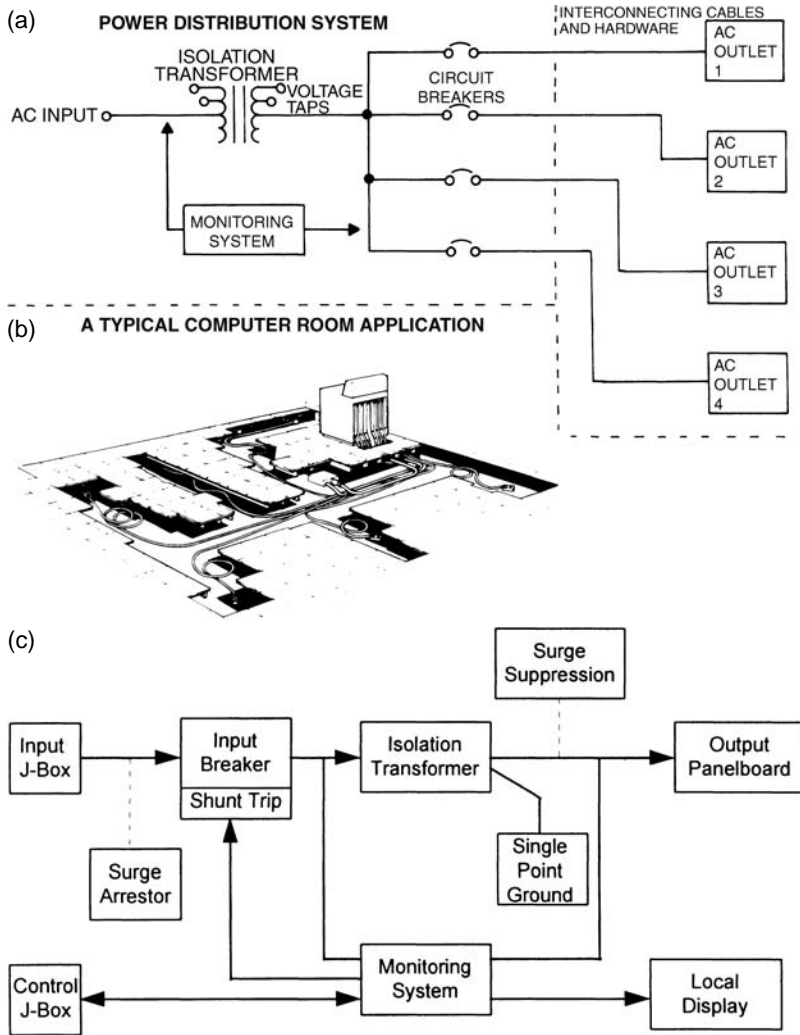

FIGURE 10.268 The basic concept of a computer-room modular power center: (a) basic line drawing of system, (b) typical physical implementation, (c) functional block diagram. Both single- and multiphase configurations are available. When ordering an MPC, the customer can specify cable lengths and terminations, making installation quick and easy. (After [17].)

Whether or not an MPC is installed at a facility, consideration should be given to the appropriate use of an isolation transformer near a sensitive load.

The AC power supply for many buildings originates from a transformer located in a basement utility room. In large buildings, the AC power for each floor can be supplied by transformers closer to the loads they serve. Most transformers are 208 Y/120 V three-phase. Many fluorescent lighting circuits operate at 277 V, supplied by a 408 Y/277 V transformer. Long feeder lines to DP systems and other sensitive loads raise the possibility of voltage fluctuations based on load demand and ground-loop-induced noise.

Figure 10.269 illustrates the preferred method of power distribution in a building. A separate dedicated isolation transformer is located near the DP equipment, providing good voltage regulation and permitting the establishment of an effective single-point star ground in the data processing center. Note that the power-distribution system voltage shown in the figure (480 V) is maintained until the DP step-down isolation transformer. Use of this higher voltage provides more efficient transfer of electricity throughout

FIGURE 10.269 Preferred power-distribution configuration for a data processing site. (After [15].)

the plant. At 480 V, the line current is about 43% of the current in a 208 V system for the same conducted power.

There are a number of tradeoffs with regard to facility AC power system design. An experienced, licensed electrical contractor and/or registered professional engineer should be consulted during the early stages of any renovation or new construction project.

Grounding Equipment Racks

The installation and wiring of equipment racks must be planned carefully to avoid problems during day-to-day operations. Figure 10.270 shows the recommended approach. Bond adjacent racks together with $\frac{3}{8}$ - to $\frac{1}{2}$ -in.-diameter bolts. Clean the contacting surfaces by sanding down to bare metal. Use lockwashers on both ends of the bolts. Bond racks together using at least six bolts per side (three bolts for each vertical rail). After securing the racks, repaint the connection points to prevent corrosion.

Run a ground strap from the *main facility ground point*, and bond the strap to the base of each rack. Spot-weld the strap to a convenient spot on one side of the rear portion of each rack. Secure the strap at the same location for each rack used. A mechanical connection between the rack and the ground strap can be made using bolts and lockwashers, if necessary. Be certain, however, to sand down to bare metal before making the ground connection. Because of the importance of the ground connection, it is recommended that each attachment be made with a combination of crimping and silver-solder. Keep the length of strap between adjacent bolted racks as short as possible by routing the strap directly under the racks.

FIGURE 10.270 Recommended grounding method for equipment racks. To make assembly of multiple racks easier, position the ground connections and AC receptacles at the same location in all racks.

Install a vertical ground bus in each rack (as illustrated in Fig. 10.270). Use about 1- $\frac{1}{2}$ -in.-wide, $\frac{1}{4}$ -in.-thick copper busbar. Size the busbar to reach from the bottom of the rack to about 1 ft short of the top. The exact size of the busbar is not critical, but it must be sufficiently wide and rigid to permit the drilling of $\frac{1}{8}$ -in. holes without deforming.

Mount the ground busbar to the rack using insulated standoffs. Porcelain standoffs commonly found in high-voltage equipment are useful for this purpose. Porcelain standoffs are readily available and reasonably priced. Attach the ground busbar to the rack at the point where the facility ground strap attaches to the rack. Silver-solder the busbar to the rack and strap at the same location in each rack used.

Install an orange-type isolated AC receptacle box at the bottom of each rack. The orange-type outlet isolates the green-wire power ground from the receptacle box. Use insulated standoffs to mount the AC outlet box to the rack. The goal of this arrangement is to keep the green-wire AC and facility system grounds separate from the AC distribution conduit and metal portions of the building structure. Try to route the power conduit and facility ground cable or strap via the same physical path. Keep metallic conduit and building structures insulated from the facility ground line, except at the bulkhead panel (main grounding point). Carefully check the local electrical code before proceeding.

Although the foregoing procedure is optimum from a signal-grounding standpoint, it should be pointed out that under a ground fault condition, performance of the system can be unpredictable if high currents are being drawn in the current-carrying conductors supplying the load. Vibration of AC circuit elements resulting from the magnetic field effects of high-current-carrying conductors is insignificant as long as all conductors are within the confines of a given raceway or conduit. A ground fault will place return current outside of the normal path. If sufficiently high currents are being conducted, the consequences can be devastating. Sneak currents from ground faults have been known to destroy wiring systems that were installed exactly to code. As always, consult an experienced electrical contractor.

Mount a vertical AC strip inside each rack to power the equipment. Insulate the power strip from the rack using porcelain standoffs or use a strip with an insulated (plastic) housing. Such a device is shown in Fig. 10.271. Power equipment from the strip using standard three-prong grounding AC plugs. Do not

FIGURE 10.271 Rack mounting detail for an insulated-shell AC power strip.

defeat the safety ground connection. Equipment manufacturers use this ground to drain transient energy. Furthermore, defeating the safety ground will violate local electrical codes.

Mount equipment in the rack using normal metal mounting screws. If the location is in a high-RF field, clean the rack rails and equipment-panel connection points to ensure a good electrical bond. This is important because in a high-RF field, detection of RF energy can occur at the junctions between equipment chassis and the rack.

Connect a separate ground wire from each piece of equipment in the rack to the vertical ground busbar. Use no. 12 stranded copper wire (insulated) or larger. Connect the ground wire to the busbar by drilling a hole in the busbar at a convenient elevation near the equipment. Fit one end of the ground wire with an enclosed-hole solderless terminal connector (no. 10-sized hole or larger). Attach the ground wire to the busbar using no. 10 (or larger) hardware. Use an internal-tooth lockwasher between the busbar and the nut. Fit the other end of the ground wire with a terminal that will be accepted by the ground terminal at the equipment. If the equipment has an isolated *signal* ground terminal, tie it to the ground busbar as well.

Whenever servicing equipment in the rack, make certain to disconnect the AC power cord before removing the unit from the rack and/or disconnecting the rack ground wire. During any service work, make the first step removal of the AC power plug; when reassembling the unit, make the last step reinsertion of the plug. Do not take chances.

Figure 10.272 shows each of the grounding elements discussed in this section integrated into one diagram. This approach fulfills the requirements of personnel safety and equipment performance.

Follow similar grounding rules for simple one-rack equipment installations. Figure 10.273 illustrates the grounding method for a single open-frame equipment rack. The vertical ground bus is supported by insulators, and individual jumpers are connected from the ground rail to each chassis.

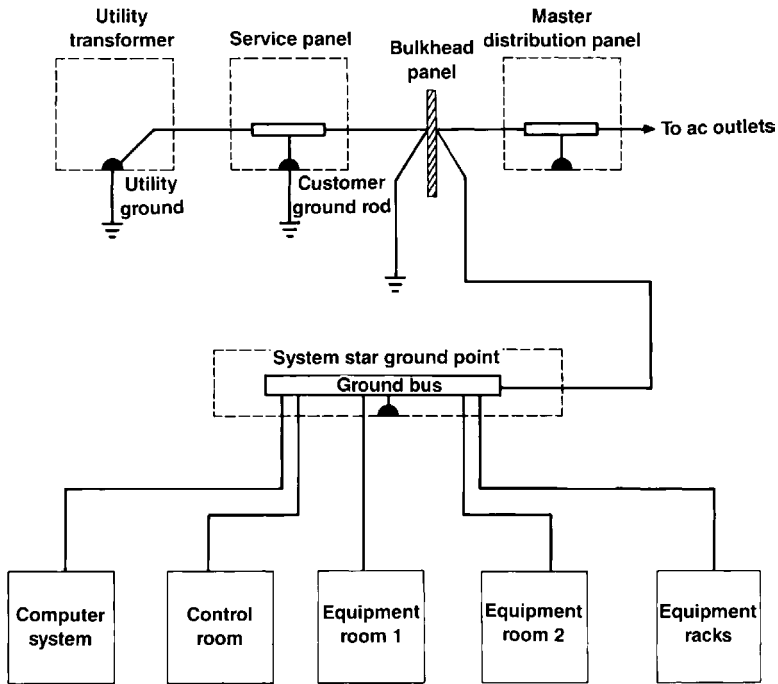

FIGURE 10.272 Equivalent ground circuit diagram for a medium-sized commercial/industrial facility.

FIGURE 10.273 Ground bus for an open-frame equipment rack.

10.10.6 Grounding Signal-Carrying Cables

Proper ground-system installation is the key to minimizing noise currents on signal-carrying cables. Audio, video, and data lines are often subject to AC power noise currents and RFI. The longer the cable run, the more susceptible it is to disturbances. Unless care is taken in the layout and installation of such cables, unacceptable performance of the overall system can result.

Analyzing Noise Currents

Figure 10.274 shows a basic source and load connection. No grounds are present, and both the source and the load float. This is the optimum condition for equipment interconnection. Either the source or the load can be tied to ground with no problems, provided only one ground connection exists. *Unbalanced* systems are created when each piece of equipment has one of its connections tied to ground, as shown in Fig. 10.275. This condition occurs if the source and load equipment have unbalanced (single-ended) inputs and outputs. This type of equipment utilizes chassis ground (or common) for one of the conductors. Problems are compounded when the equipment is separated by a significant distance.

As shown in Fig. 10.275, a difference in ground potential causes current flow in the ground wire. This current develops a voltage across the wire resistance. The ground-noise voltage adds directly to the signal itself. Because the ground current is usually the result of leakage in power transformers and line filters, the 60-Hz signal gives rise to hum of one form or another. Reducing the wire resistance through a heavier ground conductor helps the situation, but cannot eliminate the problem.

By amplifying both the high side and the ground side of the source and subtracting the two to obtain a *difference signal*, it is possible to cancel the ground-loop noise. This is the basis of the *differential input* circuit, illustrated in Fig. 10.276. Unfortunately, problems still can exist with the unbalanced-source-to-balanced-load system. The reason centers on the impedance of the unbalanced source. One side of the line will have a slightly lower amplitude because of impedance differences in the output lines. By creating an output signal that is out of phase with the original, a balanced source can be created to eliminate this error. See Fig. 10.277.

FIGURE 10.274 A basic source and load connection. No grounds are indicated, and both the source and the load float.

FIGURE 10.275 An unbalanced system in which each piece of equipment has one of its connections tied to ground.

FIGURE 10.276 Ground-loop noise can be canceled by amplifying both the high side and the ground side of the source and subtracting the two signals.

FIGURE 10.277 A balanced source configuration where the inherent amplitude error of the system shown in Fig. 10.66 is eliminated.

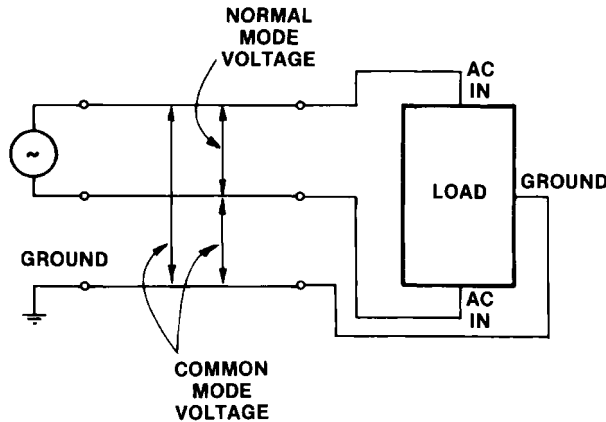

FIGURE 10.278 The principles of normal-mode and common-mode noise voltages as they apply to AC power circuits.

As an added benefit, for a given maximum output voltage from the source, the signal voltage is doubled over the unbalanced case.

Types of Noise

Two basic types of noise can appear on AC power, audio, video, and computer data lines within a facility: *normal mode* and *common mode*. Each type has a particular effect on sensitive load equipment. The normal-mode voltage is the potential difference that exists between pairs of power (or signal) conductors. This voltage also is referred to as the *transverse-mode* voltage. The common-mode voltage is a potential difference (usually noise) that appears between the power or signal conductors and the local ground reference. The differences between normal-mode and common-mode noise are illustrated in Fig. 10.278.

The common-mode noise voltage will change, depending upon what is used as the ground reference point. It is often possible to select a ground reference that has a minimum common-mode voltage with respect to the circuit of interest, particularly if the reference point and the load equipment are connected by a short conductor. Common-mode noise can be caused by electrostatic or electromagnetic induction.

In practice, a single common-mode or normal-mode noise voltage is rarely found. More often than not, load equipment will see both common-mode and normal-mode noise signals. In fact, unless the facility wiring system is unusually well-balanced, the noise signal of one mode will convert some of its energy to the other mode.

Common-mode and normal-mode noise disturbances typically are caused by momentary impulse voltage differences among parts of a distribution system that have differing ground potential references. If the sections of a system are interconnected by a signal path in which one or more of the conductors are grounded at each end, the ground offset voltage can create a current in the grounded signal conductor. If noise voltages of sufficient potential occur on signal-carrying lines, normal equipment operation can be disrupted. See Fig. 10.279.

Noise Control

Noise control is an important aspect of computer and electronic system design and maintenance [5]. The process of noise control through proper grounding techniques is more correctly called *referencing*. For this discussion, electronic systems can be viewed as a multiplicity of signal sources transmitting signals to a multiplicity of loads. Practically speaking, the impedance of the signal return path is never zero, and dedicated return paths for each source-load pair are not always practical. Packaged electronics systems typically incorporate a common signal reference plane that serves as a common return path for numerous source-load pairs. (See Fig. 10.280a.) The signal reference plane may be a large dedicated area on a circuit

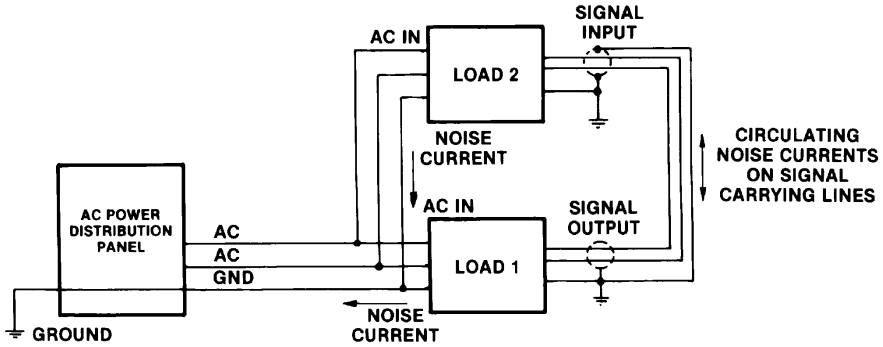

FIGURE 10.279 An illustration of how noise currents can circulate within a system because of the interconnection of various pieces of hardware.

board, the metal chassis or enclosure of the electronic equipment, or the metal frame or mounting rack that houses several different units. Ideally, the signal reference plane offers zero impedance to the signal current. Practically, however, the signal reference plane has a finite impedance. The practical result is illustrated in Fig. 10.280b, and is called *common-impedance* or *conductive coupling*.

Because a practical signal reference plane has a finite impedance, current flow in the plane will produce potential differences between various points on the plane. Source-load pairs referenced to the plane will, therefore, experience interference as a result. Z_R is common to both circuits referenced to the plane in Fig. 10.280b. Thus, I_1 and I_2 returning to their respective sources will produce interference voltages by flowing through Z_R . The total interference voltage drop seen across Z_R causes the source reference A to be at a different potential than the load reference B. This difference in potential is often called *ground voltage*

(a)

(b)

FIGURE 10.280 The equipotential plane: (a) individual signal sources, (b) net effect on the signal reference plane. (Courtesy of Intertec Publishing. After [5].)

shift (even though ground may not even be involved), and is a major source of noise and interference in electronic circuits.

Ground voltage shifts can also be caused by electromagnetic or electrostatic fields in close proximity to the source-load pairs. The interference source induces interference voltages into any closed loop by antenna action. This loop is called a *ground loop* (even though ground may not be involved). Interference voltages can be minimized by reducing the loop area as much as possible. This can be very difficult if the loop includes an entire room. The interference voltage can be eliminated entirely by breaking the loop.

Within individual electronic equipments, the signal reference plane consists of a metal plate or the metal enclosure or a rack assembly as previously discussed. Between units of equipment that are located in different rooms, on different floors, or even in different buildings, the signal reference planes of each unit must be connected together via interconnected wiring such as coax shields or separate conductors. This action, of course, increases the impedance between signal reference planes and makes noise control more difficult. Reducing noise caused by common-impedance coupling is a matter of reducing the impedance of the interconnected signal reference planes.

Regardless of the configuration encountered (i.e., circuit board, individual electronic equipment, or equipments remotely located within a facility or in separate buildings), the next question to be answered is: should the signal reference be connected to ground? Floating signal grounding, single-point grounding, and multipoint grounding are methods of accomplishing this signal-reference-to-ground connection.

IEEE Standard 1100 recommends multipoint grounding for most computers. For effective multipoint grounding, conductors between separate points desired to be at the same reference potential should be less than 0.1 wavelength ($\lambda/10$) of the interference or noise-producing signal. Longer conductor lengths will exhibit significant impedance because of the antenna effect and become ineffective as equalizing conductors between signal references. On printed circuit cards or within individual electronics equipments, short conductor lengths are usually easy to achieve. For remotely located equipments, however, short equalizing conductor lengths may be impossible. Equipments in relatively close proximity can be equalized by cutting bonding conductors to an odd multiple of $\lambda/2$ at the noise frequency. The distribution of standing waves on bonding conductors is illustrated in Fig. 10.281. The impedance, Z , is minimum for odd multiples of $\lambda/2$ but maximum for odd multiples of $\lambda/4$.

For remotely located electronics equipment within the same room, equalizing potential between respective signal reference systems may have to be accomplished with an equipotential plane. An ideal equipotential signal reference plane is one that has zero volts (thus zero impedance) between any two points on the plane. Because an *ideal* equipotential plane is not attainable, a *nominal* equipotential plane is accepted. Multipoint grounding connections are made to the plane, which ensures minimum ground voltage shift between signal reference systems connected to the plane. Collectively, the current flow in an equipotential plane can be quite large. Between any two equipments, however, the current flow should be low because of the many current paths available.

FIGURE 10.281 Standing waves on a bonding conductor resulting from the antenna effect. (After [5].)

FIGURE 10.282 Patch-panel wiring for seven-terminal normalling jack fields. Use patch cords that connect ground (sleeve) at both ends.

Practical versions of an equipotential plane include the following:

- Bolted stringer system of a raised computer floor
- Flat copper strips bonded together at 2 ft centers
- Copper conductors bonded together at 2 ft centers
- Single or multiple, flat copper strips connected between equipment

Patch-Bay Grounding

Patch panels for audio, video, and data circuits require careful attention to planning to avoid built-in grounding problems. Because patch panels are designed to tie together separate pieces of equipment, often from remote areas of a facility, the opportunity exists for ground loops. The first rule of patch-bay design is to never use a patch bay to switch low-level (microphone) signals. If mic sources must be patched from one location to another, install a bank of mic-to-line amplifiers to raise the signal levels to 0 dBm before connection to the patch bay. Most video output levels are 1 V P-P, giving them a measure of noise immunity. Data levels are typically 5 V. Although these line-level signals are significantly above the noise floor, capacitive loading and series resistance in long cables can reduce voltage levels to a point that noise becomes a problem.

Newer-design patch panels permit switching of ground connections along with signal lines. Figure 10.282 illustrates the preferred method of connecting an audio patch panel into a system. Note that the source and destination jacks are *normalled* to establish ground signal continuity. When another signal is plugged into the destination jack, the ground from the new source is carried to the line input of the destination jack. With such an approach, jack cords that provide continuity between sleeve (ground) points are required.

If only older-style, conventional jacks are available, use the approach shown in Fig. 10.283. This configuration will prevent ground loops, but because destination shields are not carried back to the source

FIGURE 10.283 Patch-panel wiring for conventional normalling jack fields. Use patch cords that connect ground (sleeve) at both ends.

when normaling, noise will be higher. Bus all destination jack sleeves together, and connect to the local (rack) ground. The wiring methods shown in Fig. 15.282 and Fig. 15.283 assume balanced input and output lines with all shields terminated at the load (input) end of the equipment.

Input/Output Circuits

Common-mode rejection ratio (CMRR) is the measure of how well an input circuit rejects ground noise. The concept is illustrated in Fig. 10.284. The input signal to a differential amplifier is applied between the plus and minus amplifier inputs. The stage will have a certain gain for this signal condition, called the *differential gain*. Because the ground-noise voltage appears on both the plus and minus inputs simultaneously, it is common to both inputs.

The amplifier subtracts the two inputs, giving only the difference between the voltages at the input terminals at the output of the stage. The gain under this condition should be zero, but in practice it is not. CMRR is the ratio of these two gains (the differential gain and the common-mode gain) in decibels. The larger the number, the better. For example, a 60-dB CMRR means that a ground signal common to the two inputs will have 60 dB less gain than the desired differential signal. If the ground noise is already 40 dB below the desired signal level, the output noise level will be 100 dB below the desired signal level. If, however, the noise is already part of the differential signal, the CMRR will do nothing to improve it.

Active-balanced I/O circuits are the basis of nearly all professional audio interconnections (except for speaker connections), many video signals, and increasing numbers of data lines. A wide variety of circuit designs have been devised for active-balanced inputs. All have the common goal of providing high CMRR and adequate gain for subsequent stages. All also are built around a few basic principles.

Figure 10.285 shows the simplest and least expensive approach, using a single operational amplifier (op-amp). For a unity gain stage, all the resistors are the same value. This circuit presents an input impedance to the line that is different for the two sides. The positive input impedance will be twice that of the negative input. The CMRR is dependent on the matching of the four resistors and the balance of the source impedance. The noise performance of this circuit, which usually is limited by the resistors, is a tradeoff between low loading of the line and low noise.

Another approach, shown in Fig. 10.286, uses a buffering op-amp stage for the positive input. The positive signal is inverted by the op-amp, then added to the negative input of the second inverting amplifier stage. Any common-mode signal on the positive input (which has been inverted) will cancel when it is added to the negative input signal. Both inputs have

FIGURE 10.284 The concept of common-mode rejection ratio (CMRR) for an active-balanced input circuit: (a) differential gain measurement; (b) calculating CMRR.

FIGURE 10.285 The simplest and least expensive active-balanced input op-amp circuit. Performance depends on resistor-matching and the balance of the source impedance.

the same impedance. Practical resistor-matching limits the CMRR to about 50 dB. With the addition of an adjustment potentiometer, it is possible to achieve 80 dB CMRR, but component aging will usually degrade this over time.

Adding a pair of buffer amplifiers before the summing stage results in an *instrumentation-grade* circuit, as shown in Fig. 10.287. The input impedance is increased substantially, and any source impedance effects are eliminated. More noise is introduced by the added op-amp, but the resistor noise usually can be decreased by reducing impedances, causing a net improvement in system noise.

Early active-balanced output circuits used the approach shown in Fig. 10.288. The signal is buffered to provide one phase of the balanced output. This signal then is inverted with another op-amp to provide the other phase of the output signal. The outputs are taken through two resistors, each of which is half of the desired source impedance. Because the load is driven from the two outputs, the maximum output voltage is double that of an unbalanced stage.

The circuit in Fig. 10.288 works reasonably well if the load is always balanced, but it suffers from two problems when the load is not balanced. If the negative output is shorted to ground by an unbalanced load connection, the first op-amp is likely to distort. This produces a distorted signal at the input to the other op-amp. Even if the circuit is arranged so that the second op-amp is grounded by an unbalanced load, the distorted output current probably will show up in the output from coupling through grounds or circuit-board traces. Equipment that uses this type of balanced stage often provides a second set of output connections that are wired to only one amplifier for unbalanced applications.

The second problem with the circuit in Fig. 10.288 is that the output does not *float*. If any voltage difference (such as power-line hum) exists between the local ground and the ground at the device receiving the signal, it will appear as an addition to the signal. The only ground-noise rejection will be from the CMRR of the input stage at the receive end.

The preferred basic output stage is the electronically balanced and floating design shown in Fig. 10.289. The circuit consists of two op-amps that are cross-coupled with positive and negative feedback. The output of each amplifier is dependent on the input signal and the signal present at the output

FIGURE 10.286 An active-balanced input circuit using two op-amps; one to invert the positive input terminal and the other to buffer the difference signal. Without adjustments, this circuit will provide about 50 dB CMRR.

FIGURE 10.287 An active-balanced input circuit using three op-amps to form an instrumentation-grade circuit. The input signals are buffered, then applied to a differential amplifier.

FIGURE 10.288 A basic active-balanced output circuit. This configuration works well when driving a single balanced load.

of the other amplifier. These designs may have gain or loss, depending on the selection of resistor values. The output impedance is set via appropriate selection of resistor values. Some resistance is needed from the output terminal to ground to keep the output voltage from floating to one of the power-supply rails. Care must be taken to properly compensate the devices. Otherwise, stability problems can result.

Cable Routing

Good engineering practice dictates that different signal levels be grouped and separated from each other. It is common practice to separate cables into the following groups:

- AC power
- Speaker lines
- Line-level audio
- Microphone-level audio
- Video lines
- Control and data lines

Always use two-conductor shielded cable for all audio signal cables. This includes both balanced and unbalanced circuits, and microphone-level and line-level cables. On any audio cable connecting two pieces of equipment, tie the shield at one end only. Connect at the receiving end of signal transmission. On video coaxial cables running to outlet jacks mounted on plates, isolate the connector from the plate. The shield should connect to ground only at the equipment input/output or patch panel. For data cables, carefully follow the recommendations of the equipment manufacturer. The preferred interconnection method for long data cables is fiber optics, which eliminates ground-loop problems altogether.

Overcoming Ground-System Problems

Although the concept of equipment grounding seems rather basic, it can become a major headache if not done correctly. Even if all of the foregoing guidelines are followed to the letter, there is the possibility of ground loops and objectionable noise on audio, video, or data lines. The larger the physical size of the facility, the greater the potential for problems. An otherwise perfect ground system can be degraded by a single wiring error. An otherwise clean signal ground can be contaminated by a single piece of equipment experiencing a marginal ground fault condition.

If problems are experienced with a system, carefully examine all elements to track down the wiring error or offending load. Do not add AC line filters and/or signal line filters to correct a problem system. In a properly designed system, even one in a high-RF field, proper grounding and shielding techniques will permit reliable operation. Adding filters merely hides the problem. Instead, correct the problem at its source. In a highly complex system such as a data processing facility, the necessity to interconnect a large number of systems may require the use of fiber-optic transmitters and receivers.

10.11 Batteries

Isidor Buchmann

10.11.1 Introduction

Research has brought about a number of different battery chemistries, each offering distinct advantages over the others. Today's most common and promising chemistries available include:

- Nickel cadmium (NiCd). Used for portable radios, cellular phones, video cameras, power tools and some biomedical instruments. NiCds have a good load characteristics, are economically priced and are simple to use.
- Nickel metal hydride (NiMH). Used for cellular phones and laptop computers where high energy is of importance and cost is secondary.
- Sealed lead acid (SLA). Used for biomedical equipment, wheel chairs, UPS systems, and other heavier applications where energy-to-weight ratio is not critical and low battery cost is desirable.
- Lithium ion (Li-ion). Used for laptop computers and some video cameras, this chemistry will likely replace some NiCds for high energy-density applications.
- Lithium polymer (Li-polymer). This battery has the highest energy density and lowest **self-discharge** but its load characteristics only suit low current applications.
- Reusable alkaline. Used for light duty applications. Because of its low self-discharge, this battery is suitable for portable entertainment devices and other noncritical appliances that are used only occasionally.

10.11.2 Choice of Battery Chemistries

No single battery offers all of the answers; rather, each chemistry is based on a number of compromises. Table 10.16 compares the pros and cons of the six most common batteries: the sealed NiCd, NiMH, SLA, Li-ion, Li-polymer, and reusable alkaline.

It is interesting to observe that the NiCd has the shortest charge time, delivers the highest load current, and offers the lowest cost-per-cycle, but is most demanding on exercise requirements. For applications where high-energy density is critical, regular exercise is impractical, and cost is secondary, the NiMH is probably the best choice. Not without problems, NiMH batteries have a cycle life one-third that of NiCds. Furthermore, field use has revealed that the NiMH also needs some level of exercise to maximize service life, but to a lesser extent than the NiCd. In comparison, the SLA needs little or no maintenance but has a low-energy density.

Among rechargeable batteries, the NiCd has been around the longest (since 1950). It is also one of the best understood chemistries and has become a standard against which other batteries are compared. This section compares the different chemistries relative to the NiCd.

TABLE 10.16 Operating Characteristics of Common Battery Types

	NiCd	NiMH	SLA	Li-ion	Li-polymer	Reusable alkaline
Energy density, Wh/kg	50	75	30	100	175	80 (initial)
Cycle life ^a (typical)	1500	500	200–300	300–500	150	10 (to 65%)
Fast-charge time, ^b h	1 1/2	2–3	8–15	3–6	8–15	3–4
Self-discharge ^c	moderate ^d	high	low	low	very low	very low
Cell voltage, ^e (nominal) V	1.25	1.25	2	3.6	2.7	1.5
Load current, ^f	very high	moderate	low	high	low	very low
Exercise requirement ^g	/30 days	/90 days	/180 days	N/A	N/A	N/A
Battery cost ^h (estimated, ref. only)	low (50.00)	moderate (80.00)	very low (25.00)	very high (100.00)	high (90.00)	very low (5.00)
Cost per cycle ⁱ (\$)	0.04	0.16	0.10	0.25	0.60	0.50
In commercial use since	1950	1970	1970	1990	(1997)	1990

^aCycle life indicates the typical number of charge-discharge cycles before the capacity decreases from the nominal 100 to 80% (65% for the reusable alkaline).

^bFast-charge time is the time required to fully charge an empty battery.

^cSelf-discharge indicates the self-discharge rate when the battery is not in use.

^dModerate refers to 1–2% capacity-loss per day.

^eCell voltage multiplied by the number of cells provides the battery terminal voltage.

^fLoad current is the maximum recommended current the battery can provide. High refers to a discharge rate of 1C; very high is a current higher than 1 C. **C rate** is a unit by which charge and discharge times are scaled. If discharged at 1, a 1000 mAh battery provides a current of 1000 mA; if discharged at 0.5C, the current is 500 mA.

^g**Exercise** requirement indicates the frequency the battery needs exercising to achieve maximum service life.

^hBattery cost is the estimated commercial price of a commonly available battery.

ⁱCost-per-cycle indicates the operating cost derived by taking the average price of a commercial battery and dividing it by the cycle count.

The Nickel Cadmium (NiCd) Battery

Among the rechargeable batteries, the NiCd remains a popular choice for applications such as portable radios, video cameras, data loggers, and power tools. There is a renewed interest in this chemistry, and many equipment manufacturers are switching back to the NiCd after having recognized the limitations of other chemistries. Some of the distinct advantages of the NiCd over other battery chemistries are

- Fast and simple charge
- High number of charge–discharge cycles (if properly maintained, the NiCd provides several thousand cycles)
- Excellent load performance, even at cold temperatures
- Simple storage and transportation (the NiCd is accepted by most air freight companies)
- Easy to recharge after prolonged storage
- Forgiving if abused
- Economical price

The NiCd is a strong and reliable worker; hard labor poses no problem. Fast charge is preferable to slow charge and pulse-charge to DC charge. Improved performance is achieved by interspersing discharge pulses between charge pulses. Commonly referred to as *burp* or *reverse load* charge, this charge method promotes the recombination of gases generated during fast charge. The result is a cooler and more effective charge than with conventional DC chargers. The battery is stimulated while charging, a function that improves battery performance. Research has shown that reverse load adds 15% to the life of the NiCd battery.

The NiCd does not respond well to sitting in chargers for days and being used only occasionally for brief periods. In fact, the NiCd is the only battery type that performs best if periodically discharged to 1 V per cell (full discharge). All other chemistries react best with shallow discharges. So important is this periodic full discharge that, if omitted, the NiCd gradually loses performance due to crystalline formation, also referred to as **memory**.

The Nickel Metal-Hydride (NiMH) Battery

The NiMH battery has certain advantages over the NiCd. For example:

- The NiMH provides 30% more capacity over a *standard* NiCd.
- The NiMH is affected by memory to a lesser extent than the NiCd. Periodic exercise cycles need to be done less often.
- Because of its low toxic metals content, the NiMH is labeled environmentally friendly.

In other aspects the NiMH lags behind the NiCd. For example:

- Number of cycles. The NiMH is rated for only, 500 charge-discharge cycles. It does not respond well to full discharging during each use; its longevity is in direct relation to the depth of discharge. (In comparison, the NiCd can accept several thousand full discharge-charge cycles. NiCd batteries for satellite applications are designed to last for 15–20 years and provide 70,000 cycles).
- Ease of fast charge. The NiMH battery requires a more complex algorithm for full-charge detection than the NiCd, if temperature sensing is not available. In addition, the NiMH cannot accept as quick a fast charge as the NiCd.
- Discharge current. The recommended discharge current of the NiMH is considerably less than that of the NiCd. For best results, manufacturers recommend a load current of $0.2C$ (one-fifth of the rated capacity). This shortcoming may not be critical for small DC loads, but in applications requiring high power or pulsed load, such as in transceivers, power tools, and GSM cellular telephones, the more rugged NiCd is the recommended choice.
- High self-discharge. Both NiMH and NiCd are affected by high self-discharge. The NiCd loses about 10% of its capacity within the first 24 h, after which the self-discharge settles to about 10% per month. For the NiMH the self-discharge is typically twice as much because the hydrogen atoms try to escape. Selecting materials that improve hydrogen bonding reduces the capacity of the battery. Research engineers are faced with a compromise between reasonably low self-discharge and high-energy density.
- Capacity. The NiMH delivers about 30% more capacity than a NiCd of the same size. The comparison is made with the *standard*, rather than *ultra-high capacity* NiCd. Some ultra-high capacity NiCd cells provide a capacity level similar to the NiMH.
- Price. The price of the NiMH is higher than that of the NiCd. Price may not be a major issue if the user requires high capacity and small size.

The NiMH is not new. In the 1970s, this battery chemistry was tested and consequently dropped because it was considered unsuitable for the applications intended. However, the modern NiMH has been improved and will likely maintain a strong market niche.

The Sealed Lead-Acid (SLA) Battery

Another commonly used chemistry is the sealed lead-acid battery. The *flooded* version is found in automobiles, but most portable equipment use the *sealed* version, also referred to as *gelcell* or *SLA*.

The SLA is commonly used when high power is required, weight is not critical, and cost must be kept low. The typical current range of the SLA is 2 to 30 Ah. Applications that fall into this category are wheel chairs, UPS units, and emergency lighting. Because of its minimal maintenance requirements and predictable storage, the SLA gained ground in the biomedical industry during the 1980s.

The SLA is not subject to memory. No harm is done by leaving the battery on float charge for a prolonged time. If removed from the charger, the SLA retains the charge four times longer than the NiCd. Based on the per ampere-hour cost, the SLA is the lowest priced battery, but in terms of cost-per-cycle, it is more expensive than the NiCd.

On the negative side, the SLA does not lend itself well to fast charging. Typical charge times are 8–16 h. The SLA must always be stored in a charged state because a discharged SLA will sulphate. If left discharged, a recharge is difficult or impossible.

Unlike the NiCd, a shallow discharge is preferred for SLA. A full discharge causes extra strain and reduces the number of times the battery can be recharged, similar to a mechanical device that wears down when being strained. In fact, each discharge–charge cycle robs the battery of a small amount of capacity. This wear-down characteristic also applies to other chemistries, including the NiMH and to a lesser extent the NiCd.

An additional difficulty with the SLA is a relatively low load current. This current is further reduced at cold temperatures. Compared to other rechargeables, the energy density is low, making the SLA unsuitable for devices demanding compact size and long play time. Because of its high lead content, the SLA is not environmentally friendly.

The Rechargeable Lithium Battery

The energy density of the rechargeable lithium is the highest among commercial batteries and the self-discharge is very low. There are several types of lithium batteries of interest; the most promising chemistries are the lithium-ion (Li-ion) and the lithium polymer (Li-polymer).

The lithium-ion provides an energy density that is twice that of the NiCd at comparable load currents. In addition, the Li-ion deep-discharges well. In fact, the Li-ion behaves similarly to the NiCd as far as charge and discharge characteristics are concerned.

Unlike other rechargeable lithium batteries, the Li-ion is stable and safe because no metallic lithium is used. However, certain precautions must still be taken. For reasons of safety and longevity, each cell must be equipped with a control circuit to limit the voltage peaks during charge and to prevent the voltage from dropping too low on discharge. In addition, the control circuit must limit the maximum charge and discharge current. With these precautions in place, the danger of metallic lithium formation is eliminated.

The lithium-polymer provides more than three times the energy density of the NiCd and features a very low self-discharge. As far as charge and discharge characteristics are concerned, the lithium polymer behaves more like the SLA battery. Charge time is 8–16 h. Shallow rather than deep discharge is preferred.

Disposal of all lithium-based batteries may cause some headaches. The concern is not their toxic metal content but the danger of explosion if moisture creeps into the cells when they corrode.

Reusable Alkaline

The idea of recharging alkaline batteries is not new. In fact, ordinary alkaline batteries have been recharged for years for applications such as flashlights in commercial aircraft. The difference between a *reusable* and a *standard* alkaline lies in the energy density and the number of times the battery can be recharged. Whereas the standard alkaline offers maximum energy density, the reusable alkaline provides a higher cycle count but compromises on the energy density.

One of the major drawbacks of the reusable alkaline is the limited number of times the battery can be cycled. The longevity is a direct function of the depth of discharge; the deeper the discharge, the fewer cycles the battery endures.

An additional limitation of the reusable alkaline is its low load current of 400 mA maximum (lower current provides better results). Although adequate for portable radios, CD players, tape recorders, and flashlights, 400 mA is insufficient to power many other devices.

Another negative aspect of the reusable alkaline is its relative high cost per cycle when compared to the NiCd. For many applications, this still represents a saving when compared to nonreusable alkalines.

To compare the operating cost between the standard and reusable alkaline, a study was done on flashlight batteries for hospital use. The low-intensity care unit achieved measurable savings by using the reusable alkaline, but the high-intensity unit did not attain the same saving; deeper and more frequent cycling of the batteries reduced their service life and offset any cost advantage.

10.11.3 Proper Charge Methods

The critical factor in terms of performance and longevity of all battery chemistries lies in the way the batteries are cared for. In this section, we examine the reasons why some batteries do not perform as expected and fall short of their life expectancy.

Chargers for the NiCd Battery

Commercial chargers are often not designed in the best interests of the battery. This is especially true of NiCd chargers that measure the charge state through temperature sensing. Temperature sensing is inaccurate because of the wide tolerances of the sensing thermistor and its positioning in respect to the cells. Ambient temperatures and exposure to the sun while charging also come into play. To assure full charge under all conditions, charger manufacturers tend to cook the batteries. Any prolonged temperature above 45°C (113°F) is harmful to the battery and should be avoided.

More advanced NiCd chargers use the delta temperature method for full-charge detection. Although still dependent on a thermistor, this type of charger is kinder on the batteries than those using the absolute battery temperature method.

With a microcontroller, more precise full-charge detection is achieved by monitoring the battery voltage and terminating the charge when a certain voltage signature occurs. Such a signature is the **negative delta V (NDV)**.

The NDV is ideal for *open-lead* NiCd chargers and battery analyzers because the batteries they service do not need a thermistor. The NDV has drawbacks, however; it only works well with matched NiCd packs. A battery with **mismatched cells** does not produce a sufficient negative slope to terminate the fast charge, and the battery may overheat due to overcharge. Chargers using the NDV must feature other charge-termination methods to provide safe charging under all conditions.

Mismatched cells are found in brand new batteries and those that have aged. Common reasons for poorly matched cells are: poor quality control at the cell manufacturing level and inadequate cell matching when packing the batteries. If not too far apart, the cells in a new pack adapt to each other after a few charge-discharge cycles in a manner similar to players in a winning sports team. In old packs, mismatched cells are irreconcilable; although still usable, the performance of these batteries is poor.

Chargers for the NiMH Battery

Unlike NiCd chargers, the chargers for NiMH batteries cannot utilize the NDV for full-charge detection because NiMH batteries do not generate an adequate voltage drop at full charge, even with perfectly matched cells. Reducing the delta to respond to a smaller voltage drop may terminate the fast charge halfway through the charge cycle. If temperature sensing is not available, an algorithm must be used that identifies a certain voltage signature that occurs at the full-charge state. Because of the complexity in circuitry and firmware required, most NiMH chargers are still based on temperature sensing.

The NiMH battery is sensitive to the amount of **trickle charge** applied to maintain full charge. In spite of its inherent high self-discharge, the trickle charge of the NiMH must be set lower than that of the NiCd. A trickle charge that is acceptable for the NiCd will overheat the NiMH and cause irreversible damage.

Chargers for the SLA Battery

The charge algorithm of the SLA differs from that of the NiCd and NiMH in that **voltage limit** rather than **current limit** is used. The charge time of the SLA is a slow 16 h. With higher charge currents and multistage charge methods, the charge time can be reduced to about 10 h. In no way can the SLA be charged as quickly as the NiCd.

A multistage charger applies three charge stages consisting of *constant-current charge*, *topping charge*, and *float charge* (see Fig. 10.290). During the constant-current stage, the battery charges to 70% in about 5 h, the remaining 30% is completed by the topping charge. The slow topping charge, lasting another 5 h, is essential for the well-being of the battery. If deprived, the SLA eventually loses the ability to accept a full charge and the performance of the battery is reduced. The third stage is the float charge, which compensates for the self-discharge after the battery has been fully charged. During the constant current charge, the SLA battery is charged at a high current, limited by the charger itself. Once the voltage limit is reached, the topping charge begins and the current starts to drop gradually. Full charge is reached when the current drops to a preset level or reaches a low-end plateau.

The proper setting of the cell voltage limit is critical and is related to the conditions under which the battery is charged. A typical voltage limit range is from 2.30 to 2.45 V. If a slow charge is acceptable, or if the

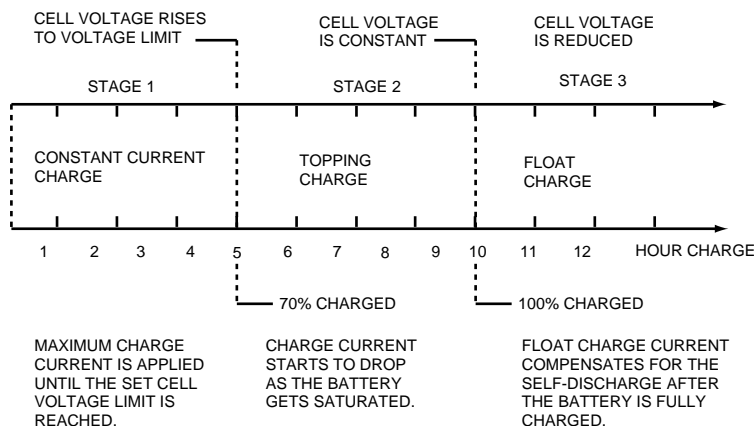

FIGURE 10.290 Charge stages of a SLA battery.

room temperature exceeds 30°C (86°F), the recommended voltage limit is 2.35 V /cell. If a faster charge is required and the room temperature remains below 30°C, 2.40 or 2.45 V/cell may be used. Table 10.17 compares the advantages and disadvantages of the different voltage settings.

10.11.4 Battery Maintenance

A common difficulty with battery-powered equipment is the progressive deterioration in reliability after the first year of service. This phenomenon is mostly due to premature aging of the battery, a reversible capacity loss that is induced by memory. This loss occurs gradually without the user’s knowledge. Although fully charged, the battery eventually regresses to a point where it can hold less than half of its original capacity, resulting in unexpected down time.

Down time almost always occurs at critical moments. Under normal conditions, the battery holds enough power until recharged. During heavy activities and longer than expected duties, a marginal battery cannot provide the extra power needed and the equipment fails.

In many ways, a rechargeable battery exhibits human-like characteristics: it needs good nutrition, it prefers moderate room temperature and, in case of the NiCd battery, requires regular exercise to prevent the phenomenon called memory.

Memory: Myth or Fact?

There is some misconception about the word memory. Memory is commonly blamed for all battery failures known to man. Originally, the word *memory* was derived from *cyclic memory*, meaning that a NiCd battery can remember how much discharge was required on previous discharges. Improvements in battery technology have virtually eliminated this phenomenon.

TABLE 10.17 Recommended Charge Voltage Limit on SLA Battery

	2.30–2.35 V/cell	2.40–2.45 V/cell
Advantage	Maximum service life; battery remains cool on charge; battery may be charged at ambient temperature exceeding 30°C (86°F).	Faster charge times; higher and more consistent capacity readings; less subject to damage due to undercharge condition.
Disadvantage	Slow charge time; capacity readings may be low and in-consistent. Produces under-charge condition, which may cause sulphation and capacity loss if the battery is not periodically cycled.	Battery life may be reduced due to elevated battery temperature while charging. A hot battery may fail to reach the cell voltage limit, causing harmful overcharge.

The problem with the modern NiCd battery is not the cyclic memory but the effects of *crystalline formation*. (When memory is mentioned we refer to crystalline formation.) The active materials of a NiCd battery (nickel and cadmium) are present in crystalline form. When the memory phenomenon occurs, these crystals grow, forming spike or tree-like crystals that cause the NiCd to gradually lose performance. In advanced stages, these crystals may puncture the separator, causing high self-discharge or an electrical short.

Regular Exercise

Crystalline formation is most prominent if the battery is left in the charger for days, or if repeatedly recharged without a periodic full discharge. It is not necessary to discharge a NiCd before each charge. A full discharge to 1 V per cell once a month is sufficient to keep the crystal formation under control. Such a discharge/charge cycle is referred to as *exercise*.

If no exercise is applied for several months, the crystals ingrain themselves, making them more difficult to dissolve. In such a case, exercise is no longer effective in restoring a battery and **recondition** is required. Recondition is a slow, deep discharge that drains the cell to a voltage threshold below 1 V per cell. Laboratory tests have shown that a NiCd cell should be discharged to at least 0.6 V to effectively dissolve the more resistant crystalline buildup. When applying recondition, the current must be carefully controlled to prevent cell reversal.

In the following study, four batteries afflicted with various degree of memory are analyzed. The batteries are first fully charged, followed by a discharge to 1 V per cell. The resulting capacities are plotted on a scale of 0–120% in the first column of Fig. 10.291. Additional discharge-charge cycles are applied and the battery capacities are plotted in the subsequent columns. The dotted line represents exercise, the solid line recondition. Exercise and recondition cycles are applied manually at the discretion of the research technician. Battery A responded well to exercise alone. This result is typical of a battery that had been in service for only a few months or had been exercised periodically. Batteries B and C required recondition (solid line) to recover full performance. The capacity of the new battery was further enhanced after recondition was applied. When examined after six months of field use, the batteries still showed excellent capacity readings.

The importance of exercise and recondition are further emphasized by a study carried out by GTE Government Systems in Virginia, to determine what percentage of batteries needed replacing within the first year of use. One group of batteries received charge only, another group was exercised, and a third group received recondition. The batteries studied were used for portable radios on the aircraft carriers U.S.S. Eisenhower with 1500 batteries and U.S.S. George Washington with 600 batteries, and the destroyer U.S.S. Ponce with 500 batteries.

Table 10.18 shows that with charge only (charge-and-use), the annual percentage of batteries failure on the U.S.S. Eisenhower was 45%. By applying exercise, the failure was reduced to 15%. By far the best results were achieved with recondition; its failure rate dropped to 5%. The same results were achieved with the U.S.S. George Washington and the U.S.S. Ponce.

FIGURE 10.291 Effects of exercise vs recondition.

TABLE 10.18 Annual Percentage of Batteries Requiring Replacement on the U.S.S. Eisenhower, U.S.S. George Washington, and U.S.S. Ponce as a Function of Battery Maintenance

Maintenance Method	Annual Percentage of Batteries Requiring Replacement, %
Charge only (charge-and-use)	45
Exercise only (discharge to 1 V/cell)	15
Reconditioning (secondary deep discharge)	5

The report states further that a battery analyzer that features the exercise and recondition functions and costs \$U.S. 2500 would pay for itself in less than one month on battery savings alone. No mention was made of the benefits of increased system reliability, an issue that is of equal or larger importance when the safety of human lives is at stake.

In respect to restoring weak batteries through exercise and recondition, not all batteries respond equally well; an older battery may show low and inconsistent capacity readings, or even get worse with each cycle applied. If this occurs, the battery should be replaced. This type of battery can be compared to a very old man to whom exercise is harmful. There are older NiCd batteries, however, that recover to near original capacity when serviced. Caution should be applied when “re-hiring” these older batteries because they may exhibit high self-discharge.

Self-Discharge

The NiCd and the NiMH exhibit a high self-discharge. If left on the shelf, a new NiCd loses about 10% of its capacity in 24 h. A problem arises if the battery self-discharges within a day, a phenomenon that is not uncommon, especially for an older battery. The cause of high self-discharge is a damaged separator, a thin, delicate insulator that isolates the positive and negative cell plates (see Fig. 10.292). Once damaged, the separator can no longer be repaired. External forces that harm the sensitive separator are: uncontrolled

FIGURE 10.292 Drawing of a NiCd cell. The negative and positive plates are rolled together and placed in a metal cylinder. The positive plate is sintered and filled with nickel hydroxide. The negative plate is coated with cadmium active material. The two plates are isolated by a separator, which are moistened with the electrolyte.

crystalline formation due to lack of exercise, poorly designed chargers that boil the battery, and old age. In some instances, cell manufacturers use a separator material that is unsuitable.

The self-discharge of a battery can most conveniently be measured with a battery analyzer. A battery should be discarded if the resulting capacity loss over 24 h at a storage temperature of 22°C (70°F) is more than 30%. No amount of cycling will improve this condition.

Battery Analyzers

The technology of battery analyzers has advanced significantly. No longer are users limited to analog units with fixed charge/discharge currents and programs that only apply one or two discharge-charge cycles.

An advanced battery analyzer evaluates the condition of each battery and implements the appropriate service to restore its performance. A recondition cycle is applied automatically if a user-selected capacity level cannot be reached. Battery chemistry and voltage and current rates are user programmable. These parameters are stored in interchangeable cups and configure the analyzer to the correct function when installed.

Because the service is performed against preset parameters, the batteries are charged and discharged under true field conditions, a feature that provides accurate test results as well as fast service. Batteries with shorted, mismatched or **soft cells** are identified in minutes, their deficiencies displayed and, if necessary, the service halted. The derived battery capacities are organized into *residual* and *final* capacities. Problems, such as insufficient capacity reserve at the end of field use, are easily identified to allow necessary corrections.

To enable servicing all batteries, including those with known defects, an analyzer must feature multiple redundant charge-termination algorithms to ensure that the batteries are charged quickly and safely and without overheating. Without this provision, battery packs with shorted or mismatched cells may sustain damage due to overcharge. User-selectable programs address the different battery needs and include: a *prime* mode to prepare a new battery for field use, an *auto* mode to recondition batteries unable to reach a user-set target capacity, and a *custom* mode to allow the operator to set a sequence of unique cycle modes composed of charge, discharge, recondition, trickle charge, or any combination thereof, including rest periods and repeats.

An important feature of an analyzer is easy operation, a quality that is especially useful when confronted with servicing an ever increasing fleet of different battery types. It is more convenient to read the test results in percentage of the rated capacity rather than in milliampere hours (mAh) as this frees the operator from memorizing the ratings of each battery tested. In addition, simple pass/fail lights help to distinguish good batteries from unserviceable ones at a glance.

Analyzers that are capable of printing service reports and battery labels simplify the task of keeping track of the batteries serviced (see Fig. 10.293). By attaching the label to the batteries, the user is always informed of the battery's history and pending maintenance. To keep current with the latest battery developments, a battery analyzer should allow firmware upgrades to enable servicing new chemistries when introduced.

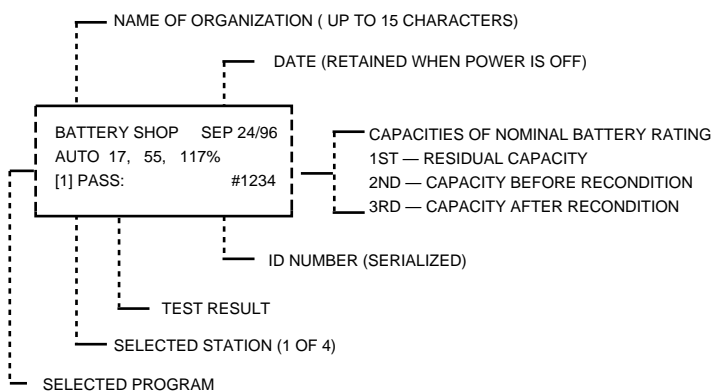

FIGURE 10.293 Sample battery label.

Advanced battery analyzers are capable of networking into a computer to form a workstation servicing 100 batteries or more simultaneously. User friendly software assists in collecting the battery test results for the database from which inventory, service reports, and graphs are generated. The software allows remote controlling of the analyzers through a central computer keyboard, including the downloading of firmware into the analyzer's flash memory to upgrade existing firmware, or to custom-program an analyzer for a special function. The battery identification number and parameters (chemistry, voltage, rating) are printed on bar code labels and attached to the batteries. By reading the bar code labels, the battery to be serviced is identified and the battery analyzer is automatically configured to the correct parameters for the battery intended.

The advancements in battery technology may not be as impressive as those achieved in microelectronics but with today's intelligent battery analyzers, the task of providing quality battery maintenance is simplified and the cost is lowered. By following the maintenance procedures recommended by the battery manufacturer, today's rechargeable batteries are capable of supplying a truly reliable and economical energy source.

10.11.5 Advancements in Battery Rapid-Testing

Portable batteries for cell phones, laptops, and cameras may be rapid-tested by applying a number of load pulses while observing the relationship between voltage and current. Ohm's Law is used to calculate the internal resistance. Comparing the readings against a table of values estimates the battery's state-of-health.

The load pulse method described above does not work well for larger batteries and AC conductance is commonly used. An AC voltage is applied to the battery terminals that floats as a ripple on top of the battery's DC voltage and charges and discharges the battery alternatively.

AC conductance has been incorporated into a number of hand-held testers to check batteries for vehicular and stationary batteries. To offer simple, compact and low-cost units, these testers load the battery with repetitive current pulses. Because these pulses are not voltage controlled, the thermal battery voltage¹ may be surpassed. The thermal voltage threshold of a lead-acid battery is 25 mV per cell. Exceeding this voltage is similar to over-driving an audio amplifier. Amplified noise and distortion is the result.

AC conductance provides accurate readings, provided the battery is fully charged, has rested or has been briefly discharged prior to taking the reading. AC conductance tends to become unreliable on low charge and sometimes fails a good battery. At other times, a faulty battery may pass as good. The sensitivity to the battery's state-of-charge is a common complaint by users. AC conductance works best in identifying batteries with definite deficiencies.

AC conductance is noninvasive, quick and the test instruments are relatively inexpensive. There are, however, some fundamental problems. Most commercial testers use only one frequency, which is commonly below 100 Hz. Multi-frequency systems would be more accurate but require complex data interpretation software and expensive hardware. In this section we focus on *electrochemical impedance spectroscopy* (EIS), a method that overcomes some of the shortcomings of AC conductance.

Electrochemical Impedance Spectroscopy (EIS)

EIS evaluates the electrochemical characteristics of a battery by applying an AC potential at varying frequencies and measuring the current response of the electrochemical cell. The frequency may vary from about 100 μ Hz to 100 kHz. 100 μ Hz is a very low frequency that takes more than two hours to complete one full cycle. In comparison, 100 kHz completes 100,000 cycles in one second.

Applying various frequencies can be envisioned as going through different layers of the battery and examining its characteristics at all levels. Similar to tuning the dial on a broadcast radio, in which individual

¹Batteries are nonlinear systems. The equations, which govern the battery's response becomes linear below 25 mV/cell at 25°C. This voltage is called the battery thermal voltage.

stations offer various types of music, so too does the battery provide different information at varying frequencies.

Battery resistance consists of pure Ohmic resistance, inductance, and capacitance. Figure 10.294 illustrates the classic Randles model.

Capacitance is responsible for the capacitor effect; and the inductance is accountable for the so-called magnetic field, or coil effect. The voltage on a capacitor lags behind the current. On a magnetic coil, on the other hand, the current lags behind the voltage. When applying a sine wave to a battery, the reactive resistance produces a phase shift between voltage and current. This information is used to evaluate the battery.

EIS has been used for a number of years to perform in-flight analysis of satellite batteries, as well as estimating grid corrosion and water loss on aviation and stationary batteries. EIS gives the ability to observe the kinetic reaction of the electrodes and analyze changes that occur in everyday battery usage. Increases in impedance readings hint at minute intrusion of corrosion and other deficiencies. Impedance studies using the EIS methods have been carried out on lead-acid, nickel-cadmium, nickel-metal-hydride and lithium-ion batteries. Best results are obtained on a single cell.

One of the difficulties of EIS is data interpretation. It is easy to amass a large amount of data; making practical use of it is more difficult. Analyzing the information is further complicated by the fact that the readings are not universal and do not apply equally to all battery makes and types. Rather, each battery type generates its own set of signatures. Without well-defined reference readings and software to interpret the results, gathering information has little meaning for the ordinary person.

Modern technology can help by storing characteristic settings of a given battery type in the test instrument. Advanced digital signal processors are able to carry out millions of instructions per second. Software translates the data into a single reading. EIS has the potential of becoming a viable alternative to AC conductance in checking automotive, traction, and stationary batteries. Noteworthy advancements are being made in this field.

Defining Terms

Cell mismatch: Cells within a battery pack that have different capacity levels.

C-rate: Unit by which charge and discharge times are scaled. At 1C, the charge current equals the battery rating, that is, a 1000-mAh battery is charged and discharged at 1000 mA.

Current-limiting chargers: A charger that keeps the charge current constant during the charge process but allows the voltage to fluctuate.

Exercise: Commonly understood as one or more discharge cycles to 1 V per cell (NiCd and NiMH) with subsequent recharge.

Memory: Reversible capacity loss found on NiCd and to a lesser extent on NiMH batteries. The modern definition of memory refers to crystalline formation of the cell plates.

Negative delta V (NDV): The NDV is a drop in battery voltage after full charge is reached. During the initial charge state the NiCd battery terminal voltage rises quickly, then levels off. After the 70% charge level, the voltage rises again, peaks at full charge and drops slightly.

Recondition: Secondary discharge, which drains the battery of its remaining energy, during which the crystalline formation (memory) is dissolved.

Self-discharge: Capacity loss due to internal leakage between the positive and negative cell plates.

Soft cell: A cell whose voltage rises well above the specifications during charging. This high voltage is caused by high cell impedance.

FIGURE 10.294 Randles model of a lead acid battery. The overall battery resistance consists of pure Ohmic resistance, inductance, and capacitance. There are many other models.

Trickle charge: Maintenance charge to keep the battery in full-charge state after the charge cycle. Trickle charge compensates for self-discharge.

Voltage-limiting charger: A charger that limits the voltage after a preset voltage table is reached but allows the current to drop while maintaining the voltage limit.

11.1 Printed Wiring Boards

Ravindranath Kollipara and Vijai K. Tripathi

11.1.1 Introduction

Printed wiring board (PWB) is, in general, a layered dielectric structure with internal and external wiring that allows electronic components to be mechanically supported and electrically connected internally to each other and to the outside circuits and systems. The components can be complex packaged very large-scale integrated (VLSI), RF, and other ICs with multiple I/Os or discrete surface mount active and passive components. PWBs are the most commonly used packaging medium for electronic circuits and systems. Electronic packaging has been defined as the design, fabrication, and testing process that transforms an electronic circuit into a manufactured assembly. The main functions of the packaging include signal

distribution to electronic circuits that process and store information, power distribution, heat dissipation, and the protection of the circuits.

The type of assembly required depends on the electronic circuits, which may be discrete, integrated, or hybrid. Integrated circuits are normally packaged in plastic or ceramic packages, which are electrically connected to the outside I/O connections and power supplies with pins that require plated through holes (PTH) or pins and pads meant for surface mounting the package by use of the surface mount technology (SMT). These plastic or ceramic packages are connected to the PWBs by using the pins or the leads associated with the packages.

In addition to providing a framework for interconnecting components and packages, such as IC packages, PWBs can also provide a medium (home) for component design and placement such as inductors and capacitors. PWBs are, generally, a composite of organic and inorganic dielectric material with multiple layers. The interconnects or the wires in these layers are connected by **via** holes, which can be plated and are filled with metal to provide the electrical connections between the layers. In addition to the ground planes, and power planes used to distribute bias voltages to the ICs and other discrete components, the signal lines are distributed among various layers to provide the interconnections in an optimum manner. The properties of importance that need to be minimized for a good design are the signal delay, distortion, and crosstalk noise induced primarily by the electromagnetic coupling between the signal lines. Coupling through substrate material and ground bounce and switching noise due to imperfect power/ground planes also leads to degradation in signal quality.

In this chapter, the basic properties and applications of PWBs are introduced. These include the physical properties, the wiring board design, and the electrical properties. The reader is referred to other sources for detailed discussion on these topics.

11.1.2 Board Types, Materials, and Fabrication

The PWBs can be divided into four types of boards: (1) rigid boards, (2) flexible and rigid-flex boards, (3) metal-core boards, and (4) injection molded boards. The board that is most widely used is the rigid board. The boards can be further classified into single-sided, double-sided, or multilayer boards. The ever increasing packaging density and faster propagation speeds, which stem from the demand for high-performance systems, have forced the evolution of the boards from single-sided to double-sided to multilayer boards. On single-sided boards, all of the interconnections are on one side. Double-sided boards have connections on both sides of the board and allow wires to crossover each other without the need for jumpers. This was accomplished at first by Z-wires, then by eyelets, and at present by PTHs. The increased pin count of the ICs has increased the routing requirements, which led to multilayer boards. The necessity of a controlled impedance for the high-speed **traces**, the need for bypass capacitors, and the need for low inductance values for the power and ground distribution networks have made the requirement of power and ground planes a must in high-performance boards. These planes are possible only in multilayer boards. In multilayer boards, the PTHs can be buried (providing interconnection between inner layers), semiburied (providing interconnection from one of the two outer layers to one of the internal layers), or through vias (providing interconnection between the outer two layers).

The properties that must be considered when choosing PWB substrate materials are their mechanical, electrical, chemical, and thermal properties. Early PWBs consisted of copper-clad phenolic and paper laminate materials. The copper was patterned using resists and etched. Holes were punched in the laminate to plug the component leads, and the leads were soldered to the printed copper pattern. At present, the copper-clad laminates and the prepregs are made with a variety of different matrix resin systems and reinforcements (ASM, 1989). The most commonly used resin systems are fire resistant (FR-4) difunctional and polyfunctional epoxies. Their glass transition temperatures T_g range from 125 to 150°C. They have well-understood processability, good performance, and low price. Other resins include high-temperature, one-component epoxy, polyimide, cyanate esters, and polytetrafluoroethylene (PTFE) (trade name Teflon). Polyimide resins have high T_g , long-term thermal resistance, low coefficient of thermal expansion (CTE), long PTH life and high reliability, and are primarily used for high-performance multilayer boards with a

large number of layers. Cyanate esters have low dielectric constants and high T_g , and are used in applications where increased signal speed and improved laminate-dimensional stability are needed. Teflon has the lowest dielectric constant, low dissipation factor, and excellent temperature stability but is difficult to process and has high cost. It is used mainly in high-performance applications where higher densities and transmission velocities are required.

The most commonly used reinforcement is continuous filament electrical (E-) glass. Other high-performance reinforcements include high strength (S-) glass, high modulus (D-) glass, and quartz (Seraphim et al., 1989). The chemical composition of these glasses determines the key properties of CTE and dielectric constant. As the level of silicon dioxide (SiO_2) in the glass increases, the CTE and the dielectric constant decrease. The substrates of most rigid boards are made from FR-4 epoxy resin-impregnated E-glass cloth. Rolls of glass cloth are coated with liquid resin (A-stage). Then the resin is partially cured to a semistable state (B-stage or prepreg). The rolls are cut into large sheets and several sheets are stacked to form the desired final thickness. If the laminates are to be copper clad, then copper foils form the outside of the stack. The stack is then laminated and cured irreversibly to form the final resin state (C-stage) (ASM, 1989).

The single-sided boards typically use phenolic or polyester resins with random mat glass or paper reinforcement. The double-sided boards are usually made of glass-reinforced epoxy. Most multilayer boards are also made of glass-reinforced epoxy. The internal circuits are made on single- or double-sided copper-clad laminates. The inner layers are stacked up with B-stage polymer sheets separating the layers. Rigid pins are used to establish layer-to-layer orientation. The B-stage prepreg melts during lamination and reflows. When it is cured, it glues the entire package into a rigid assembly (ASM, 1989). An alternative approach to pin-parallel composite building is a sequential buildup of the layers, which allows buried vias. Glass reinforced polyimide is the next most used multilayer substrate material due to its excellent handling strength and its higher temperature cycling capability. Other laminate materials include Teflon and various resin combinations of epoxy, polyimide, and cyanate esters with reinforcements. The dielectric thickness of the flat laminated sheets ranges from 0.1 to 3.18 mm (0.004 to 0.125 in.), with 1.5 mm (0.059 in.) being the most commonly used for single- and double-sided boards. The inner layers of a multilayer board are thinner with a typical range of 0.13–0.75 mm (0.005–0.030 in.) (ASM, 1989). The number of layers could be 20 or more. The commonly used substrate board materials and their properties are listed in Table 11.1.

The most common conductive material used is copper. The substrate material can be purchased as copper-clad laminates or unclad laminates. The foil thickness of copper-clad laminates are normally expressed in ounces of copper per square foot. The available range is from 1/8 to 5 oz with 1-oz copper (0.036 mm or 0.0014 in.) being the most commonly used cladding. The process of removing copper in the unwanted regions from the copper-clad laminates is called subtractive technology. If copper or other metal is added on to the unclad laminates, the process is called additive technology. Other metals used during electroplating may include Sn, Pb, Ni, Au, and Pd. Selectively screened or stenciled pastes that contain silver or carbon are also used as conducting materials (ASM, 1989).

Solder masks are heat- and chemical-resistant organic coatings that are applied to the PWB surfaces to limit solderability to the PTHs and surface-mount pads, provide a thermal and electrical insulation layer isolating adjacent circuitry and components, and protect the circuitry from mechanical and handling damage, dust, moisture, and other contaminants. The coating materials used are thermally cured epoxies or ultraviolet curable acrylates. Pigments or dyes are added for color. Green is the standard color. Fillers and additives are added to modify rheology and improve adhesion (ASM, 1989).

Flexible and rigid-flex boards are required in some applications. A flexible printed board has a random arrangement of printed conductors on a flexible insulating base with or without cover layers (ASM, 1989). Like the base material, conductor, adhesive, and cover layer materials also should be flexible. The boards can be single-sided, double-sided, or multilayered. However, multilayered boards tend to be too rigid and are prone to conductor damage. Rigid-flex boards are like multilayered boards with bonding and connections between layers confined to restricted areas of the wiring plane. Connections between the rigid laminated areas are provided by multiconductor layers sandwiched between thin base layers and are flexible. The metal claddings are made of copper foil, beryllium copper, aluminium, inconel, or conductive polymer thick films with copper foil being the most commonly used. Typical adhesives systems used include polyester, epoxy/modified epoxy, acrylic, phenolics, polyimide, and fluorocarbons. Laminates, which eliminate the use of adhesives by placing conductors directly on the insulator, are called adhesiveless laminates. Dielectric base materials include polyimide films, polyester films, aramids, reinforced composites, and fluorocarbons. The manufacturing steps are similar to those of the rigid boards. As insulating film or coating applied over the conductor side acts as a permanent protective cover. It protects the conductors from moisture, contamination, and damage and reduces stress on conductors during flexing. Pad access holes and registration holes are drilled or punched in an insulating film coated with an adhesive, and the film is aligned over the conductor pattern and laminated under heat and pressure. Often, the same base material is used as the insulating film. When coatings are used instead of films, they are screen printed onto the circuit, leaving pad areas exposed. The materials used are acrylated epoxy, acrylated polyurethane, and thiolenes, which are liquid polymers and are cured using ultraviolet (UV) radiation or infrared (IR) heating to form a permanent, thin, tough coating (ASM, 1989).

When selecting a board material, the thermal expansion properties of the material must be a consideration. If the components and the board do not have a closely matched CTE, then the electrical and/or mechanical connections may be broken and reliability of the board will suffer. The widely used epoxy-glass PWB material has a CTE that is larger than that of the encapsulating material (plastic or ceramic) of the components. When leaded devices in dual-in-line (DIP) package format are used, the mechanical forces generated by the mismatches in the CTEs are taken by the PTHs, which accommodate the leads and provide electrical and mechanical connection. When surface mount devices (SMDs) are packaged, the solder joint, which provides both the mechanical and electrical connection, can accommodate little stress without deformation. In such cases, the degree of component and board CTE mismatch and the thermal environment in which the board operates must be considered and if necessary, the board must be CTE tailored for the components to be packaged. The three typical approaches to CTE tailoring are constraining dielectric structures, constraining metal cores, and constraining low-CTE metal planes (ASM, 1989; Seraphim et al., 1989).

Constraining inorganic dielectric material systems include cofired ceramic printed boards and thick-film ceramic wiring boards. Cofired ceramic multilayer board technology uses multiple layers of green ceramic tape into which via holes are made and on which circuit metallization is printed. The multiple layers are aligned and fired at high temperatures to yield a much higher interconnection density capability and much better controlled electrical properties. The ceramic used contains more than 90% of alumina and has a much higher thermal conductivity than that of epoxy-glass making heat transfer efficient. The thick-film ceramic wiring boards are usually made of cofired alumina and are typically bonded to an aluminium thermal plane with a flexible thermally conducting adhesive when heat removal is required. Both organic and inorganic fiber-reinforcements can be used with the conventional PWB resin for CTE tailoring. The organic fibers include several types of aramid fibers, notably Kevlar 29 and 49 and Technora HM-50. The inorganic fiber most commonly used for CTE tailoring is quartz (ASM, 1989).

In the constraining metal core technology, the PWB material can be any one of the standard materials like epoxy-glass, polyimide-glass, or Teflon-based materials. The constraining core materials include metals, composite metals, and low-CTE fiber-resin combinations, which have a low-CTE material with sufficient strength to constrain the module. The two most commonly used constraining core materials are copper-invar-copper (CIC) and copper-molybdenum-copper (CMC). The PWB and the core are bonded with a rigid adhesive. In the constraining low-CTE metal plane technology, the ground and power planes in a standard multilayer board are replaced by an approximately 0.15-mm-thick CIC layers. Both epoxy and polyimide laminates have been used (ASM, 1989).

Molded boards are made with resins containing fillers to improve thermal and mechanical properties. The resins are molded into a die or cavity to form the desired shape, including three-dimensional features. The board is metalized using conventional seeding and plating techniques. Alternatively, three-dimensional prefabricated films can also be transfer molded and further processed to form structures with finer dimensions. With proper selection of filler materials and epoxy compounds or by molding metal cores, the molded boards can be CTE tailored with enhanced thermal dissipation properties (Seraphim et al., 1989).

The standard PWB manufacturing primarily involves five technologies (ASM, 1989).

1. **Machining.** This involves drilling, punching, and routing. The drill holes are required for PTHs. The smaller diameter holes cost more and the larger aspect ratios (board thickness-to-hole diameter ratios) resulting from small holes make plating difficult and less reliable. They should be limited to thinner boards or buried vias. The locational accuracy is also important, especially because of the smaller features (pad size or annular ring), which are less tolerant to misregistration. The registration is also complicated by substrate dimensional changes due to temperature and humidity fluctuations, and material relaxation and shifting during manufacturing operations. The newer technologies for drilling are laser and water-jet cutting. CO₂ laser radiation is absorbed by both glass and epoxy and can be used for cutting. The typical range of minimum hole diameters, maximum aspect ratios, and locational accuracies are given in Table 11.2.
2. **Imaging.** In this step the artwork pattern is transferred to the individual layers. Screen printing technology was used early on for creating patterns for print-and-etch circuits. It is still being used for simpler single- and double-sided boards because of its low capital investment requirements and high volume capability with low material costs. The limiting factors are the minimum line width and spacings that can be achieved with good yields. Multilayer boards and fine line circuits are processed using photoimaging. The photoimageable films are applied by flood screen printing, liquid roller coating, dip coating, spin coating, or roller laminating of dry films. Electrophoresis is also being used recently. Laminate dimensional instability contributes to the misregistration and should be controlled. Emerging photoimaging technologies are direct laser imaging and imaging by liquid crystal light valves. Again, Table 11.2 shows typical minimum trace widths and separations.
3. **Laminating.** It is used to make the multilayer boards and the base laminates that make up the single- and double-sided boards. Prepregs are sheets of glass cloth impregnated with B-stage epoxy resin and are used to bond multilayer boards. The types of pressing techniques used are hydraulic cold or hot press lamination with or without vacuum assist and vacuum autoclave nomination. With these

TABLE 11.2 Typical Limits of PWB Parameters

Parameter	Limit
Minimum trace width, mm	0.05–0.15
Minimum trace separation, mm	~0.25
Minimum PTH diameter, mm	0.2–0.85
Location accuracy of PTH, mm	0.015–0.05
Maximum aspect ratios	3.5–15.0
Maximum number of layers	20 or more
Maximum board thickness, mm	7.0 or more

techniques, especially with autoclave, layer thicknesses, and dielectric constants can be closely controlled. These features allow the fabrication of controlled-impedance multilayer boards of eight layers or more. The autoclave technique is also capable of laminating three-dimensional forms and is used to produce rigid-flex boards.

4. **Plating.** In this step, metal finishing is applied to the board to make the necessary electrical connections. Plating processes could be wet chemical processes (electroless or electrolytic plating) or dry plasma processes (sputtering and chemical vapor deposition). Electroless plating, which does not need an external current source, is the core of additive technology. It is used to metallize the resin and glass portions of a multilayer board's PTHs with high aspect ratios (>15:1) and the three-dimensional circuit paths of molded boards. On the other hand, electrolytic plating, which requires an external current source, is the method of choice for bulk metallization. The advantages of electrolytic plating over electroless plating include greater rate of plating, simpler and less expensive process, and the ability to deposit a broader variety of metals. The newer plasma processes can offer pure, uniform, thin foils of various metals with less than 1-mil line widths and spacings and have less environmental impacts.
5. **Etching.** It involves removal of metals and dielectrics and may include both wet and dry processes. Copper can be etched with cupric chloride or other isotropic etchants, which limit the practical feature sizes to more than two times the copper thickness. The uniformity of etching is also critical for fine line feature circuits. New anisotropic etching solutions are being developed to extend the fine line capability.

The typical range of minimum trace widths, trace separations, printed through hole diameters, and maximum aspect ratios are shown in [Table 11.2](#). The board cost for minimum widths, spacings, and PTH diameters, and small tolerances for the pad placements is high and reliability may be less.

11.1.3 Design of Printed Wiring Boards

The design of PWBs has become a challenging task, especially when designing high-performance and high-density boards. The designed board has to meet signal-integrity requirements (crosstalk, simultaneously switching output (SSO) noise, delay, and reflections), **electromagnetic compatibility (EMC)** requirements (meeting **electromagnetic interference (EMI)** specifications and meeting minimum **susceptibility** requirements), thermal requirements (being able to handle the mismatches in the CTEs of various components over the temperature range, power dissipation, and heat flow), mechanical requirements (strength, rigidity/flexibility), material requirements, manufacturing requirements (ease of manufacturability, which may affect cost and reliability), testing requirements (ease of testability, incorporation of **test coupons**), and environmental requirements (humidity, dust). When designing the circuit, the circuit design engineer may not have been concerned with all of these requirements when verifying his circuit design by simulation. But the PWB designer, in addition to wiring the board, must ensure that these requirements are met so that the assembled board functions to specification. Computer-aided design (CAD) tools are indispensable for the design of all but simple PWBs.

The PWB design process is part of an overall system design process. As an example, for a digital system design, the sequence of events may roughly follow the order shown in [Fig. 11.1](#) (ASM, 1989; Byers, 1991). The logic design and verification are performed by a circuit designer. The circuit designer and the signal-integrity and EMC experts should help the board designer in choosing proper parts, layout, and electrical rule development. This will reduce the number of times the printed circuit has to be reworked and speeds up the product's time to market. The **netlist** generation is important for both circuit simulation and PWB design programs. The netlist contains the nets (a complete set of physical interconnectivity of the various parts in the circuit) and the circuit devices. Netlist files are usually divided into the component listings and the pin listings.

Once the circuit is successfully simulated by the circuit designer, the PWB designer starts on the board design. The board designer should consult with the circuit designer to determine critical path circuits, line-length requirements, power and fusing requirements, bypassing schemes, and any required guards

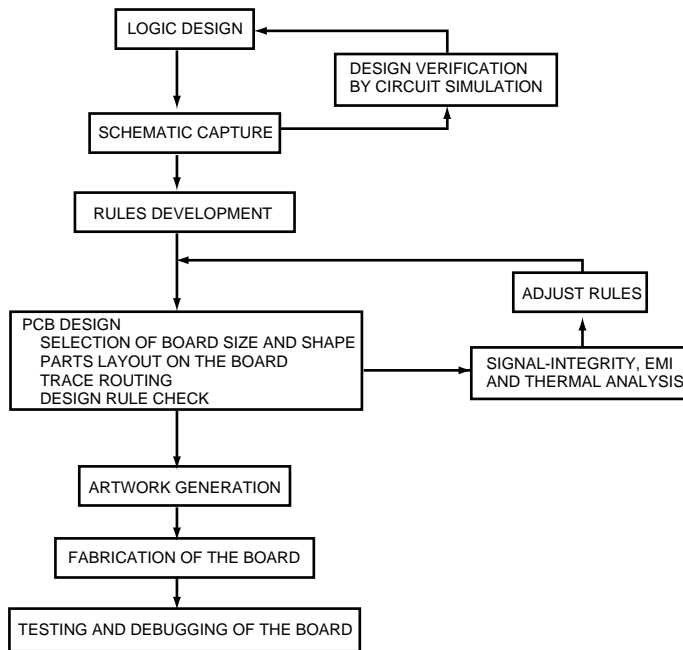

FIGURE 11.1 Overall design flow.

or shielding. First the size and shape of the board are chosen from the package count and the number of connectors and switches in the design netlist. Some designs may require a rigidly defined shape, size and defined connector placement, for example, PWB outlines for computer use. This may compromise the optimum layout of the circuit (Byers, 1991).

Next the netlist parts are chosen from the component library and placed on the board so that the interconnections form the simplest pattern. If a particular part is not available in the library, then it can be created by the PCB program's library editor or purchased separately. Packages containing multiple gates are given their gate assignments with an eye toward a simpler layout. There are software packages that automate and speed up the component placement process. However, they may not achieve complete component placement. Problems with signal path length and clock skewing may be encountered, and so part of the placement may have to be completed manually. Placement can also be done interactively (Byers, 1991).

Once the size and shape of the board is decided on, any areas on the board that cannot be used for parts are defined using fill areas that prevent parts placement within their perimeter. The proper parts placement should result in a cost-effective design and meet manufacturing standards. Critical lines may not allow vias in which case they must be routed only on the surface. Feedback loops must be kept short and equal line length requirements and shielding requirements, if any, should be met. Layout could be on a grid with components oriented in one direction to increase assembly speed, eliminate errors, and improve inspection. Devices should be placed parallel to the edges of the board (ASM, 1989; Byers, 1991).

The actual placement of a component may rely on the placement of a part before it. Usually, the connectors, user accessible switches and controls, and displays may have rigidly defined locations. Thus, these should be placed first. Next I/O interface chips, which are typically next to the connectors, are placed. Sometimes a particular group of components may be placed as a block in one area, for example, memory chips. Then the automatic placement program may be used to place the remaining components. The algorithms can be based on various criteria. Routability, the relative ease with which all of the traces can be completed, may be one criterion. Overall total connection length may also be used to find an optimal layout. Algorithms based on the requirements for distances, density, and number of crossings can be formulated to help with the layout. After the initial placement, a placement improvement program can

be run that fine tunes the board layout by component swapping, logic gate swapping, or when allowed even pin swapping. Parts can also be edited manually. Some programs support block editing, macros and changing of package outlines. The PWB designer may check with the circuit design engineer after a good initial layout is completed to make sure that all of the requirements are met when the board is routed (Byers, 1991).

The last step in the PWB layout process is the placement of the interconnection traces. Most PCB programs have an autorouter software that does most, if not all, of the trace routing. The software uses the wire list netlist and the placement of the parts on the board from the previous step as inputs and decides which trace should go where based on an algorithm. Most routers are point-to-point routers. The most widely used autorouter algorithm is the Lee algorithm. The Lee router works based on the cost functions that change its routing parameters. Cost functions may be associated with direction of traces (to force all of the tracks on a particular layer of the board vertically, the cost of the horizontal tracks can be set high), maximum trace length, maximum number of vias, trace density, or other criteria. In this respect, Lee's algorithm is quite versatile. Lee routers have a high trace completion rate (typically 90% or better) but are slow. There are other autorouters that are faster than the Lee router but their completion rate may not be as high as the Lee router. These include Hightower router, pattern router, channel router, and gridless router (ASM, 1989; Byers, 1991). In many cases, fast routers can be run first to get the bulk of the work done in a short time and then the Lee router can be run to finish routing the remaining traces.

The autorouters may not foresee that placing one trace may block the path of another. There are some routers called clean-up routers that can get the offending traces out of the way by rip-up or shove-aside. The rip-up router works by removing the offending trace, completing the blocked trace, and proceeding to find a new path for the removed trace. The rip-up router may require user help in identifying the trace that is to be removed. Shove-aside routers work by moving traces when an uncompleted trace has a path to its destination but does not have enough room for the track. Manual routing and editing may be needed if the automatic trace routing is not 100% complete. Traces may be modified without deleting them (pushing and shoving, placing or deleting vias, or moving segments from one layer to another) and trace widths may be adjusted to accommodate a connection. For example, a short portion of a trace width may be narrowed so that it may pass between the IC pads without shorting them and is called necking down (Byers, 1991).

Once the parts layout and trace pattern are found to be optimal, the board's integrity is verified by subjecting the trace pattern to **design rule** check for digital systems. A CAD program checks to see that the tracks, vias, and pads have been placed according to the design rule set. The program also makes sure that all of the nodes in each net are connected and that there are no shorted or broken traces (Byers, 1991). Any extra pins are also listed. The final placement is checked for signal-integrity, EMI compliance, and thermal performance. If any problems arises, the rules are adjusted and the board layout and/or trace routing are modified to correct the problems.

Next a netlist file of the PWB artwork is generated, which contains the trace patterns of each board layer. All of the layers are aligned using placement holes or datum drawn on each layer. The artwork files are sent to a format photoplotter and photographic transparencies suitable for PWB manufacturing are produced. From the completed PWB design, solder masks, which apply an epoxy film on the PWB prior to flow soldering to prevent solder bridges from forming between adjacent traces, are also generated. Silkscreen mats could also be produced for board nomenclature. The PWB programs may also support drill file formats that numerically control robotic drilling machines used to locate and drill properly sized holes in the PWB (Byers, 1991).

Finally, the board is manufactured and tested. Then the board is ready for assembly and soldering. Finished boards are tested for system functionality and specifications.

11.1.4 PWB Interconnection Models

The principal electrical properties of the PWB material are relative dielectric constant, loss tangent, and dielectric strength. When designing high-speed and high-performance boards, the wave propagation along the traces should be well controlled. This is done by incorporating power and signal planes in the

FIGURE 11.2 PWB interconnect examples.

boards, and utilizing various transmission line structures with well-defined properties. The electrical analog and digital signals are transferred by all of the PWB interconnects and the fidelity of these connections is dependent on the electrical properties of interconnects, as well as the types of circuits and signals. The interconnects can be characterized as electrically short and modeled as lumped elements in circuit simulators if the signal wavelength is large as compared to the interconnect length ($\lambda > 30 * l$). For digital signals the corresponding criterion can be expressed in terms of signal rise time being large as compared to the propagation delay (e.g., $T_r > 10 T_d$). Propagation delay represents the time taken by the signal to travel from one end of the interconnect to the other end and is obviously equal to the interconnect length divided by the signal velocity, which in most cases corresponds to the velocity of light in the dielectric medium. Vias, bond wires, pads, short wires and traces, and bends in PWBs shown in Fig. 11.2 can be modeled as lumped elements, whereas, long traces must be modeled as distributed circuits or transmission lines.

The transmission lines are characterized by their characteristic impedances and propagation constants, which can also be expressed in terms of the associated distributed parameters $R, L, G,$ and C per unit length of the lines (Magnuson, Alexander, and Tripathi, 1992). In general, the characteristic parameters are expressed as

$$\gamma \equiv \alpha + j\beta = \sqrt{(R + j\omega L)(G + j\omega C)}$$

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}}$$

FIGURE 11.3 Signal degradation due to losses and dispersion as it travels along an interconnect.

Propagation constant $\gamma = \alpha + j\beta$ characterizes the amplitude and phase variation associated with an AC signal at a given frequency or the amplitude variation and signal delay associated with a digital signal. The characteristic impedance is the ratio of voltage to current associated with a wave and is equal to the impedance the lines must be terminated in for zero reflection. The signal amplitude, in general, decreases and it lags behind in phase as it travels along the interconnect with a velocity, in general, equal to the group velocity. For example, the voltage associated with a wave at a given frequency can be expressed as

$$V = V_0 e^{-\alpha z} \cos(\omega t - \beta z)$$

where V_0 is the amplitude at the input ($z = 0$) and z is the distance.

For low loss and lossless lines the signal velocity and characteristic impedance can be expressed as

$$v = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{\mu_0 \epsilon_0 \epsilon_{r\text{eff}}}}$$

$$Z_0 = \sqrt{\frac{L}{C}} = \frac{\sqrt{\mu_0 \epsilon_0 \epsilon_{r\text{eff}}}}{C}$$

The effective dielectric constant $\epsilon_{r\text{eff}}$ is an important parameter used to represent the overall effect of the presence of different dielectric mediums surrounding the interconnect traces. For most traces $\epsilon_{r\text{eff}}$ is either equal to or approximately equal to the ϵ_r , the relative dielectric constant of the board material, except for the traces on the top layer where $\epsilon_{r\text{eff}}$ is a little more than the average of the two media.

The line losses are expressed in terms of the series resistance and shunt conductance per unit length (R and G) due to conductor and dielectric loss, respectively. The signals can be distorted or degraded due to these conductor and dielectric losses, as illustrated in Fig. 11.3 for a typical interconnect. The resistance is, in general, frequency dependent since the current distribution across the conductors is nonuniform and depends on frequency due to the skin effect. Because of this exclusion of current and flux from the inside of the conductors, resistance increases and inductance decreases with increasing frequency. In the high-frequency limit, the resistance and inductances can be estimated by assuming that the current is confined over the cross section one skin depth from the conductor surface. The skin depth is a measure of how far the fields and currents penetrate into a conductor and is given by

$$\delta = \sqrt{\frac{2}{\omega \mu \sigma}}$$

The conductor losses can be found by evaluating R per unit length and using the expression for γ or by using an incremental inductance rule, which leads to

$$\alpha_c = \frac{\beta \Delta Z_0}{2Z_0}$$

where α_c is the attenuation constant due to conductor loss, Z_0 is the characteristic impedance, and ΔZ_0 is the change in characteristic impedance when all of the conductor walls are recessed by an amount $\delta/2$. This expression can be readily implemented with the expression for Z_0 . The substrate loss is accounted

for by assigning the medium a conductivity σ , which is equal to $\omega\epsilon_0\epsilon_r''$. For many conductors buried in near homogeneous medium

$$G = C \frac{\sigma}{\epsilon}$$

If the lines are not terminated in their characteristic impedances, there are reflections from the terminations. These can be expressed in terms of the ratio of reflected voltage or current to the incident voltage or current and are given as

$$\frac{V_{\text{reflected}}}{V_{\text{incident}}} = - \frac{I_{\text{reflected}}}{I_{\text{incident}}} = \frac{Z_R - Z_0}{Z_R + Z_0}$$

where Z_R is the termination impedance and Z_0 is the characteristic impedance of the line. For a perfect match, the lines must be terminated in their characteristic impedances. If the signal is reflected, the signal received by the receiver is different from that sent by the driver. That is, the effect of mismatch includes signal distortion, as illustrated in Fig. 11.4, as well as ringing and increase in crosstalk due to multiple reflections resulting in an increase in coupling of the signal to the passive lines.

The electromagnetic coupling between the interconnects is the factor that sets the upper limit to the number of tracks per channel or, in general, the interconnect density. The time-varying voltages and currents result in capacitive and inductive coupling between the interconnects. For longer interconnects, this coupling is distributed and modeled in terms of distributed self- and mutual line constants of the multiconductor transmission line systems. In general, this coupling results in both the near- and far-end crosstalk as illustrated in Fig. 11.5 for two coupled microstrips. Crosstalk increases noise margins and degrades signal quality. Crosstalk increases with longer trace coupling distances, smaller separation between traces, shorter pulse rise and fall times, larger magnitude currents or voltages being switched, and decreases with the use of adjacent power and ground planes or with power and ground traces interlaced between signal traces on the same layer.

The commonly used PWB transmission line structures are microstrip, embedded microstrip, stripline, and dual stripline, whose cross sections are shown in Fig. 11.6. The empirical CAD oriented expressions for transmission line parameters, and the models for wires, ribbons, and vias are given in Table 11.3.

The traces on the outside layers (microstrips) offer faster clock and logic signal speeds than the stripline traces. Hooking up components is also easier in microstrip structure than in stripline structure. Stripline offers better noise immunity for RF emissions than microstrip. The minimum spacing between the signal traces may be dictated by maximum crosstalk allowed rather than by process constraints. Stripline allows closer spacing of traces than microstrip for the same layer thickness. Lower characteristic impedance structures have smaller spacing between signal and ground planes. This makes the boards thinner allowing drilling of smaller diameter holes, which in turn allow higher circuit densities. Trace width and individual layer thickness tolerances of $\pm 10\%$ are common. Tight tolerances ($\pm 2\%$) can be specified, which would

FIGURE 11.4 Voltage waveform is different when lines are not terminated in their characteristic impedance.

FIGURE 11.5 Example of near-end and far-end crosstalk signal.

result in higher board cost. Typical impedance tolerances are $\pm 10\%$. New statistical techniques have been developed for designing the line structures of high-speed wiring boards (Mikazuki and Matsui, 1994).

The low dielectric constant materials improve the density of circuit interconnections in cases where the density is limited by crosstalk considerations rather than by process constraints. Benzocyclobutene is one of the low dielectric constant polymers with excellent electrical, thermal, and adhesion properties.

In addition, water absorption is lower by a factor of 15 compared to conventional polyimides. Teflon also has low dielectric constant and loss, which are stable over wide ranges of temperature, humidity, and frequency (ASM, 1989; Evans, 1994).

In surface mount technology, the components are soldered directly to the surface of a PWB, as opposed to through-hole mounting. This allows efficient use of board real estate, resulting in smaller boards and simpler assembly. Significant improvement in electrical performance is possible with the reduced package parasitics and the short interconnections. However, the reliability of the solder joint is a concern if there are CTE mismatches (Seraphim et al., 1989).

In addition to establishing an impedance-reference system for signal lines, the power and ground planes establish stable voltage levels for the circuits (Montrose, 1995). When large currents are switched, large voltage drops can be developed between the power supply and the components. The planes minimize the voltage drops by providing a very small resistance path and by supplying a larger capacitance and lower inductance contribution when two planes are closely spaced. Large decoupling capacitors are also added between the power and ground planes for increased voltage stability. High-performance and high-density

boards require accurate computer simulations to determine the total electrical response of the components and complex PWB structures involving various transmission lines, vias, bends, and planes with vias.

11.1.5 Signal-Integrity and EMC Considerations

The term signal-integrity refers to the issues of timing and quality of the signal. The timing analysis is performed to ensure that the signal arrives at the destination within the specified time window. In addition, the signal shape should be such that it causes correct switching and avoids false switching or multicrossing of the threshold. The board features that influence the signal-integrity issues of timing and quality of signal are stub length, parallelism, vias, bends, planes, and termination impedances. Increasing clock speeds and signal edge rates make the signal-integrity analysis a must for the design of high speed PWBs. The signal-integrity tools detect and help correct problems associated with timing, crosstalk, ground bounce, dispersion, resonance, ringing, clock skew, and susceptibility (Maliniak, 1995). Some CAD tool vendors offer stand-alone tools that interface with simulation and layout tools. Other vendors integrate signal-integrity capabilities into the PWB design flow. Both prelayout and postlayout tools are available. Prelayout tools incorporate signal-integrity design rules up front and are used before physical design to investigate tradeoffs. Postlayout tools are used after board layout and provide a more in-depth analysis of the board.

The selection of the signal-integrity tools depends on the accuracy required and on the run times, in addition to the cost. Tools employing full-wave approach solve the Maxwell's field equations and provide accurate results. However, the run times are longer because they are computation intensive. Accurate modeling of radiation losses and complex three-dimensional structures including vias, bends, and tees can only be performed by full-wave analysis. Tools employing a hybrid approach are less accurate but run times are short. If the trace dimensions are smaller (roughly by a factor of 10) compared to the free space wavelength of the fields, then quasistatic methods can be used to compute the distributed circuit quantities like self- and mutual inductances and capacitances. These are then used in a circuit simulator like SPICE (*s* imulated *p* rogram for *i* ntegrated *c* ircuit *e* mphasis) to compute the time-domain response, from which signal delay and distortion are extracted (Maliniak, 1995).

The inputs for the signal-integrity tools are the device SPICE or behavioral models and the layout information including the thickness of the wires, the metal used, and the dielectric constant of the board. The input/output buffer information specification (IBIS) is a standard used to describe the analog behavior of a digital IC's I/O buffers. The IBIS models provide a nonproprietary description of board drivers and receivers that are accurate and faster to simulate. The models are based on DCI-V curves, AC transition data, and package parasitic and connection information. A SPICE-to-IBIS translation program is also available, which uses existing SPICE models to perform simulation tests and generate accurate IBIS models. An IBIS on-line repository, which maintains the IBIS models from some IC vendors, is also available. Other IC vendors provide the IBIS models under nondisclosure agreements.

The PWBs, when installed in their systems, should meet the North American and international EMC compliance requirements. EMC addresses both emissions, causing EMI and susceptibility, vulnerability to EMI. The designer needs to know the manner in which electromagnetic fields transfer from the circuit boards to the chassis and/or case structure. Many different layout design methodologies exist for EMC (Montrose, 1995). To model EMC, the full electromagnetic behavior of components and interconnects, not simple circuit models, must be considered. A simple EMC model has three elements: (1) a source of energy, (2) a receptor, and (3) a coupling path between the source and receptor. All three elements must be present for interference to exist. The emissions could be coupled by either radiation or by conduction. Emissions are **suppressed** by reducing noise source level and reducing propagation efficiency. Immunity is enhanced by increasing susceptor noise margin or reducing propagation efficiency. In general, the higher the frequency, the greater is the likelihood of a radiated coupling path and the lower the frequency, the greater is the likelihood of a conducted coupling path. The five major considerations in EMI analysis are frequency, amplitude, time, impedance, and dimensions (Montrose, 1995).

The use of power and ground planes embedded in the PWB with proper use of stripline and microstrip topology is one of the important methods of suppression of the RF energy internal to the board. Radiation may still occur from bond wires, lead frames, sockets, and interconnect cables. Minimizing lead inductance of PWB components reduces radiated emissions. Minimizing trace lengths of high-speed traces reduces radiation. On single- or double-sided boards, the power and ground traces should be adjacent to each other to minimize loop currents, and signal paths should parallel the power and ground traces. In multilayer boards, signal routing planes should be adjacent to solid image planes. If logic devices in multilayer boards have asymmetrical pull-up and pull-down current ratios, then an imbalance is created in the power and ground plane structure. The flux cancellation between RF currents that exist within the board traces, components, and circuits, in relation to a plane is not optimum when pull-up and pull-down current ratios are different and traces are routed adjacent to a power plane. In such cases, high-speed signal and clock traces should be routed adjacent to a ground plane for optimal EMI suppression (Montrose, 1995).

To minimize fringing between the power and ground planes and the resulting RF emissions, power planes should be physically smaller than the closest ground planes. Typical reduction size is 20 times the thickness between the power and the ground plane on each side. Any signal traces on the adjacent routing plane located over the absence of copper area must be rerouted. Selecting proper type of grounding is also critical for EMI suppression. The distance between any two neighboring ground point locations should not exceed 1/20 of the highest frequency wavelength generated on the board in order to minimize RF ground loops. Moats are acceptable in an image plane only if the adjacent signal routing layer does not have traces that cross the moated area. Partition the board into high-bandwidth, medium-bandwidth, and low-bandwidth areas, and isolate each section using partitions or moats. The peak power currents generated when logic gates switch states may inject high-frequency switching noise into the power planes. Fast edge rates generate greater amount of spectral bandwidth of RF energy. The slowest possible logic family that meets adequate timing margins should be selected to minimize EMI effects (Montrose, 1995).

Surface mount devices have lower lead inductance values and smaller loop areas due to smaller package size as compared to through hole mounted ones and, hence, have lower RF emissions. Decoupling capacitors remove RF energy generated on the power planes by high-frequency components and provide a localized source of DC power when simultaneous switching of output pins occur. Bypassing capacitors remove unwanted RF noise that couples component or cable common-mode EMI into susceptible areas. Proper values and proper placement on the board of decoupling and bypassing capacitors prevent RF energy transfer from one circuit to another and enhance EMC. The capacitance between the power and ground planes also acts as a decoupling capacitor (Montrose, 1995).

Clock circuits may generate significant EMI and should be designed with special attention. A localized ground plane and a shield may be required over the clock generation circuits. Clock traces should be considered critical and routed manually with characteristic terminations. Clock traces should be treated as transmission lines with good impedance control and with no vias or minimum number of vias in the traces to reduce reflections and ringing, and creation of RF common-mode currents. Ground traces should be placed around each clock trace if the board is single or double sided. This minimizes crosstalk and provides a return path for RF current. Shunt ground traces may also be provided for additional RF suppression. Bends should be avoided, if possible, in high-speed signal and clock traces and, if present, bend angles should not be smaller than 90° and they must be chamfered. Analog and input/output sections should be isolated from the digital section. PWBs must be protected from electrostatic discharge (ESD) that might enter at I/O signal and electrical connection points. For additional design techniques and guidelines for EMC compliance and a listing of North American and international EMI requirements and specifications, refer to Montrose (1995).

Signal-integrity and EMC considerations should be an integral part of printed circuit board (PCB) design. Signal integrity, EMI problems, and thermal performance should be addressed early in the development cycle using proper CAD tools before physical prototypes are produced. When boards are designed taking these considerations into account, the signal quality and signal-to-noise ratio are improved. Whenever possible, EMC problems should be solved at the PCB level than at the system level. Proper layout of PWB ensures EMC compliance at the level of cables and interconnects.

Defining Terms

Design rules: A set of electrical or mechanical rules that must be followed to ensure the successful manufacturing and functioning of the board. These may include minimum track widths and track spacings, track width required to carry a given current, maximum length of clock lines, and maximum allowable distance of coupling between a pair of signal lines.

Electromagnetic compatibility (EMC): The ability of a product to coexist in its intended electromagnetic environment without causing or suffering functional degradation or damage.

Electromagnetic interference (EMI): A process by which disruptive electromagnetic energy is transmitted from one electronic device to another via radiated or conducted paths or both.

Netlist: A file of component connections generated from a schematic. The file lists net names and the pins, which are a part of each net in the design.

Schematic: A drawing or set of drawings that shows an electrical circuit design.

Suppression: Designing a product to reduce or eliminate RF energy at the source without relying on a secondary method such as a metal housing.

Susceptibility: A relative measure of a device or system's propensity to be disrupted or damaged by EMI exposure.

Test coupon: Small pieces of board carrying a special pattern, made alongside a required board, which can be used for destructive testing.

Trace: A node-to-node connection, which consists of one or more tracks. A track is a metal line on the PWB. It has a start point, an end point, a width, and a layer.

Via: A hole through one or more layers on a PWB that does not have a component lead through it. It is used to make a connection from a track on one layer to a track on another layer.

11.2 Hybrid Microelectronics Technology

Jerry E. Sergent

11.2.1 Introduction

Hybrid microelectronics technology is one branch of the electronics packaging discipline. As the name implies, the hybrid technology is an integration of two or more technologies, utilizing a film-deposition process to fabricate conductor, resistor, and dielectric patterns on a ceramic substrate for the purpose of mounting and interconnecting semiconductors and other devices as necessary to form an electronics circuit.

The method of deposition is what differentiates the hybrid circuit from other packaging technologies and may be one of two types: *thick film* or *thin film*. Other methods of metallizing a ceramic substrate, such as direct bond copper, active metal brazing, and plated copper, may also be considered to be in the hybrid family, but do not have a means for directly fabricating resistors and are not considered here. Semiconductor technology provides the **active components**, such as integrated circuits, transistors, and diodes. The **passive components**, such as resistors, capacitors, and inductors, may also be fabricated by thick- or thin-film methods or may be added as separate components.

The most common definition of a hybrid circuit is a circuit that contains two or more components, one of which must be active, which are mounted on a substrate that has been metallized by one of the film technologies. This definition is intended to eliminate single-chip packages, which contain only one active component, and also to eliminate such structures as resistor networks. A hybrid circuit may, therefore, be as simple as a diode-resistor network or as complicated as a multilayer circuit containing in excess of 100 integrated circuits.

The first so-called hybrid circuits were manufactured from polymer materials for use in radar sets in World War II and were little more than carbon-impregnated epoxies printed across printed circuit traces. The modern hybrid era began in the 1960s when the first commercial cermet thick-film materials became available. Originally developed as a means of reducing the size and weight of rocket payloads, hybrid circuits are now used in a variety of applications, including automotive, medical, telecommunication, and commercial, in addition to continued use in space and military applications. Today, the hybrid microelectronics industry is a multibillion dollar business and has spawned new technologies, such as the multichip module technology, which have extended the application of microelectronics into other areas.

11.2.2 Substrates for Hybrid Applications

The foundation for the hybrid microcircuit is the substrate, which provides the base on which the circuit is formed. The substrate is typically ceramic, a mixture of metal oxides and/or nitrides and glasses that are formulated to melt at a high temperature. The constituents are formed into powders, mixed with an organic binder, patterned into the desired shape, and fired at an elevated temperature. The result is a hard, brittle composition, usually in the configuration of a flat plate, suitable for metallization by one of the film processes. The ceramics used for hybrid applications must have certain mechanical, chemical, and electrical characteristics as described in [Table 11.4](#).

The most common material is 96% alumina (Al_2O_3), with a typical composition of 96% Al_2O_3 , 0.8% MgO, and 3.2% SiO_2 . The magnesia and silica form a magnesium-alumino-silicate glass with the alumina

TABLE 11.4 Desirable Properties of Substrates for Hybrid Applications

• Electrical insulator
• Chemically and mechanically stable at processing temperatures
• Good thermal dissipation characteristics
• Low dielectric constant, especially at high frequencies
• Capable of being manufactured in large sizes and maintain good dimensional stability throughout processing
• Low cost
• Chemically inert to postfiring fabrication steps
• Chemically and physically reproducible to a high degree

when the substrate is manufactured at a firing temperature of 1600°C. The characteristics of alumina are presented in [Table 11.5](#).

Other materials used in hybrid applications are described as follows:

- *Beryllium oxide, BeO, (Beryllia)*. Beryllia has excellent thermal properties (almost 10 times better than alumina at 250°C), and also has a lower **dielectric constant** (6.5).
- *Steatite*. Steatite has a lower concentration of alumina and is used primarily for low-cost thick-film applications.
- *Glass*. Borosilicate or quartz glass can be used where light transmission is required (e.g., displays). Because of the low melting point of these glasses, their use is restricted to the thin-film process and some low-temperature thick-film materials.
- *Enamel steel*. This is a glass or porcelain coating on a steel core. It has been in commercial development for some time and has found some limited acceptance in thick-film applications.
- *Silicon carbide, SiC*. SiC has a higher **thermal conductivity** than beryllia, but also has a high dielectric constant (40), which renders it unsuitable for high-speed applications.
- *Silicon*. Silicon has a very high thermal conductivity and matches the thermal expansion of semiconductors perfectly. Silicon is commonly used in thin-film applications because of the smooth surface.
- *Aluminum nitride (AlN)*. AlN substrates have a thermal conductivity less than that of beryllia, but greater than alumina. At higher temperatures, however, the gap between the thermal conductivities

TABLE 11.5 Typical Properties of Alumina

Property	96% Alumina	99% Alumina
<i>Electrical Properties</i>		
Resistivity	10 ¹⁴ Ω-cm	10 ¹⁶ Ω-cm
Dielectric constant	9.0 at 1 MHz, 25°C	9.2 at 1 MHz, 25°C

of AlN and BeO narrows somewhat. In addition, the **temperature coefficient of expansion (TCE)** of aluminum nitride is close to that of silicon, which lowers the stress on the bond under conditions of temperature extremes. Certain of the copper technologies, such as plated copper or **direct-bonded copper (DBC)**, may be used as a conductor system if the AlN surface is properly prepared.

11.2.3 Thick-Film Materials and Processes

Thick-film technology is an additive process that utilizes screen printing methods to apply conductive, resistive, and insulating films, initially in the form of a viscous paste, onto a ceramic substrate in the desired pattern. The films are subsequently dried and fired at an elevated temperature to activate the adhesion mechanism to the substrate.

There are three basic types of thick-film materials:

- Cermet thick-film materials, a combination of glass ceramic and metal (hence the name cermet). Cermet films are designed to be fired in the range 850–1000°C.
- **Refractory** thick-film materials, typically tungsten, molybdenum, and titanium, which also may be alloyed with each other in various combinations. These materials are designed to be cofired with ceramic substrates at temperatures ranging up to 1600°C and are postplated with nickel and gold to allow component mounting and wire bonding.
- Polymer thick films, a mixture of polymer materials with conductor, resistor, or insulating particles. These materials cure at temperatures ranging from 85–300°C.

This chapter deals primarily with cermet thick-film materials, as these are most directly associated with the hybrid technology.

Thick-Film Materials

A cermet thick-film paste has four major ingredients: an active element, an adhesion element, an organic binder, and a solvent or thinner. The combination of the organic binder and thinner are often referred to as the vehicle, since it acts as the transport mechanism of the active and adhesion elements to the substrate. When these constituents are mixed together and milled for a period of time, the result is a thick, viscous mixture suitable for screen printing.

Active Element

The nature of the material that makes up the active element determines the electrical properties of the fired film. If the active material is a metal, the fired film will be a conductor; if it is a conductive metal oxide, it will be a resistor; and, if it is an insulator, it will be a dielectric. The active metal is in powder form ranging from 1 to 10 μm , with a mean diameter of about 5 μm .

Adhesion Element

The adhesion element provides the adhesion mechanism of the film to the substrate. There are two primary constituents used to bond the film to the substrate. One adhesion element is a glass, or frit, with a relatively low melting point. The glass melts during firing, reacts with the glass in the substrate, and flows into the irregularities on the substrate surface to provide the adhesion. In addition, the glass flows around the active material particles, holding them in contact with each other to promote sintering and to provide a series of three-dimensional continuous paths from one end of the film to the other.

A second class of conductor materials utilizes metal oxides to provide the adhesion. In this case, a pure metal is placed in the paste and reacts with oxygen atoms on the surface of the substrate to form an oxide. The primary adhesion mechanism of the active particles is sintering, both to the oxide and to each other, which takes place during firing. Conductors of this type offer improved adhesion and have a pure metal surface for added bondability, solderability, and conductivity. Conductors of this type are referred to as fritless materials, oxide-bonded materials, or molecular-bonded materials.

A third class of conductor materials utilizes both reactive oxides and glasses. These materials, referred to as mixed-bonded systems, incorporate the advantages of both technologies and are the most frequently used conductor materials.

Organic Binder

The organic binder is a **thixotropic** or **pseudoplastic fluid** and serves two purposes: it acts as a vehicle to hold the active and adhesion elements in suspension until the film is fired, and it gives the paste the proper fluid characteristics for screen printing. The organic binder is usually referred to as the nonvolatile organic since it does not readily evaporate, but begins to burn off at about 350°C. The binder must oxidize cleanly during firing, with no residual carbon, which could contaminate the film. Typical materials used in this application are ethyl cellulose and various acrylics.

For nitrogen-fireable films, where the firing atmosphere can contain only a few ppm of oxygen, the organic vehicle must decompose and thermally depolymerize, departing as a highly volatile organic vapor in the nitrogen blanket provided as the firing atmosphere.

Solvent or Thinner

The organic binder in its usual form is too thick to permit screen printing, which necessitates the use of a solvent or thinner. The thinner is somewhat more volatile than the binder, evaporating rapidly above 70–100°C. Typical materials used for this application are terpineol, butyl carbitol, and certain of the complex alcohols into which the nonvolatile phase can dissolve.

The ingredients of the thick-film paste are mixed together in proper proportions and milled on a three-roll mill for a sufficient period of time to ensure that they are thoroughly mixed and that no agglomeration exists.

Thick-Film Conductor Materials

Most thick-film conductor materials are noble metals or combinations of noble metals, which are capable of withstanding the high processing temperatures in an oxidizing atmosphere. The exception is copper, which must be fired in a pure nitrogen atmosphere.

Thick-film conductors must perform a variety of functions:

- Provide a path for electrical conduction
- Provide a means for component attach
- Provide a means for terminating thick-film resistors

The selection of a conductor material depends on the technical, reliability, and cost requirements of a particular application. Figure 11.7 illustrates the process compatibility of the various types of conductors.

		PROCESS

FIGURE 11.7 Process compatibility of thick-film conductors.

Gold

Gold (Au) is used in applications where a high degree of reliability is required, such as military and space applications, and where eutectic die bonding is necessary. Gold is also used where gold ball bonding is required or desired. Gold has a strong tendency to form intermetallic compounds with other metals used in the electronic assembly process, especially tin (Sn) and aluminum (Al), and the characteristics of these alloys may be detrimental to reliability. Therefore, when used in conjunction with tin or aluminum, gold must frequently be alloyed with other noble metals, such as platinum (Pt) or palladium (Pd) to prevent AuSn or AuAl alloys from forming. It is common to use a PtAu alloy when PbSn solder is to be used, and to use a PdAu alloy when Al wire bonding is required to minimize intermetallic compound formation.

Silver

Silver (Ag) shares many of the properties of gold in that it alloys readily with tin and leaches rapidly into molten Sn/Pb solders in the pure state. Pure silver conductors must have special bonding materials in the adhesion mechanism or must be alloyed with Pd and/or Pt in order to be used with Sn/Pb solder. Silver is also susceptible to **migration** when moisture is present. Although most metals share this characteristic to a greater or lesser degree, Ag is highly susceptible due to its low ionization potential.

Alloys of Silver with Platinum and/or Palladium

Alloying Ag with Pd and/or Pt slows down both the leaching rate and the migration rate, making it practical to use these alloys for soldering. These are used in the vast majority of commercial applications, making them by far the most commonly used conductor materials. Until recently, silver-bearing materials have been rarely used in multilayer applications due to their tendency to react with and diffuse into dielectric materials, causing short circuits and weakened voltage handling capability. Advancements in these materials have improved this property. A disadvantage of Pd/Pt/Ag alloys is that the electrical resistance is significantly increased. In some cases, pure Ag is nickel (Ni) plated to increase leach resistance.

Copper

Originally developed as a low-cost substitute for gold, copper is now being selected when solderability, leach resistance, and low resistivity are required. These properties are particularly attractive for power hybrid circuits. The low resistivity allows the copper conductor traces to handle higher currents with a lower voltage drop, and the solderability allows power devices to be soldered directly to the metallization for better thermal transfer.

Thick-Film Resistor Material

Thick-film resistors are formed by adding metal oxide particles to glass particles and firing the mixture at a temperature/time combination sufficient to melt the glass and to sinter the oxide particles together. The resulting structure consists of a series of three-dimensional chains of metal oxide particles embedded in a glass matrix. The higher the metal oxide-to-glass ratio, the lower is the resistivity and vice versa.

Referring to Fig. 11.8, the electrical resistance of a material in the shape of a rectangular solid is given by the classic formula

FIGURE 11.8 Resistance of a rectangular solid.

$$R = \frac{\rho_B L}{WT} \quad (11.1)$$

where

- R = electrical resistance, Ω
- ρ_B = bulk resistivity of the material, ohms-length
- L = length of the sample in the appropriate units
- W = width of the sample in the appropriate units
- T = thickness of the sample in the appropriate units

A bulk property of a material is one that is independent of the dimensions of the sample. When the length and width of the sample are much greater than the thickness, a more convenient unit to use is the sheet resistance, which is equal to the bulk resistivity divided by the thickness,

$$\rho_s = \frac{\rho_B}{T} \quad (11.2)$$

where ρ_s is the sheet resistance in ohms/square/unit thickness.

The sheet resistance, unlike the bulk resistivity, is a function of the dimensions of the sample. Thus, a sample of a material with twice the thickness as another sample will have half the sheet resistivity, although the bulk resistivity is the same. In terms of the sheet resistivity, the electrical resistivity is given by

$$R = \frac{\rho_s L}{W} \quad (11.3)$$

If the length is equal to the width (the sample is a square), the electrical resistance is the same as the sheet resistivity independent of the actual dimensions of the sample. This is the basis of the units of sheet resistivity, ohms/square/unit thickness. For thick-film resistors, the standard adopted for unit thickness is 0.001 in. or 25 mm of *dried* thickness. The specific units for thick-film resistors are $\Omega/\square/0.001$ (read ohms per square per mil) of dried thickness. For convenience, the units are generally referred to as, simply, Ω/\square .

A group of thick-film materials with identical chemistries that are blendable is referred to as a *family* and will generally have a range of values from 10 Ω/\square to 1 $M\Omega/\square$ in decade values, although intermediate values are available as well. There are both high and low limits to the amount of material that may be added. As more and more material is added, a point is reached where there is not enough glass to maintain the structural integrity of the film. A practical lower limit of sheet resistivity of resistors formed in this manner is about 10 Ω/\square . Resistors with a sheet resistivity below this value must have a different chemistry and often are not blendable with the regular family of materials. At the other extreme, as less and less material is added, a point is reached where there are not enough particles to form continuous chains, and the sheet resistance rises very abruptly. Within most resistor families, the practical upper limit is about 2 $M\Omega/\square$. Resistor materials are available to about 20 $M\Omega/\square$, but the chemical composition of these materials is not amenable to blending with lower value resistors.

The active phase for resistor formulation is the most complex of all thick-film formulations due to the large number of electrical and performance characteristics required. The most common active material used in air-fireable resistor systems is ruthenium, which can appear as RuO_2 (ruthenium dioxide) or as BiRu_2O_7 (bismuth ruthenate).

Properties of Thick-Film Resistors

The conduction mechanisms in thick-film resistors are very complex and have not yet been well defined. Mechanisms with metallic, semiconductor, and insulator properties have all been identified. High ohmic value resistors tend to have more of the properties associated with semiconductors, whereas low ohmic values tend to have more of the properties associated with conductors:

- High ohmic value resistors tend to have a more negative *temperature coefficient of resistance* (TCR) than low ohmic value resistors. This is not always the case in commercially available systems due to the presence of TCR modifiers, but always holds true in pure metal oxide–glass systems.
- High ohmic value resistors exhibit substantially more current noise than low ohmic value resistors.

- High ohmic value resistors are more susceptible to high voltage pulses and static discharge than low ohmic value resistors. Some resistor families can be reduced in value by more than an order of magnitude when exposed to an *electrostatic discharge (ESD)* charge of only moderate value.

Temperature Coefficient of Resistance

All materials exhibit a change in resistance with material, either positive or negative, and many are nonlinear to a high degree. By definition, the TCR at a given temperature is the slope of the resistance-temperature curve at that temperature. The TCR of thick-film resistors is generally linearized over one or more intervals of temperature, typically in the range from -55 to $+125^{\circ}\text{C}$, as shown in Eq. (11.4) as

$$\text{TCR} = \frac{R(T_2) - R(T_1)}{R(T_1)(T_2 - T_1)} \times 10^6 \quad (11.4)$$

where

TCR = temperature coefficient of resistance, ppm/ $^{\circ}\text{C}$

$R(T_2)$ = resistance at temperature T_2

$R(T_1)$ = resistance at temperature T_1

T_1 = temperature at which $R(T_1)$ is measured, reference temperature

T_2 = temperature at which $R(T_2)$ is measured

A commercial resistor paste carefully balances the metallic, nonmetallic, and semiconducting fractions to obtain a TCR as close to zero as possible. This is not a simple task, and the hot TCR may be quite different from the cold TCR. Paste manufacturers give both the hot and cold values when describing a resistor paste. Although this does not fully define the curve, it is adequate for most design work.

It is important to note that the TCR of most materials is not linear, and the single point measurement is at best an approximation. The only completely accurate method of describing the temperature characteristics of a material is to examine the actual graph of temperature vs. resistance. The TCR for a material may be positive or negative. By convention, if the resistance increases with increasing temperature, the TCR is positive. Likewise, if the resistance decreases with increasing temperature, the TCR is negative.

Voltage Coefficient of Resistance (VCR)

The expression for the VCR is similar in form to the TCR and may be represented by Eq. (11.5) as

$$\text{VCR} = \frac{R(V_2) - R(V_1)}{R(V_1)(V_2 - V_1)} \quad (11.5)$$

where

$R(V_1)$ = resistance at V_1

$R(V_2)$ = resistance at V_2

V_1 = voltage at which $R(V_1)$ is measured

V_2 = voltage at which $R(V_2)$ is measured

Because of the semiconducting nature of resistor pastes, the VCR is always negative. As V_2 is increased, the resistance decreases. Also, because higher resistor decade values contain more glass and oxide constituents, and are more semiconducting, higher paste values tend to have more negative VCRs than lower values.

The VCR is also dependent on resistor length. The voltage effect on a resistor is a gradient; it is the volt/mil rather than the absolute voltage that causes resistor shift. Therefore, long resistors show less voltage shift than short resistors, for similar compositions and voltage stress.

Resistor Noise

Resistor noise is an effective method of measuring the quality of the resistor and its termination. On a practical level, noise is measured according to MIL-STD-202 on a Quatech Noise Meter. The resistor current noise is compared to the noise of a standard low noise resistor and reported as a **noise index** in decibel.

The noise index is expressed as microvolt/volt/frequency decade. The noise measured by MIL-STD-202 is $1/f$ noise, and the measurement assumes this is the only noise present. However, there is thermal or white noise present in all materials that is not frequency dependent and adds to the $1/f$ noise. Measurements are taken at low frequencies to minimize the effects of thermal noise. The noise index of low-value resistors is lower than high-value resistors because the low-value resistors have more metal and more free electrons. Noise also decreases with increasing resistor area (actually resistor volume).

High-Temperature Drift

The high-temperature drift characteristic of a resistor is an important material attribute, as it affects the long-term performance of the circuit. A standard test condition is 125°C for 1000 h at normal room humidity. A more aggressive test would be 150°C for 1000 h or 175°C for 40 h. A trimmed thick-film resistor is expected to remain within 1% of the original value after testing under these conditions.

Power Handling Capability

Drift due to high power is usually due to internal resistor heating. It is different from thermal aging in that the heat is generated at the point-to-point metal contacts within the resistor film. When a resistor is subjected to heat from an external source, the whole body is heated to the test temperature. Under power, local heating can result in a much higher temperature. Because lower value resistors have more metal and, therefore, many more contacts, low-value resistors tend to drift less than higher value resistors under similar loads.

Resistor pastes are generally rated at 50 W/in^2 of active resistor area. This is a conservative figure, however, and the resistor can be rated at 100 or even 200 W/in^2 . A burn-in process will substantially reduce subsequent drift since most of the drift occurs in the first hours of load.

Process Considerations

The process windows for printing and firing thick-film resistors are extremely critical in terms of both temperature control and atmosphere control. Small variations in temperature or time at temperature can cause significant changes in the mean value and distribution of values. In general, the higher the ohmic value of the resistor, the more dramatic is the change. As a rule, high ohmic values tend to decrease as temperature and/or time is increased, whereas very low values ($<100\ \Omega/\square$) may tend to increase.

Thick-film resistors are very sensitive to the firing atmosphere. For resistor systems used with air fireable conductors, it is critical to have a strong oxidizing atmosphere in the firing zone of the furnace. In a neutral or reducing atmosphere, the metallic oxides that comprise the active material reduces to pure metal at the temperatures used to fire the resistors, dropping resistor values by more than an order of magnitude. Again, high ohmic value resistors are more sensitive than low ohmic value. Atmospheric contaminants, such as vapors from hydrocarbons or halogenated hydrocarbons, breaks down at firing temperatures, creating a strong reducing atmosphere. For example, one of the breakdown components of hydrocarbons is carbon monoxide, one of the strongest reducing agents known. Concentrations of fluorinated hydrocarbons in a firing furnace of only a few ppm can drop the value of a $100\text{ k}\Omega$ resistor to below $10\text{ k}\Omega$.

Properties of Thick-Film Dielectric Materials

Multilayer Dielectric Materials

Thick-film dielectric materials are used primarily as insulators between conductors, either as simple crossovers or in complex multilayer structures. Small openings, or vias, may be left in the dielectric layers so that adjacent conductor layers may interconnect. In complex structures, as many as several hundred vias per layer may be required. In this manner, complex interconnection structures may be created. Although the majority of thick-film circuits can be fabricated with only three layers of metallization, others may require several more. If more than three layers are required the yield begins dropping dramatically with a corresponding increase in cost.

Dielectric materials used in this application must be of the devitrifying or recrystallizable type. These materials in paste form are a mixture of glasses that melt at a relatively low temperature. During firing,

when they are in the liquid state, they blend together to form a uniform composition with a higher melting point than the firing temperature. Consequently, on subsequent firings they remain in the solid state, which maintains a stable foundation for firing sequential layers. By contrast, vitreous glasses always melt at the same temperature and would be unacceptable for layers either to sink and short to conductor layers underneath, or to swim and form an open circuit. Additionally, secondary loading of ceramic particles is used to enhance devitrification and to modify the TCE.

Dielectric materials have two conflicting requirements in that they must form a continuous film to eliminate short circuits between layers while, at the same time, they must maintain openings as small as 0.010-in. In general, dielectric materials must be printed and fired twice per layer to eliminate pinholes and prevent short circuits between layers.

The TCE of thick-film dielectric materials must be as close as possible to that of the substrate to avoid excessive bowing, or warpage, of the substrate after several layers. Excessive bowing can cause severe problems with subsequent processing, especially where the substrate must be held down with a vacuum or where it must be mounted on a heated stage. In addition, the stresses created by the bowing can cause the dielectric material to crack, especially when it is sealed within a package. Thick-film material manufacturers have addressed this problem by developing dielectric materials that have an almost exact TCE match with alumina substrates. Where a serious mismatch exists, matching layers of dielectric must be printed on the bottom of the substrate to minimize bowing, which obviously increases the cost.

Dielectric materials with higher dielectric constants are also available for manufacturing thick-film capacitors. These generally have a higher loss tangent than chip capacitors and utilize a great deal of space. Although the initial tolerance is not good, thick-film capacitors can be trimmed to a high degree of accuracy.

Overglaze Materials

Dielectric overglaze materials are vitreous glasses designed to fire at a relatively low temperature, usually around 550°C. They are designed to provide mechanical protection to the circuit, to prevent contaminants and water from spanning the area between conductors, to create solder dams, and to improve the stability of thick-film resistors after trimming.

When soldering a device with many leads, it is imperative that the volume of solder under each lead be the same. A well-designed overglaze pattern can prevent the solder from wetting other circuit areas and flowing away from the pad, keeping the solder volume constant. In addition, overglaze can help to prevent solder bridging between conductors.

Overglaze material has long been used to stabilize thick-film resistors after laser trim. In this application, a green or brown pigment is added to enhance the passage of a yttrium–aluminum–garnet (YAG) laser beam. Colors toward the shorter wavelength end of the spectrum, such as blue, tend to reflect a portion of the YAG laser beam and reduce the average power level at the resistor. There is some debate as to the effectiveness of overglaze in enhancing the resistor stability, particularly with high ohmic values. Several studies have shown that, although overglaze is undoubtedly helpful at lower values, it can actually increase the resistor drift of high-value resistors by a significant amount.

Processing Thick-Film Circuits

Screen Printing

The thick-film fabrication process begins with the generation of artwork from the drawings of the individual layers created during the design stage. The artwork represents the exact pattern to be deposited on a 1:1 scale. A stainless-steel wire mesh screen ranging from 80 to 400 mesh count is coated with a photosensitive material and exposed using the artwork for the layer to be printed. The selection of the mesh count depends on the linewidth to be printed. For 0.010 in lines and spaces, a 325 mesh is adequate. For lines down to 0.005 in., a 400 mesh screen is required, and for coarse materials such as solder paste, an 80 mesh screen is needed. The unexposed photoresistive material is washed away leaving openings in the screen where paste is to be deposited. The screen is mounted into a screen printer that has, at a minimum, provisions for controlling squeegee pressure, squeegee speed, and the snapoff distance. Most thick-film materials are

printed by the off-contact process in which the screen is separated from the substrate by a distance called the snapoff. As the squeegee is moved, it stretches the screen by a small amount, creating tension in the wire mesh. As the squeegee passes, the tension in the screen causes the mesh to snap back, leaving the paste on the screen. The snapoff distance is probably the most critical parameter in the entire screen printing process. If it is too small, the paste will tend to be retained in the screen mesh, resulting in an incomplete print; if it is too large, the screen will be stretched too far, resulting in a loss of tension. A typical snapoff distance for an 8×10 in. screen is 0.025 in.

Drying

Thick-film pastes are dried prior to firing to evaporate the volatile solvents from the printed films. If the volatile solvents are allowed to enter the firing furnace, flash evaporation may occur, leaving pits or craters in the film. In addition, the byproducts of these materials may result in reduction of the oxides that comprise the fired film. Most solvents in thick-film pastes have boiling points in the range of 180–250°C. Because of the high surface area/volume of deposited films, drying at 80–160°C for a period of 10–30 min is adequate to remove most of the solvents from wet films.

Firing

Belt furnaces having independently controlled heated zones through which a belt travels at a constant speed are commonly used for firing thick films. By adjusting the zone temperature and the belt speed, a variety of time vs. temperature profiles can be achieved. The furnace must also have provisions for atmosphere control during the firing process to prevent reduction (or, in the case of copper, oxidation) of the constituents.

Figure 11.9 illustrates two typical thick-film circuits.

11.2.4 Thin-Film Technology

Thin-film technology, in contrast to thick-film technology, is a subtractive technology in that the entire substrate is coated with several layers of material and the unwanted material is etched away in a succession of photoetching processes. The use of photolithographic processes to form the patterns enables much narrower and more well-defined lines than can be formed by the thick-film process. This feature promotes the use of thin-film technology for high-density and high-frequency applications.

Thin-film circuits typically consist of three layers of material deposited on a substrate. The bottom layer serves two purposes: it is the resistor material and also provides the adhesion to the substrate. The adhesion mechanism of the film to the substrate is an oxide layer, which forms at the interface between the film and the substrate. The bottom layer must, therefore, be a material that oxidizes readily. The middle layer acts as an interface between the resistor layer and the conductor layer, either by improving the adhesion of the conductor or by preventing diffusion of the resistor material into the conductor. The top layer acts as the conductor layer.

Deposition Technology

The term thin film refers more to the manner in which the film is deposited onto the substrate, as opposed to the actual thickness of the film. Thin films are typically deposited by a vacuum deposition technique or by electroplating.

Sputtering

Sputtering is the principal method by which thin films are applied to substrates. In the most basic form of sputtering, a current is established in a conducting plasma formed by striking an arc in a partial vacuum of approximately 10^{-6} pressure with a potential applied. The gas used to establish the plasma is typically an inert gas, such as argon, that does not react with the target material. The substrate and a target material are situated in the plasma with the substrate at ground potential and the target at a high potential, which may be AC or DC. The high potential attracts the gas ions in the plasma to the point where they collide with the

FIGURE 11.9 Thick-film circuits: Hermetic (above) and nonhermetic.

target with sufficient kinetic energy to dislodge microscopically sized particles with enough residual kinetic energy to travel the distance to the substrate and adhere. This process is referred to as *triode sputtering*.

Ordinary triode sputtering is a very slow process, requiring hours to produce useable films. By utilizing magnets at strategic points, the plasma can be concentrated in the vicinity of the target, greatly speeding up the deposition process. The potential that is applied to the target is typically RF energy at a frequency of approximately 13 MHz, which may be generated by a conventional electronic oscillator or by a magnetron. The magnetron is capable of generating considerably more power with a correspondingly higher deposition rate.

By adding small amounts of other gases, such as oxygen and nitrogen, to the argon, it is possible to form oxides and nitrides of certain target materials on the substrate. It is this technique, called *reactive sputtering*, which is used to form tantalum nitride, a common resistor material.

Evaporation

The evaporation of a material into the surrounding area occurs when the vapor pressure of the material exceeds the ambient pressure and can take place from either the solid state or the liquid state. In the thin film process, the material to be evaporated is placed in the vicinity of the substrate and heated until the vapor pressure of the material is considerably above the ambient pressure. The evaporation rate is directly

proportional to the difference between the vapor pressure of the material and the ambient pressure and is highly dependent on the temperature of the material.

Evaporation must take place in a relatively high vacuum ($<10^{-6}$ torr) for three reasons:

1. To lower the vapor pressure required to produce an acceptable evaporation rate, thereby lowering the required temperature required to evaporate the material.
2. To increase the mean free path of the evaporated particles by reducing the scattering due to gas molecules in the chamber. As a further result, the particles tend to travel in more of a straight line, improving the uniformity of the deposition.
3. To remove atmospheric contaminants and components, such as oxygen and nitrogen, which tend to react with the evaporated film.

At 10^{-7} torr, a vapor pressure of 10^{-2} torr is required to produce an acceptable evaporation rate. For most metals, this temperature is in excess of 1000°C . The refractory metals, or metals with a high melting point such as tungsten, titanium, or molybdenum, are frequently used as carriers, or *boats*, to hold other metals during the evaporation process. To prevent reactions with the metals being evaporated, the boats may be coated with alumina or other ceramic materials.

In general, the kinetic energy of the evaporated particles is substantially less than that of sputtered particles. This requires that the substrate be heated to about 300°C to promote the growth of the oxide adhesion interface. This may be accomplished by direct heating of the substrate mounting platform or by radiant infrared heating.

There are several techniques by which evaporation can be accomplished. The two most common of these are resistance heating and electron-beam (E-beam) heating.

Evaporation by resistance heating usually takes place from a boat made with a refractory metal, a ceramic crucible wrapped with a wire heater, or a wire filament coated with the evaporant. A current is passed through the element, and the generated heat heats the evaporant. It is somewhat difficult to monitor the temperature of the melt by optical means due to the propensity of the evaporant to coat the inside of the chamber, and control must be done by empirical means.

The E-beam evaporation method takes advantage of the fact that a stream of electrons accelerated by an electric field tend to travel in a circle when entering a magnetic field. This phenomenon is utilized to direct a high-energy stream of electrons onto an evaporant source. The kinetic energy of the electrons is converted into heat when they strike the evaporant. E-beam evaporation is somewhat more controllable since the resistance of the boat is not a factor, and the variables controlling the energy of the electrons are easier to measure and control. In addition, the heat is more localized and intense, making it possible to evaporate metals with higher 10^{-2} torr temperatures and lessening the reaction between the evaporant and the boat.

Comparison Between Sputtering and Evaporation

The adhesion of a sputtered film is superior to that of an evaporated film, and is enhanced by presputtering the substrate surface by random bombardment of argon ions prior to applying the potential to the target. This process removes several atomic layers of the substrate surface, creating a large number of broken oxygen bonds and promoting the formation of the oxide interface layer. The oxide formation is further enhanced by the residual heating of the substrate that results from the transfer of the kinetic energy of the sputtered particles to the substrate when they collide.

It is difficult to evaporate alloys such as NiCr due to the difference between the 10^{-2} torr temperatures. The element with the lower temperature tends to evaporate somewhat faster, causing the composition of the evaporated film to be different from the composition of the alloy. To achieve a particular film composition, the composition of the melt must contain a higher portion of the material with the higher 10^{-2} torr temperature and the temperature of the melt must be tightly controlled. By contrast, the composition of a sputtered film is identical to that of the target.

Evaporation is limited to the metals with lower melting points. Refractory metals and ceramics are virtually impossible to deposit by evaporation.

Reactive deposition of nitrides and oxides is very difficult to control.

Electroplating

Electroplating is accomplished by applying a potential between the substrate and the anode, which are suspended in a conductive solution of the material to be plated. The plating rate is a function of the potential and the concentration of the solution. In this manner, most metals can be plated to a metal surface.

This is considerably more economical and results in much less target usage. For added savings, some companies apply photoresist to the substrate and electroplate gold only where actually required by the pattern.

Photolithographic Processes

In the photolithographic process, the substrate is coated with a photosensitive material that is exposed through a pattern formed on a glass plate. Ultraviolet light, X rays, and electron beams may all be used to expose the film. The photoresist may be of the positive or negative type, with the positive type being prevalent due to its inherently higher resistance to the etchant materials. The unwanted material that is not protected by the photoresist may be removed by wet, or chemical etching, or by dry, or sputter etching, in which the unwanted material is removed by ion bombardment. In essence, the exposed material acts as a sputtering target. The photoresist, being more compliant, simply absorbs the ions and protects the material underneath.

Thin-Film Materials

Virtually any inorganic material may be deposited by the sputtering process, although RF sputtering is necessary to deposit dielectric materials or metals, such as aluminum, that oxidize readily. Organic materials are difficult to sputter because they tend to release absorbed gases in a high vacuum, which interferes with the sputtering process. A wide variety of substrate materials are also available, but these in general must contain or be coated with an oxygen compound to permit adhesion of the film.

Thin-Film Resistors

Materials used for thin-film resistors must perform a dual role in that they must also provide the adhesion to the substrate, which narrows the choice to those materials that form oxides. The resistor film begins forming as single points on the substrate in the vicinity of substrate faults or other irregularities, which might have an excess of broken oxygen bonds. The points expand into islands, which in turn join to form continuous films. The regions where the islands meet are called *grain boundaries* and are a source of collisions for the electrons. The more grain boundaries present, the more negative is the TCR. Unlike thick-film resistors, however, the boundaries do not contribute to the noise level. Further, laser trimming does not create microcracks in the glass-free structure, and the inherent mechanisms for resistor drift are not present in thin films. As a result, thin-film resistors have better stability, noise, and TCR characteristics than thick-film resistors.

The most common types of resistor material are nichrome (NiCr) and tantalum nitride (TaN). Although NiCr has excellent stability and TCR characteristics, it is susceptible to corrosion by moisture if not passivated by sputtered quartz or by evaporated silicon monoxide (SiO). TaN, on the other hand, may be passivated by simply baking in air for a few minutes. This feature has resulted in the increased use of TaN at the expense of NiCr, especially in military programs. The stability of passivated TaN is comparable to that of passivated NiCr, but the TCR is not as good unless annealed for several hours in a vacuum to minimize the effect of the grain boundaries. Both NiCr and TaN have a relatively low maximum sheet resistivity on alumina, about $400 \Omega/\square$ for NiCr and $200 \Omega/\square$ for TaN. This requires lengthy and complex patterns to achieve a high value of resistance, resulting in a large area and the potential for low yield.

The TaN process is the most commonly used due to its inherently high stability. In this process N_2 is introduced into the argon gas during the sputtering process, forming TaN by reacting with pure Ta atoms on the surface of the substrate. By heating the film in air at about 425°C for 10 min, a film of TaO is formed over the TaN, which is virtually impervious to further O_2 diffusion at moderately high temperatures, which helps to maintain the composition of the TaN film and to stabilize the value of the resistor. TaO is

FIGURE 11.10 A thin-film circuit.

essentially a dielectric and, during the stabilization of the film, the resistor value is increased. The amount of increase for a given time and temperature is dependent on the thickness and sheet resistivity of the film. Films with a lower sheet resistivity increase proportionally less than those with a higher sheet resistivity. The resistance increases as the film is heated longer, making it possible to control the sheet resistivity to a reasonable accuracy on a substrate-by-substrate basis.

Other materials, based on chromium and rhenium alloys, are also available. These materials have a higher sheet resistivity than NiCr and TaN and offer the same degree of stability.

Barrier Materials

When Au is used as the conductor material, a barrier material between the Au and the resistor is required. When gold is deposited directly on NiCr, the Cr has a tendency to diffuse through the Au to the surface, which interferes with both wire bonding and eutectic die bonding. To alleviate this problem, a thin layer of pure Ni is deposited over the NiCr, which also improves the solderability of the surface considerably. The adhesion of Au to TaN is very poor. To provide the necessary adhesion, a thin layer of 90Ti/10W may be used between the Au and the TaN.

Conductor Materials

Gold is the most common conductor material used in thin-film hybrid circuits because of the ease of wire and die bonding and its high resistance to tarnish and corrosion. Aluminum and copper are also used in some applications. A thin-film circuit is illustrated in Fig. 11.10.

11.2.5 Resistor Trimming

One of the advantages of the hybrid technology over other **packaging** technologies is the ability to adjust the value of resistors to a more precise value by a process called *trimming*. By removing a portion of the resistor with a laser or by abrasion, as shown in Fig. 11.11, the value can be increased from the as-processed state to a predetermined value. The laser trimming process can be highly automated and can trim a resistor to a tolerance of better than 1% in less than a second.

More than any other development, laser trimming has contributed to the rapid growth of the hybrid microelectronics industry over the past few years. Once it became possible to trim resistors to precision

FIGURE 11.11 A laser-trimmed thick-film resistor.

values economically, hybrid circuits became cost competitive with other forms of packaging and the technology expanded rapidly.

Lasers used to trim thick-film resistors are generally a YAG crystal, which has been doped with neodymium. YAG lasers are of lower power and are capable of trimming film resistors without causing serious damage if the parameters are adjusted properly. Even with the YAG laser, it is necessary to lower the maximum power and spread out the beam to avoid overtrimming and to increase the trimming speed. This is accomplished by a technique called *Q-switching*, which decreases the peak power and widens the pulse width such that the overall average power is the same. One of the effects of this technique is that the first and last pulses of a given trim sequence have substantially greater energy than the intervening ones. The first pulse does not create a problem, but the last pulse occurs within the body of the resistor, penetrating deeper into the substrate and creating the potential for resistor drift by creating minute cracks (microcracks) in the resistor, which emanate from the point of trim termination.

The microcracks occur as a result of the large thermal gradient, which exists between the area of the last pulse and the remainder of the resistor. Over the life of the resistor, the cracks will propagate through the body of the resistor until they reach a termination point, such as an active particle or even another microcrack. The propagation distance can be up to several mils in a high-value resistor with a high concentration of glass. The microcracks cause an increase in the value of the resistor and also increase the noise by increasing the current density in the vicinity of the trim. With proper design of the resistor, and with proper selection of the cut mode, the amount of drift can be held to less than 1%.

The propagation of the microcracks can be accelerated by the application of heat, which also has the effect of stabilizing the resistor. Where high-precision resistors are required, the resistors may be trimmed slightly low, exposed to heat for a period of time, and retrimmed to a value in a noncritical area.

The amount of drift depends on the amount of propagation distance relative to the distance from the termination point of the trim to the far side of the resistor. This can be minimized by either making the resistor larger or by limiting the distance that the laser penetrates into the resistor. As a rule of thumb, the value of the resistor should not be increased by more than a factor of two to minimize drift.

In the abrasive trimming process, a fine stream of sand propelled by compressed air is directed at the resistor, abrading away a portion of the resistor and increasing the value. Trimming resistors to a high precision is more difficult with abrasive trimming due to the size of the particle stream, although tolerances of 1% can be achieved with proper setup and slow trim speeds. It has also proven difficult to automate

TABLE 11.6 Comparison of Thick-Film and Thin-Film Circuits

Thick Film	Thin Film
Multilayer structures are much simpler and more economical to fabricate than with the thin-film technology.	The lines and spaces are much smaller than can be attained by the thick-film process. In a production environment, the thin-film process can produce lines and spaces 0.001 in. in width, whereas the thick film process is limited to 0.01 in.
The range of resistor values is wider. Thin-film designers are usually limited to a single value of sheet resistivity from which to design all of the resistors in the circuit.	The line definition available by the thin-film process is considerably better than that of the thick-film process. Consequently, the thin-film process operates much better at high frequencies.
For a given application, the thick-film process is usually less expensive.	The electrical properties of thin-film resistors are substantially better than thick-film resistors in terms of noise, stability, and precision.

the abrasive trimming process to a high degree, and it remains a relatively slow process. In addition, substantially larger resistors are required.

Despite these shortcomings, abrasive trimming plays an important role in the hybrid industry. The cost of an abrasive trimmer is substantially less than that of a laser trimmer, and the setup time is much less. In a developmental mode where only a few prototype units are required, abrasive trimming is generally more economical and faster than laser trimming.

In terms of performance, abrasively trimmed resistors are more stable than laser-trimmed resistors and generate less noise because no microcracks are generated during the abrasive trimming process. In the power hybrid industry, resistors that carry high currents or that dissipate high power are frequently abrasively trimmed by trimming a groove in the middle of the resistor. This technique minimizes current crowding and further enhances the stability.

11.2.6 Comparison of Thick-Film and Thin-Film Technologies

Most circuits can be fabricated with either the thick- or the thin-film technology. The ultimate result of both processes is an interconnection pattern on a ceramic substrate with integrated resistors, and, to a degree, they can be considered to be competing technologies. Given a particular set of requirements, however, the choice between technologies is usually quite distinct. Table 11.6 summarizes the particular advantages of each technology.

11.2.7 The Hybrid Assembly Process

The assembly of a hybrid circuit involves mechanically mounting the components on the substrate and electrically connecting the components to the proper substrate traces.

In the most fundamental configuration, the **semiconductor die** is taken directly from the wafer without further processing (generally referred to as a bare die). In this process, the die is mechanically mounted to the substrate with epoxy, solder, or by direct eutectic bonding of the silicon to the substrate metallization, and the electrical connections are made by bonding small wires from the bonding pads to the appropriate conductor. This is referred to as chip-and-wire technology, illustrated in Fig. 11.10.

Other approaches require subsequent processing of the die at the wafer level. The most common configurations are *ultrasonic bonding* (Fig. 11.12), *tape automated bonding (TAB)*, shown in Fig. 11.13, and the so-called *flip chip* or *bumped chip* approach, depicted in Fig. 11.14. These are discussed later.

The Chip-and-Wire Process

Bare semiconductor die may be mounted with epoxy, solder, or by direct eutectic bonding. The most common method of both active and passive component attachment is with epoxy, both conductive and nonconductive. This method offers a number of advantages over other techniques, including ease of repair,

FIGURE 11.12 Ultrasonic bonding of heavy aluminum wire.

reliability, productivity, and low process temperature. Most epoxies have a filler added for electrical and/or thermal conductivity. The most common material used for conductive epoxies is silver, which provides both. Other conductive filler materials include gold, palladium–silver for reduced silver migration, and copper plated with a surface coating of tin. Nonconductive filler materials include aluminum oxide and magnesium oxide for improved thermal conductivity. For epoxy attach, it is preferred that the bottom surface of the die be gold. Solder attachment of a die to a substrate is commonly used in the power hybrid industry. For this application, a coating of Ti/Ni/Ag alloy on the bottom is favored to gold. Since many

FIGURE 11.13 Tape automated bonding technique.

FIGURE 11.14 Flip chip bonding technique.

power dice are, by necessity, physically large, a compliant solder, such as one of the PbIn alloys is preferred. Eutectic bonding refers to the direct bonding of a silicon device to gold metallization, which takes place at 370°C with a combination of 94% gold and 6% silicon by weight. Gold is the only metal to which the eutectic temperature in combination with silicon is sufficiently low to be practical.

Wire bonding is used to make the electrical connections from the aluminum contacts to the substrate metallization or to a lead frame, from other components, such as chip resistors or chip capacitors, to substrate metallization, from package terminals to the substrate metallization, or from one point on the substrate metallization to another.

There are two basic methods of *wire bonding*, *thermocompression wire bonding* and *ultrasonic wire bonding*. Thermocompression wire bonding, as the name implies, utilizes a combination of heat and pressure to form an intermetallic bond between the wire and a metal surface. In pure thermocompression bonding, a gold wire is passed through a hollow capillary and a ball formed on the end by means of an electrical arc. The substrate is heated to about 300°C, and the ball is forced into contact with the bonding pad on the device with sufficient force to cause the two metals to bond. The capillary is then moved to the bond site on the substrate, feeding the wire as it goes, and as the wire is bonded to the substrate by the same process, except that the bond is in the form of a stitch, as opposed to the ball on the device. The wire is then clamped and broken at the stitch by pulling and another ball formed as described. Thermocompression bonding is rarely used for the following reasons:

- The high substrate temperature precludes the use of epoxy for device mounting.
- The temperature required for the bond is above the threshold temperature for gold-aluminum intermetallic compound formation. The diffusion rate for aluminum into gold is much greater than for gold into aluminum. The aluminum contact on a silicon device is very thin, and, when it diffuses into the gold, voids, called Kirkendall voids, are created in the bond area, increasing the electrical resistance of the bond and decreasing the mechanical strength.
- The thermocompression bonding action does not effectively remove trace surface contaminants that interfere with the bonding process.

The ultrasonic bonding process uses ultrasonic energy to vibrate the wire (primarily aluminum wire) against the surface to blend the lattices together. Localized heating at the bond interface caused by the scrubbing action, aided by the oxide on the aluminum wire, assists in forming the bond. The substrate itself is not heated. Intermetallic compound formation is not as critical, as with the thermocompression bonding

process, as both the wire and the device metallization are aluminum. Kirkendall voiding on an aluminum wire bonded to gold substrate metallization is not as critical, since there is substantially more aluminum available to diffuse than on device metallization. Ultrasonic bonding makes a stitch on both the first and second bonds because of the fact that it is very difficult to form a ball on the end of an aluminum wire because of the tendency of aluminum to oxidize. For this reason, ultrasonic bonding is somewhat slower than thermocompression, since the capillary must be aligned with the second bond site when the first bond is made. Ultrasonic bonding to package leads may be difficult if the leads are not tightly clamped, since the ultrasonic energy may be propagated down the leads instead of being coupled to the bond site.

The use of thermosonic bonding of gold wire overcomes the difficulties noted with thermocompression bonding. In this process, the substrate is heated to 150°C and ultrasonic energy is coupled to the wire through the transducer action of the capillary, scrubbing the wire into the metal surface and forming a ball-stitch bond from the device to the substrate, as in thermocompression bonding.

Thermosonic gold bonding is the most widely used bonding technique, primarily because it is faster than ultrasonic aluminum bonding. Once the ball bond is made on the device, the wire may be moved in any direction without stress on the wire, which greatly facilitates automatic wire bonding, as the movement need only be in the x and y directions.

By contrast, before the first ultrasonic stitch bond is made on the device, the circuit must be oriented so that the wire moves toward the second bond site only in the direction of the stitch. This necessitates rotational movement, which not only complicates the design of the bonder, but increases the bonding time as well.

The wire size is dependent on the amount of current that the wire is to carry, the size of the bonding pads, and the throughput requirements. For applications where current and bonding size is not critical, wire 0.001 in. in diameter is the most commonly used size. Although 0.0007-in. wire is less expensive, it is difficult to thread through a capillary without frequent breaking and consequent line stoppages.

For high-volume applications, gold is the preferred method due to bonding speed. Once a ball bond is made, the wire can be dressed in any direction. Stitch bonding, on the other hand, requires that the second bond be lined up with the first prior to bonding, which necessitates rotation of the holding platform with a corresponding loss in bonding rate.

Figure 11.12 illustrates aluminum ultrasonic bonding of heavy wire, whereas thermosonic bonding is illustrated in Fig. 11.9 and Fig. 11.10.

Devices in die form have certain advantages over packaged devices in hybrid circuit applications, including

- **Availability:** Devices in the chip form are more readily available than other types and require no further processing.
- **Thermal management:** Devices in the chip form are mounted in intimate contact with the substrate, which maximizes the contact area and improves the heat flow out of the circuit.
- **Size:** Except for the flip-chip approach, the chip-and-wire approach utilizes the least substrate area.
- **Cost:** Since they require no special processing, devices in the chip form are less expensive than packaged devices.

Coupled with these advantages, however, are at least two disadvantages

- **Fragility:** Devices in the chip form are susceptible to mechanical handling, static discharge, and corrosion as a result of contamination. In addition, the wire bonds require only a few grams of force in the normal direction to fail.
- **Testability:** This is perhaps the most serious problem with devices in the die form. It is difficult to perform functional testing at high speeds and at temperature extremes as a result of the difficulties in probing. Testing at cold temperatures is virtually prohibitive as a result of moisture condensation. The net result when several devices must be utilized in a single hybrid is lower yields at first

electrical test. If the yield of a single chip is 0.98, then the initial yield that can be expected in a hybrid circuit with 10 devices is $0.98^{10} = 0.817$. This necessitates added troubleshooting and repair time with a corresponding detrimental effect on both cost and reliability.

Tape Automated Bonding and Flip-Chip Bonding

The tape automated bonding process was developed in the early 1970s, and has since been adopted by several companies as a method of chip packaging. There are two basic approaches to the TAB process, the *bumped-chip process* and the *bumped-tape process*.

In one form of the bumped-chip process, the wafer is passivated with silicon nitride and windows are opened up over the bonding pads by photoetching. The wafer is then coated with thin layers of titanium, palladium, and gold applied in succession by sputtering. The titanium and palladium act as barrier layers to prevent the formation of intermetallic compounds between the gold and the aluminum. Using a dry film photoresist with a thickness of about 0.0015 in., windows are again opened over the bonding pads and gold is electroplated to a thickness of about 0.001 in. at these points. The photoresist is removed, and the wafer is successively dipped in gold, palladium, and titanium etches, leaving only the gold bumps over the bonding pads. To prepare the tape, a copper foil, is laminated to a 35-mm polyimide film with holes punched at intervals. A lead frame, which is designed to align with the bumps on the chip and to give stress relief after bonding to the substrate, is etched in the copper foil, and the ends of the leads are gold plated. The remainder of the leads may be either tin plated or gold plated, depending on whether the leads are intended to be attached to the substrate by soldering or by thermocompression bonding. The wafer is mounted to a ceramic block with a low-temperature wax, and the die is separated by sawing through completely. The leads are attached to the bumps by thermocompression bonding (usually referred to as the inner-lead bonding process) with a heated beryllia **thermode** whose tip size is the same as that of the die. During the bonding process, the wax melts allowing the chip to be removed from the ceramic block. The inner-lead bonding process may be highly automated by using pattern recognition systems to locate the chip with respect to the lead frame. A TAB assembly mounted to the substrate is shown in Fig. 11.13.

The bumped-tape process is somewhat less expensive than the bumped-chip process, and the technology is not as complex. Early efforts at bumped-tape bonding utilized the same gold-plated leads as in the bumped-chip process and proved somewhat unreliable due to the direct gold-aluminum contact. More recently, the use of sputtered aluminum on the lead frame has eliminated this problem, and has further reduced the processing temperature by utilizing ultrasonic bonding to attach the leads. Low-cost devices may use only a strip of copper or aluminum, whereas devices intended for pretesting use a multilayer copper-polyimide structure. The so-called area array TAB, developed by Honeywell, utilizes a multilayer structure, which can form connections within the periphery of the chip, greatly increasing the lead density without increasing the size of the chip and simplifying the interconnection structure on the chip itself.

TAB technology has other advantages over chip-and-wire technology in the areas of high frequency and high-lead density. TAB may be used on pads about one-third the size required by gold thermosonic bonding, and the larger size of the TAB leads lowers the series inductance, increasing the overall operating frequency. These factors contribute to the use of TAB in the very high-speed integrated circuit (VHSIC) program, which utilizes chips with in excess of 400 bonds operating at high speeds. In addition, the devices are in direct contact with the substrate, easing the problem of removing heat from the device. This is a critical feature, since high-speed operation is usually accompanied by increased power dissipation.

Flip-chip technology, as shown in Fig. 11.14, is similar to TAB technology in that successive metal layers are deposited on the wafer, ending up with solder-plated bumps over the device contacts. One possible configuration utilizes an alloy of nickel and aluminum as an interface to the aluminum bonding pads. A thin film of pure nickel is plated over the Ni/Al, followed by copper and solder. The copper is plated to a thickness of about 0.0005 in., and the solder is plated to about 0.003 in. The solder is then reflowed to form a hemispherical bump. The devices are then mounted to the substrate face down by reflow solder methods. During reflow, the face of the device is prevented from contacting the substrate metallization by the copper bump. This process is sometimes referred to as the *controlled collapse* process.

Testing of flip-chip devices is not as convenient compared to TAB devices, since the solder bumps are not as amenable to making ohmic contact as the TAB leads. Testing is generally accomplished by lining the devices over a **bed of nails**, which is interfaced to a testing system. At high speeds, this does not realistically model the configuration that the device actually sees on a substrate, and erroneous data may result.

Flip-chip technology is the most space efficient of all of the packaging technologies, since no room outside the boundaries of the chip is required. Further, the contacts may be placed at any point on the chip, reducing the net area required and simplifying the interconnection pattern.

Surface mount techniques have also been successfully used to assembly hybrid circuits. The metallized ceramic substrate is simply substituted for the conventional printed circuit board and the process of screen printing solder, component placement, and reflow solder is identical.

Defining Terms

Active component: An electronic component that can alter the waveshape of an electronic signal, such as a diode, a transistor, or an integrated circuit. By contrast, ideal resistors, capacitors, and inductors leave the waveform intact and are referred to as passive components.

Bed of nails: A method of interfacing a component or electronic circuit to another assembly, consisting of inverted, spring-loaded probes located at predetermined points.

Dielectric constant: A measurement of the ability of a material to hold electric charge.

Direct bond copper (DBC): A method of bonding copper to a substrate, which blends a portion of the copper with a portion of the substrate at the interface.

Migration: Transport of metal ions from a positive surface to a negative surface in the presence of moisture and electric potential.

Noise index: A measurement of the amount of noise generated in a component as a result of random movement of carriers from one energy state to another.

Packaging: The technology of converting an electronic circuit from a schematic or prototype to a finished form.

Passive components: Components that, in the ideal form, cannot alter the waveshape of an electronic signal.

Plasma: A gas that has been ionized to produce a conducting medium.

Pseudoplastic fluid: A fluid in which the viscosity is nonlinear, with the rate of change lessening as the pressure is increased.

Refractory metal In this context, a metal with a high melting point.

Semiconductor die: A semiconductor device in the unpackaged state.

Temperature coefficient of expansion (TCE): A measurement of the dimensional change of a material as a result of temperature change.

Thermal conductivity: A measurement of the ability of a material to conduct heat.

Thermal management: The technology of removing heat from the point of generation in an electronics circuit.

Thermode: A device used to transmit heat from one surface to another to facilitate lead or wire bonding.

Thixotropic fluid: A fluid in which the viscosity is nonlinear, with the rate of change increasing as the pressure is increased.

Vapor pressure: A measurement of the tendency of a material to evaporate. A material with a low vapor pressure will evaporate more readily.

11.3 Surface Mount Technology

Glenn R. Blackwell

11.3.1 Introduction

This chapter is intended for the practising engineer who is familiar with standard **through-hole** (insertion mount) circuit board design, manufacturing, and test, but who now needs to learn more about the realm of surface mount technology (SMT). Numerous references will be given, which will also be of help to the engineer who may be somewhat familiar with SMT, but needs more in-depth information in specific areas. The reader with little knowledge about SMT is referred to a basic introductory article (Mims, 1987) and to a journal series which covered design of an SMT memory board (Leibson, 1987).

11.3.2 Definition

Surface mount technology is a collection of scientific and engineering methods needed to design, build, and test products made with electronic components, which mount to the surface of the printed circuit board without holes for leads (Higgins, 1991) as illustrated in Fig. 11.15. This definition notes both the breadth of topics necessary to understand SMT, as well as that the successful implementation of SMT will require the use of *concurrent engineering* (Classon, 1993; Shina, 1991). Concurrent engineering means that a team of design, manufacturing, test, and marketing people will concern themselves with board layout, parts and parts placement issues, soldering, cleaning, test, rework, and packaging before any product

FIGURE 11.15 Comparison of 8-lead DIP and SMT components (National Semiconductor, with permission).

is manufactured. The careful control of all of these issues improves both yield and reliability of the final product. In fact, SMT cannot be reasonably implemented without the use of concurrent engineering and the principles contained in *design for manufacturability (DFM)* and *design for testability (DFT)* and, therefore, any facility that has not embraced these principles should do so if SMT is to be successfully implemented.

Considerations in the Implementation of SMT

The main reasons to consider implementation of SMT include the following:

- Reduction in circuit board size
- Reduction in circuit board weight
- Reduction in number of layers in the circuit board
- Reduction in trace lengths on the circuit board

Note that not all of these reductions may occur in any given product redesign from **through-hole technology** (THT) to SMT. Reduction in circuit board size can vary from 40 to 60% (TI, 1984). By itself, this reduction presents many advantages in packaging possibilities. Camcorders and cell phones are only possible through the use of SMT. The reduction in weight means that circuit boards and components are less susceptible to vibration problems. Reduction in the number of layers in the circuit board means the bare board will be significantly less expensive to build. Reduction in trace lengths means that high-frequency signals will have fewer problems or that the board will be able to operate at higher frequencies than a through-hole board with longer trace/lead lengths. Of course, there are some disadvantages using SMT. During the assembly of a through-hole board, either the component leads go through the holes or they do not, and the component placement machines can typically detect the difference in force involved and signal for help. During SMT board assembly, the placement machine does not have such direct feedback, and accuracy of final soldered placement becomes a stochastic (probability-based) process, dependent on such items as the following:

- Component pad design
- Accuracy of the PCB artwork and fabrication, which affects the accuracy of pad location
- Accuracy of solder paste deposition location and deposition volume
- Accuracy of adhesive deposition location and volume if adhesive is used
- Accuracy of placement machine vision system(s)
- Variations in component sizes from the assumed sizes
- Thermal issues in the solder reflow process.

In THT test there is a lead and a through-hole at every potential test point, making it easy to align a bed-of-nails tester. In SMT designs there are not holes corresponding to every device lead. The design team must consider design for test, form fit and function, time-to-market, existing capabilities, and the cost and time to characterize a new process when deciding on a change of technologies. Once circuit design is complete, substrate design and fabrication, most commonly of a printed circuit board (PCB), enters the process. Generally, PCB assembly configurations using SMDs are classified as shown in Fig. 11.16.

- **Type I:** Only SMDs are used, typically on both sides of the board. No through-hole components are used. Top and bottom may contain both large and small active and passive SMDs. This type of board uses reflow soldering only.
- **Type II:** A double-sided board, with SMDs on both sides. The top side may have all sizes of active and passive SMDs, as well as through-hole components, whereas the bottom side carries passive SMDs and small active components such as transistors. This type of board requires both reflow and wave soldering, and will require placement of bottom-side SMDs in adhesive.
- **Type III:** Top side has only through-hole components, which may be active or passive, whereas the bottom side has passive and small active SMDs. This type of board uses wave soldering only, and also requires placement of the bottom-side SMDs in adhesive.

FIGURE 11.16 Type I, II, and III SMT circuit boards. (Source: Intel. 2000. Packaging Handbook. Intel Corp., Santa Clara, CA. With permission.)

A type I bare board will first have solder paste applied to the component pads on the board. Once solder paste has been deposited, active and passive parts are placed in the paste. For prototype and low-volume lines this can be done with manually guided X-Y tables using vacuum needles to hold the components, whereas in medium and high-volume lines automated placement equipment is used. This equipment will pick parts from reels, sticks, or trays, then place the components at the appropriate pad locations on the board, hence the term *pick and place* equipment.

After all parts are placed in the solder paste, the entire assembly enters a reflow oven to raise the temperature of the assembly high enough to reflow the solder paste and create acceptable solder joints at the

component lead/pad transitions. Reflow ovens most commonly use convection and IR heat sources to heat the assembly above the point of solder liquidus, which for 63/37 tin-lead eutectic solder is 183° C. Because of the much higher thermal conductivity of the solder paste compared to the IC body, reflow soldering temperatures are reached at the leads/pads before the IC chip itself reaches damaging temperatures. The board is inverted and the process repeated. It is good practice to reflow the “bottom” side first with small components, then upon inversion of the board apply solder paste and then place the larger parts. It is generally accepted that although the bottom-side paste will reflow again, parts smaller than 24-lead ICs will maintain their location due to the strong surface tension of the bottom-side molten Sn-Pb solder. This will have to be investigated further with changes to lead-free solder.

If mixed-technology type II is being produced, the board will then be inverted, an adhesive will be dispensed at the centroid of each SMD, parts will be placed, the adhesive will be cured, the assembly will be reighted, through-hole components will be mounted, and the circuit assembly will then be wave soldered, which will create acceptable solder joints for both the through-hole components and bottom-side SMDs. A design team considering the use of SMT IC components on bottom-side must verify with the IC manufacturer’s data sheets that wave-soldering of the ICs is acceptable. Intel, for example, recommends against wave-soldering any of its ICs.

A type III board will first be inverted, adhesive dispensed, SMDs placed on the bottom-side of the board, the adhesive cured, the board reighted, through-hole components placed, and the entire assembly wave-soldered. It is imperative to note that only passive components and small active SMDs can be successfully bottom-side wave-soldered without considerable experience on the part of the design team and the board assembly facility. It must also be noted that successful wave soldering of SMDs requires a dual-wave machine with one turbulent wave and one laminar wave.

It is common for a manufacturer of through-hole boards to convert first to a type II or type III substrate design before going to an all-SMD type I design. This is especially true if amortization of through-hole insertion and wave-soldering equipment is necessary. Many factors contribute to the reality that most boards are mixed-technology type II or type III boards. Although most components are available in SMT packages, through-hole connectors are still commonly used for the additional strength the through-hole soldering process provides, and high-power devices such as three-terminal regulators are still commonly through-hole due to off-board heat-sinking demands. Both of these issues have been addressed by manufacturers and solutions are available that allow type I boards with connectors and power devices (Holmes, 1993).

Again, it is imperative that all members of the design, build, and test teams be involved from the design stage. Today’s complex board designs mean that it is entirely possible to exceed the ability to adequately test a board if test is not designed-in, or to robustly manufacture a board if in-line inspections and handling are not adequately considered. Robustness of both test and manufacturing are only assured with full involvement of all parties to overall board design and production.

11.3.3 Surface Mount Device (SMD) Definitions

The new user of surface mount designs (SMDs) must rapidly learn the packaging sizes and types for SMDs. Resistors, capacitors, and most other passive devices come in two-terminal packages, as shown in Fig. 11.17, which have end-terminations designed to rest on substrate pads/lands.

FIGURE 11.17 Example of passive relative component sizes (not to scale).

Basic SMD ICs come in a wide variety of packages, from 8-lead *small outline packages* (SOLs) to 208-lead quad flat packs (QFPs). Examples of SO20 and QFP128 packages are shown in Fig. 11.18.

Other common commercial packages currently include *plastic leaded chip carriers* (PLCCs), which may as *bumped quad flat packs* (BQFPs) as shown in Fig. 11.18, *tape automated bonding* (TAB), *ball grid array* (BGA), and other newer technologies, and the IC possibilities become overwhelming. Additionally, bare die may be placed on the substrate with either the bond pads up and wire-bonding to the substrate (*chip on board, or COB*) or they may be “flipped” with their bond pads down (*flip chip*), with solderable bumps attached to the die bond pads. Figure 11.19 shows a flip chip example with adhesive underfill which helps prevent cracking of the solder joints. Beker and Adams discuss flip chip issues in more detail.

As another example of a foray into newer technologies, Achong and Chen discuss BGA land pattern and assembly issues. The reader is referred to the standards of the Institute for Interconnecting and Packaging Electronic Circuits (IPC) to find the latest package standards.

Each IC manufacturer’s data books will have packaging information for their products. The engineer should be familiar with the term *lead pitch*, which means the center-to-center distance between IC leads. All DIP ICs have a lead pitch of 0.1” (= 100 mils), while the pitch on SMT ICs may be in thousandths of an inch, also known as mils, or may be in millimeters. Common pitches are 0.050 in. (50-mil pitch), 0.025 in. (25-mil pitch), frequently called fine pitch; and 0.020 in. and smaller, frequently called ultrafine pitch. Metric equivalents are 1.27, 0.635, and 0.508 mm, and smaller. Conversions from metric to inches are easily approximated if one remembers that 1 mm is approximately 40 mils. It is important to note that virtually all new ICs are designed to metric standards. Common pitch values include 1, 0.8, 0.65 and 0.5 mm.

11.3.4 Substrate Design Guidelines

As noted previously, substrate (typically PCB) design has an effect not only on board/component layout, but also on the actual manufacturing process. Incorrect land design or layout can negatively affect the placement process, the solder process, the test process, or any combination of the three. Substrate design must take into account the mix of surface mount devices that are available for use in manufacturing.

The considerations which will be noted here as part of the design process are neither all encompassing, nor in sufficient detail for a true SMT novice to adequately deal with all of the issues involved in the process.

FIGURE 11.18 SO20 and PQFP128 packages.

FIGURE 11.19 Flip chip with underfill.

They are intended to guide an engineer through the process, allowing access to more detailed information, as necessary. General references are noted at the end of this chapter, and specific references will be noted as applicable. In addition, conferences such as the APEX, National Electronics Production and Productivity Conference (NEPCON) and Surface Mount International (SMI) are invaluable sources of information for both the beginner and the experienced SMT engineer. It should be noted that although these guidelines are noted as steps, they are not necessarily in an absolute order, and several back-and-forth iterations among the steps may be required to result in a final satisfactory process and product. After the circuit design (schematic capture) and analysis, step one in the process is to determine whether all SMDs will be used in the final design making of a type I board, or whether a mix of SMDs and through hole parts will be used, leading to a type II or type III board. This is a decision that will be governed by some or all of the following considerations:

- Current parts stock
- Existence of current through hole (TH) placement and/or wave solder equipment
- Amortization of current TH placement and solder equipment
- Existence of reflow soldering equipment
- Cost of new reflow soldering equipment
- Desired size of the final product
- Panelization of smaller type I boards
- Thermal issues related to high-power circuit sections on the board

It is desirable to segment the board into areas based on function: RF, low power, high power, etc., using all SMDs where appropriate, and mixed-technology components as needed. Power portions of the circuit may point to the use of through-hole components if air flow is the primary heat-dissipation method, although circuit board materials are available that will sink substantial amounts of heat. Using one solder technique (reflow or wave) can be desirable from a processing standpoint, and may outweigh other considerations. Another primary concern is minimization of EMI/RFI. Many references address these issues XXX.

Step two in the SMT process is to define all of the footprints of the SMDs under consideration for use in the design. The footprint is the copper pattern, commonly made up of pads or lands, on the circuit board upon which the SMD will be placed. The *Intel Packaging Handbook* says, "The design of land patterns is very critical, because it determines solder joint strength and thus the reliability of solder joints, and also impacts solder defects, cleanability, testability, and repair or rework. In other words, the very producibility or success of SMT is dependent upon the land pattern design. The lack of standardization of surface mount packages has compounded the problem of standardizing the land pattern. There are a variety of package types offered by the industry, and the variations in a given package type can be numerous. For example, for the small outline package (SOP), there are not only two lead types (gull-wing and J-lead), but there are multiple body types such as narrow wide and thin (as well as a variety of pitch dimensions *gb*). In addition, the tolerance on components varies significantly, adding to the manufacturing problems for SMC users."

Footprint examples are shown in Fig. 11.20, and footprint recommendations are available from IC manufacturers and in the appropriate data books. They are also available in various ECAD packages used for the design process, as well as in the several references that include an overview of the SMT process (Hollomon, 1995; Prasad, 1997). However, the reader is cautioned about using the general references for anything other than the most common passive and active packages. Even the position of pin 1 may be different among IC manufacturers of the same package. The footprint definition may also include the position of the solder resist pattern surrounding the copper pattern. Footprint definition sizing will vary depending on whether reflow or wave solder process is used. Wave solder footprints will require recognition of the direction of travel of the board through the wave, to minimize solder shadowing in the final fillet, as well as to meet requirements for solder thieves. The copper footprint must allow for the formation of an appropriate, inspectable solder fillet.

FIGURE 11.20 SMT footprint considerations: (a) passive land and component (b) QFP component and footprint (Source: National Semiconductor, With permission.)

If done as part of the electronic design automation (EDA) process using appropriate electronic computer-aided design (ECAD) software, the software will automatically assign copper directions to each component footprint, as well as appropriate coordinates and dimensions. These may need adjustment based on considerations related to wave soldering, test points, RF, power and EMI/RFI issues, and board production limitations. Allowing the software to select 5-mil traces when the board production facility to be used can only reliably do 8-mil traces would be inappropriate. Likewise, the solder mask patterns must be governed by the production capabilities.

Final footprint and trace decisions will

- Allow for optimal solder fillet formation
- Minimize necessary trace and footprint area
- Allow for adequate test points

- Minimize board area, if appropriate
- Set minimum interpart clearances for placement and test equipment to safely access the board, as well as any keep-in and keep-out areas
- Allow adequate distance between components for post reflow operator inspections
- Allow room for adhesive dots on wave-soldered boards
- Minimize solder bridging

Design teams should restrict wave-solder-side SMDs to passive components and transistors. Although small SMT ICs can be successfully wave soldered, this is inappropriate for an initial SMT design and as mentioned earlier is not recommended by some IC manufacturers. Decisions that will provide optimal footprints include a number of mathematical issues:

- Component dimension tolerances
- Board production capabilities, both artwork and physical tolerances across the board relative to a 0-0 fiducial
- Solder deposition volume consistencies reflow sizes
- Placement machine accuracies
- Test probe location control

These decisions may require a statistical computer program, which should be used if available to the design team. The stochastic nature of the overall process suggests a statistical programmer will be of value.

11.3.5 Thermal Design Considerations

Thermal management issues remain major concerns in the successful design of an SMT board and product. Consideration must be taken of the variables affecting both board temperature and junction temperature of the IC. The design team must understand the basic heat transfer characteristics of most SMT IC packages (ASME, 1993). Since the silicon chip of an SMD is equivalent to the chip in an identical-function DIP package, the smaller SMD package means the internal lead frame metal has a smaller mass than the lead frame in a DIP package, as shown in Fig. 11.21. This lesser ability to conduct heat away from the chip is somewhat offset by the leadframe of many SMDs being constructed of copper, which has a lower thermal resistance than the Kovar and Alloy 42 materials commonly used for DIP packages. However, with less metal and shorter lead lengths to transfer heat to ambient air, more heat is typically transferred to the circuit board itself. Several board thermal analysis software packages are available, and are highly recommended for boards that are expected to develop high thermal gradients (Flotherm). XXX Since all electronics components generate heat in use, and elevated temperatures negatively affect the reliability and failure rate of semiconductors, it is important that heat generated by SMDs be removed as efficiently as possible. In most electronic devices and assemblies, heat is removed primarily by some combination of conduction and convection, although some radiation effects are present.

The design team needs to have expertise with the variables related to thermal transfer:

- Junction temperature: T_j
- Thermal resistances: $\Theta_{jc}, \Theta_{ca}, \Theta_{cs}, \Theta_{sa}$
- Power dissipation: P_D
- Thermal characteristics of substrate material

FIGURE 11.21 The make-up of SMT solder paste.

SMT packages have been developed to maximize heat transfer to the substrate. These include various analog and digital ICs with integral heat spreaders and various power transistor packages. Note that all of these devices are designed primarily for processing with the solder paste process, and some specifically recommend against their use with wave-solder applications. In the conduction process, heat is transferred from one element to another by direct physical contact between the elements. Ideally the material to which heat is being transferred should not be adversely affected by the transfer. As an example, the **glass transition temperature** T_g of FR-4 is 125°C. Heat transferred to the board has little or no detrimental effect as long as the board temperature stays at least 50°C below T_g . Good heat sink material exhibits high thermal conductivity, which is not a characteristic of fiberglass. Therefore, the traces and other copper features must be depended on to provide the thermal transfer path (Choi, Kim, and Ortega, 1994). Conductive heat transfer is also used in the transfer of heat from THT IC packages to heat sinks, which also requires use of thermal grease to fill all air gaps between the package and the flat surface of the sink.

The discussion of lead properties of course does not apply to leadless devices such as *leadless ceramic chip carriers* (LCCCs). Design teams using these and similar packages must understand the better heat transfer properties of the alumina used in ceramic packages and must match **coefficients of thermal expansion (CTEs or TCEs)** between the LCCC and the substrate since there are no leads to bend and absorb mismatches of expansion. Use of ceramic devices may lead the design team to consider the use of Low Temperature Co-fired Ceramic (LTCC) substrates and assembly technologies XXX.

Since the heat transfer properties of the system depend on substrate material properties, it is necessary to understand several of the characteristics of the most common substrate material, FR-4 fiberglass. The glass transition temperature has already been noted, and board designers must also understand that multilayer FR-4 boards do not expand identically in the X, Y, and Z directions as temperature increases. Plate-through-holes will constrain z-axis expansion in their immediate board areas, whereas non-through-hole areas will expand further in the z axis, particularly as the temperature approaches and exceeds T_g (Lee et al., 1984). This unequal expansion can cause delamination of layers and plating fracture. If the design team knows that there will be a need for higher abilities to dissipate heat and/or needs for higher glass transition temperatures and lower coefficients of thermal expansion than FR-4 possesses, many other materials are available, examples of which are shown in Table 11.7.

Note in the table that copper-clad Invar has both variable T_g , and variable thermal conductivity depending on the volume mix of copper and Invar in the substrate. Copper has a high TCE, and Invar has a low TCE, and so the TCE increases with the thickness of the copper layers. In addition to heat transfer considerations, board material decisions must also be based on the expected stress and humidity in the application.

Convective heat transfer involves transfer due to the motion of molecules, typically airflow over a heat sink. Convective heat transfer, like conductive, depends on the relative temperatures of the two media involved. It also depends on the velocity of air flow over the boundary layer of the heat sink. Convective heat transfer is primarily affected when forced air flow is provided across a substrate and when convection effects are maximized through the use of heat sinks. The rules that designers are familiar with, when designing THT heat-sink device designs, also apply to SMT designs.

The design team must consider whether passive conduction and convection will be adequate to cool a populated substrate or whether forced-air cooling or liquid cooling will be needed. Passive conductive

TABLE 11.7 Thermal Properties of Common PCB Materials Glass TCE-Thermal Substrate Transition, Coefficient of Thermal Moisture

Material	Temperature, T_g , °C	X-Y Expansion, PPM/°C	Conductivity, W/M °C	Absorption, %
FR-4 epoxy glass	125	13-18	0.16	0.10
Polymide glass	250	12-16	0.35	0.35
Copper-clad Invar	Depends on resin	5-7	160XY-15-20Z	NA
Poly aramid fiber	250	3-8	0.15	1.65
Alumina/ceramic	NA	5-7	20-45	NA

cooling is enhanced with thermal layers in the substrate, such as the previously mentioned copper/Invar. There will also be designs that rely on the traditional through-hole device with heat sink to maximize heat transfer. An example of this would be the typical three-terminal voltage regulator mounted on a heat sink or directly to a metal chassis for heat conduction, for which standard calculations apply (Motorola, 1993).

Many specific examples of heat transfer may need to be considered in board design and, of course, most examples involve both conductive and convective transfer. For example, the air gap between the bottom of a standard SMD and the board affects the thermal resistance from the case to ambient, Θ_{ca} . A wider gap will result in a higher resistance, due to poorer convective transfer, whereas filling the gap with a thermal-conductive epoxy will lower the resistance by increasing conductive heat transfer. Thermal-modeling software is the best way to deal with these types of issues, due to the rigorous application of computational fluid dynamics (CFD) (Lee, 1994).

11.3.6 Adhesives

In the surface mount assembly process, type II and type III boards will always require adhesive to mount the SMDs for passage through the solder wave. This is apparent when one envisions components on the bottom side of the substrate with no through hole leads to hold them in place. Adhesives will stay in place after the soldering process and throughout the life of the substrate and the product, since there is no convenient means for adhesive removal once the solder process is complete. Additionally, adhesives can be used to enhance both thermal and electrical conduction between device features and board features. This means use of an adhesive must consider a number of both physical and chemical characteristics:

- Electrical conductivity
- Thermal conductivity
- Thermal coefficient of expansion similar to the substrate and the components
- Stable in both storage and after application, prior to curing
- Stable physical drop shape, retains drop height and fills z-axis distance between the board and the bottom of the component. Thixotropic with no adhesive migration.
- Noncorrosive to substrate and component materials
- Nonconductive electrically
- Chemically inert to flux, solder, and cleaning materials used in the process
- Curable as appropriate to the process: UV, oven, or air cure
- Removable for rework and repair
- Once cured, unaffected by temperatures in the solder process

Adhesive can be applied by stenciling/screening techniques similar to solder paste stencil/screen application, by pin-transfer techniques, and by syringe deposition. Stencil and pin-transfer techniques are suitable for high-volume production lines with few product changes over time. Syringe deposition, an X-Y table riding over the board with a volumetric pump and syringe tip, is more suitable for lines with a varying product mix, prototype lines, and low-volume lines where the open containers of adhesive necessary in pin-transfer and screen techniques are avoided. Newer syringe systems are capable of handling high-volume lines. See Fig. 11.22 for methods of adhesive deposition.

If type II or type III assemblies are used and thermal transfer between components and the substrate is a concern, the design team must consider thermally conductive adhesives.

Regardless of the type of assembly, the type of adhesive used, or the curing technique used, adhesive volume and height must be carefully controlled.

Detailed information on the appropriate volumes, application, and use of adhesives in electronic manufacturing is beyond the scope of this chapter. The reader wishing further information is referred to Prasad.

FIGURE 11.22 Idealized cone approximation of solder fillet.

11.3.7 Solder Paste and Joint Formation

Standard SMT Paste Technology

Solder joint formation is the culmination of the entire process. Regardless of the quality of the design, or any other single portion of the process, if high-quality reliable solder joints are not formed, the final product is not reliable. It is at this point that PPM levels take on their finest meaning. For a medium-size substrate (nominal 6×8 in.), with a medium density of components, a typical mix of active and passive parts on the topside and only passive and 3- or 4-terminal active parts on bottomsides, there may be in excess of 1000 solder joints/board. If solder joints are manufactured at the 3 sigma level (99.73% good joints, or 0.27% defect rate, or 2700 defects/1 million joints) there will be 2.7 defects per board! At the 6 sigma level, of 3.4 PPM, there will be a defect on 1 board out of every 294 boards produced. If your anticipated production level is 1000 units/day, you will have 3.4 rejects based solely on solder joint problems, not counting other sources of defects.

Solder paste may be deposited by syringe, or by screen or stencil printing techniques. Stencil techniques are best for high-volume/speed production although they do require a specific stencil for each board design. Syringe and screen techniques may be used for high-volume lines and are also suited to mixed-product lines where only small volumes of a given board design are to have solder paste deposited. Syringe deposition is the only solder paste technique that can be used on boards that already have some components mounted. It is also well suited for prototype lines and for any use requires only software changes to develop a different deposition pattern (see Fig. 11.23). Solder joint defects have many possible origins:

- Poor or inconsistent solder paste quality
- Inappropriate solder pad design/shape/size/trace connections
- Substrate artwork or production problems: for example, mismatch of copper and mask, warped substrate
- Solder paste deposition problems: for example, wrong volume or location
- Component lead problems: for example, poor coplanarity or poor tinning of leads
- Placement errors: for example, part rotation or X - Y offsets
- Reflow profile: for example, preheat ramp too fast or too slow; wrong temperatures created on substrate
- Board handling problems: for example, boards get jostled prior to reflow

Once again, a complete discussion of all of the potential problems that can affect solder joint formation is beyond the scope of this chapter. Many references are available which address the issues. An excellent

CALCULATION OF SOLDER FILLET VOLUME FOR PIP PROCESS
(PIP = PIN IN PASTE)

R1 = RADIUS OF SOLDER PAD ON BOARD
R2 = RADIUS OF THT LEAD
H = HEIGHT OF SOLDER FILLET = R1-R2, ASSUMES 45 DEGREE FILLET ANGLE

ASSUMPTIONS: THAT THE SOLDER FILLET IS CORRECTLY FORMED WITH NO VOIDS
FOR SINGLE-SIDED BOARDS, THERE IS NO SOLDER FILL OF THE THROUGH-HOLE IN THE PCB
FOR DOUBLE-SIDED BOARDS, THE TOP AND BOTTOM FILLETS ARE IDENTICAL
FOR DOUBLE-SIDED BOARDS, THERE IS COMPLETE SOLDER FILL OF THE THROUGH-HOLE IN THE PCB
THROUGH-HOLE SOLDER FILL VOLUME IS = THE VOLUME OF THE HOLE ($\pi R^2 T$) MINUS THE VOLUME OF
THE LEAD IN THE HOLE ($\pi R_2^2 T$), WHERE HOLE LENGTH T IS = PCB THICKNESS
VOLUME OF THE TRUNCATED CONE THAT DEFINES THE TOP AND BOTTOM FILLET IS:
 $V_{\text{cone}} = 1/3 \pi H (R_1^2 + R_1 R_2 + R_2^2)$

FIGURE 11.23 Calculation measurements for truncated cone approximation of solder fillet.

overview of solder joint formation theory is found in Lau (1991). Update information about this and all SMT topics is available each year at conferences, such as SMI and NEPCON.

Although commonly used solder paste for both THT and SMT production contains 63-37 eutectic tin-lead solder, other metal formulations are available, including 96-4 tin-silver (*silver solder*). The fluxes available are also similar, with typical choices being made between RMA, water-soluble, and no-clean fluxes. The correct decision rests as much on the choice of flux as it does on the proper metal mixture. A solder paste supplier can best advise on solder pastes for specific needs. Many studies are in process to determine a no-lead replacement for lead-based solder in commercial electronic assemblies. The design should investigate the current status of these studies as well as the status of no-lead legislation as part of the decision making process.

To better understand solder joint formation, one must understand the make-up of solder paste used for SMT soldering. The solder paste consists of microscopic balls of solder, most commonly tin-lead with the accompanying oxide film, flux, and activator and thickener solvents as shown in Fig. 11.24.

Regardless of the supplier, frequent solder paste tests are advisable, especially if the solder is stored for prolonged periods before use. At a minimum, viscosity, percent metal, and solder sphere formation should be tested (Capillo, 1990). Solder sphere formation is particularly important since acceptable particle sizes will vary depending on the pitch of the smallest pitch part to be used, and the consistency of solder sphere formation will affect the quality of the final solder joint. Round solder spheres have the smallest surface area for a given volume, and therefore will have the least amount of oxide formation. Uneven distribution

PASSIVE COMPONENT PLACED INTO SOLDER PASTE.
(EXAGGERATED)

FIGURE 11.24 Part placed into solder paste with a passive part.

of sphere sizes within a given paste can lead to uneven heating during the reflow process, with the result that the unwanted solderballs will be expelled from the overall paste mass at a given pad/lead site. Fine-pitch paste has smaller ball sizes and, consequently, more surface area on which oxides can form.

It should be noted at this point that there are three distinctly different solder balls referred to in this chapter and in publications discussing SMT. The solder sphere test refers to the ability of a volume of solder to form a ball shape due to its inherent surface tension when reflowed (melted). This ball formation is dependent on minimum oxides on the microscopic metal balls that make up the paste, the second type of solder ball. It is also dependent on the ability of the flux to reduce the oxides that are present, as well as the ramp up of temperature during the preheat and drying phases of the reflow oven profile. Too steep a time/temperature slope can cause rapid escape of entrapped volatile solvents, resulting in expulsion of small amounts of metal, which will form undesirable solder balls of the third type, that is, small metal balls scattered around the solder joint(s) on the substrate itself rather than on the tinned metal of the joint.

Pin in Paste Technology

Pin in paste (PIP) technology, also known as alternate assembly and reflow technology (AART) by Universal Instruments and others, allow the use of THT parts with solder paste and reflow soldering. Paste is deposited onto the board at through-hole locations, the leads of a THT part are placed through the paste, and at the conclusion of the placement process the board and components are reflowed. The two major concerns with the use of the PIP process are the deposition of an adequate volume of solder paste and the use of THT components whose body can withstand reflow soldering temperatures. In the wave solder process, only component leads were raised to soldering temperatures, but in the reflow process the entire part must withstand the process temperatures.

The solder paste volume calculation consists of two parts, (1) solder fill for the through-hole and (2) solder for fillet inspection. The second part may or may not be necessary, depending on whether the solder joints will undergo visual inspection or not. Lack of necessity for fillets reduces the amount of solder paste that must be deposited. This makes the deposition easier. The solder fill calculation is straightforward: (volume of the through hole) – (volume of the part lead). Consideration must then be

given that solder paste designed for stencil application shrinks to approximately $1/2$ its applied-volume after reflow—therefore, twice as much must be applied as the desired volume of metal remaining after reflow. An example for a THT inch-dimensioned $1/2$ watt resistor inserted in a PCB $0.062''$ thick would be

- $V_{\text{hole}} = \pi R_H^2 T$, where R_H is the radius of the through hole and T is the thickness of the PCB.
- $V_{\text{lead}} = \pi R_L^2 T$, where R_L is the radius of the Lead and T is the thickness of the PCB.
- $V_{\text{paste}} = (V_{\text{hole}} - V_{\text{lead}}) \times 2 = ((\pi * 0.0155''^2 * 0.062'') - (\pi * 0.0125''^2 * 0.062'')) \times 2 = 32.7 \text{ E-6 in}^3$.

If top and bottom fillets are desired, the easiest approximation is the truncated cone with 45° sides, shown in Fig. 11.22. For the $1/2$ resistor example and a radius of the solder pad = 0.025 , the resulting volumes would be

- Volume of paste applied for filling the through hole = 32.7 E-6 in^3
- Volume of paste applied for filling each fillet = 14.3 E-6 in^3
- Total volume of for through-hole fill and top & bottom fillets = 61.3 E-6 in^3

No Lead Solder Paste

Few technical issues have hit the electronics industry as hard in recent years as the switch from Sn-Pb solder to lead-free attachment. Both by mandate, e.g., the European Commission requirement to eliminate lead in consumer products, as well as voluntarily, electronic component manufacturers and assemblers must come to grips with issues surrounding the transition to lead-free attachment of components. While various industry, academic, and governmental agencies that have studied alternatives to lead in solder now seem to agree on SnAgCu as the preferred alternative, as discussed by Bradley, Handwerker, and Sohn, there is still much to be done to create a minimal-problem transition.

Lau and Liu discuss the issues surrounding the various formulations of SnAgCu solder. Laske and Jensen discuss implementation issues with SnAgCu. They note that although Bi-containing alloys have the advantage of low melting temperature, Pb contamination is a very real concern for the next decade, from existing components, board finishes, etc., and Bi alloys do not tolerate lead contamination. Although they do not feel it is a major issue, Lau and Liu note that the elevated melting temperature of 217°C will bring with it major process control concerns. Laske and Jensen do present a lead-free process implementation used by one Motorola facility.

If the elevated temperatures or other issues make one feel that the SnAgCu alloys may not be appropriate for their facility, Dreezen and Luyckx present information on lead free assembly with conductive adhesives.

11.3.8 Parts Inspection and Placement

Briefly, all parts must be inspected prior to use. Functional parts' testing should be performed on the same basis as for through-hole devices. Each manufacturer of electronic assemblies is familiar with the various processes used on through-hole parts, and similar processes must be in place on SMDs. Problems with solderability of leads and lead **planarity** are two items which can lead to the largest number of defects in the finished product. Solderability is even more important with SMDs than with through-hole parts, since all electrical and mechanical strength rests within the solder joint, there being no hole-with-lead to add mechanical strength.

Lead coplanarity is defined as follows. If a multilead part, for example, an IC, is placed on a planar surface, lack of coplanarity exists if the solderable part of any lead does not touch that surface. Coplanarity requirements vary depending on the pitch of the component leads and their shape, but generally out-of-plane measurements should not exceed 4 mils (0.004 in.) for 50-mil pitch devices, and 2 mils for 25-mil pitch devices.

All SMDs undergo thermal shocking during the soldering process, and particularly if the SMDs are to be wave soldered (type I or type II boards), which means they will be immersed in the molten solder wave for 2-4 s. Therefore, all plastic-packaged parts must be controlled for moisture content. If the parts have not been stored in a low-humidity environment (<25% relative humidity) the absorbed moisture will expand during the solder process and crack the package, a phenomenon known as pop corning, since the crack is accompanied by a loud pop, and the package expands due to the expansion of moisture, just like popcorn, expands.

FIGURE 11.25 Part placed into solder paste with an active part.

Parts Placement

Proper parts placement not only places the parts within an acceptable window relative to the solder pad pattern on the substrate, the placement machine will apply enough downward pressure on the part to force it halfway into the solder paste (see Fig. 11.25 and Fig. 11.26).

FIGURE 11.26 Typical thermal profile for SMT reflow soldering (types I or II assemblies). (Source: Cox, R.N. 1992. Reflow Technology Handbook. Research Inc., Minneapolis, MN. With permission.)

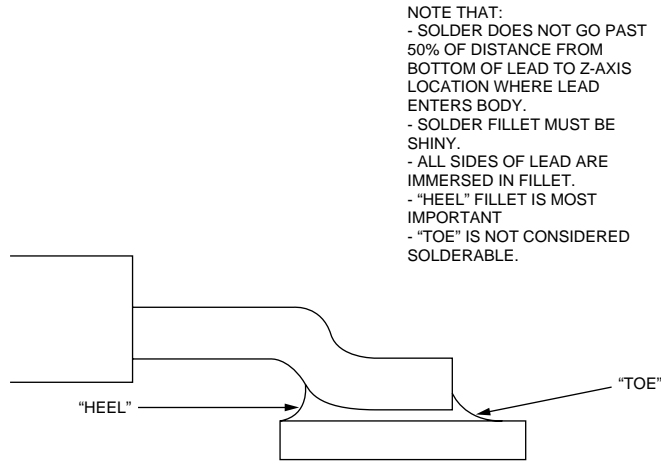

FIGURE 11.27 General inspection criteria for J-lead and gull wing components.

This assures both that the part will sit still when the board is moved and that acceptable planarity offsets among the leads will still result in an acceptable solder joint. Parts placement may be done manually for prototype or low-volume operations, although the author suggests the use of guided X-Y tables with vacuum part pickup for even the smallest operation. Manual placement of SMDs does not lend itself to repeatable work. For medium- and high-volume work, a multitude of machines are available. See Fig. 11.27 for the four general categories of automated placement equipment.

One good source for manufacturer's information on placement machines and most other equipment used in the various SMT production and testing phases is the annual *Directory of Suppliers to the Electronics Manufacturing Industry* published by *Electronic Packaging and Production* (see Further Information section). Among the elements to consider in the selection of placement equipment, whether fully automated or X-Y-vacuum assist tables, are

- Volume of parts to be placed/hour
- Conveyorized links to existing equipment
- Packaging of components to be handled, tubes, reels, trays, bulk, etc.
- Ability to download placement information from CAD/CAM systems
- Ability to modify placement patterns by the operator
- Vision capability needed, for board fiducials and/or fine-pitch parts

11.3.9 Reflow Soldering

Once SMDs have been placed in solder paste, the assembly will be reflow soldered. This can be done in either batch-type ovens, or conveyorized continuous-process ovens. The choice depends primarily on the board throughput/hour required. Whereas many early ovens were of the vapor phase type, most ovens today use IR heating, convection heating, or a combination of the two. The ovens are zoned to provide a thermal profile necessary for successful SMD soldering. An example of an oven thermal profile is shown in Fig. 11.26.

The phases of reflow soldering, which are reflected in the example profile in Fig. 11.26 are

- *Preheat*: The substrate, components, and solder paste preheat.
- *Dry*: Solvents evaporate from the solder paste. Flux activates, reduces oxides, and evaporates. Both low- and high-mass components have enough soak time to reach temperature equilibrium.
- *Reflow*: The solder paste temperature exceeds the liquidus point and reflows, wetting both the component leads and the board pads. Surface tension effects occur, minimizing wetted volume.

- *Cooling*: The solder paste cools below the liquidus point, forming acceptable (shiny and appropriate volume) solder joints.

The setting of the reflow profile is not trivial. It will vary depending on whether the flux is RMA, water soluble, or no clean, and it will vary depending on both the mix of low- and high-thermal mass components, and on how those components are laid out on the board. See *Cox's Reflow Technology Handbook* for additional information. The profile should exceed the liquidus temperature of the solder paste by 20–25°C. Although final setting of the profile will depend on actual quality of the solder joints formed in the oven, initial profile setting should rely heavily on information from the solder paste vendor, as well as the oven manufacturer. Remember that the profile shown in Fig. 11.26 is the profile to be developed on the substrate, and the actual control settings in various stages of the oven itself may be considerably different, depending on the thermal inertia of the product in the oven and the heating characteristics of the particular oven being used.

Defects as a result of poor profiling include

- Component thermal shock
- Solder splatter
- Solder balls formation
- Dewetted solder
- Cold or dull solder joints

Note in Fig. 11.27 that the “toe” fillet on the gull-wing package is generally considered an unreliable indicator of a good solder joint. During the manufacturing process this end of the lead may be cut after tinning, leaving bare copper exposed at the end of the lead.

It should be noted that many other problems may contribute to defective solder joint formation. One example would be placement misalignment, which contributes to the formation of solder bridges. Other problems that may contribute to defective solder joints include poor solder mask adhesion and unequal solder land areas at opposite ends of passive parts, which creates unequal moments as the paste liquifies and develops surface tension. Wrong solder paste volumes, whether too much or too little, will create defects, as will board shake in placement machines and coplanarity problems in IC components. Many of these problems should be covered and compensated for during the design process and the qualification of SMT production equipment. Final analysis of the process is performed based on the quality of the solder joints formed in the reflow process. Whatever criteria may have been followed during the overall process, solder joint quality is the final determining factor of the correctness of the various process steps. As noted earlier, the quality level of solder joint production is a major factor in successful board assembly. A primary criteria is the indication of wetting at the junction of the reflowed solder and the part termination.

The discussion in section 11.3.7.3 noted the higher melting point of the SnAgCu lead-free solder. As Apell notes, “Due to the higher melting points of lead-free solder formulations, the profiling requirements will change. . . . peak temperature and time above liquidus must be achieved without overheating the assembly or components.”

Presentation of criteria for all the various SMD package types and all of the possible solder joint problems is beyond the scope of this chapter. The reader is directed to Hollomon (1995), Hwang (1989), Lau (1991), Klein-Wassink (1989), and Prasad (1997) for an in-depth discussion on these issues.

11.3.10 Prototype Systems

Systems for all aspects of SMT assembly are available to support low-volume/prototype needs. These systems will typically have manual solder-paste deposition and parts placement systems, with these functions being assisted for the user. Syringe solder paste deposition may be as simple as a manual medical-type syringe dispenser, which must be guided and squeezed freehand. More sophisticated systems will have the syringe mounted on an X-Y arm to carry the weight of the syringe, and will apply air pressure to the top of the syringe with a foot-pedal control, freeing the operator's arm to guide the syringe to the proper location on the substrate and perform the negative z-axis maneuver, which will bring the syringe tip into the proper

location and height above the substrate. Dispensing is then accomplished by a timed air-pressure burst applied to the top of the syringe under foot-pedal control. Paste volume is likewise determined by trial and error with the time/pressure relation, and depends on the type and manufacturer of paste being dispensed.

Parts placement may be as simple as tweezers and progress to hand-held vacuum probes to allow easier handling of the components. As mentioned previously, X-Y arm/tables are available that have vacuum-pick nozzles to allow the operator to pick a part from a tray, reel, or stick, and move the part over the correct location on the substrate. The part is then moved down into the solder paste, the vacuum is turned off manually or automatically, and the nozzle is raised away from the substrate.

Soldering of prototype/low-volume boards may be done by contact soldering of each component, by a manually guided hot-air tool, or in a small batch or conveyORIZED oven. Each step up in soldering sophistication is, of course, accompanied by an increase in the investment required.

For manufacturers with large prototype requirements, it is possible to set up an entire line that would involve virtually no hardware changes from one board to another using the following steps:

- ECAD design and analysis produce Gerber files.
- CNC circuit board mill takes Gerber files and mills out two-sided boards.
- Software translation package generates solder-pad centroid information.
- Syringes older paste deposition system takes translated Gerber file and dispenses appropriate amount at each pad centroid.
- Software translation package generates part centroid information.
- Parts placement equipment places parts based on translated part centroid information.
- Assembly is reflow soldered.

The only manual process in this system is adjustment of the reflow profile based on the results of soldering an assembly. The last step in the process would be to test the finished prototype board. This system could also be used for very small volume production runs, and all components as described are available. With a change from milled boards to etched boards, the system can be used as a flexible assembly system.

Defining Terms

Coefficient of thermal expansion (CTE or TCE): A measure of the ratio between the measure of a material and its expansion as temperature increases. May be different in X, Y, and Z axes. Expressed in parts per million per degree Celsius, it is a measure that allows comparison of materials that are to be joined.

Coplanarity: A simplified definition of *planarity*, which is difficult to measure. Noncoplanarity is the distance between the highest and lowest leads and is easily measured by placing the IC on a flat surface, such as a glass plate. The lowest leads will then rest on the plate, and the measured difference to the lead highest above the plate is the measurement of noncoplanarity

Glass transition temperature (T_g): Below T_g , a polymer substance, such as fiberglass, is relatively linear in its expansion/contraction due to temperature changes. Above T_g , the expansion rate increases dramatically and becomes nonlinear. The polymer will also lose its stability, that is, an FR-4 board droops above T_g .

Gull wing: An SMD lead shape as shown in Fig. 11.18 for SOPs and QFPs, and in Fig. 11.26. So called because it looks like a gulls wing in flight.

Plastic leaded chip carrier (PLCC): Shown in Fig. 11.18, it is a mature SMT IC package and is the only package that has the leads bent back under the IC itself.

Planarity: Lying in the same plane. A plane is defined by the exit of the leads from the body of the IC. A second plane is defined at the average of the lowest point all leads are below the first plane. Nonplanarity is the maximum variation in mils or millimeters of any lead of an SMD from the lowest point plane.

Quad flat pack: Any flat pack IC package that has leads on all four sides.

Through hole: Also a *plate through hole* (PTH). A hole in a substrate that extends completely through a substrate, is solder plated, and is intended for a component lead.

Through-hole technology: The technology of using leaded components which require holes through the substrate for their mounting (insertion) and soldering.

Via: A hole in the substrate intended only to establish electrical connectivity, and not intended to hold a component lead.

11.4 Shielding and EMI Considerations

Donald White

11.4.1 Introduction

Two of many requirements of electronic-system packaging are to ensure that the corresponding equipments are in compliance with applicable national and international **electromagnetic compatibility** (EMC)

regulations for emission and immunity control. In the U.S., this refers to FCC, Rules and Regulations, Parts 15.B on emission, and internationally to CISPR 22 and IEC-1000-4 (formerly, IEC 801 family) for emission and immunity control.

Emission and immunity (susceptibility) control each have two parts: conducted (on hard wire) and radiated (radio-wave coupling). This section deals only with the latter on **electromagnetic interference (EMI) radiated emission** and susceptibility control.

In general, reciprocity applies for EMI and its control. When a shield is added to reduce radiated emission, it also reduces radiated immunity. Quantitatively speaking, however, reciprocity does not apply since the bilateral conditions do not exist, viz., the distance from the source to the shield does not equal the distance from the shield to the victim. Thus, generally, expect different shielding effectiveness values for each direction.

11.4.2 Cables and Connectors

One principal method of dealing with EMI is to shield the source, the victim, or both, so that only intentional radiation will couple between them. The problem, then, is to control unintentional radiation coupling into or out of victim circuits, their PCBs, their housings, and equipment interconnecting cables.

Generalizing, the greatest cause of EMI failure is from interconnecting cables. Cables are often referred to as *the antenna farm* since they serve to unintentionally pickup or radiate emissions to or from the outside world thereby causing EMI failures. However, cables are not the subject of this section. Connectors are loosely referred to as devices to stop outside **conducted emissions** from getting in or vice versa.

11.4.3 Shielding

If the system is designed correctly in the first place, little shielding may be needed to clean up the remaining EMI. One classical example is the design and layout of printed circuit boards (PCBs). Multilayer boards radiate at levels 20–35 dB below levels from double-sided, single-layer boards. Since logic interconnect trace radiation is the principal PCB radiator, it follows that multilayer boards are cost effective vs. having to shield the outer box housing.

Shielding Effectiveness

Figure 11.28 shows the concept of shielding and its measure of effectiveness, called **shielding effectiveness (SE)**. The hostile source in the illustration is at the left and the area to be protected is on the right. The metal barrier in the middle is shown in an edge-elevation view.

$$\text{SHIELDING EFFECTIVENESS RATIO} = \text{REFLECTION LOSS} \times \text{ABSORPTION LOSS}$$

$$SE_{dB} = R_{dB} + A_{dB} \quad \text{FOR ONLY FAR FIELD: } SE_{dB} = 20 \log_{10} (E_{y \text{ before}} / E_{y \text{ after}})$$

$$= 20 \log_{10} (H_{z \text{ before}} / H_{z \text{ after}})$$

FIGURE 11.28 Shielding effectiveness analysis.

The oncoming electromagnetic wave (note the orthogonal orientation of the electric and magnetic fields and the direction of propagation: $E \times H =$ Poynting's vector) is approaching the metal barrier. The wave impedance ($Z_w = E/H$) is 377Ω in the **far field** (distance $> \lambda/2\pi$). Z_w is greater in the **near field** (distance $< \lambda/2\pi$) for high-impedance waves or E fields and less than 377Ω in the near field for low-impedance waves or H fields. The wave impedance is related to the originating circuit impedance at the frequency in question.

The wavelength λ , in meters, used in the previous paragraph is related to the frequency in megahertz.

$$\lambda_m = 300/f_{\text{MHz}} \tag{11.6}$$

Since the wave impedance and metal barrier impedance Z_b (usually orders of magnitude lower) are not matched, there is a large reflection loss RL_{dB} established at the air-metal interface

$$RL_{\text{dB}} = 20 \log_{10}(Z_w/(4 * Z_b)) \tag{11.7}$$

where Z_w is the wave impedance equal to 377Ω in the far field.

Figure 11.28 shows that what is not reflected at the metal barrier interface continues to propagate inside where the electromagnetic energy is converted into heat. This process is called *absorption loss* AL_{dB} defined as

$$AL_{\text{dB}} = 8.6t/\delta \tag{11.8}$$

$$\delta = 1/\sqrt{\pi f \sigma \mu} \tag{11.9}$$

where

- t = metal thickness in any units
- δ = skin depth of metal in same units
- f = frequency, Hz
- σ = absolute conductivity of the metal, mho
- μ = absolute permeability of the metal, H/m

The shielding effectiveness SE_{dB} is the combination of both the reflection and absorption losses

$$SE_{\text{dB}} = RL_{\text{dB}} + AL_{\text{dB}} \tag{11.10}$$

Figure 11.29 shows the general characteristics of shielding effectiveness. As mentioned before, the interface between near and far fields occur at the distance $r = \lambda/2\pi$. The electric field is shown decreasing

FIGURE 11.29 The general characteristics of shielding effectiveness.

FIGURE 11.30 PCB component shielding. (Source: emf-emi control^R, Inc. Copyright 1995.)

at -20 dB/decade with increasing frequency while the magnetic field increases at $+20$ dB/decade. The two fields meet at the far-field interface, called *plane waves* at higher frequencies.

Figure 11.29 shows the absorption loss (dotted line) appearing when the metal thickness is approaching a fraction of one skin depth (adds 8.6 dB attenuation).

Different Levels of Shielding

Shielding may be performed at the component level, PCB or backplane level, card-cage level, box level, or entire system level (such as a shielded room). The latter is excluded from this discussion.

Component Shielding

Figure 11.30 shows a shield at the component level used on a clock on a PCB. The shield is grounded to the signal return, V_0 , or board ground traces, as most conveniently located.

The argument for shielding at the component level is that after using a multilayer board only the components can significantly radiate if further radiation reduction is needed.

Tests indicate that shielding effectiveness of component shields at radio frequencies above 10 MHz may vary from 10 to 25 dB over radiation from no shields.

Printed-Circuit Board Shielding

The reason that multilayer PCBs radiate at much lower levels than double-sided, single-layer boards is that the trace return is directly under the trace in the V_{cc} or V_0 planes, forming a microstrip line. This is similar to the technique of using a phantom ground plane on single-layer boards as shown in Fig. 11.31. The trace height is now small compared to a trace that must wander over one or more rows as in single-layer boards.

The remaining traces left to radiate in multilayer boards are the top traces (for example, north-south) and the bottom traces on the solder side (east-west). Many military spec PCBs shield both the top and bottom layers, but industrial boards generally do not do this because of the extra costs. They also make maintenance of the PCBs nearly impossible.

To shield the top side, the board would have to be broached to clear the surface-mount components. The bottom side shield can simply be a single-sided board (foil on the outside) brought up to the solder tabs. The board can be secured in place and bonded to the PCB (at least at the four corners). For greater shielding (see **aperture leakage**), additional bonding is needed.

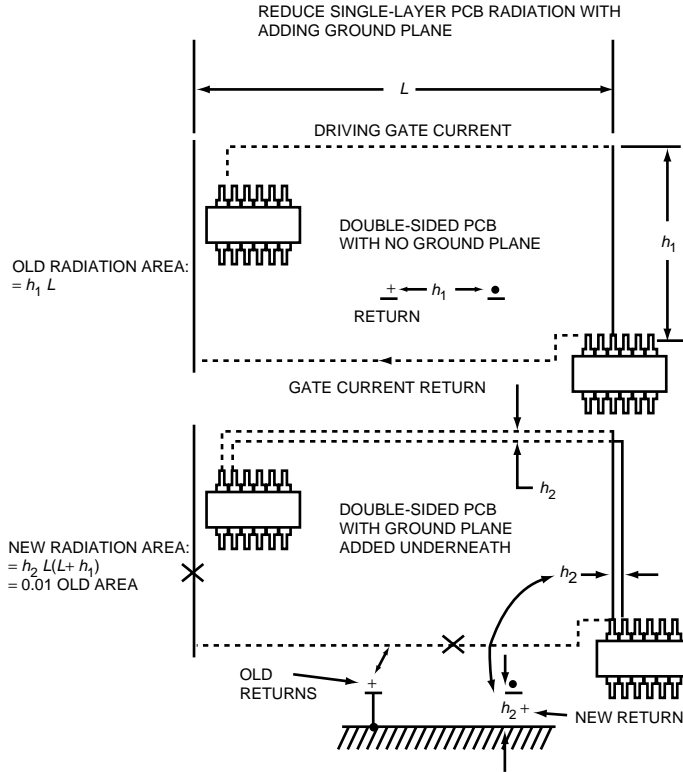

FIGURE 11.31 Using a phantom-ground plane in single-layer boards to reduce radiation.

Card-Cage Shielding

Card-cage shielding (metalizing all six sides of a plastic card cage) can add additional shielding effectiveness if the cards are single-layer boards. If multilayer boards, expect no shielding improvement since the trace-to-ground dimensions are much less than those of the card cage.

Shielding at the Box or Housing Level

Classically, the most effective level to shield is at the box-housing level. The attitude often is what radiated EMI you do not stop at the lower levels can be accomplished at the box level by adding conductive coatings and aperture-leakage control.

How much shielding is required at the box level to comply with FCC Parts 15.B or CISPR 22, Class B (residential locations)? Naturally, this depends on the complexity and number of PCBs, the clock frequency, the logic family, etc. At the risk of generalizing, however, if little EMI control is exercised at the PCB level, roughly 40 dB of shielding effectiveness will be required for the entire box over the frequency range of roughly 50–500 MHz.

To achieve a 40-dB overall box shielding, a deposited conductive coating would have to provide at least 50 dB. The coating impedance Z_b in ohms/square is determined from Eq. (11.7)

$$SE_{dB} = 20 \log_{10}(Z_w / (4 * Z_b))$$

where Z_w is the wave impedance equal to 377Ω in the far field. For $SE = 50$ dB, solving the above equation for Z_b

$$Z_b = Z_w / (4 * 10^{SE} / 20) \tag{11.11}$$

$$94 / 10^{2.5} = 0.3 \Omega / sq.$$

FIGURE 11.32 Principal aperture leakages in boxes.

This means that the conductive coating service house needs to provide the equivalent of a conductive coating of about $0.3 \Omega/\text{sq}$.

The electroless process is one of the principal forms of conductive coatings in use today. This process coats both inside and outside the plastic housing. One mil ($24 \mu\text{m}$) of copper is more than enough to achieve this objective as long as it is uniformly or homogeneously deposited.

Sometimes, a flashing of nickel is used over an aluminum or copper shield to provide abrasion protection to scratches and normal abuse. The flashing may be of the order of $1 \mu\text{m}$. Nickel does not compromise the aluminum or copper shielding. It simply adds to the overall shielding effectiveness.

11.4.4 Aperture-Leakage Control

As it develops, selecting and achieving a given shielding effectiveness of the conductive coating is the easy part of the box or housing shielding design. Far more difficult is controlling the many different aperture leakages depicted in Fig. 11.32. Therein it is seen that there are large apertures, such as needed for windows for cathode ray tube (CRT) and light emitting diode (LED) displays, holes for convection cooling, and slots for mating panel members.

To predict aperture leakages, the geometry is first defined in Fig. 11.33. The longest aperture dimension is l_{mm} , given in millimeters. The shortest aperture dimension is h_{mm} , given in millimeters. The thickness of the metal or conductive coating is d_{mm} , also given in millimeters.

FIGURE 11.33 Aperture dimensions used in mathematic models.

FIGURE 11.34 Aperture leakages using Eq. (11.12).

The aperture leakage SE_{dB} is predicted by using

$$SE_{dB} = 100 - 20 \log_{10}(l_{mm} f_{MHz}) + 20 \log_{10}(1 + \ln_e(l_{mm}/h_{mm})) + 30 l_{mm}/d_{mm} \tag{11.12}$$

with all terms having been previously defined.

To gain a better mental picture of the shielding effectiveness of different apertures, Eq. (11.12) is plotted in Fig. 11.34.

Illustrative Example 1

Even small scratches can destroy the performance of conductive coatings. For example, suppose that a single (inside) conductive coating has been used to achieve 50 dB of shielding effectiveness in the 50 MHz–1 GHz spectrum. Further, suppose that a screwdriver accidentally developed a 4-in. (102-mm) × 10-mil (0.25-mm) scratch. From Eq. (11.12), the resulting shielding effectiveness to the seventh harmonic of a 90-MHz onboard clock is

$$SE_{dB} = 100 - 20 \log_{10}(102 * 630) + 20 \log_{10}(1 + \ln_e(102/0.25))$$

$$= 100 - 96 + 17 = 21dB$$

Controlling Aperture Leakages

The success in achieving desired shielding effectiveness, then, is to control all major aperture leakages. As the SE requirement increases, it is also necessary to control minor aperture leakages as well.

Most aperture leakage control is divided into four sections

- Viewing windows
- Ventilating apertures
- Slots and seams
- All other apertures

Viewing Apertures

The first of the four aperture-leakage categories is viewing aperture windows. This applies to apertures such as CRTs, LED displays, and panel meters.

There are two ways to shore up leaky windows: (1) knitted wire mesh or screens and (2) thin-conductive films. In both cases, the strategy is to block the RF while passing the optical viewing with minimum attenuation.

Knitted-Wire Meshes and Screens

The amount of RF blocking (aperture leakage) from a knitted-wire mesh or screen is

$$SE_{dB} = 20 \log_{10}(\lambda/2/D) = 103 - (f_{MHz} D_{mm})dB \tag{11.13}$$

where D_{mm} is the screen mesh wire separation in millimeter.

Figure 11.35 shows one method for mounting screens and wire mesh. Mesh also comes in the form of metalized textiles with wire-to-wire separations as small as 40 μm , hence the wires are not even discernible, but appear more like an antiglare screen.

Thin Films

Another approach to providing RF shielding is to make a thin-film shield, which provides a surface impedance while passing most of the optical light through the material. Operating on the reflection-loss principle, typical shielding effectiveness of about 30 dB may be obtained (from Eq. (11.7), film impedances correspond to about 3 Ω /square). When the impedance is lowered to gain greater SE, optical blockage begins to exceed 50%. Figure 11.36 shows the performance of typical thin films.

As also applicable to screens and meshes, thin films must be bonded to the aperture opening 360° around the periphery. Otherwise, the film is compromised and SE suffers significantly.

Ventilating Holes

Convection cooling requires many small holes or slots at the top cover or upper panels of an electronic enclosure. If the array of holes is tight with relatively little separation (the subtends is less than 10% of a wavelength), the aperture leakage corresponds to that of a single hole defined in Eq. (11.12).

Additional attenuation is achievable by making the depth of the hole comparable to or exceeding the dimension of the hole or slot. This, then, generates the waveguide-beyond-cutoff effect in which the last term of Eq. (11.12) now applies as well.

Illustrative Example 2

Suppose an egg-crate array of square holes is placed in the top of a monitor for convection cooling. The squares are 4 mm on a side and 5 mm deep. Determine the shielding effectiveness of this configuration at 1.7 GHz.

FIGURE 11.35 Method of mounting wire screen over an aperture.

FIGURE 11.36 Effectiveness of thin-films shields.

From Eq. (11.12)

$$\begin{aligned} SE_{\text{dB}} &= 100 - 20 \log_{10}(4 * 1700) + 20 \log_{10}(1 + \ln_e(4/4)) + 30 * 5/4 \\ &= 100 - 77 + 0 + 38 = 61 \text{ dB} \end{aligned}$$

This is only possible with the electroless process of conductive coating of a plastic enclosure since the metal must be plated through the hole as well for the waveguide-beyond-cutoff concept to work.

Commercial versions of this process are shown in Fig. 11.37 for the hexagonal honeycomb used in all shielded rooms and most shielded electronic enclosures. Air flow is smoothly maintained while SE exceeds 100 dB.

FIGURE 11.37 Hexagonal honeycomb shields.

Electrical Gaskets

In some respects electrical gaskets are similar to mechanical gaskets. First, the tolerances of mating metal members may be relaxed considerably to reduce the cost of the fabrication. A one penny rubber washer makes the leakless mating of a garden hose with its bib a snap. The gasket does not work, however, until the joint is tightened enough to prevent blowby. The electrical equivalent of this is the joint must have sufficient pressure to achieve an *electrical seal* (meaning the advertised SE of the gasket is achievable). Second, the gasket should not be over-tightened. Otherwise *coldflow* or distortion will result and the life of the gasket may be greatly reduced. Electrical gaskets have similar considerations.

Figure 11.38 shows the cross-sectional view of an electrical gasket in place between two mating metal parts. The gap between the members is to be filled with a metal bonding material (the gasket), which provides a low-impedance path in the gap between the members, thereby avoiding a slot radiator discussed in earlier sections.

Usually, it is not necessary to use electrical gaskets to achieve SE of 40 dB below 1 GHz. It is almost always necessary to use electrical gaskets to achieve 60-dB SE . This raises the question of what to do to achieve between 40 and 60 dB overall SE ?

Gaskets can be relatively expensive, increase cost of installation and maintenance and are subject to corrosion and aging effects. Therefore, trying to avoid their use in the 40–60 dB range becomes a motivated objective. This can often be achieved, for example, by replacing a cover plate with an inverted shallow pan, which is less expensive than the gasket. Other mechanical manipulations to force the electromagnetic energy to go around corners is often worth 10–20 dB more in equivalent SE .

Electrical gaskets are available in three different forms: (1) spring-finger stock, (2) wire-mesh gaskets, and (3) conductive impregnated elastomers.

Spring-Finger Stock

The oldest and best known of the electrical gasket family is the spring-finger stock shown in Fig. 11.39. This gasket is used in applications where many openings and closings of the mating metal parts are anticipated. Examples include shielded room doors, shielded electronic enclosures, and cover pans.

FIGURE 11.38 Electrical gasket filling the gap between mating metal parts: (a) joint unevenness = ΔH just touching, (b) compressed gasket in place.

FIGURE 11.39 Spring finger gaskets.

Spring-finger gaskets may be applied by using adhesive backing, sweat soldering into place, riveting, or eyeleting.

Wire-Mesh Gaskets

Another popular electrical gasket is the multilayer, knitted-wire mesh. Where significant aperture space needs to be absorbed, the gasket may have a center core of spongy material such as neoprem or rubber. Figure 11.40 shows a number of methods of mounting wire-mesh gaskets.

Conductive-Impregnated Elastomers

A third type of gasket is the conductive-impregnated elastomers. In this configuration, the conductive materials are metal flakes or powder dispersed throughout the carrier. This gasket and some of its applications are shown in Fig. 11.41.

FIGURE 11.40 Knitted-wire mesh mountings.

FIGURE 11.41 Conductive elastomeric gaskets.

Shielding Composites

Another material for achieving shielding is called composites. Here the plastic material is impregnated with flakes or powder of a metal such as copper or aluminum. Early versions were not particularly successful since it was difficult to homogeneously deploy the filler without developing leakage spots or clumps of the metal flakes. This led to making the composites into multilayers of sheet material to be formed around a mold.

Today, injection molding of uniformly deployed copper or aluminum flakes (about 20% by volume) is readily achievable.

A more useful version of these composites is to employ metal filaments with aspect ratios (length-to-diameter) of about 500. For comparable shielding effectiveness, only about 5% loading of the plastic carrier is needed.

Filament composites exhibit the added benefit of providing wall cooling about 50 times that of conductive coatings. One difficulty, however, is making good electrical contact to the composite at the periphery. This may require electroplating or application of an interface metal tape.

11.4.5 System Design Approach

If the overall shielding effectiveness of a box or equipment housing is to be X dB, then what is the objective for the design of each of the leaky apertures? And, what must be the shielding effectiveness of the conductive coating of the housing?

Leaky apertures combine like resistors in parallel. The overall SE of the enclosure is poorer than any one aperture:

$$SE_{\text{overall}} = 20 \log_{10} \left[\sum \text{antilog } SE_N \right] \quad (11.14)$$

where SE_N is the SE of the N th aperture.

The required SE_N may be approximated by assuming that each aperture leakage must meet the same shielding amount, hence

$$SE_N = SE_{\text{overall}} + 20 \log_{10} N \quad (11.15)$$

Illustrative Example 3

A box housing has three separate aperture leakages: the CRT, convection cooling holes, and seams at mating conductive coating parts. Determine the aperture leakage requirements of each to obtain an overall SE of 40 dB.

From Eq. (11.14)

$$SE_{\text{each}} = 40 \text{ dB} + 20 \log_{10}(3) = 50 \text{ dB}$$

To fine tune this value, the aperture leakage can be relaxed in one area if tightened in another. This is often desired where a relaxation can avoid an expensive additive such as an electrical gasket. In this example, it may be desired to relax the seam gasket to produce 45 dB, if the other two leakages are tightened to 60 dB.

Finally, the basic SE of the conductive coating must exceed the SE of each aperture leakage (or the most stringent of the aperture leakages). A margin of 10 dB is suggested since 6 dB will produce a 4-dB degradation at the aperture, where as 10 dB will allow a 3-dB degradation. Thus, in example 3, the SE of the base coating would have to be 60 dB to permit controlling three apertures to 50 dB to result in an overall SE of 40 dB.

Defining Terms

Aperture leakage: The compromise in shielding effectiveness resulting from holes, slits, slots, and the like used for windows, cooling openings, joints, and components.

Broadband EMI: Electrical disturbance covering many octaves or decades in the frequency spectrum or greater than receiver bandwidth.

Common mode: As applied to two or more wires, all currents flowing therein which are in-phase.

Conducted emission (CE): The potential EMI which is generated inside the equipment and is carried out of the equipment over I/O lines, control leads, or power mains.

Coupling path: The conducted or radiated path by which interfering energy gets from a source to a victim.

Crosstalk: The value expressed in dB as a ratio of coupled voltage on a victim cable to the voltage on a nearby culprit cable.

Differential mode: On a wire pair when the voltages or currents are of opposite polarity.

Electromagnetic compatibility (EMC): Operation of equipments and systems in their installed environments which cause no unfavorable response to or by other equipments and systems in same.

Electromagnetic environmental effects (E3): A broad umbrella term used to cover EMC, EMI, RFI, electromagnetic pulse (EMP), electrostatic discharge (ESD), radiation hazards (RADHAZ), lightning, and the like.

Electromagnetic interference (EMI): When electrical disturbance from a natural phenomena or an electrical/electronic device of system causes an undesired response to another.

Electrostatic discharge (ESD): Fast risetime, intensive discharges from humans, clothing, furniture, and other charged dielectric sources.

Far field: In radiated-field vernacular, EMI point source distance greater than about 1/6 wavelength.

Ferrites: Powdered magnetic material in the form of beads, rods, and blocks used to absorb EMI on wires and cables.

Field strength: The radiated voltage or current per meter corresponding to electric or magnetic fields.

Narrowband EMI: Interference whose emission bandwidth is less than the bandwidth of EMI measuring receiver or spectrum analyzer.

Near field: In radiated-field vernacular, EMI point source distance less than about 1/6 wavelength.

Noise-immunity level: The voltage threshold in digital logic families above which a logic zero may be sensed as a one and vice versa.

Normal mode: The same as differential mode, emission or susceptibility from coupling to/from wire pairs.

Radiated emission (RE): The potential EMI that radiates from escape coupling paths such as cables, leaky apertures, or inadequately shielded housings.

Radiated susceptibility: Undesired potential EMI that is radiated into the equipment or system from hostile outside sources.

Radio frequency interference (RFI): Exists when either the transmitter or receiver is carrier operated, causing unintentional responses to or from other equipment or systems.

Shielding effectiveness (SE): Ratio of field strengths before and after erecting a shield. SE consist of absorption and reflection losses.

Transients: Short surges of conducted or radiated emission during the period of changing load conditions in an electrical or electronic system or from other sources.

11.5 Heat Management

Zbigniew J. Staszak

11.5.1 Introduction

Thermal cooling/heat management is one of four major functions provided and maintained by a packaging structure or system, with the other three being: (1) mechanical support, (2) electrical interconnection for power and signal distribution, and (3) environmental protection, all aimed at effective transfer of the semiconductor chip performance to the system. Heat management can involve a significant portion of the total packaging design effort and should result in providing efficient heat transfer paths at all packaging levels, that is, level 1 packaging (chip(s), carrier—both single-chip and multichip modules), level 2 (the module substrate—card), level 3 (board, board-to-board interconnect structures), and level 4 (box, rack, or cabinet housing the complete system), to an ultimate **heat sink** outside, while maintaining internal device temperature at acceptable levels in order to control thermal effects on circuits and system performance.

The evolution of chip technology and of packaging technology is strongly interdependent. Very large-scale integrated (VLSI) packaging and interconnect technology are driven primarily by improvements in chip and module technologies, yield, and reliability.

Packaging performance limits are thus being pushed for high-speed (subnanosecond edge speeds), high-power ($\sim 50\text{--}100\text{ W/cm}^2$) chips with reliable operation and low cost. However, there is a tradeoff between power and delay; the highest speed demands that gates be operated at high power. Though packaging solutions are dominated by applications in digital processing for computer and aerospace (avionics) applications, analog and mixed analog/digital, power conversion, and microwave applications cannot be overlooked. The net result of current chip and substrate characteristics is that leading-edge electrical and thermal requirements that have to be incorporated in packaging can be met with some difficulty and only with carefully derived *electrical design rules* (Davidson and Katopis, 1989) and complex thermal management techniques (ISHM, 1984).

The drive toward high functional density, extremely high speed, and highly reliable operation is constrained by available **thermal design** and *heat removal techniques*. A clear understanding of thermal control technologies, as well as the thermal potential and limits of advanced concepts, is critical. Consequently, the choice of thermal control technology and the particular decisions made in the course of evolving the thermal packaging design often have far-reaching effects on both the reliability and cost of the electronic system or assembly (Nakayama, 1986; Antonetti, Oktay, and Simons, 1989).

Temperature changes encountered during device fabrication, storage, and normal operation are often large enough to place limits on device characterization and lifetime. Temperature related effects, inherent in device physics, lead to performance limitations, for example, propagation delays, degradation of noise margins, decrease in electrical isolation provided by reverse-biased junctions in an IC, and other effects. **Thermally enhanced failures**, such as oxide wearout, fracturing, package delamination, wire bond breakage, deformation of metallization on the chip, and cracks and voids in the chip, substrate, die bond, and solder joints lead to reliability limitations (Jeannotte, Goldmann, and Howard, 1989).

The dependence of the **failure rate** on temperature is a complex relationship involving, among other things material properties and environmental conditions, and in a general form can be described by the Arrhenius equation depicted in Fig. 11.42.

FIGURE 11.42 Normalized failure rate $\lambda(T)/\lambda(T_R)$ as a function of temperature showing an exponential dependence of failure rate with temperature; for example, for $E_A = 0.5\text{ eV}$ an increase of 10°C in temperature almost doubles, whereas an increase of 20°C more than triples the failure rate at about room temperature.

This relation is well suited for device-related functional failures; however, for thermally induced structural failures it has to be applied with care since these failures depend both on localized temperature as well as the history of fabrication and assembly, thermal cycling for test purposes (thermal shock testing), and powering up during operation (operational thermal stress), thus being more complicated in nature.

$$\lambda(T) = \lambda(T_R) \exp \left[\frac{E_A}{k} \left(\frac{1}{T_R} - \frac{1}{T} \right) \right]$$

where

$\lambda(T)$ = failure rate (FIT) at temperature T , K

$\lambda(T_R)$ = failure rate (FIT) at temperature T_R , K

E_A = activation energy, eV, typical values for integrated circuits are 0.3–1.6 eV

k = Boltzman's constant, 8.616×10^{-5} eV/K

In the definition of $\lambda(T)$, FIT is defined as one failure per billion device hours (10^{-9} /h) or 0.0001%/1000 h. Improvements in thermal parameters and in removable heat densities require enhancements in chip technology, package design, packaging materials compositions, assembly procedures, and cooling techniques (systems). These must be addressed early in the design process to do the following:

- Reduce the rise in temperature and control the variation in the device operating temperature across all the devices, components, and packaging levels in the system.
- Reduce deformations and stresses produced by temperature changes during the fabrication process and normal operation.
- Reduce variations in electrical characteristics caused by thermal stresses.

11.5.2 Heat Transfer Fundamentals

In the analysis of construction of VLSI-based chips and packaging structures, all modes of heat transfer must be taken into consideration, with natural and forced air/liquid convection playing the main role in the cooling process of such systems. The temperature distribution problem may be calculated by applying the (energy) conservation law and equations describing heat conduction, convection, and radiation (and, if required, phase change). Initial conditions comprise the initial temperature or its distribution, whereas boundary conditions include adiabatic (no exchange with the surrounding medium, i.e., surface isolated, no heat flow across it), isothermal (constant temperature), or/and miscellaneous (i.e., exchange with external bodies, adjacent layers, or surrounding medium). Material physical parameters, and thermal conductivity, **specific heat**, thermal coefficient of expansion, and **heat transfer coefficients**, can be functions of temperature.

Basic Heat Flow Relations, Data for Heat Transfer Modes

Thermal transport in a solid (or in a stagnant fluid: gas or liquid) occurs by *conduction*, and is described in terms of the *Fourier equation* here expressed in a differential form as

$$q = -k\nabla T(x, y, z)$$

where

q = heat flux (power density) at any point x, y, z , W/m²

k = thermal conductivity of the material of conducting medium (W/m-degree), here assumed to be independent of x, y, z (although it may be a function of temperature)

T = temperature, °C, K

In the one-dimensional case, and for the transfer area A (m) of heat flow path length L (m) and thermal conductivity k not varying over the heat path, the temperature difference ΔT (°C, K) resulting from the

conduction of heat $Q(W)$, normal to the transfer area, can be expressed in terms of a **conduction thermal resistance** θ (degree/W). This is done by analogy to electrical current flow in a conductor, where heat flow $Q(W)$ is analogous to electric current $I(A)$, and temperature $T(^{\circ}C, K)$ to voltage $V(V)$, thus making thermal resistance θ analogous to electrical resistance $R(\Omega)$ and thermal conductivity k (W/m-degree) analogous to electrical conductivity, σ (1/ $\Omega - m$):

$$\theta = \frac{\Delta T}{Q} = \frac{L}{kA}$$

Expanding for multilayer (n layer) composite and rectilinear structure

$$\theta = \sum_{i=1}^n \frac{\Delta l_i}{k_i A_i}$$

where

Δl_i = thickness of the i th layer, m

k_i = thermal conductivity of the material of the i th layer, W/m degree

A_i = cross-sectional area for heat flux of the i th layer, m^2

In semiconductor packages, however, the heat flow is not constrained to be one dimensional because it also spreads laterally. A commonly used estimate is to assume a 45° heat spreading area model, treating the flow as one dimensional but using an effective area A_{eff} that is the arithmetic mean of the areas at the top and bottom of each of the individual layers Δl_i of the flow path. Assuming the heat generating source to be square, and noting that with each successive layer A_{eff} is increased with respect to the cross-sectional area A_i for heat flow at the top of each layer, the thermal (spreading) resistance θ_{sp} is expressed as follows:

$$\theta_{\text{sp}} = \frac{\Delta l_i}{k A_{\text{eff}}} = \frac{\Delta l_i}{k A_i \left(1 + \frac{2\Delta l_i}{\sqrt{A_i}} \right)}$$

On the other hand, if the heat generating region can be considered much smaller than the solid to which heat is spreading, then the semi-infinite heat sink case approach can be employed. If the **heat flux** is applied through a region of radius R , then either $\theta_{\text{sp}} = 1/\pi k R$ for uniform heat flux and the maximum temperature occurring at the center of the region, or $\theta_{\text{sp}} = 1/4kR$ for uniform temperature over the region of the heat source (Carstaw and Jaeger, 1967).

The preceding relations describe only static heat flow. In some applications, however, for example, switching, it is necessary to take into account transient effects. When heat flows into a material volume $V(m^3)$ causing a temperature rise, thermal energy is stored there, and if the heat flow is finite, the time required to effect the temperature change is also finite, which is analogous to an electrical circuit having a capacitance that must be charged in order for a voltage to occur. Thus the required power/heat flow Q to cause the temperature ΔT in time Δt is given as follows:

$$Q = \rho c_p V \frac{\Delta T}{\Delta t} = C_{\theta} \frac{\Delta T}{\Delta t}$$

where

C_{θ} = thermal capacitance, W-s/degree

ρ = density of the medium, g/m^3

c_p = specific heat of the medium, W-s/g-degree

Again, we can make use of electrical analogy, noting that thermal capacitance C_{θ} is analogous to electrical capacitance $C(F)$.

A rigorous treatment of multidimensional heat flow leads to a time-dependent heat flow equation in a conducting medium, which in Cartesian coordinates, and for $Q_V(W/m^3)$ being the internal heat

FIGURE 11.43 Temperature dependence of thermal conductivity k , specific heat c_p , and coefficient of thermal expansion (CTE) β of selected packaging materials.

source/generation, is expressed in the form of

$$k \nabla^2 T(x, y, z, t) = -Q_V(x, y, z, t) + \rho c_p \frac{\partial T(x, y, z, t)}{\partial t}$$

An excellent treatment of analytical solutions of heat transfer problems has been given by Carslaw and Jaeger (1967). Although analytical methods provide results for relatively simple geometries and idealized boundary/initial conditions, some of them are useful (Newell, 1975; Kennedy, 1960). However, thermal analysis of complex geometries requires multidimensional numerical computer modeling limited only by the capabilities of computers and realistic CPU times. In these solutions, the designer is normally interested in the behavior of device/circuit/package over a wide range of operating conditions including temperature dependence of material parameters, finite dimensions and geometric complexity of individual layers, nonuniformity of thermal flux generated within the active regions, and related factors.

Figure 11.43 displays temperature dependence of thermal material parameters of selected packaging materials, whereas Table 11.8 summarizes values of parameters of insulator, conductor, and semiconductor materials, as well as gases and liquids, needed for thermal calculations, all given at room temperature. Note the inclusion of the thermal coefficient of expansion β ($^{\circ}\text{C}^{-1}, \text{K}^{-1}$), which shows the expansion and contraction ΔL of an unrestrained material of the original length L_o while heated and cooled according to the following equation:

$$\Delta L = \beta L_o (\Delta T)$$

Convection heat flow, which involves heat transfer between a moving fluid and a surface, and *radiation heat flow*, where energy is transferred by electromagnetic waves from a surface at a finite temperature, with or without the presence of an intervening medium, can be accounted for in terms of heat transfer coefficients h ($\text{W}/\text{m}^2\text{-degree}$). The values of the heat transfer coefficients depend on the local transport phenomena occurring on or near the package/structure surface. Only for simple geometric configurations can these values be analytically obtained. Little generalized heat transfer data is available for VLSI type conditions, making it imperative to create the ability to translate real-life designs to idealized conditions (e.g., through correlation studies). Extensive use of empirical relations in determining heat transfer correlations is made through the use of dimensional analysis in which useful design correlations relate the transfer coefficients to geometrical/flow conditions (Furkay, 1984).

^aApproximate values, depending on exact composition of the material. (Source: Compiled based in part on: Touloukian, Y.S. and Ho, C.Y. 1979. *Master Index to Materials and Properties*. Plenum Publishing, New York.)

For *convection*, both free-air and forced-air (gas) or -liquid convection have to be considered, and both flow regimes must be treated: **laminar flow** and **turbulent flow**. The detailed nature of convection flow is heavily dependent on the geometry of the thermal duct, or whatever confines the fluid flow, and it is nonlinear. What is sought here are crude estimates, however, just barely acceptable for determining whether a problem exists in a given packaging situation, using as a model the relation of *Newton's law of cooling* for convection heat flow Q_c (W)

$$Q_c = h_c A_S (T_S - T_A)$$

where

h_c = average convective heat transfer coefficient, W/m²-degree

A_S = cross-sectional area for heat flow through the surface, m²

T_S = temperature of the surface, $^\circ\text{C}$, K

T_A = ambient/fluid temperature, $^\circ\text{C}$, K

For *forced convection* cooling applications, the designer can relate the temperature rise in the coolant temperature $\Delta T_{\text{coolant}}$ ($^\circ\text{C}$, K), within an enclosure/heat exchanger containing subsystem(s) that obstruct

the fluid flow, to a volumetric flow rate $G(\text{m}^3/\text{s})$ or fluid velocity $v(\text{m/s})$ as

$$\Delta T_{\text{coolant}} = T_{\text{coolant-out}} - T_{\text{coolant-in}} = \frac{Q_{\text{flow}}}{\rho G c_p} = \frac{Q_{\text{flow}}}{\rho v A c_p} = \frac{Q_{\text{flow}}}{\dot{m} c_p}$$

where

$T_{\text{coolant-out/in}}$ = the outlet/inlet coolant temperatures, respectively, °C, K

Q_{flow} = total heat flow/dissipation of all components within the enclosure upstream of the component of interest, W

\dot{m} = mass flow rate of the fluid, g/s

Assuming a fixed temperature difference, the **convective heat transfer** may be increased either by obtaining a greater heat transfer coefficient h_c or by increasing the surface area. The heat transfer coefficient may be increased by increasing the fluid velocity, changing the coolant fluid, or utilizing *nucleate boiling*, a form of immersion cooling.

For nucleate boiling, which is a liquid-to-vapor phase change at a heated surface, increased heat transfer rates are the results of the formation and subsequent collapsing of bubbles in the coolant adjacent to the heated surface. The bulk of the coolant is maintained below the boiling temperature of the coolant, while the heated surface remains slightly above the boiling temperature. The **boiling heat transfer** rate Q_b can be approximated by a relation of the following form:

$$Q_b = C_{sf} A_S (T_S - T_{\text{sat}})^n = h_b A_S (T_S - T_{\text{sat}})$$

where

C_{sf} = constant, a function of the surface/fluid combination, $\text{W/m}^2\text{-K}^n$ (Rohsenow and Harnett, 1973)

T_{sat} = temperature of the boiling point (saturation) of the liquid, °C, K

n = coefficient, usual value of 3

h_b = boiling heat transfer coefficient, $C_{sf}(T_S - T_{\text{sat}})^{n-1}$, $\text{W/m}^2\text{-degree}$

Increased heat transfer of surface area in contact with the coolant is accomplished by the use of *extended surfaces*, plates or pin fins, giving the heat transfer rate Q_f by a fin or fin structure as

$$Q_f = h_c A \eta (T_b - T_f)$$

where

A = full wetted area of the extended surfaces, m^2

η = fin efficiency

T_b = temperature of the fin base, °C, K

T_f = temperature of the fluid coolant, °C, K

Fin efficiency η ranges from 0 to 1; for a straight fin $\eta = \tanh mL / mL$, where $m = \sqrt{2h_c/k\delta}$, L = the fin length (m), and δ = the fin thickness (m) (Kern and Kraus, 1972).

Formulas for heat convection coefficients h_c can be found from available empirical correlation and/or theoretical relations and are expressed in terms of dimensional analysis with the dimensionless parameters: Nusselt number Nu , Rayleigh number Ra , Grashof number Gr , Prandtl number Pr , and Reynolds number Re , which are defined as follows:

$$Nu = \frac{h_c L_{\text{ch}}}{k}, \quad Ra = Gr Pr, \quad Gr = \frac{g\beta\rho^2}{\mu^2} L_{\text{ch}}^3 \Delta T, \quad Pr = \frac{\mu c_p}{k}, \quad Re = v L_{\text{ch}} \frac{\rho}{\mu}$$

where

- L_{ch} = characteristic length parameter, m
- g = gravitational constant, 9.81 m/s²
- μ = fluid dynamic viscosity, g/m-s
- $\Delta T = T_S - T_A$, degree

Examples of such expressions for selected cases used in VLSI packaging conditions are presented next. Convection heat transfer coefficients h_c averaged over the plate characteristic length are written in terms of correlations of an average value of Nu vs. Ra , Re , and Pr .

1. For natural (air) convection over external flat horizontal and vertical platelike surfaces,

$$Nu = C(Ra)^n$$

$$h_c = (k/L_{ch})Nu = (k/L_{ch})C(Ra)^n = C'(L_{ch})^{3n-1} \Delta T^n$$

where

- C, n = constants depending on the surface orientation (and geometry in general), and the value of the Rayleigh number, see Table 11.9.
- $C' = kC[(g\beta\rho^2/\mu^2)Pr]^n$

Most standard applications in electronic equipment, including packaging structures, appear to fall within the laminar flow region (see Fig. 11.44). Ellison (1987) has found that the preceding expressions for natural air convection cooling are satisfactory for cabinet surfaces; however, they significantly underpredict the heat transfer from small surfaces. By curve fitting the empirical data under laminar conditions, the following formula for natural convection to air for small devices encountered in the electronics industry was found:

$$h_c = 0.83 f(\Delta T/L_{ch})^n (\text{W/m}^2\text{-degree})$$

where $f = 1.22$ and $n = 0.35$ for vertical plate, $f = 1.00$ and $n = 0.33$ for horizontal plate facing upward, that is, upper surface $T_S > T_A$, or lower surface $T_S < T_A$, and $f = 0.50$ and $n = 0.33$ for horizontal plate facing downward, that is, lower surface $T_S > T_A$, or upper surface $T_S < T_A$.

TABLE 11.9 Constants for Average Nusselt Numbers for Natural Convection^a and Simplified Equations for Average Heat Transfer Coefficients h_c (W/m²-degree) for Natural Convection to Air over External Flat Surfaces (at Atmospheric Pressure)^b

Configuration	L_{ch}	Flow Regime	C	n	h_c for Natural Convection Air Cooling		
					h_c	$C'(27^\circ\text{C})$	$C'(75^\circ\text{C})$
Vertical plate	H	$10^4 < Ra < 10^9$ laminar	0.59	0.25	$C'(\Delta T/L_{ch})^{0.25}$	1.51	1.45
		$10^9 < Ra < 10^{12}$ turbulent	0.13	0.33	$C'(\Delta T)^{0.33}$	1.44	1.31
Horizontal plate (heated side up)	$WL/[2(W + L)]$	$10^4 < Ra < 10^7$ laminar	0.54	0.25	$C'(\Delta T/L_{ch})^{0.25}$	1.38	1.32
		$10^7 < Ra < 10^{10}$ turbulent	0.15	0.33	$C'(\Delta T)^{0.33}$	1.66	1.52
		$10^5 < Ra < 10^{10}$	0.27	0.25	$C'(\Delta T/L_{ch})^{0.25}$	0.69	0.66
		(heated side down)					

where H, L , and W are height, length, and width of the plate, respectively

^aCompilation based on two sources. (Sources: McAdams, W.H. 1954. *Heat Transmission*. McGraw-Hill, New York, and Kraus, A.D. and Bar-Cohen, A. 1983. *Thermal Analysis and Control of Electronic Equipment*. Hemisphere, New York.)

^bPhysical properties of air and their temperature dependence, with units converted to metric system, are depicted in Fig. 11.44. (Source: Keith, F. 1973. *Heat Transfer*. Harper & Row, New York.)

FIGURE 11.44 Temperature dependence of physical properties of air: density ρ , thermal conductivity k , dynamic viscosity μ , and CTE β . Note that specific heat c_p is almost constant for given temperatures, and as such is not displayed here.

2. For forced (air) convection (cooling) over external flat plates

$$Nu = C(Re)^m(Pr)^n$$

$$h_c = (k/L_{ch})C(Re)^m(Pr)^n = C''(L_{ch})^{m-1}\nu^m$$

where

- C, m, n = constants depending on the geometry and the Reynolds number, see Table 11.10
- $C'' = kC(\rho/\mu)^m(Pr)^n$
- L_{ch} = length of plate in the direction of fluid flow (characteristic length)

Experimental verification of these relations, as applied to the complexity of geometry encountered in electronic equipment and packaging systems, can be found in literature.

Ellison (1987) has determined that for *laminar forced air flow*, better agreement between experimental and calculated results is obtained if a correlation factor f , which depends predominantly on air velocity, is used, in which case the heat convection coefficient h_c becomes

$$h_c = f(k/L_{ch})Nu$$

Though the correlation factor f was determined experimentally for laminar flow over 2.54×2.54 cm ceramic substrates producing the following values: $f = 1.46$ for $\nu = 1$ m/s, $f = 1.56$ for $\nu = 2$ m/s, $f = 1.6$ for $\nu = 2.5$ m/s, $f = 1.7$ for $\nu = 5$ m/s, $f = 1.78$ for $\nu = 6$ m/s, $f = 1.9$ for $\nu = 8$ m/s, $f = 2.0$ for $\nu = 10$ m/s, and we expect the correlation factor to be somewhat different for other materials and other plate sizes, the quoted values are useful for purposes of estimation.

TABLE 11.10 Constants for Average Nusselt Numbers for Forced Convection^a, and Simplified Equations for Average Heat Transfer Coefficients h_c (W/m^2 -degree) for Forced Convection Air Cooling over External Flat Surfaces and at Most Practical Fluid Speeds (at Atmospheric Pressure)^b

Flow Regime	C	m	n	h_c for Forced Convection Air Cooling		
				h_c	$C''(27^\circ C)$	$C''(75^\circ C)$
$Re < 2 \times 10^5$ laminar	0.664	0.5	0.333	$C''(\nu/L_{ch})^{0.5}$	3.87	3.86
$Re > 3 \times 10^5$ turbulent	0.036	0.8	0.333	$C''\nu^{0.8}/(L_{ch})^{0.2}$	5.77	5.34

^bPhysical properties of air and their temperature dependence, with units converted to metric system, are depicted in Fig. 11.44 (Source: Keith, F. 1973. *Heat Transfer*. Harper & Row, New York.)

Buller and Kilburn (1981) performed experiments determining the heat transfer coefficients for laminar flow forced air cooling for integrated circuit packages mounted on printed wiring boards (thus for conditions differing from that of a flat plate), and correlated h_c with the air speed through use of the Colburn J factor, a dimensionless number, in the form of

$$h_c = J \rho c_p v (Pr)^{-2/3} = 0.387(k/L_{ch}) Re^{0.54} Pr^{0.333}$$

where

$$J = 0.387*(Re)^{-0.46}$$

L_{ch} = redefined characteristic length, allows to account for the three-dimensional nature of the package, $[(A_F/C_F)(A_T/L)]^{0.5}$

W, H = width and height of the frontal area, respectively

$A_F = W, H$, frontal area normal to air flow

$C_F = 2(W + H)$, frontal circumference

$A_T = 2H(W + L) + (W + L)$, total wetted surface area exposed to flow

L = length in the direction of flow.

Finally, Hannemann, Fox, and Mahalingham (1991) experimentally determined average heat transfer coefficient h_c for finned heat sink of the fin length L (m), for forced convection in air under laminar conditions at moderate temperatures and presented it in the form of

$$h_c = 4.37(v/L)^{0.5} (W/m^2\text{-degree})$$

Radiation heat flow between two surfaces or between a surface and its surroundings is governed by the *Stefan–Boltzman equation* providing the (nonlinear) **radiation heat transfer** in the form of

$$Q_r = \sigma A F_T (T_1^4 - T_2^4) = h_r A (T_1 - T_2)$$

where

Q_r = radiation heat flow, W

σ = Stefan-Boltzman constant, $5.67 \times 10^{-8} \text{ W/m}^2\text{-K}^4$

A = effective area of the emitting surface, m^2

F_T = exchange radiation factor describing the effect of geometry and surface properties

T_1 = absolute temperature of the external/emitting surface, K

T_2 = absolute temperature of the ambient/target, K

h_r = average **radiative heat transfer** coefficient, $\sigma F_T (T_1^4 - T_2^4)/(T_1 - T_2)$, $\text{W/m}^2\text{-degree}$

For two-surface radiation exchange between plates, F_T is given by

$$F_T = \frac{1}{\frac{1 - \varepsilon_1}{\varepsilon_1} + \frac{1 - \varepsilon_2}{\varepsilon_2} \frac{A_1}{A_2} + \frac{1}{F_{1-2}}}$$

where

ε_1 = emissivity of material 1

ε_2 = emissivity of material 2

A_1 = radiation area of material 1

A_2 = radiation area of material 2

F_{1-2} = geometric view factor (Ellison, 1987; Siegal and Howell, 1981)

The emissivities of common packaging materials are given in Table 11.11. Several approximations are useful in dealing with radiation:

- For a surface that is smaller compared to a surface by which it is totally enclosed (e.g., by a room or cabinet), $\varepsilon_2 = 1$ (no surface reflection) and $F_{1-2} = 1$, then $F_T = \varepsilon_1$.

TABLE 11.11 Emissivities of Some of Materials Used in Electronic Packaging

Aluminum, polished	0.039–0.057
Copper, polished	0.023–0.052
Stainless steel, polished	0.074
Steel, oxidized	0.80
Iron, polished oxidized	0.14–0.38
	0.31–0.61
Porcelain, glazed	0.92
Paint, flat black lacquer	0.96–0.98
Quartz, rough, fused	0.93–0.075

- For most packaging applications in a human environment, $T_1 \approx T_2$, then $h_r = 4\sigma F_T T_1^3$.
- For space applications, where the target is space with T_2 approaching 0 K, $Q_r = \sigma F_T T_1^4$.

For purposes of physical reasoning, convection and radiation heat flow can be viewed as being represented by (nonlinear) thermal resistances, *convective* θ_c and *radiational* θ_r , respectively,

$$\theta_{c,r} = \frac{1}{hA_S}$$

where h is either the convective or radiative heat transfer coefficients, h_c or h_r , respectively, the total heat transfer, both convective and radiative, $h = h_c + h_r$. Note that for nucleate boiling ηh_c should be used.

11.5.3 Study of Thermal Effects in Packaging Systems

The *thermal evaluation* of solid-state devices and integrated circuits (ICs), and VLSI-based packaging takes two forms: *theoretical analysis* and *experimental characterization*. Theoretical analysis utilizes various approaches: from simple to complex closed-form analytical solutions and numerical analysis techniques, or a combination of both. Experimental characterization of the device/chip junction/surface temperature(s) of packaged/unpackaged structures takes both direct, infrared microradiometry, or liquid crystals and thermographic phosphorous, or, to a lesser extent, thermocouples, and indirect (parametric) electrical measurements.

Thermal Resistance

A *figure-of-merit* of thermal performance, thermal resistance is a measure of the ability of its mechanical structure (material, package, and external connections) to provide heat removal from the active region and is used to calculate the device temperature for a given mounting arrangement and operating conditions to ensure that a maximum safe temperature is not exceeded [Baxter 1977]. It is defined as

$$\theta_{JR} = \frac{T_J - T_R}{P_D}$$

where

θ_{JR} = thermal resistance between the junction or any other circuit element/active region that generates heat and the reference point, °C/W, K/W

T_J, T_R = temperature of the junction and the reference point, respectively, °C

P_D = power dissipation in the device, W

The conditions under which the device is thermally characterized have to be clearly described. In fact, thermal resistance is made up of constant terms that are related to device and package materials and geometry in series with a number of variable terms. These terms are related to the heat paths from the package boundary to some point in the system that serves as the reference temperature and are determined by the method of mounting, the printed-wiring-board (PWB) if used, other heat generating components

on the board or in the vicinity, air flow patterns, and related considerations. For discrete devices, thermal parameters—**junction temperature**, thermal resistance, *thermal time constants*—are well defined since the region of heat dissipation and measurement is well defined. For integrated circuits, however, heat is generated at multiple points (resistors, diodes, or transistors) at or near the chip surface resulting in a nonuniform temperature distribution. Thus θ_{jR} can be misleading unless temperature uniformity is assured or thermal resistance is defined with respect to the hottest point on the surface of the chip. A similar situation exists with a multichip package, where separate thermal resistances should be defined for each die. As a result, the data on spatial temperature distribution are necessary, as well as the need to standardize the definition of a suitable reference temperature and the configuration of the test arrangement, including the means of mounting the device(s) under test.

In thermal evaluation of microelectronic packages/modules, the *overall (junction-to-coolant)* thermal resistance θ_{tot} , including forced convection and characterizing the requirements to cool a chip within a single- or multichip module, can be described in terms of the following:

- **Internal thermal resistance** θ_{int} , largely bulk conduction from the circuits to the case/package surface, thus also containing thermal spreading and contact resistances

$$\theta_{\text{int}} = \frac{T_{\text{chip}} - T_{\text{case/pkg}}}{P_{\text{chip}}}$$

Thermal contact resistance R_c , occurring at material interface, is dependent on a number of factors including the surface roughness, the properties of the interfacing materials, and the normal stress at the interface. The formula(s) relating the *interfacial normal pressure* P to R_c have been given (Yovanovich and Antonetti, 1988) as

$$R_c = 1/C[P/H]^{0.95}$$

where C is a constant related to the surface texture, and the conductivities of the adjoining materials, k_1 and k_2 , and H is the microhardness of the softer surface.

- **External thermal resistance** θ_{ext} , primarily convective, from the case/package surface to the coolant fluid (gas or liquid)

$$\theta_{\text{ext}} = \frac{T_{\text{case/pkg}} - T_{\text{coolant-out}}}{P_m}$$

- **Flow (thermal) resistance** θ_{flow} , referring to the transfer of heat from the fluid coolant to the ultimate heat sink, thus associated with the heating of the fluid as it absorbs energy passing through the heat exchanger

$$\theta_{\text{flow}} = \frac{T_{\text{coolant-out}} - T_{\text{coolant-in}}}{Q_{\text{flow}}}$$

thus expressing the device junction/component temperature as follows:

$$T_j = \Delta T_{j\text{-chip}} + P_{\text{chip}}\theta_{\text{int}} + P_m\theta_{\text{ext}} + Q_{\text{flow}}\theta_{\text{flow}} + T_{\text{coolant-in}}$$

where

- T_{chip} = the chip temperature
- $T_{\text{case/pkg}}$ = the case/package temperature (at a defined location)
- P_{chip}, P_m = the power dissipated within the chip and the module, respectively
- $\Delta T_{j\text{-chip}}$ = the junction to chip temperature rise (can be negligible if power level are low)

Note that in the literature, the total thermal resistance θ_{tot} , usually under natural convection cooling conditions, is also referred to as θ_{j-a} (junction–ambient), θ_{int} as θ_{j-c} (junction–case), and θ_{ext} as θ_{c-a} (case–ambient).

Thermal Modeling/Simulation

The problem of theoretical thermal description of solid-state devices, circuits, packages, and assemblies requires the solution of heat transfer equations with appropriate initial and boundary conditions and is solved with the level of sophistication ranging from approximate analytical through full numerical of increased sophistication and complexity. To fully theoretically describe the thermal state of a solid-state/VLSI device and, in particular, the technology requirements for large-area packaged chips, thus ensuring optimum design and performance of VLSI-based packaging structures, thermal modeling/simulation has to be coupled with thermal/mechanical modeling/simulation leading to analysis of thermal stress and tensions, material fatigue, reliability studies, **thermal mismatch**, etc., and to designs both low thermal resistance and low thermal stress coexist.

Development of a suitable calculational model is basically a trial- and error process. In problems involving complex geometries, it is desirable to limit the calculation to the smallest possible region, by eliminating areas weakly connected to the region of interest, or model only part of the structure if geometric symmetry, symmetrical loading, symmetric power/temperature distribution, isotropic material properties, and other factors can be applied. In addition, it is often possible to simplify the geometry considerably by replacing complex shapes with simpler shapes (e.g., of equivalent volume and resistance to heat flow). All of these reduce the physical structure to a numerically (or/and analytically) tractable model. Also, decoupling of the component level problem from the substrate problem, as the chip and the package can be assumed to respond thermally as separate components, might be a viable concept in evaluation of temperature fields. This is true if thermal time constants differ by orders of magnitude. Then the superposition can be used to obtain a temperature response of the total package.

The accuracy with which any given problem can be solved depends on how well the problem can be modeled, and in the case of *finite-difference* (with electrical equivalents) or *finite-element models*, which are the most common approaches to thermal (and thermal–mechanical) analysis of packaging systems, on the fineness of the spatial subdivisions and control parameters used in the computations. To improve computational efficiency and provide accurate results in local areas of complexity, some type of *grid continuation strategy* should be used. A straightforward use of uniform discretization meshes seems inappropriate, since a mesh sufficiently fine to achieve the desired accuracy in small regions, where the solution is rough, introduces many unnecessary unknowns in regions where the solution is smooth, thus unnecessarily increasing storage and CPU time requirements. A more sophisticated approach involves starting with coarse grids with relatively few unknowns, inexpensive computational costs, and low accuracy, and using locally finer grids on which accurate solutions may be computed. Coarse grids are used to obtain good starting iterates for the finer meshes and can also be used in the creation of the finer meshes by indicating regions where refinement is necessary.

Electrical network finite-difference models for study of various phenomena occurring in solid-state devices, circuits, and systems have been widely reported in literature (Ellison 1987; Fukuoka and Ishizuka, 1984; Riemer, 1990). One of the advantages of such a technique is a simple physical interpretation of the phenomena in question in terms of electrical signals and parameters existing in the network/circuit model (see Fig. 11.45). For all but very simple cases, the equivalent circuits are sufficiently complex that computer solution is required. It is important to note, however, that once the equivalent circuit is established the analysis can readily be accomplished by existing network analysis programs, such as SPICE (SPICE2G User's Manual).

Finite element models (FEMs) have been gaining recognition as tools to carry out analyses of VLSI packages due to the versatility of FEM procedures for the study of a variety of electronic packaging problems, including wafer manufacturing, chip packaging, connectors, board-level simulation, and system-level simulation. Thermal/mechanical design of VLSI packages (Miyake, Suzuki, and Yamamoto, 1985) requires an effective method for the study of specific regions of complexity (e.g., sharp corners, material discontinuity, thin material layers, and voids). As fully refined models are too costly, especially in complex two- and three-dimensional configurations, *local analysis procedures* (Simon et al., 1988) can be used for the problems of this kind. The local analysis approach to finite element analysis allows a very refined mesh to be introduced in an overall coarse FEM so that geometric and/or material complexities can be accurately modeled.

FIGURE 11.45 (a) Views of a ceramic package and its general mesh in three-dimensional discretization of this rectangular type packaging structure. (b) a lumped RC thermal model of a unit cell/volume with (nonlinear) thermal resistances representing conduction, convection, and radiation; capacitances account for time-dependent thermal phenomena, and current sources represent heat generation/dissipation properties (thermal current). Nodal points, with voltages (and voltage sources) corresponding to temperatures, can be located either in the center or at corners of unit cells. Each node may be assigned an initial (given) temperature, heat generation/dissipation rate, and modes of heat transport in relation to other nodes. Voltage controlled current sources could be used to replace resistances representing convection and radiation.

This method allows efficient connection of two bordering lines with differing nodal densities in order to form an effective transition from coarse to refined meshes. Linear (or) arbitrary constraints are imposed on the bordering lines in order to connect the lines and reduce the number of independent freedoms in the model. Refined mesh regions can be nested one within another as multilevel refined meshes to achieve greater accuracy in a single FEM, as illustrated in Fig. 11.46.

Several analytical and numerical computer codes varying widely in complexity and flexibility are available for use in the thermal modeling of VLSI packaging. The programs fall into the two following categories:

1. *Thermal characterization* including, analytical programs such as TXYZ (Albers, 1984) and TAMS (Ellison, 1987), as well as numerical analysis programs based on a finite-difference (with electrical equivalents) approach such as TRUMP (Edwards, 1969), TNETFA (Ellison, 1987), SINDA (COSMIC, 1982b).
2. *General nonlinear codes*, such as ANSYS (Swanson) ADINAT (Adina), NASTRAN (COSMIC, 1982a), NISA (COSMIC, 1982c), and GIFTS (Casa) (all based on finite-element approach), to name only a few.

FIGURE 11.46 Example of grid continuation strategy used in discretization of a packaging structure: (a) a two-dimensional cross-section of a plastic package, (b) fine refinement in the area of interest, that is, where gradients of the investigated parameter(s), thermal or thermal-mechanical, are expected to be most significant, (c) a two-dimensional two-level refinement.

Because of the interdisciplinary nature of electronic packaging engineering, and the variety of backgrounds of packaging designers, efforts have been made to create interface programs optimized to address specific design and research problems of VLSI-packaging structures that would permit unexperienced users to generate and solve complex packaging problems (Shiang, Staszak, and Prince, 1987; Nalbandian, 1987; Godfrey et al., 1993).

Experimental Characterization

Highly accurate and versatile thermal measurements, in addition to modeling efforts, are indispensable to ensure optimal thermal design and performance of solid-state devices and VLSI-based packaging structures. The need for a systematic analysis of flexibility, sensibility, and reproducibility of current methods and development of appropriate method(s) for thermal characterization of packages and assemblies is widely recognized (Oettinger and Blackburn, 1990).

The basic problem of measurement of thermal parameters of all solid-state devices and VLSI-chips is the measurement of temperatures of the active components, for example $p-n$ junctions, or the integrated circuit chip surface temperature. Nonelectrical techniques, which can be used to determine the operating temperature of structures, involve the use of infrared microradiometry, liquid crystals, and other tools, and require that the surface of the operating device chip is directly accessible. The electrical techniques for measuring the temperature of semiconductor chips can be performed on fully packaged devices, and use a *temperature sensitive electrical parameter* (TSEP) of the device, which can be characterized/calibrated with respect to temperature and subsequently used as the temperature indicator.

Methodology for experimental evaluation of transient and steady-state thermal characteristics of solid-state and VLSI-based devices and packaging structures is dependent on the device/structure normal operating conditions. In addition, validity of the data obtained has to be unchallengeable; each thermal measurement is a record of a unique set of parameters, so as to assure repeatability, everything must be the same each time, otherwise the data gathered will have little relevance. Also, the choice of thermal environmental control and mounting arrangement, still air, fluid bath, temperature controlled heat sink, or wind tunnel, must be addressed.

In general, the idea of thermal measurements of all devices is to measure the active region temperature rise $\Delta T(t)$ over the reference (case, or **ambient**) temperature T_R , caused by the power P_D being dissipated there, for example, during the bias pulse width. Expanding the time scale, steady-state values can be obtained. Employing electrical methods in thermal measurements, the TSEP that is to be used should be consistent with the applied heating method, whereas the measurements have to be repeatable and meaningful. Most commonly used TSEPs are $p-n$ junction forward voltage or emitter-base voltage (bipolar devices), threshold voltage or intrinsic drain source diode voltage (metal oxide semiconductors (MOSs)). There are two phases in the experimental evaluation process:

- *Calibration* of the TSEP (no power or negligibly low power dissipated in the device) characterizing the variation of TSEP with temperature.
- *Actual measurement* (device self-heated).

The TSEP is monitored/recorded during or immediately after the removal of a **power** (heating) **dissipation** operating condition, thus determining the increase (change) in the junction temperature in the device under test (DUT). The process of characterization/calibration is carried out in a temperature controlled measurement head (chamber, oven) and should be performed under thermal equilibrium conditions, when the equivalence of the structure active region temperature with the structure case temperature is assured. TSEP can exhibit deviation from its normally linear slope, thus the actual calibration curve should be plotted or fitting techniques applied. Also, location of the temperature sensor and the way it is attached or built-in affects the results.

Figure 11.47 illustrates the idea of the emitter-only-switching method (Oettinger and Blackburn, 1990), which is a popular and fairly accurate approach for thermal characterization of transistors. Its principle can also be used in thermal measurement of other device/circuits as long as there is an accessible $p-n$ junction that can be used as a TSEP device. This method is intended both for steady-state and transient measurements. The circuit consists of two current sources of different values, heating current i_H and

FIGURE 11.47 (a) Schematic of measurement circuit using the emitter-switching-only method for measuring temperature of an *npn* bipolar transistor, (b) heating and measurement currents waveforms; heating time t_H , measurement time t_M , (c) calibration plot of the TSEP: base-emitter voltage vs. temperature.

measurement current i_M , and a diode D , and a switch. When the switch is open, the current flowing through the device-under-test is equal to $i_H + i_M$ (power dissipation phase). When the switch is closed, the diode is reverse biased, and the current of the DUT is equal to i_M (measurement phase); i_M should be small enough to keep power dissipation in the DUT during this phase negligible.

An approach that has been found effective in experimental evaluation of packaged IC chips employs the use of specially designed test structures that simulate the materials and processing of real chips, but not the logical functions. These look like product chips in fabrication and in assembly and give (electrical) readouts of conditions inside the package (Oettinger, 1984). Any fabrication process is possible that provides high fabrication yield. Such devices may be mounted to a wide variety of test vehicles by many means. In general, they can be used to measure various package parameters—thermal, mechanical, and electrical—and may be thought of as a process monitor since the obtained data reflect the die attach influence or lead frame material influence, or any number of factors and combination of factors.

For thermal measurements, the use of these structures overcomes inherent difficulties in measuring temperatures of active integrated chips. Many IC chips have some type of accessible TSEP element (*p-n* junction), parasitic, input protection, base-emitter junction, output clamp, or isolation diode (substrate diode). Such TSEP devices, as in discrete devices, have to be switched from the operating (heating) mode to measurement (sensing) mode, resulting in unavoidable delays and temperature drops due to cooling processes. Also, the region of direct electrical access to the TSEP does not always agree with the region of highest temperature.

In thermal test chips, heating and sensing elements might be (or are) separated. This eliminates the necessity of electrical switching, and allows measurements to be taken with the DUT under continuous biasing. Also, heating and sensing devices can be placed on the chip in a prescribed fashion, and access to temperature sensing devices can be provided over all of the chip area resulting in variable heat dissipation and sensed temperature distribution. This provides thermal information from all areas of the chip, including the ones of greatest **thermal gradients**. In addition, arrays of test chips can be built up from a standard chip size. It is desirable to use a die of the same or nearly same size as the production or proposed die for thermal testing and to generate a family of test dies containing the same test configuration on different die sizes. The particular design of the (thermal) test chip depends on the projected application, for example, chip die attachment, or void study, or package characterization. Examples of pictorial representations of thermal test chips are given in Fig. 11.48.

More sophisticated, multisensor test chips contain test structures for the evaluation of thermal resistance, electrical performance, corrosion, and thermomechanical stress effects of packaging technologies (Mathuna, 1992). However, multisensor chips have to be driven by computerized test equipment (Alderman, Tustaniwskyi, and Usell, 1986; Boudreaux et al., 1991) in order to power the chip in a manner that

FIGURE 11.48 Pictorial representations of examples of thermal test chips: (a) diffused resistors as heating elements and a single *p-n* junction (transistor, diode) as a sensing element (Oettinger, 1984), (b) diffused resistors as heating elements and an array of sensing elements—diodes (Alderman, Tustaniwskyi, and Usell, 1986), (c) polysilicon or implant resistor network as heating elements and diodes as sensing elements (Boudreaux et al., 1991), (d) an array of heaters and sensors; each heater/sensor arrangement consists of two (bipolar) transistors having common collector and base terminals, but separate emitters for heating and sensing (Staszak et al., 1987).

permits spatially uniform/nonuniform power dissipation and to sense the test chip temperature at multiple space points, all as a function of time, and to record temperatures associated with separate thermal time constants of various parts of the tested structure, ranging from tens and hundreds of nanoseconds on the transistor level, tens and hundreds of microseconds for the chip itself, tens to hundreds of microseconds for the substrate, and seconds and minutes for the package.

11.5.4 Heat Removal/Cooling Techniques in Design of Packaging Systems

Solutions for adequate cooling schemes and optimum thermal design require an effective combination of expertise in electrical, thermal, mechanical, and materials effect, as well as in industrial and manufacturing engineering. Optimization of packaging is a complex issue: compromises between electrical functions, an optimal heat flow and heat related phenomena, and economical manufacturability have to be made, leading to packaging structures that preserve the performance of semiconductors with minimum package delay to the system. Figure 11.49 shows the operating ranges of a variety of heat removal/cooling techniques.

FIGURE 11.49 Heat transfer coefficient for various heat removal/cooling techniques.

The data are presented in terms of heat transfer coefficients that correlate dissipated power or heat flux with a corresponding increase in temperature.

Current single-chip packages, dual in line package (DIP) (cerdip), pin grid array (PGA) (ceramic, TAB, short pin, pad-grid array), and flat packages (fine chip ceramic, quad flat package (QFP)), surface-mounted onto cards or board and enhanced by heat sinks, are capable of dissipating not more than a few watts per square centimeter, thus are cooled by natural and forced-air cooling. Multichip packaging, however, demands power densities beyond the capabilities provided by air cooling. The state-of-the-art of multichip packaging, multilayer ceramic (cofired multilayer thick-film ceramic substrate, glass-ceramics/copper substrate, polyimide-ceramics substrate), thin-film copper/aluminum-polyimide substrates, chip on board with TAB, and silicon substrate (silicon-on-silicon), require that in order to comply with the preferential increase in temperature not exceeding, for example, 50°C, sophisticated cooling techniques are indispensable. Traditional liquid forced cooling that employs a cold plate or heat exchanger, which physically contacts the device to be cooled, is good for power densities below 20 W/cm². For greater power densities, a possible approach is a water jet impingement to generate a fluid interface with a high rate of heat transfer (Mahalingham, 1985). In most severe cases, forced liquid cooling (and boiling) is often the only practical cooling approach: either indirect water cooling (microchannel cooling (Tuckerman and Pease, 1981)) or immersion cooling (Yokouchi, Kamehara, and Niwa, 1987) (in dielectric liquids like fluorocarbon). Cryogenics operation of CMOS devices in liquid nitrogen is a viable option (Clark et al., 1992).

A major factor in the cooling technology is the quality of the substrate, which also affects the electrical performance. All of the substrate materials (e.g., alumina/polyimide, epoxy/kevlar, epoxy-glass, beryllia, alumina, aluminum nitride, glass-ceramics, and diamond or diamondlike films (Tzeng et al., 1991)) have the clear disadvantage of a relative dielectric constant significantly greater than unity. This results in degraded chip-to-chip propagation times and in enhanced line-to-line capacitive coupling. Moreover, since chip integration will continue to require more power per chip and will use large-area chips, the substrate must provide for a superior thermal path for heat removal from the chip by employing high **thermal conductivity** materials as well as assuring thermal expansion compatibility with the chip. Aluminum nitride and silicon carbide ceramic with good thermal conductivity ($k = 100\text{--}200\text{ W/m}\cdot\text{°C}$ and $260\text{ W/m}\cdot\text{°C}$, respectively) and good thermal expansion match (**coefficient of thermal expansion (CTE)** = $4 \times 10^{-6}/\text{°C}$ and $2.6 \times 10^{-6}/\text{°C}$, respectively) to the silicon substrate (CTE = $2.6 \times 10^{-6}/\text{°C}$), copper-invar-copper ($k = 188\text{ W/m}\cdot\text{°C}$ and thermal expansion made to approximate that of silicon), and diamond for substrates and heat spreaders ($k = 1000\text{--}2000\text{ W/m}\cdot\text{°C}$) are prime examples of the evolving trends. However, in cases where external cooling is provided not through the substrate base but by means of heat sinks bonded on the back side of the chip or package, high conductivity substrates are not required, and materials such as alumina ($k = 30\text{ W/m}\cdot\text{°C}$ and CTE = $6 \times 10^{-6}/\text{°C}$) or glass-ceramics ($k = 5\text{ W/m}\cdot\text{°C}$ and a tailorable CTE = $4\text{--}8 \times 10^{-6}/\text{°C}$, matching that required by silicon or GaAs, CTE = $5.9 \times 10^{-6}/\text{°C}$), with low dielectric constants for low propagation delays, are utilized. Designers should also remember thermal enhancement techniques for minimizing the thermal contact resistance (including greases, metallic foils and screens, composite materials, and surface treatment (Fletcher, 1990)).

The evolution of packaging and interconnects over the last decade comprises solutions ranging from air-cooled single-chip packages on a printed wiring board, custom, or semicustom chips and new materials and technologies, that is, from surface mount packages through silicon-on-silicon (also known as wafer scale integration) and chip-on-board packaging techniques, to perfected multichip module technology with modules operating in liquid-cooled systems.

11.5.5 Concluding Remarks

Active research areas in heat management of electronic packaging include all levels of research from the chip through the complete system. The trend toward increasing packing densities, large-area chips, and increased power densities, imply further serious heat removal and heat-related considerations. These problems can only be partly handled by brute-force techniques, coupled with evolutionary improvements in existing packaging technologies. However, requirements to satisfy the demands of high performance

functional density, speed, power/heat dissipation, and levels of customization give rise to the need for exploring new approaches to the problem and for refining and better understanding existing approaches.

Techniques employing forced air and liquid convection cooling through various advanced schemes of cooling systems, including direct cooling of high-power dissipation chips (such as immersion cooling that allow also for uniformity of heat transfer coefficients and coolant temperature throughout the system), very fine coolant channels yielding an extremely low thermal resistance, and nucleate boiling heat transfer as well as cryogenic operation of CMOS devices, demand subsequent innovations in the format of packages and associated components/structures in order to accommodate such technologies.

Moreover, the ability to verify packaging designs, and to optimize materials and geometries before hardware is available, requires further developments of models and empirical tools for thermal design of packaging structures and systems. Theoretical models have to be judiciously combined with experimentally determined test structures for thermal (and thermal stress) measurements, creating conditions for equivalence of theoretical and empirical models. This in turn will allow generation of extensive heat transfer data for a variety of packaging structures under various conditions, thus translating real-world designs into modeling conditions.

Nomenclature

- A = area, m^2
- A_{eff} = effective cross-sectional area for heat flow, m^2
- A_S = cross-sectional area for heat flow through the surface, m^2
- A_i = cross-sectional area of the material of the i th layer, m^2
- C = capacitance, F; constant
- C_θ = thermal capacitance, W-s/degree
- C_{sf} = constant, a function of the surface/fluid combination in the boiling heat transfer, $W/m^2 \cdot K^n$
- c_p = specific heat, W-s/g-degree
- E_A = activation energy, eV
- F_T = total radiation factor; exchange factor
- F_{1-2} = radiation geometric view factor
- f = constant
- G = volumetric flow rate, m^3/s
- Gr = Grashof number $(g\beta\rho^2/\mu^2)(L_{\text{ch}})^3\Delta T$, dimensionless
- g = gravitational constant, m/s^2
- H = height (of plate), m
- h = heat transfer coefficient, $W/m^2 \cdot \text{degree}$
- h_b = boiling heat transfer coefficient, $W/m^2 \cdot \text{degree}$
- h_c = average convective heat transfer coefficient, $W/m^2 \cdot \text{degree}$
- h_r = average radiative heat transfer coefficient, $W/m^2 \cdot \text{degree}$
- I, i = current, A
- i_M = measurement current, A
- i_H = heating currents, A
- J = Colburn factor, dimensionless
- k = thermal conductivity, $W/m^2 \cdot \text{degree}$
- k_i = thermal conductivity of the material of the i th layer, $W/m^2 \cdot \text{degree}$
- k = Boltzman's constant, 8.616×10^{-5} eV/K
- L = length (of plate, fin), m
- L_{ch} = characteristic length parameter, m
- m = mass flow, g/s; constant, $\sqrt{hc/k\delta}$
- n = constant; coefficient
- Nu = Nusselt number, dimensionless
- P_{chip} = power dissipated within the chip, W

P_D	= power dissipation, W
P_m	= power dissipated within the module, W
Pr	= Prandtl number, dimensionless, $\mu c_p/k$
Q	= heat flow, W
Q_b	= boiling heat transfer rate, W
Q_c	= convection heat flow, W
Q_f	= heat transfer rate by a fin/fin structure, W
Q_{flow}	= total heat flow/dissipation of all components within the enclosure upstream of the component of interest, W
Q_r	= radiation heat flow, W
Q_V	= volumetric heat source generation, W/m ³
q	= heat flux, W/m ²
R	= resistance, Ω ; radius, m
R_c	= thermal contact resistance, °C/W, K/W
Ra	= Raleigh number, $Gr Pr$, dimensionless
Re	= Reynolds number, $v L_{\text{ch}}(\rho/\mu)$, dimensionless
T	= temperature, °C, K
T_A	= ambient temperature, °C, K
T_b	= temperature of the fin base, °C, K
$T_{\text{case/pckg}}$	= temperature of the case/package at a defined location, °C, K
T_{chip}	= temperature of the chip, °C, K
$T_{\text{coolant-in/out}}$	= temperature of the coolant inlet/outlet, °C, K
T_f	= temperature of the fluid coolant, °C, K
T_J	= temperature of the junction, °C, K
T_R	= reference temperature, °C, K
T_S	= temperature of the surface, °C, K
T_{sat}	= temperature of the boiling point saturation of the liquid, °C, K
t	= time, s
t_M	= measurement time, s
t_H	= heating time, s
V	= voltage, V; volume, m ³
v	= fluid velocity, m/s
W	= width (of plate), m
β	= coefficient of thermal expansion, 1/°C
Δl_i	= thickness of the i th layer, m
ΔT	= temperature difference, °C, K
$\Delta T_{j\text{-chip}}$	= temperature rise between the junction and the chip, °C, K
Δt	= time increment, s
δ	= fin thickness, m
ε	= emissivity
η	= fin efficiency
θ	= thermal resistance, °C/W, K/W
δ	= fin thickness, m
$\theta_{\text{ext/int}}$	= external/internal thermal resistance, °C/W, K/W
θ_{J_R}	= thermal resistance between the junction or any other circuit element/active region that generates heat and the reference point, °C/W, K/W
θ_{flow}	= flow (thermal) resistance, °C/W, K/W
θ_{sp}	= thermal spreading resistance, °C/W, K/W
λ	= failure rate,
μ	= dynamic viscosity, g/m-s
ρ	= density, g/m ³
σ	= electrical conductivity, 1/ Ω m; Stefan–Boltzman constant, 5.673×10^{-8} W/m ² -K ⁴

Defining Terms¹

Ambient temperature: Temperature of atmosphere in intimate contact with the electrical part/device.

Boiling heat transfer: A liquid-to-vapor phase change at a heated surface, categorized as either *pool boiling* (occurring in a stagnant liquid) or *flow boiling*.

Coefficient of thermal expansion (CTE): The ratio of the change in length dimensions to the change in temperature per unit starting length.

Conduction heat transfer: Thermal transmission to heat energy from a hotter region to a cooler region in a conducting medium.

Convection heat transfer: Transmission of thermal energy from a hotter to a cooler region through a moving medium (gas or liquid.)

External thermal resistance: A term used to represent thermal resistance from a convenient point on the outside surface of an electronic package to an ambient reference point.

Failure, thermal: The temporary or permanent impairment of device or system functions caused by thermal disturbance or damage.

Failure rate: The rate at which devices from a given population can be expected or were found to fall as a function of time; expressed in FITs, where FIT is defined as one failure per billion device hours ($10^{-9}/\text{h}$ or 0.0001% /1000 h of operation).

Flow regime, laminar: A constant and directional flow of fluid across a clean workbench. The flow is usually parallel to the surface of the bench.

Flow regime, turbulent: Flow where fluid particles are disturbed and fluctuate.

Heat flux: The outward flow of heat energy from a heat source across or through a surface.

Heat sink: The supporting member to which electronic components, or their substrate, or their package bottom is attached. This is usually a heat conductive metal with the ability to rapidly transmit heat from the generating source (component).

Heat transfer coefficient: Thermal parameter that encompasses all of the complex effects occurring in the convection heat transfer mode, including the properties of the fluid gas/liquid, the nature of the fluid motion, and the geometry of the structure.

Internal thermal resistance: A term used to represent thermal resistance from the junction or any heat generating element of a device, inside an electronic package, to a convenient point on the outside surface of the package.

Junction temperature: The temperature of the region of transistor between the *p* and *n* type semiconductor material in a transistor or diode element.

Mean time to failure (MTTF): A term used to express the reliability level. It is the arithmetic average of the lengths of time to failure registered for parts or devices of the same type, operated as a group under identical conditions. The reciprocal of the failure rate.

Power dissipation: The dispersion of the heat generated from a film circuit when a current flows through it.

Radiation heat transfer: The combined process of emission, transmission, and absorption of thermal energy between bodies separated by empty space.

Specific heat: The quantity of heat required to raise the temperature of 1 g of a substance 1°C.

Temperature cycling: An environmental test where the (film) circuit is subjected to several temperature changes from a low temperature to a high temperature over a period of time.

Thermal conductivity: The rate with which a material is capable of transferring a given amount of heat through itself.

Thermal design: The schematic heat flow path for power dissipation from within a (film) circuit to a heat sink.

¹Based in part on *Hybrid Microcircuit Design Guide* published by ISHM and IPC, and Tummala, R.R. and Rymaszewski, E.J. 1989. *Microelectronics Packaging Handbook*. Van Nostrand Reinhold, New York.

- Thermal gradient:** The plot of temperature variances across the surface or the bulk thickness of a material being heated.
- Thermal management or control:** The process or processes by which the temperature of a specified component or system is maintained at the desired level.
- Thermal mismatch:** Differences of coefficients of thermal expansion of materials that are bonded together.
- Thermal network:** Representation of a thermal space by a collection of conveniently divided smaller parts, each representing the thermal property of its own part and connected to others in a prescribed manner so as not to violate the thermal property of the total system.
- Thermal resistance:** A thermal characteristic of a heat flow path, establishing the temperature drop required to transport heat across the specified segment or surface; analogous to electrical resistance.

12.1 Intelligence Coding¹

Leon W. Couch, II

12.1.1 Introduction

The purpose of a communication system is to transmit message intelligence of a source to a sink (user). The exact waveform present at the sink is *unknown* until after it is received; otherwise, no intelligence would be transmitted and there would be no need for the communication system. More intelligence is communicated to the sink when the user at the sink is “surprised” by the message that was transmitted, that is, the transmission of intelligence implies the communication of messages that are not known ahead of time (*a priori*). On the other hand, in energy or power systems it is known *a priori* what the received waveform will be, and it is the energy imparted by the received waveform that is the desired quantity.

Noise limits our ability to communicate. If there were no noise, we could communicate messages electronically to the outer limits of the universe using an infinitely small amount of power. This has been obvious on an intuitive basis since the early days of radio. The theory that describes noise and the effect of noise on the transmission of information, however, was not developed until the 1940s by such persons as S.O. Rice (1944) and C.E. Shannon (1948).

Communication systems may be described by the block diagram shown in Fig. 12.1. Regardless of the particular applications, all communications systems involve three main subsystems: the *transmitter*, the *channel*, and the *receiver*. The message from the source is represented by the intelligence input waveform $m(t)$. The message delivered to the sink is denoted by $\tilde{m}(t)$. The tilde indicates that the message received may not be the same as that transmitted; that is, the message at the sink $\tilde{m}(t)$ may be corrupted by noise in the channel or there may be other impairments in the system, such as undesired filtering or undesired nonlinearities. The message information may be in analog or digital form, depending on the particular system, and it may represent audio, video, or some other type of intelligence. In multiplexed systems there may be multiple input and output message sources and sinks. The spectra (or frequencies) of $m(t)$ and $\tilde{m}(t)$ are concentrated about $f = 0$; consequently, they are said to be *baseband signals*.

The signal processing block at the transmitter conditions the source for more efficient transmission. For example, in a digital system the processor might consist of a microprocessor that provides redundancy reduction of the source. It may also provide channel encoding so that error detection and correction can be used at the signal processing unit at the receive site to reduce errors caused by noise in the channel. In an analog communication system the signal processor may be nothing more than an analog low-pass filter. In a hybrid system, the signal processor might take samples of an analog input and digitize them to provide a pulse code modulation (PCM) *digital word* for transmission over the system. The signal at the output of the transmitter signal processor is also a baseband signal since it has frequencies concentrated near $f = 0$.

¹Material in this chapter is adapted from Couch, L.W., II. 1995. *Modern Communication Systems*, Chaps. 1 and 5. Prentice-Hall, Englewood Cliffs, NJ. Used with permission.

FIGURE 12.1 A basic communication system. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

The transmitter carrier circuits convert the processed baseband signal into a frequency band that is appropriate for propagation over the transmission medium of the channel. For example, if the channel consists of a twisted-pair telephone line, the spectrum of $s(t)$ will be in the audio range of, for example, 300–3700 Hz, but if the channel consists of a fiber optic link, the spectrum of $s(t)$ will be at light frequencies. If the channel propagates baseband signals, no carrier circuits are necessary, and $s(t)$ can be just the output of the processing circuits at the transmitter. Carrier circuits are needed when the channel can only propagate frequencies located in a band around f_c where $f_c \gg 0$. (The c subscript denotes carrier frequency.) In this case $s(t)$ is said to be a *bandpass* signal since it is designed to have frequencies located in a band about f_c . For example, an amplitude modulated (AM) broadcasting station with an assigned frequency of 850 kHz has a carrier frequency of $f_c = 850$ kHz. The mapping of the baseband input information waveform $m(t)$ into the bandpass signal $s(t)$ is called **modulation** ($m(t)$ is the audio signal in AM broadcasting). Any bandpass signal has the form

$$s(t) = R(t) \cos[\omega_c t + \theta(t)] \tag{12.1}$$

where $\omega_c = 2\pi f_c$. If $R(t) = 1$ and $\theta(t) = 0$, $s(t)$ would be a pure sinusoid of frequency $f = f_c$ with *zero* bandwidth. In the modulation process provided by the carrier circuits, the baseband input waveform $m(t)$ causes $R(t)$ and/or $\theta(t)$ to change as a function of $m(t)$. These fluctuations in $R(t)$ and $\theta(t)$ cause $s(t)$ to have a *finite* bandwidth that depends on the characteristics of $m(t)$ and on the mapping functions used to generate $R(t)$ and $\theta(t)$.

Channels may be classified into two categories: *hardwire* and *software*. Some examples of hardwire channels are twisted-pair telephone lines, coaxial cables, waveguides, and fiber optic cables. Some typical software channels are air, vacuum, and seawater. It should be realized that the general principles of digital and analog modulation apply to all types of channels, although channel characteristics may impose constraints that favor a particular type of signaling. In general, the channel medium attenuates the signal so the noise level of the channel and/or the noise introduced by an imperfect receiver cause the delivered information $\tilde{m}(t)$ to be deteriorated from that of the source. The channel noise may arise from natural electrical disturbances (e.g., lightning) or from man-made sources such as high-voltage transmission lines, ignition systems of cars, or even switching circuits of a nearby digital computer. The channel may contain active amplifying devices, such as repeaters in telephone systems or satellite transponders in space communication systems. These devices, of course, are necessary to help keep the signal above the noise level. In addition, the channel may provide *multiple paths* between its input and output that have different time delays and attenuation characteristics. Even worse, these characteristics may vary with time. This variation produces signal fading at the channel output. You have probably observed this type of fading when listening to distant shortwave stations.

The receiver takes the corrupted signal at the channel output and converts it to a baseband signal that can be handled by the receiver baseband processor. The baseband processor “cleans up” this signal and delivers an estimate of the source information $\tilde{m}(t)$ to the communication system output.

The goal of the engineer is to design communication systems so that the information is transmitted to the sink with as little deterioration as possible while satisfying design constraints such as allowable transmitted energy, allowable signal bandwidth, and cost. In digital systems the measure of deterioration

is usually taken to be the *probability of bit error* (P_e), also called the *bit error rate* (BER), of the delivered data. In analog systems the performance measure is usually taken to be the *signal-to-noise ratio* (S/N) at the receiver output.

12.1.2 Complex Envelope Representation

All **bandpass waveforms**, whether they arise from a modulated signal, interfering signals, or noise, may be represented in a convenient form by using an appropriate complex envelope. Here, $v(t)$ will be used to denote the bandpass waveform canonically; specifically, $v(t)$ can represent the signal when $s(t) = v(t)$, the noise when $n(t) = v(t)$, the filtered signal plus noise at the channel output when $r(t) = v(t)$, or any other type of bandpass waveform. Any bandpass waveform can be represented by (Couch, 1995)

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \quad (12.2a)$$

when $\text{Re}\{\cdot\}$ denotes the real part of $\{\cdot\}$, $g(t)$ is called the **complex envelope** of $v(t)$, and f_c is the associated carrier frequency (hertz) where $\omega_c = 2\pi f_c$. Furthermore, two other equivalent representations are

$$v(t) = R(t) \cos[\omega_c t + \theta(t)] \quad (12.2b)$$

and

$$v(t) = x(t) \cos \omega_c t - y(t) \sin \omega_c t \quad (12.2c)$$

where

$$g(t) = x(t) + jy(t) = |g(t)|e^{j\angle g(t)} = R(t)e^{j\theta(t)} \quad (12.3)$$

$$x(t) = \text{Re}\{g(t)\} = R(t) \cos \theta(t) \quad (12.4a)$$

$$y(t) = \text{Im}\{g(t)\} = R(t) \sin \theta(t) \quad (12.4b)$$

$$R(t) = |g(t)| = \sqrt{x^2(t) + y^2(t)} \quad (12.5a)$$

$$\theta(t) = \angle g(t) = \tan^{-1} \left(\frac{y(t)}{x(t)} \right) \quad (12.5b)$$

The waveforms $g(t)$, $x(t)$, $y(t)$, $R(t)$, and $\theta(t)$ are all **baseband waveforms**, and, except for $g(t)$, they are all real waveforms. Thus, Eq. (12.2) is a low-pass-to-bandpass transformation. $R(t)$ is called the **real envelope** of $v(t)$. Here, $x(t)$ is said to be the *in phase modulation* associated with $v(t)$, and $y(t)$ is said to be the *quadrature modulation* associated with $v(t)$. The polar form of $g(t)$, represented by $R(t)$ and $\theta(t)$, is given by Eq. (12.3) where the identities between Cartesian and polar coordinates are given by Eq. (12.4) and Eq. (12.5). $R(t)$ and $\theta(t)$ are real waveforms and, in addition, $R(t)$ is always nonnegative. $R(t)$ is said to be the *amplitude modulation* (AM) on $v(t)$, and $\theta(t)$ is said to be the *phase modulation* (PM) on $v(t)$. In general, bandpass noise includes both AM, $R(t)$, and PM, $\theta(t)$, noise components.

The usefulness of the complex envelope representation for bandpass waveforms cannot be overemphasized. In modern communication systems, the bandpass signal is often partitioned into two channels, one for $x(t)$ called the I (in-phase) channel and one for $y(t)$ called the Q (quadrature-phase) channel.

12.1.3 Representation of Modulated Signals

Modulation is the process of encoding the source intelligence $m(t)$ (modulating signal) into a bandpass signal $s(t)$ (**modulated signal**). Consequently, the modulated signal is just a special application of the bandpass representation. The modulated signal is given by

$$s(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \quad (12.6)$$

TABLE 12.1(a) Complex Envelope Functions for Various Types of Modulation^a

Type of Modulation	Mapping Functions $g[m]$	Corresponding Quadrature Modulation	
		$x(t)$	$y(t)$
AM	$A_c [1 + m(t)]$	$A_c [1 + m(t)]$	0
DSB-SC	$A_c m(t)$	$A_c m(t)$	0
PM	$A_c \exp\{j D_p m(t)\}$	$A_c \cos [D_p m(t)]$	$A_c \sin [D_p m(t)]$
FM	$A_c \exp\left\{j D_f \int_{-\infty}^t m(\sigma) d\sigma\right\}$	$A_c \cos \left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$	$A_c \sin \left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$
SSB-AM-SC ^b	$A_c [m(t) \pm j \hat{m}(t)]$	$A_c m(t)$	$\pm A_c \hat{m}(t)$
SSB-PM ^b	$A_c \exp\{j D_p [m(t) \pm j \hat{m}(t)]\}$	$A_c e^{\mp D_p \hat{m}(t)} \cos [D_p m(t)]$	$A_c e^{\mp D_p \hat{m}(t)} \sin [D_p m(t)]$
SSB-FM ^b	$A_c \exp\left\{j D_f \int_{-\infty}^t [m(\sigma) \pm j \hat{m}(\sigma)] d\sigma\right\}$	$A_c \exp\left\{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma\right\} \times \cos \left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$	$A_c \exp\left\{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma\right\} \times \sin \left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$
SSB-EV ^b	$A_c \exp\{\ln [1 + m(t)] \pm j \hat{\ln} [1 + m(t)]\}$	$A_c [1 + m(t)] \times \cos \{\hat{\ln} [1 + m(t)]\}$	$\pm A_c [1 + m(t)] \times \sin \{\hat{\ln} [1 + m(t)]\}$
SSB-SQ ^b	$A_c \exp\{(1/2)\{\ln [1 + m(t)] \pm j \hat{\ln} [1 + m(t)]\}\}$	$A_c \sqrt{1 + m(t)} \times \cos \{\frac{1}{2} \hat{\ln} [1 + m(t)]\}$	$\pm A_c \sqrt{1 + m(t)} \times \sin \{\frac{1}{2} \hat{\ln} [1 + m(t)]\}$
QM	$A_c m_1(t) + j m_2(t)$	$A_c m_1(t)$	$A_c m_2(t)$

^a $A_c > 0$ is a constant that sets the power level of the signal as evaluated by use of (12.13); L, linear; NL, nonlinear; $[\hat{\cdot}]$ is the Hilbert transform (i.e., -90° phase-shifted version) of $[\cdot]$.

^b Use upper signs for upper sideband signals and lower signs for lower sideband signals.

(Source: Couch, L.W., II. 1995. *Modern Communication Systems*, pp. 234–235. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

where $\omega = 2\pi f_c$. Here, f_c is the carrier frequency. The complex envelope $g(t)$ is a function of the modulating signal $m(t)$. That is

$$g(t) = g[m(t)] \tag{12.7}$$

Table 12.1 gives the big picture for the modulating problem. Examples of the mapping function $g[m]$ are given for amplitude modulation, double-sideband suppressed carrier (DSB-SC), phase modulation, frequency modulation (FM), single-sideband AM suppressed carrier (SSB-AM-SC), single-sideband PM (SSB-PM), single-sideband FM (SSB-FM), single-sideband envelope detectable (SSB-EV), single-sideband square-law detectable (SSB-SQ), and quadrature modulation (QM). Digitally modulated bandpass signals are obtained when $m(t)$ is a digital baseband signal, for example, the output of a transistor transistor logic (TTL) circuit.

Obviously, it is possible to use other $g(m)$ functions that are not listed in Table 12.1. The question is: Are they useful? The $g(m)$ functions are desired that are easy to implement and that will give desirable spectral properties. Furthermore, in the receiver the inverse function $m(g)$ is required. The inverse should be single valued over the range used and should be easily implemented. The mapping should suppress as much noise as possible so that $m(t)$ can be recovered with little corruption.

TABLE 12.1(b) Complex Envelope Functions for Various Types of Modulation^a

Type of Modulation	Corresponding Amplitude and Phase Modulation		Linearity	Remarks
	$R(t)$	$\theta(t)$		
AM	$A_c 1 + m(t) $	$\begin{cases} 0, & m(t) > -1 \\ 180^\circ, & m(t) < -1 \end{cases}$	L^c	$m(t) > -1$ required for envelope detection
DSB-SC	$A_c m(t) $	$\begin{cases} 0, & m(t) > 0 \\ 180^\circ, & m(t) < 0 \end{cases}$	L	Coherent detection required
PM	A_c	$D_p m(t)$	NL	D_p is the phase deviation constant (rad/V)
FM	A_c	$D_f \int_{-\infty}^t m(\sigma) d\sigma$	NL	D_f is the frequency deviation constant (rad/V-s)
SSB-AM-SC ^b	$A_c \sqrt{[m(t)]^2 + [\hat{m}(t)]^2}$	$\tan^{-1}[\pm \hat{m}(t)/m(t)]$	L	Coherent detection required
SSB-PM ^b	$A_c e^{\mp D_p \hat{m}(t)}$	$D_p m(t)$	NL	
SSB-FM ^b	$A_c \exp\left\{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma\right\}$	$D_f \int_{-\infty}^t m(\sigma) d\sigma$	NL	
SSB-EV ^b	$A_c [1 + m(t)]$	$\pm \hat{\ln} [1 + m(t)]$	NL	$m(t) > -1$ is required so that the $\ln(\cdot)$ will have a real value
SSB-SQ ^b	$A_c \sqrt{1 + m(t)}$	$\pm \frac{1}{2} \hat{\ln} [1 + m(t)]$	NL	$m(t) > -1$ is required so that $\ln(\cdot)$ will have a real value
QM	$A_c \sqrt{m_1^2(t) + m_2^2(t)}$	$\tan^{-1}[m_2(t)/m_1(t)]$	L	Used in NTSC color television; requires coherent detection

^a $A_c > 0$ is a constant that sets the power level of the signal as evaluated by use of (12.13); L, linear; NL, nonlinear; $\hat{[\cdot]}$ is the Hilbert transform (i.e., -90° phase-shifted version) of $[\cdot]$.

^b Use upper signs for upper sideband signals and lower signs for lower sideband signals.

^c In the strict sense, AM signals are not linear because the carrier term does not satisfy the linearity (superposition) condition.

(Source: Couch, L.W., II. 1995. *Modern Communications Systems*, pp. 234–235. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

12.1.4 Spectrum and Power of Bandpass Signals

The spectrum of a bandpass signal is directly related to the spectrum of its complex envelope. If a bandpass voltage (or current) waveform is represented by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \tag{12.8}$$

then the **voltage** (or **current**) **spectrum** for this bandpass waveform is

$$V(f) = \frac{1}{2}(G(f - f_c) + G^*(-f - f_c)) \tag{12.9}$$

and the **power spectral density (PSD)** of the waveform is

$$\wp_v(f) = \frac{1}{4}(\wp_g(f - f_c) + \wp_g(-f - f_c)) \tag{12.10}$$

where $G(f) = \mathfrak{F}[g(t)]$ is the **Fourier transform** of $g(t)$ and $\wp_g(f)$ is the PSD of $g(t)$. Starting with Eq. (12.8), Eq. (12.9) can be proven as follows:

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\} = \frac{1}{2}g(t)e^{j\omega_c t} + \frac{1}{2}g^*(t)e^{-j\omega_c t}$$

Thus,

$$V(f) = \mathfrak{S}(v(t)) = \frac{1}{2}\mathfrak{S}(g(t)e^{j\omega_c t}) + \frac{1}{2}\mathfrak{S}(g^*(t)e^{-j\omega_c t}) \tag{12.11}$$

If we use $\mathfrak{S}(g^*(t)) = G^*(-f)$ and the frequency translation property of Fourier transforms, this equation becomes

$$V(f) = \frac{1}{2}\{G(f - f_c) + G^*(-(f + f_c))\} \tag{12.12}$$

which reduces to Eq. (12.9). In a similar way Eq. (12.10) can also be proved (Couch, 1995, p. 236).

The total average normalized power of a bandpass waveform, $v(t)$, is (Couch, 1995, p. 237)

$$P_v = \langle v^2(t) \rangle = \int_{-\infty}^{\infty} \wp_v(f) df = \frac{1}{2}\langle |g(t)|^2 \rangle \tag{12.13}$$

where normalized implies that the load is equivalent to 1 Ω . Here, $\langle [\cdot] \rangle$ denotes the average value of $[\cdot]$, which is defined by

$$\langle [\cdot] \rangle = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} [\cdot] dt \tag{12.14a}$$

If $[\cdot]$ is periodic, this average may be evaluated by integrating over one period

$$\langle [\cdot] \rangle = \frac{1}{T_0} \int_a^{a+T_0} [\cdot] dt \quad \text{periodic case} \tag{12.14b}$$

where T_0 is the period of $[\cdot]$ and a is any convenient real constant. It is also realized that

$$\langle v^2(t) \rangle = V_{\text{rms}}^2 \tag{12.15}$$

where V_{rms} is the rms value of $v(t)$.

Another type of power rating, called the *peak envelope power* (PEP) is useful for transmitter specifications. PEP is the average power that would be obtained if $|g(t)|$ were to be held constant at its peak value. This is equivalent to evaluating the average power of an unmodulated RF sinusoid that has a peak value of $A_p = \max[v(t)]$. The normalized PEP is given by

$$P_{\text{PEP}} = \frac{1}{2}[\max |g(t)|]^2 \tag{12.16}$$

A proof of this theorem follows by applying the definition of PEP to Eq. (12.13). The PEP is useful for specifying the power capability of AM, SSB, and television transmitters.

Example: Spectrum and Power of an AM Signal

Evaluate the magnitude spectrum for an amplitude modulated signal. From [Table 12.1](#), the complex envelope of an AM signal is

$$g(t) = A_c[1 + m(t)]$$

so that the spectrum of the complex envelope is

$$G(f) = A_c\delta(f) + A_cM(f) \tag{12.17}$$

where $\delta(f)$ is a Dirac delta function and $M(f)$ is the spectrum of the modulating signal $m(t)$. Using Eq. (12.6), we obtain the AM signal waveform

$$s(t) = A_c[1 + m(t)] \cos \omega_c t$$

FIGURE 12.2 Spectrum of an AM signal: (a) magnitude spectrum of modulation, (b) magnitude spectrum of AM signal. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 239. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

and, using Eq. (12.9), the AM spectrum

$$S(f) = \frac{1}{2} A_c [\delta(f - f_c) + M(f - f_c) + \delta(f + f_c) + M(f + f_c)] \tag{12.18}$$

where, since $m(t)$ is real, $M^*(f) = M(-f)$ and $\delta(f) = \delta(-f)$ (the delta function is defined to be even). Suppose that the magnitude spectrum of the modulation happens to be a triangular function, as shown in Fig. 12.2(a). This spectrum might arise from an analog audio source where the bass frequencies are emphasized. The resulting AM spectrum, using Eq. (12.18), is shown in Fig. 12.2(b). Since $G(f - f_c)$ and $G^*(-f - f_c)$ do not overlap, the magnitude spectrum is

$$|S(f)| = \begin{cases} \frac{1}{2} A_c \delta(f - f_c) + \frac{1}{2} A_c |M(f - f_c)|, & f > 0 \\ \frac{1}{2} A_c \delta(f + f_c) + \frac{1}{2} A_c |M(-f - f_c)|, & f < 0 \end{cases} \tag{12.19}$$

The 1 in $g(t) = A_c(1 + m(t))$ causes delta functions to occur in the spectrum at $f = \pm f_c$ where f_c is the assigned carrier frequency.

Using Eq.(12.13), we obtain the total average normalized signal power

$$\begin{aligned} P_s &= \frac{1}{2} A_c^2 \langle |1 + m(t)|^2 \rangle = \frac{1}{2} A_c^2 \langle 1 + 2m(t) + m^2(t) \rangle \\ &= \frac{1}{2} A_c^2 \langle 1 + 2\langle m(t) \rangle + \langle m^2(t) \rangle \rangle \end{aligned}$$

If we assume that the DC value of the modulation is zero, then $\langle m(t) \rangle = 0$, and the average normalized signal power becomes

$$P_s = \frac{1}{2} A_c^2 [1 + P_m] \tag{12.20}$$

where $P_m = \langle m^2(t) \rangle$ is the normalized power in the modulation $m(t)$, $\frac{1}{2} A_c^2$ is the carrier power, and $\frac{1}{2} A_c^2 P_m$ is the power in the sidebands of $s(t)$.

Specific numerical results depend on the modulation waveforms used and on the value of A_c . For example, assume $A_c = 100$ and that the modulating signal is a 1-kHz sine-wave test tone given by $m(t) = 0.8 \sin(2\pi 1000t)$. Then $P_m = \langle m^2(t) \rangle = M_{\text{rms}}^2 = (0.8/\sqrt{2})^2 = 0.320$.

Using Eq. (12.20), the **normalized average signal power** is

$$P_s = \frac{1}{2} (100)^2 [1 + 0.320] = 6600 \text{ W} \tag{12.21}$$

Furthermore, if $s(t)$ is a voltage waveform that appears across a $50\text{-}\Omega$ resistive load R_L , then the **actual** (i.e., unnormalized) **average power** dissipated in the load for this AM signal is

$$(P_s)_{\text{actual}} = \frac{(S_{\text{rms}})^2}{R_L} = \frac{P_s}{R_L} = \frac{6600}{50} = 132 \text{ W} \tag{12.22}$$

The actual average carrier power is $\frac{1}{2}A_c^2/R_L = 100 \text{ W}$ and the actual average sideband power is $\frac{1}{2}A_c^2 P_m/R_L = 32 \text{ W}$. Using Eq. (12.16), the actual PEP is

$$(P_{\text{PEP}})_{\text{actual}} = \frac{A_c^2}{2R_L} [1 + \max m(t)]^2 = \frac{(100)^2}{2(50)} (1 + (0.8))^2 = 324 \text{ W} \tag{12.23}$$

12.1.5 Bandpass Filtering and the Equivalent Low-Pass Filter

If a bandpass signal $v_1(t)$ is filtered by a bandpass filter, then the filtered output signal is

$$v_2(t) = v_1(t) * h(t) \tag{12.24}$$

where the asterisk denotes the convolution operation and $h(t)$ is the impulse response of the bandpass filter. In the frequency domain this becomes

$$V_2(f) = H(f)V_1(f) \tag{12.25}$$

where $H(f)$ is the transfer function of the bandpass filter. In general, the mathematics involved with bandpass filter problems are more difficult than those for low-pass filter problems.

A shortcut technique will be given for modeling a bandpass filter by using an equivalent low-pass filter that has a complex valued impulse response. This is shown in Fig. 12.3. Here, $v_1(t)$ and $v_2(t)$ are the input and output bandpass waveforms with the corresponding complex envelopes $g_1(t)$ and $g_2(t)$. The impulse response of the bandpass filter, $h(t)$, can also be represented by its corresponding complex envelope $k(t)$. In addition, as shown in Fig. 12.3(a), the frequency domain description $H(f)$ can be expressed in terms of $K(f)$ with the help of Eq. (12.8) and Eq. (12.9). Figure 12.3(b) shows a typical bandpass frequency response characteristic $|H(f)|$. The complex envelopes for the input, output, and impulse response of a

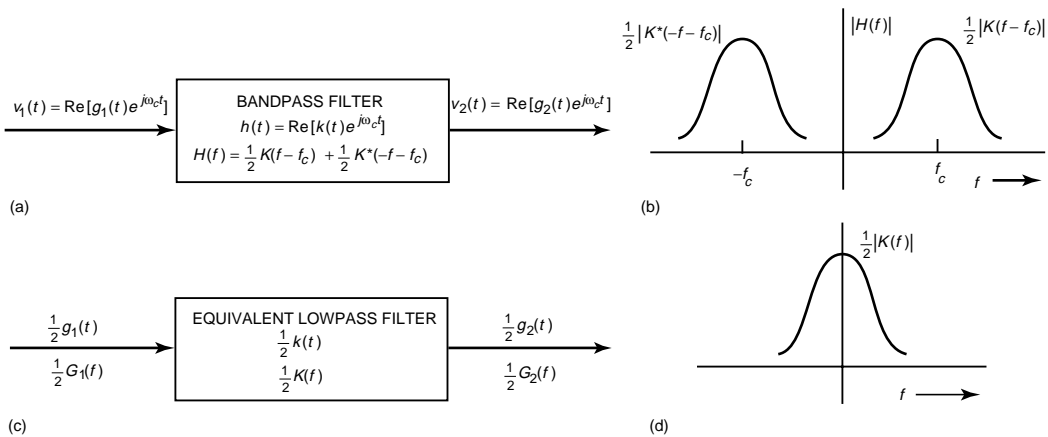

FIGURE 12.3 Bandpass filtering: (a) bandpass filter, (b) typical bandpass filter frequency response, (c) equivalent (complex impulse response) lowpass filter, (d) typical equivalent lowpass filter frequency response. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 240. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

bandpass filter are related by (Couch, 1995, p. 240)

$$\frac{1}{2}g_2(t) = \frac{1}{2}g_1(t) * \frac{1}{2}k(t) \quad (12.26)$$

where $g_1(t)$ is the complex envelope of the input and $k(t)$ is the complex envelope of the impulse response. It also follows that

$$\frac{1}{2}G_2(f) = \frac{1}{2}G_1(f)\frac{1}{2}K(f) \quad (12.27)$$

These equations indicate that any bandpass filter systems may be described and analyzed by using an *equivalent low-pass filter* as shown in Fig. 12.3(c). A typical equivalent low-pass frequency response characteristic is shown in Fig. 12.3(d). Since equations for equivalent low-pass filters are usually much less complicated than those for bandpass filters, the equivalent low-pass filter system model is very useful. This is the basis for computer programs that simulate bandpass communication systems by using equivalent low-pass models.

It is realized that the linear bandpass filter can produce variations in the phase modulation at the output, $\theta_2(t)$, where $\theta_2(t) = \angle g_2(t)$, as a function of the amplitude modulation on the input complex envelope $R_1(t)$, where $R_1(t) = |g_1(t)|$. This is called *AM-to-PM conversion*. Similarly, the filter can also cause variations on the AM at the output, $R_2(t)$, because of the PM on the input, $\theta_1(t)$. This is called *PM-to-AM conversion*.

Since $h(t)$ represents a linear filter, $g_2(t)$ will be a linear filtered version of $g_1(t)$; however, $\theta_2(t)$ and $R_2(t)$, the PM and AM components of $g_2(t)$, will be a *nonlinear* filtered version of $g_1(t)$ since $\theta_2(t)$ and $R_2(t)$ are nonlinear functions of $g_2(t)$. The analysis of the nonlinear distortion is very complicated. Although many analysis techniques have been published in the literature, none has been entirely satisfactory. Panter (1965) gives a three-chapter summary of some of these techniques, and a classical paper is also recommended (Bedrosian and Rice, 1968). Furthermore, nonlinearities that occur in a practical system will also cause nonlinear distortion and AM-to-PM conversion effects. Nonlinear effects can be analyzed by several techniques, including power-series analysis (Couch, 1995). If a nonlinear effect in a bandpass system is to be analyzed, a Fourier series technique that uses the Chebyshev transform has been found to be useful (Spilker, 1977).

12.1.6 Generalized Transmitters

Transmitters generate the modulated signal at the carrier frequency f_c from the modulating signal $m(t)$. In Secs. 12.1.2 and 12.1.3 it was demonstrated that any type of modulated signal could be represented by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \quad (12.28)$$

or, equivalently,

$$v(t) = R(t) \cos [\omega_c t + \theta(t)] \quad (12.29)$$

and

$$v(t) = x(t) \cos \omega_c t - y(t) \sin \omega_c t \quad (12.30)$$

where the complex envelope

$$g(t) = R(t)e^{j\theta(t)} = x(t) + jy(t) \quad (12.31)$$

is a function of the modulating signal $m(t)$. The particular relationship that is chosen for $g(t)$ in terms of $m(t)$ defines the type of modulation that is used, such as FM, SSB, or FM (see Table 12.1). A generalized approach may be taken to obtain universal transmitter models that may be reduced to those used for a particular modulation type. We will also see that there are equivalent models that correspond to different

FIGURE 12.4 Generalized transmitter using the AM–PM generation technique. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 282. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

circuit configurations, yet they may be used to produce the same type of modulated signal at their outputs. It is up to the designer to select an implementation method that will maximize performance, yet minimize cost based on the state of the art in circuit development. There are two canonical forms for the generalized transmitter, as indicated by Eq. (12.29) and Eq. (12.30). Equation (12.29) describes an AM–PM type circuit as shown in Fig. 12.4. The baseband signal processing circuit generates $R(t)$ and $\theta(t)$ from $m(t)$. The R and θ are functions of the modulating signal $m(t)$ as given in Table 12.1(b) for the particular modulation type desired. The signal processing may be implemented either by using nonlinear analog circuits or a computer that incorporates the R and θ algorithms under software program control. In the implementation using a computer, one analog-to-digital converter (ADC) will be needed at the input and two digital-to-analog converters (DACs) will be needed at the output. The remainder of the AM–PM canonical form requires radio frequency (RF) circuits, as indicated in the figure.

Figure 12.5 illustrates the second canonical form for the generalized transmitter. This uses in-phase and quadrature-phase (IQ) processing. Similarly, the formulas relating $x(t)$ and $y(t)$ to $m(t)$ are shown in Table 12.1(a), and the baseband signal processing may be implemented by using either analog hardware or digital hardware with software. The remainder of the canonical form utilizes RF circuits as indicated.

Once again, it is stressed that any type of signal modulation, AM, FM, SSB, quadrature phase shift keying (QPSK), etc., may be generated by using either of these two canonical forms. Both of these forms conveniently separate baseband processing from RF processing. Digital techniques are especially useful to

FIGURE 12.5 Generalized transmitter using the quadrature generation technique. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 282. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

realize the baseband processing portion. Furthermore, if digital computing circuits are used, any desired modulation type can be obtained by selecting the appropriate software algorithm.

Most of the practical transmitters in use today are special variations on these canonical forms. Practical transmitters may perform the RF operations at some convenient lower RF frequency and then up-convert to the desired operating frequency. In the case of RF signals that contain no AM, frequency multipliers may be used to arrive at the operating frequency. Of course, power amplifiers are usually required to bring the output power level up to the specified value. If the RF signal contains no amplitude variations, class C amplifiers (relatively high efficiency) may be used; otherwise, class B amplifiers are used.

12.1.7 Generalized Receiver: The Superheterodyne Receiver

The receiver has the job of extracting the source information from the received modulated signal that has been corrupted by noise. Often it is desired that the receiver output be a replica of the modulating signal that was present at the transmitter input. There are two main classes of receivers: the *tuned radio frequency* (TRF) receiver and the *superheterodyne* receiver.

The TRF receiver consists of a number of cascaded high-gain RF bandpass stages that are tuned to the carrier frequency f_c , followed by an appropriate detector circuit (envelope detector, product detector, FM detector, etc.). The TRF is not very popular because it is difficult to design tunable RF stages so that the desired station can be selected and yet have a narrow bandwidth so that adjacent channel stations are rejected. In addition, it is difficult to obtain high gain at radio frequencies and to have sufficiently small stray coupling between the output and input of the RF amplifying chain so that the chain will not become an oscillator at f_c .

Most receivers employ the superheterodyne receiving technique as shown in Fig. 12.6. (*Dual-conversion* superheterodyne receivers can also be built. Here a second mixer and a second IF stage follow the first IF stage shown in Fig. 12.6.) This technique consists of either down converting or up converting the input signal to some convenient frequency band, called the *intermediate frequency* (IF) band, and then extracting the information (or modulation) by using the appropriate detector. This basic receiver structure is used for the reception of all types of bandpass signals, such as television, FM, AM, satellite, and radar signals. The RF amplifier has a bandpass characteristic that passes the desired signal and provides amplification to override additional noise that is generated in the mixer stage. The RF filter characteristic also provides some rejection of adjacent channel signals and noise, but the main adjacent channel rejection is accomplished by the IF filter.

The IF filter is a bandpass filter that selects either the up-conversion or down-conversion component (whichever is chosen by the receiver designer). When up conversion is selected, the complex envelope of the IF (bandpass) filter output is the same as the complex envelope for the RF input, except for the effect of

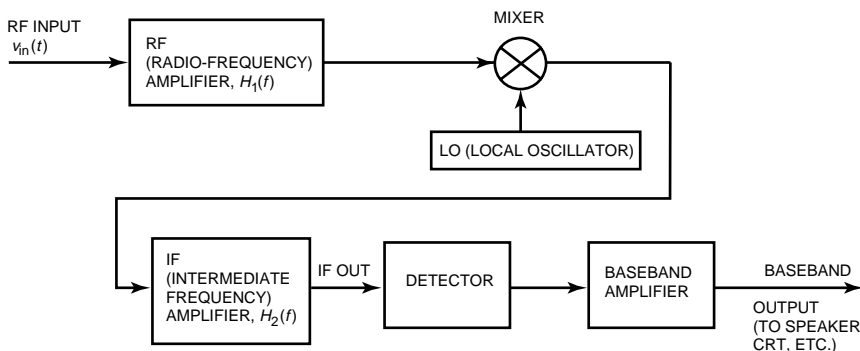

FIGURE 12.6 A superheterodyne receiver. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 283. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

RF filtering $H_1(f)$ and IF filtering $H_2(f)$. However, if down conversion is used with $f_{LO} > f_c$, the complex envelope at the IF output will be the conjugate of that for the RF input. This means that the sidebands of the IF output will be inverted (i.e., the upper sideband on the RF input will become the lower sideband, etc., on the IF output). If $f_{LO} < f_c$, the sidebands are not inverted. In some special applications the local oscillator (LO) frequency is selected to be the carrier frequency ($f_{LO} = f_c$), and then the superheterodyne receiver becomes a direct-conversion receiver also called a *homodyne* or a *synchrodyne* receiver. In this case the IF filter is replaced by a low-pass filter so that the mixer-LPF combination becomes a product detector and the detector stage of Fig. 12.6 is deleted. Thus, the direct-conversion receiver is the same as a TRF receiver with product detection.

The center frequency selected for the IF amplifier is chosen based on the following three considerations:

- The frequency should be such that a stable high-gain amplifier can be economically attained.
- The frequency needs to be low enough so that with practical circuit elements in the IF filters, values of Q can be attained that will provide a steep attenuation characteristic outside the bandwidth of the IF signal. This decreases the noise and minimizes the interference from adjacent channels.
- The frequency needs to be high enough so that the receiver image response can be made acceptably small.

The *image response* is the reception of an unwanted signal located at the image frequency due to insufficient attenuation of the image signal by the RF amplifier filter. The image is best illustrated by an example.

Example: AM Broadcast Superheterodyne Receiver

Assume that an AM broadcast band radio is tuned to receive a station at 850 kHz and that the LO frequency is on the high side of the carrier frequency. If the IF frequency is 455 kHz, the LO frequency will be $850 + 455 = 1305$ kHz (see Fig. 12.7). Furthermore, assume that other signals are present at the RF input of the radio and, particularly, that there is a signal at 1760 kHz; this signal will be down converted by the mixer to $1760 - 1305 = 455$ kHz. That is, the undesired (1760-kHz) signal will be translated to 455 kHz and will be added at the mixer output to the desired (850-kHz) signal, which was also down converted to 455 kHz. This *undesired* signal that has been converted to the IF band is called the *image signal*. If the gain of the RF amplifier is down by, say, 25 dB at 1760 kHz as compared to 850 kHz, and if the undesired signal is 25 dB stronger at the receiver input than the desired signal, both signals will have the same level when translated to the IF. In this case the undesired signal will definitely interfere with the desired signal in the detection process.

For down converters (i.e., $f_{IF} = |f_c - f_{LO}|$) the image frequency is

$$f_{image} = \begin{cases} f_c + 2f_{IF}, & \text{if } f_{LO} > f_c \text{ (high-side injection)} \\ f_c - 2f_{IF}, & \text{if } f_{LO} < f_c \text{ (low-side injection)} \end{cases} \tag{12.32a}$$

FIGURE 12.7 Spectra of signals and transfer function of an RF amplifier in a superheterodyne receiver. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 285. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

TABLE 12.2 Some Popular IF Frequencies in the U.S.

IF Frequency	Application
262.5 kHz	AM broadcast radios (in automobiles)
455 kHz	AM broadcast radio
10.7 MHz	FM broadcast radio
21.4 MHz	FM two-way radio
30 MHz	Radar receivers
43.75 MHz (video carrier)	TV sets
60 MHz	Radar receivers
70 MHz	Satellite receivers

Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 285. Prentice-Hall, Englewood Cliffs, NJ. With permission.

where f_c is the desired RF frequency, f_{IF} is the IF frequency, and f_{LO} is the local oscillator frequency. For up converters (i.e., $f_{IF} = f_c + f_{LO}$) the image frequency is

$$f_{\text{image}} = f_c + 2f_{LO} \quad (12.32b)$$

From Fig. 12.7 it is seen that the image response will usually be reduced if the IF frequency is increased, since f_{image} will occur farther away from the main peak (or lobe) of the RF filter characteristic $|H_1(f)|$.

We also realize that other spurious responses (in addition to the image response) will occur in practical mixer circuits. These must also be taken into account in good receiver design.

Table 12.2 illustrates some typical IF frequencies that have become *de facto* standards. For the intended application, the IF frequency is low enough that the IF filter will provide good adjacent channel signal rejection when circuit elements with realizable Q are used; yet the IF frequency is large enough to provide adequate image-signal rejection by the RF amplifier filter.

The type of detector selected for use in the superheterodyne receiver depends on the intended application. For example, a product detector may be used in a phase shift keyed (PSK) digital system, and an envelope detector is used in AM broadcast receivers. If the complex envelope $g(t)$ is desired for generalized signal detection or for optimum reception in digital systems, the $x(t)$ and $y(t)$ quadrature components, where $x(t) + jy(t) = g(t)$, may be obtained by using quadrature product detectors, as illustrated in Fig. 12.8. Here, $x(t)$ and $y(t)$ could be fed into a signal processor to extract the modulation information. Disregarding the effects of noise, the signal processor could recover $m(t)$ from $x(t)$ and $y(t)$ (and, consequently, demodulate the IF signal) by using the inverse of the complex envelope generation functions given in Table 12.1(a).

FIGURE 12.8 IQ (in-phase and quadrature-phase) detector. (Source: Couch, L.W., II. 1995. *Modern Communication Systems*, p. 286. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

The superheterodyne receiver has many advantages and some disadvantages. The main advantage is that extraordinarily high gain can be obtained without instability (self-oscillation). The stray coupling between the output of the receiver and the input does not cause oscillation because the gain is obtained in disjoint frequency bands: RF, IF, and baseband. The receiver is easily tunable to another frequency by changing the frequency of the LO signal (which may be supplied by a frequency synthesizer) and by tuning the bandpass of the RF amplifier to the desired frequency. Furthermore, high-Q elements, which are needed to produce steep filter skirts for adjacent channel rejections, are needed only in the fixed tuned IF amplifier. The main disadvantage of the superheterodyne receiver is the response to spurious signals that will occur if one is not careful with the design.

A discussion of receivers would not be complete without considering some of the causes of *interference*. Often the receiver owner thinks that a certain signal, such as an amateur radio signal, is causing the difficulty. This may or may not be the case. The origin of the interference may be at any of the three following locations:

- At the interfering signal *source*, the transmitter may generate out-of-band signal components (such as harmonics) that fall in the band of the desired signal.
- At the *receiver* itself, the front end may overload or produce spurious responses. Front-end overload occurs when the RF and/or mixer stage of the receiver is driven into the nonlinear range by the interfering signal and the nonlinearity causes cross modulation on the desired signal at the output of the receiver RF amplifier.
- In the *channel*, a nonlinearity in the transmission medium may cause undesired signal components in the band of the desired signal.

For more discussion of receiver design and examples of practical receiver circuits, the reader is referred to the *ARRL Handbook* (ARRL, 1994).

Defining Terms

Actual average power: For voltage waveform impressed across a resistive load R_L , the actual average power is V_{rms}^2/R_L watts. For a current waveform flowing through a resistive load R_L , the actual average power is $I_{\text{rms}}^2 R_L$ watts.

Bandpass waveform: The spectrum of the waveform is nonzero for frequencies in some band concentrated about a frequency $f_c \gg 0$; f_c is called the carrier frequency.

Baseband waveform: The spectrum of the waveform is nonzero for frequencies near $f = 0$.

Complex envelope: The function $g(t)$ of a bandpass waveform $v(t)$ where the bandpass waveform is described by $v(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$.

Current spectrum: The Fourier transform of a current waveform.

Fourier transform: If $w(t)$ is a waveform, then the Fourier transform of $w(t)$ is

$$W(f) = \mathfrak{F}[w(t)] = \int_{-\infty}^{\infty} w(t)e^{-j2\pi ft} dt$$

where f has units of hertz.

Modulated signal: The bandpass signal $s(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$ where fluctuations of $g(t)$ are caused by an intelligence source such as audio, video, or data.

Modulation: The intelligence or information source, $m(t)$, that causes fluctuations in a bandpass signal.

Normalized average power: The average power dissipated in a 1- Ω resistive load. The normalized average power is the average of the square of the voltage or current waveform.

Power spectral density (PSD): A function of frequency $\mathcal{P}_w(f)$ associated with a waveform $w(t)$, such that the area under the PSD over a frequency band gives the normalized average power for that waveform corresponding to that band of frequencies [Couch 1995, p. 62].

Real envelope: The function $R(t) = |g(t)|$ of a bandpass waveform $v(t)$ where the bandpass waveform is described by

$$v(t) = \operatorname{Re}\{g(t)e^{j\omega_c t}\} = R(t) \cos[\omega_c t + \theta(t)]$$

Voltage spectrum: The Fourier transform of a voltage waveform.

12.2 Amplitude Modulation

Robert Kubichek

12.2.1 Amplitude Modulation

There are two basic types of communication systems, *baseband* systems and *passband* systems. In baseband systems, the signal is transmitted without modifying the frequency content. A simple intercom is an example of this approach. Here, a microphone senses the input or **message signal**, and injects the resulting signal $m(t)$ into a cable or *channel*. At the receiver, the signal is filtered to remove noise, amplified and reproduced into sound using a speaker. In passband communication systems, the message signal is *modulated* by translating its spectrum to a new frequency location called the *carrier frequency*, f_c . **Modulation** offers numerous advantages over baseband communication including

- Maximize efficiency: Signals can be modulated into regions of the spectrum where there is lower noise and interference, or better propagation characteristics.
- Frequency-domain multiplexing (FDM): Multiple signals can be modulated into nonoverlapping frequency bands and transmitted simultaneously over the same channel. In commercial broadcasting, for example, this allows AM and FM signals to be multiplexed onto the same radio frequency channel.

- Physical considerations: The physical size of antennas and other electronic components tend to decrease with increasing frequency. This makes it feasible to build smaller radio receivers, transmitters, and antennas when higher frequencies are used.

Frequency Domain Concepts

To understand the basic concepts of modulation, we first review time- and frequency-domain representations of signals. The information present in $m(t)$ can be completely specified by a complex function of speech amplitude vs. frequency, $M(f)$, obtained using the *Fourier transform*. Since $M(f)$ contains all of the information in $m(t)$, it is possible to go back and forth between $m(t)$ and $M(f)$ using the forward and inverse Fourier transforms.

Forward transform:

$$M(f) = \int_{-\infty}^{\infty} m(t)e^{-j2\pi ft} dt \tag{12.33}$$

Inverse transform:

$$m(t) = \int_{-\infty}^{\infty} M(f)e^{j2\pi ft} df \tag{12.34}$$

Although we usually think of positive-valued frequencies, Eq. (12.33) shows that negative frequency values are also mathematically valid. We can get a better feel for this idea by considering the signal $\sin 2\pi f_c t$, which is a pure tone with frequency f_c Hz. The relationship $\sin 2\pi f_c t = -\sin 2\pi(-f_c)t$ shows that a pure tone at $-f_c$ Hz has the same magnitude as the positive frequency pure tone, but is different in phase by 180° .

Modulation Theorem

The *modulation theorem* states that when any signal is multiplied by a sine-wave signal of frequency f_c , the resulting signal has a spectrum similar to the original, but translated out to frequency $\pm f_c$. That is, consider a signal $x(t)$ produced by multiplying $m(t)$ against a tone signal

$$x(t) = m(t) \cos(2\pi f_c t) \tag{12.35}$$

The frequency-domain result is

$$X(f) = 0.5\{M(f - f_c) + M(f + f_c)\} \tag{12.36}$$

where $M(f - f_c)$ and $M(f + f_c)$ represent the entire message spectrum translated to two new locations, the carrier frequency f_c and the negative carrier frequency $-f_c$, respectively. This multiplication process is called *mixing* or *heterodyning*. Figure 12.9 shows an example of the modulation theorem where $M(f)$ represents the baseband spectrum and $X(f)$ is the modulated spectrum. A second example in Fig. 12.10 shows the passband signal $x(t)$ from Fig. 12.9 being modulated to produce components at $2f_c$, 0, and $-2f_c$ Hz. This approach can be used in a receiver to *demodulate* the passband signal and reproduce the

FIGURE 12.9 Example of the modulation theorem: (a) the modulator, (b) the input message spectrum, (c) the modulated spectrum composed of upper and lower sidebands (USB and LSB).

FIGURE 12.10 Example of modulation theorem used in demodulation: (a) the demodulator, (b) and (c) the two components of the output signal, (d) the combined demodulator output spectrum before filtering.

original baseband signal. This is accomplished simply by removing the spectral components at $\pm 2f_c$ using a filter.

The spectrum $M(f)$ is a complex function that can be represented either by real and imaginary or by magnitude and phase components $|M(f)|$ and $\phi(f)$, respectively. When $m(t)$ is real valued, the magnitude spectrum is an even function ($|M(f)| = |M(-f)|$) and phase is an odd function ($\phi(f) = -\phi(-f)$) of frequency. Most basic communication concepts can be illustrated using only the magnitude spectrum $|M(f)|$; this will be the approach taken in this chapter.

Bandwidth: Baseband versus Passband

Bandwidth is defined as the range of positive frequencies occupied by a signal. Thus, for the baseband signal shown in Fig. 12.9(b), the bandwidth equals the highest frequency present, B Hz. By comparison, the modulated signal shown in Fig. 12.9(c) has a bandwidth of $2B$ Hz, which occupies double the bandwidth of the baseband signal and, therefore, represents poor spectral efficiency.

Linear Systems

Low-pass and *bandpass* filters (denoted LPF and BPF, respectively) are fundamental components in amplitude modulation systems. These filters, along with the communication channel itself, are often modeled as *linear systems*, which implies that system output amplitude is strictly proportional to the system input amplitude. Figure 12.11 shows a linear system with the input and output amplitude spectra given by $X(f)$ and $Y(f)$, respectively. The proportionality between input and output at any given frequency is described by the system *transfer function* $H(f)$: $Y(f) = X(f)H(f)$. Figure 12.11 also shows transfer functions for both low-pass and bandpass filters.

Concept of Amplitude Modulation

We can write Eq. (12.33) in more general terms

$$w(t) = A(t) \cos [2\pi f_c t + \theta(t)] \quad (12.37)$$

FIGURE 12.11 Example of low-pass and bandpass linear filters: (a) the linear system, (b) the input signal spectrum, (c) low-pass filter and output spectrum, (d) a bandpass filter and output spectrum.

where both the amplitude and phase are allowed to vary as functions of time. If the message signal $m(t)$ affects only the amplitude $A(t)$, the resulting signal is termed **amplitude modulation**. This generic category includes the well known commercial broadcast amplitude modulation (AM) system, as well as **double sideband (DSB)**, **single sideband (SSB)**, and **vestigial sideband (VSB)** transmission. When the message signal is transmitted by modulating the phase component $\theta(t)$, the result is called *angle modulation*. This includes *frequency modulation (FM)* and *phase modulation (PM)* techniques to be covered in [Section 12.3](#).

Double Sideband-Suppressed Carrier (DSB-SC)

A transmission system directly implementing Eq. (12.35) is shown in [Fig. 12.9\(a\)](#) and is called double-sideband (DSB) modulation. The two lobes observed in the magnitude spectrum in [Fig. 12.9\(c\)](#) are called the *upper sideband (USB)* and *lower sideband (LSB)*. The USB and LSB are mirror images of each other (but with opposite phases) and each contains sufficient information to reconstruct the message signal $m(t)$.

A transmitter requires an *oscillator* to generate the **carrier signal** $c(t) = \cos(2\pi f_c t)$ and a *mixer* to multiply $m(t)$ and $c(t)$.

An alternative modulation system is shown in [Fig. 12.12](#). This technique uses an electronic switch rather than a carrier and a mixer. To see why this works, consider that switching $m(t)$ on and off is the same as multiplying $m(t)$ with a square wave $s(t)$ having frequency f_c ; $x(t) = m(t)s(t)$. Using Fourier series, $s(t)$ can be written as a trigonometric expansion:

$$s(t) = 0.5 + a_1 \cos 2\pi f_0 t + a_3 \cos 2\pi 3 f_0 t + a_5 \cos 2\pi 5 f_0 t + \dots$$

where a_i represent the i th Fourier series coefficient. The switching output is then given by

$$x(t) = 0.5m(t) + a_1m(t) \cos 2\pi f_0 t + a_3m(t) \cos 2\pi 3 f_0 t + a_5m(t) \cos 2\pi 5 f_0 t + \dots$$

Applying the modulation theorem to each term, we see that the expansion represents an infinite sum of DSB signals with passbands centered at $0, \pm f_0, \pm 3 f_0, \pm 5 f_0$, etc. A bandpass filter selects the desired DSB signal at $\pm f_c$ and attenuates the remaining undesired harmonics as shown in [Fig. 12.13](#).

[Figure 12.10](#) shows a simple design for a receiver (or **detector** or *demodulator*). The receiver requires a local oscillator to generate $2 \cos(2\pi f_c t)$, a mixer, and a low-pass filter at the mixer output to remove the

FIGURE 12.12 DSB-SC modulation using a switching circuit.

FIGURE 12.13 The switched signal spectrum, $X(f)$, can be filtered to create a DSB signal: (a) the switched signal spectrum, (b) the bandpass filter response, (c) the DSB output spectrum.

components at $\pm 2f_c$. Receiver operation is described in Table 12.3 in both time- and frequency-domain equations.

Ideally, the receiver oscillator, or *local* oscillator, produces a carrier signal in phase with the transmitter oscillator, that is, $C_{trans}(t) = C_{rcvr}(t) = \cos(2\pi f_c t)$; this is called *coherent detection* or *product detection*. Keeping both oscillators perfectly in phase, however, can be quite difficult. To find out what happens if the transmitter carrier $C_{trans}(t)$ and receiver carrier $C_{rcvr}(t)$ have different phases, we can write $C_{trans}(t) = \cos(2\pi f_c t)$ and $C_{rcvr}(t) = \cos(2\pi f_c t + \varphi)$, where φ represents phase error. An analysis similar to Table 12.3 gives the result $z(t) = m(t) \cos(\varphi)$. This shows that any nonzero phase errors will decrease the receiver output amplitude by an amount $\cos(\varphi)$, the worst case occurring when $\varphi = \pi/2$, which produces zero output.

To minimize phase error effects, DSB systems often employ *phase-locked loops* in the receivers to lock the local oscillator into phase synchrony with the received signal. In another approach, a pilot signal is transmitted simultaneously with the DSB signal but on a different frequency. The pilot is typically a sine wave in phase with $C_{trans}(t)$ and chosen to be harmonically related to f_c . It is used at the receiver to generate an in-phase local oscillator signal.

Double Sideband Plus Carrier (DSB+C)

Figure 12.14 shows a DSB system similar to that in Fig. 12.9 except for the constant DC level added to $m(t)$ prior to the mixer stage. The mixer output signal is, thus

$$x(t) = [A + m(t)] \cos(2\pi f_c t) = A \cos(2\pi f_c t) + m(t) \cos(2\pi f_c t) \tag{12.38}$$

This consists of a simple DSB signal (the second term) plus a carrier of amplitude A (the first term). The carrier concentrates all of its energy at frequency f_c and shows up in the magnitude spectrum as a spike. This is

TABLE 12.3 Demodulation Equations

Description	Time Domain	Frequency Domain
Received signal	$x(t) = m(t) \cos(2\pi f_c t)$	$X(f) = 0.5\{M(f + f_c) + M(f - f_c)\}$
Mixer output	$y(t) = 2x(t) \cos(2\pi f_c t)$ $= 2m(t) \cos(2\pi f_c t) \cos(2\pi f_c t)$	$Y(f) = 2 * 0.5\{X(f + f_c) + X(f - f_c)\}$ $= 0.5M(f + 2f_c) + 0.5M(f + f_c - f_c)$ $+ 0.5M(f - f_c + f_c) + 0.5M(f - 2f_c)$
Some algebra: (use the trig identity: $\cos^2 A = 0.5 + 0.5 \cos(2A)$)	$y(t) = m(t) + m(t) \cos(4\pi f_c t)$	$Y(f) = 0.5M(f + 2f_c) + M(f) + 0.5M(f - 2f_c)$
Low-pass filter output	$z(t) = m(t)$	$Z(f) = M(f)$

FIGURE 12.14 Insertion of carrier producing DSB+C signal showing (a) DSB+C modulator, (b) the message spectrum, (c) the DSB+C spectrum.

the classic AM transmission scheme and is also known as DSB plus carrier (DSB+C). The system described in the last section is often called DSB-suppressed carrier or DSB-SC to differentiate it from DSB+C.

Figure 12.15 illustrates the DSB-SC and DSB+C waveforms. In DSB+C, the message signal is contained in the positive (or negative) *envelope* and the carrier is confined within the envelope boundary. No simple relationship between $m(t)$ and the envelope is evident in DSB-SC waveform.

The amount of signal impressed on the carrier is measured by a *modulation index*, defined as

$$m = -\min[m(t)]/A$$

which is sometimes stated as a percentage. Figure 12.16, for example, shows AM signals with 100, 50, and 120% modulation indices. The 120% modulation case shows that the envelope containing $m(t)$ is distorted, making it impossible to recover $m(t)$ during demodulation. This is called *overmodulation*.

The modulation index is also indicative of the power efficiency of the AM transmission. From Eq. (12.38) it is clear that the term due to the carrier conveys no useful information, whereas the sideband term contains all of the message signal content. Efficiency can be defined as the ratio of energy containing useful information to the total transmitted energy, and can be written in terms of the modulation index:

$$E = m^2 / (2 + m^2) \times 100\%$$

The highest efficiency is at 100% ($m = 1$) modulation and results in only 33% efficiency. Lower modulation values result in even lower efficiencies. By contrast, suppressed-carrier DSB systems are 100% efficient since they waste no energy in a carrier; this is a key disadvantage of AM systems.

The DSB+C signal can be generated without a mixing circuit by using a nonlinear device (NLD) such as a diode, as in Fig. 12.17. For example, suppose the input x and output y of an NLD can be modeled as

$$y = a_1x + a_2x^2$$

FIGURE 12.15 The envelope of the DSB-SC signal (b) cannot be used to reconstruct the message signal (a). In contrast, the message is preserved in the DSB+C envelope (c).

FIGURE 12.16 DSB+C signal with (a) 100%, (b) 50%, (c) 120% modulation index.

Noting that the NLD input is $(\cos 2\pi f_c t + m(t))$, the output is given by

$$y(t) = a_1(\cos(2\pi f_c t) + m(t)) + a_2(\cos(2\pi f_c t) + m(t))^2$$

which can be simplified to give

$y(t) = a_1 m(t) + a_2 m^2(t) + a_2/2$	baseband terms
$+ a_1 \cos(2\pi f_c t) + 2a_2 m(t) \cos(2\pi f_c t)$	passband terms
$+ a_2/2 \cos(4\pi f_c t)$	double frequency term

A bandpass filter centered at f_c will reject all but the passband term at f_c giving the outputs $z(t) = a_1(1 + Cm(t)) \cos(2\pi f_c t)$, with $C = 2a_2/a_1$, which is the desired DSB+C signal. The ease of this method often makes it the preferred choice, especially for high-power applications such as broadcast AM transmitters.

The simplicity of generating DSB+C signals makes it attractive for use in DSB-SC generation. Figure 12.18 shows a *balanced modulator* consisting of two AM modulators whose inputs are opposite in sign and whose outputs are subtracted from each other. By inspection, the balanced modulator output is $y(t) = 2m(t) \cos(2\pi f_c t)$; in other words, the carriers of the two DSB+C modulators have been suppressed to yield a DSB-SC signal. The balanced modulator can be thought of as a multiplier or mixer circuit operating on $m(t)$ and $\cos(2\pi f_c t)$.

FIGURE 12.17 DSB+C modulator using a nonlinear device (NLD).

FIGURE 12.18 Balanced modulator to generate DSB-SC signals.

The DSB+C signal can be demodulated coherently, as described for DSB-SC signals. The real benefit of using DSB+C systems, however, is the ability to receive using *envelope detection* methods.

These receivers do not require coherent local oscillators and are much cheaper and easier to built than coherent receivers. Envelope detection is illustrated by the simple systems shown in Fig. 12.19. In Fig. 12.19(a), a diode clips the incoming signal to isolate the positive envelope of the signal. A resistor-capacitor (RC) stage is used to low-pass filter the diode output to remove most of the carrier component. The resulting signal is capacitively coupled to remove the unwanted DC component and then amplified for output through earphones or a speaker. Figure 12.19(b) shows a more general design called *rectifier detection*. A potential drawback with these techniques occurs if $m(t)$ contains significant low-frequency information: this energy will be attenuated by the capacitive coupling.

FIGURE 12.19 DSB+C detection using (a) envelope detection, (b) rectifier detection.

Single-Sideband

Double-sideband methods transmit redundant information since the baseband signal is duplicated in both the upper and lower sidebands. Consequently, the required bandwidth is twice the needed amount. In contrast, a single-sideband signal contains only the USB or LSB, thus reducing bandwidth by one-half. This is the primary advantage of SSB communication.

The most common technique for generating SSB signals is by applying a sharp bandpass filter to the DSB-SC signal, as shown in Fig. 12.20. This sideband filter passes only the desired sideband and suppresses the other sideband before the signal is amplified and transmitted.

FIGURE 12.20 USB single sideband generation using a sharp BPF to remove the LSB: (a) shows the message spectrum, (b) the DSB-SC spectrum, (c) the sideband filter response, (d) the resulting USB SSB spectrum.

FIGURE 12.21 SSB generation using an intermediate frequency stage followed by a second modulator stage.

To help understand SSB operation, we note that the baseband signal can be expressed as the sum of a negative frequency part $M_-(f)$ and a positive frequency part $M_+(f)$: $M(f) = M_-(f) + M_+(f)$, as shown in Fig. 12.20. Similarly, the passband DSB-SC signal can be written as

$$X(f) = 0.5\{M_-(f + f_c) + M_+(f + f_c) + M_-(f - f_c) + M_+(f - f_c)\}$$

The USB-SSB signal shown in Fig. 12.20(d) is created by suppressing the lower sidebands, $M_+(f + f_c)$ and $M_-(f - f_c)$, giving

$$Y_{\text{USB}}(f) = 0.5\{M_-(f + f_c) + M_+(f - f_c)\}$$

A significant disadvantage of SSB transmission results from the need for sideband filters with extremely sharp rolloff characteristics. Such “brick wall” response is difficult to achieve in the real world, especially at high frequencies used in many communications systems. A typical bandpass filter (BPF) response has a much more gentle rolloff characteristic that could result in attenuating the low-frequency part of the message signal, or in passing part of the unwanted sideband, thus causing signal distortion. Consequently, single-sideband transmission typically suffers from poor low-frequency response.

This problem can be partially addressed by creating a DSB signal at a low intermediate frequency f_{IF} , where $f_{\text{IF}} \ll f_c$, as shown in Fig. 12.21. A sharp sideband filter (which is much easier to implement at low frequency) is used to create a SSB-SC signal at frequency f_{IF} . This signal is modulated up to the desired carrier frequency where there are again two sidebands present. Since these are separated by a distance of $2f_{\text{IF}}$, the undesired sideband can be removed using an easily implemented BPF with gentle rolloff response as in Fig. 12.22.

An alternative method for SSB generation not requiring sideband filters is called the *phase-shifting method*. Mathematical analysis shows that the time-domain representations of the USB and LSB signals can be written as

$$y_{\text{USB}}(t) = m(t) \cos(2\pi f_c t) - m_H(t) \sin(2\pi f_c t)$$

and

$$y_{\text{LSB}}(t) = m(t) \cos(2\pi f_c t) + m_H(t) \sin(2\pi f_c t)$$

where $m_H(t)$ is the *Hilbert transform* of $m(t)$ computed as a -90° phase shift of all frequency components. In both cases the SSB signal is made up of a DSB signal (the left-hand term) combined with a second term that cancels out the undesired sideband. The right-hand term is equal in magnitude to the DSB term, but has one sideband exactly 180°

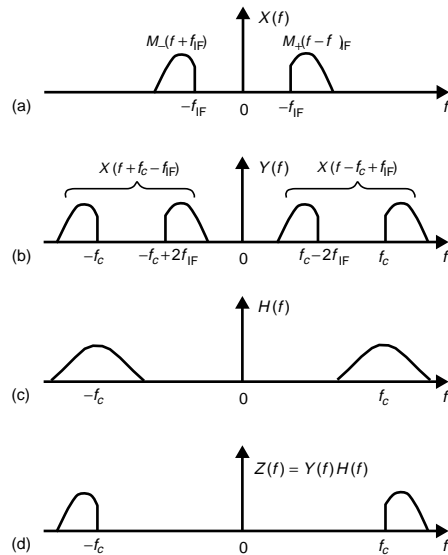

FIGURE 12.22 SSB modulation: (a) intermediate frequency SSB signal $X(f)$, (b) after modulation to passband, (c) gentle rolloff sideband filter response, (d) removal of unwanted sideband to produce the final SSB signal $Z(f)$.

out of phase. Thus, one of the sidebands is canceled when this term is added to or subtracted from the DSB component. Figure 12.23 shows a phase-shifting USB modulator implementing these equations. The primary disadvantage of this approach is the need for precision wide-band phase-shift networks that can be difficult to implement.

Although SSB generation is rather complex, detection can be accomplished using a coherent demodulation system identical to that used for DSB-SC signals (Fig. 12.10(a)). For example, when a USB SSB signal $Y_{USB}(f)$ is mixed with the local oscillator signal $2 \cos(2\pi f_c t)$, the modulation theorem gives $Z(f) = 2 * 0.5 \{ Y_{USB}(f + f_c) + Y_{USB}(f - f_c) \}$, or

$$\begin{aligned} Z(f) &= 0.5 \{ M_-(f + f_c + f_c) + M_+(f - f_c + f_c) + M_-(f + f_c - f_c) + M_+(f - f_c - f_c) \} \\ &= 0.5 M_-(f + 2f_c) + 0.5 M_+(f - 2f_c) + M_+(f) + M_-(f) \\ &= 0.5 M_-(f + 2f_c) + 0.5 M_+(f - 2f_c) + M(f) \end{aligned}$$

The result is the desired baseband signal plus unwanted harmonics at $\pm 2f_c$, which are removed by the receiver LPE.

As with the DSB receiver, achieving coherent detection requires a local oscillator in-phase with the transmitter oscillator. This can be done by transmitting a pilot signal, using a phase-locked loop (PLL) in the receiver circuit, or by simply tuning the local oscillator for the best output signal.

Alternatively, a carrier can be inserted into the SSB signal, which can then be demodulated using simple envelope detection. This SSB+C approach has the advantages of both low bandwidth and low-complexity receiver design, but is inefficient in power use due to the added carrier and usually performs poorly in the presence of noise.

Vestigial Sideband (VSB)

The chief disadvantage of SSB is poor low-frequency response resulting from the difficulty of realizing perfect sideband filters or, for the phase-shifting method, perfect wide-band 90° phase shifters. On the other hand, double sideband modulation methods have good low-frequency response, but suffer from excessive bandwidth. **Vestigial sideband (VSB)** modulation is a compromise between these two techniques, offering excellent low frequency response along with reasonably low bandwidth.

A VSB signal can be generated using a sideband filter similar to that used in SSB transmission. For VSB, however, a controlled portion of the rejected sideband is retained. Figure 12.24 shows a comparison of SSB and VSB sideband filters and the corresponding output signals. Note that low-frequency energy in the demodulated baseband signal is significantly attenuated by the SSB sideband filter. In contrast, no distortion is apparent in the demodulated VSB signal. As shown in the figure, this is because the negative and positive frequency components (labeled A and B) add constructively at baseband

FIGURE 12.23 SSB modulator using the phase-shifting method.

FIGURE 12.24 Comparison of SSB and VSB generation: (a) DSB-SC spectrum, (b) SSB and VSB sideband filter response, (c) spectra of filtered signal, (d) reconstruction of baseband signal.

of the band. Achieving this result requires that the pass-band filter has *vestigial symmetry*. This simply means that the filter's frequency response must have odd symmetry about frequency f_c and amplitude $H_{\max}/2$, where H_{\max} is the maximum filter response. Two examples are shown in Fig. 12.25.

As with DSB-SC and SSB-SC, a carrier can be added to the transmitted VSB signal allowing inexpensive envelope detection to be used in the receiver. This scheme is used in commercial broadcast television and makes it possible to mass produce relatively inexpensive high-quality receivers.

Quadrature Amplitude Modulation (QAM)

Single-sideband transmission makes very efficient use of the spectrum; for example, two SSB signals can be transmitted within the bandwidth normally required for a single DSB signal. However, DSB signals can achieve the same efficiency by means of *quadrature amplitude modulation* (QAM), which permits two DSB signals to be transmitted and received simultaneously using the same carrier frequency. Suppose we want to transmit two message signals, $m_1(t)$ and $m_2(t)$. The QAM DSB modulator shown schematically in Fig. 12.26 can be represented mathematically as

$$x(t) = m_1(t) \cos(2\pi f_c t) + m_2(t) \sin(2\pi f_c t)$$

The detection circuit shown in Fig. 12.27 can be used to receive the QAM signal. To show that the two message signals are fully recovered, we see that the two outputs are

$$\begin{aligned} y_1(t) &= \text{LPF}\{2x_{\text{QAM}}(t) \cos(2\pi f_c t)\} \\ &= \text{LPF}\{2m_1(t) \cos^2(2\pi f_c t) + 2m_2(t) \sin(2\pi f_c t) \cos(2\pi f_c t)\} \\ &= m_1(t) \end{aligned}$$

and, similarly

$$\begin{aligned} y_2(t) &= \text{LPF}\{2x_{\text{QAM}}(t) \sin(2\pi f_c t)\} \\ &= \text{LPF}\{2m_1(t) \cos(2\pi f_c t) \sin(2\pi f_c t) + 2m_2(t) \sin^2(2\pi f_c t)\} \\ &= m_2(t) \end{aligned}$$

where $\text{LPF}\{\cdot\}$ represents the low-pass filtering operation, which eliminates the double frequency terms at $2f_c$. Thus, the two DSB signals coexist separately within the same bandwidth by virtue of the 90° phase shift between them. The signals are said to be in **quadrature**. Demodulation uses two local oscillator signals that are also in quadrature (a sine and a cosine signal). The chief disadvantage of QAM is the need for a coherent local oscillator at the receiver exactly in-phase with the transmitter oscillator signal. Slight errors in phase or frequency can cause both loss of signal and interference between the two signals (called *cochannel interference* or *crosstalk*).

FIGURE 12.25 Two examples of sideband filter responses having vestigial symmetry.

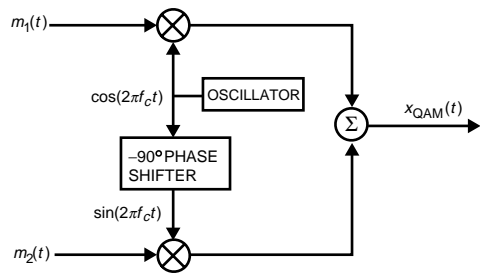

FIGURE 12.26 QAM modulator.

FIGURE 12.27 QAM demodulator.

Noise Effects

Real-world communication channels adversely affect the received signal due to noise and attenuation. A communication receiver designed to operate in the presence of noise is similar to the designs shown but with an additional bandpass filter inserted immediately before the receiver input (see Fig. 12.28). The filter removes noise and interference energy outside the passband.

The *input signal-to-noise ratio* (SNR_i) is defined as the ratio of received signal power to noise power at the band-pass filter output: $SNR_i = S_i / NB$, where S_i is the received signal power, N is the spectral noise power in watts per hertz, and B is the bandwidth of the baseband signal $m(t)$. An *output signal-to-noise ratio* (SNR_o) is also defined and is measured at the receiver output. This latter measure is indicative of the receiver's output quality since it measures the noise content of the output signal. Another useful measure of performance is the ratio of output to input SNR values, i.e., $P = SNR_o / SNR_i$. Values of P equal to 1.0 or greater indicate good performance, whereas smaller values of P imply poorer system performance. Table 12.4 shows P values for each amplitude modulation method. A few points are worth discussing in greater detail. First, these results show that for a fixed level of transmitted power, the suppressed-carrier systems all produce about the same level of noise and signal power at the receiver output. In particular, we note that SSB-SC requires the same transmitter power as DSB-SC, even though DSB-SC uses both sidebands whereas SSB uses only one. The reason for this is that none of the DSB-SC energy is wasted: the receiver utilizes both sidebands to reproduce the output signal. The remaining systems, DSB+C, SSB+C, and VSB+C all require much more transmitter power to achieve the same output SNR as the suppressed carrier methods, assuming envelope detection is being used. Another fact not shown in the table is that envelope detection systems exhibit a *threshold effect*. That is, when the input signal SNR_i drops below a certain value, the output SNR begins to decline at a much more rapid rate. For DSB+C signals, this threshold occurs when received SNR is below approximately 10 dB, which is much lower level than the 30 dB or so needed for good reception. For most practical applications, the threshold effect has a minimal effect on amplitude modulation systems.

Superheterodyne Receivers

Early receiver designs used a tunable local oscillator (LO) to select the desired station and a bandpass filter to reject stations at nearby frequencies, out-of-band noise, and interference. The filter was *ganged* with the local oscillator so that its center frequency tracked the oscillator frequency (Fig. 12.29). However,

FIGURE 12.28 Receiver noise considerations: (a) demodulator using RF bandpass filter showing where SNR_i and SNR_o are measured, (b) received signal spectrum, (c) bandpass output spectrum.

TABLE 12.4 Performance of Modulation Techniques in Noise: Performance Ratio P

Modulation Technique	Suppressed Carrier	Carrier Present
DSB	1	$P_m^2 / [A^2 + P_m^2]$ using envelope detection P_m is average power in $m(t)$
SSB	1	Much less than DSB+C
VSB	≈ 1	Much less than DSB+C
QAM	1	Not applicable

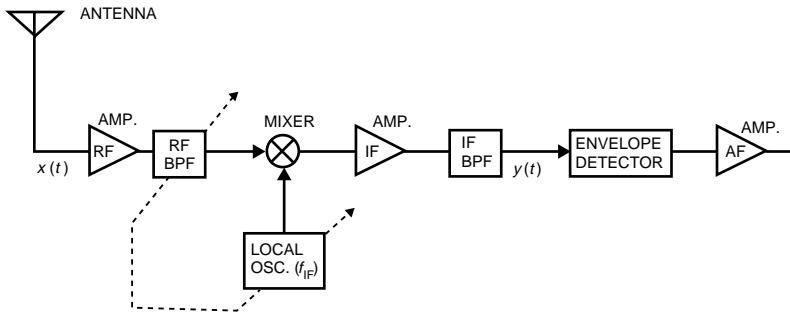

FIGURE 12.29 Superheterodyne AM (DSB+C) receiver.

designing the tunable bandpass filter with sharp cut-off response is difficult. A cheaper and much more effective approach called the **superheterodyne** receiver is shown in Fig. 12.30. The front-end *RF section* of this receiver uses an inexpensive ganged tunable filter with a gentle rolloff response to eliminate most noise and interference. It is standard practice for the LO to be tuned to 455 kHz above the desired station (hence, the name super heterodyning) for voice reception. (Automobile receiver designs often use an IF of 262.5 kHz.) This translates the desired station to a fixed *intermediate frequency* (IF) of 455 kHz. The IF section contains a sharp-rolloff bandpass filter; this is practical because of the fixed center frequency f_{IF} and because f_{IF} is relatively low. The IF BPF filter provides the needed *selectivity* to reject adjacent stations that were not removed by the RF bandpass filter. An envelope detector follows the IF stage to produce the audio output signal.

Although an RF bandpass filter with sharp rolloff is not required in this technique, there is a limit on how broad its response can be. Consider a station located at a frequency $2f_i = 910$ kHz above the desired frequency. If this station is not removed by the RF section, it will be moved to the IF frequency on top of the desired station and cause unacceptable interference, as shown in Fig. 12.29. The

FIGURE 12.30 Superheterodyne receiver operation: (a) the desired signal and undesired image spectra (shows as a dotted line), (b) and (c) the two components of the mixer output, (d) the IF bandpass output given by $Y(f) = \text{BPF}(X(f + f_c + f_{IF}) + X(f - f_c - f_{IF}))$. Notice that the image signal must be removed by the RF stage or it will interfere with the desired signal in the IF stage.

TABLE 12.5 Comparison of Amplitude Modulation Techniques

Modulation Scheme	Advantages	Disadvantages	Comments
DSB-SC	Good power efficiency. Good low-frequency response.	More difficult to generate than DSB+C. Detection requires coherent local oscillator, pilot, or phase-locked loop (PLL). Poor spectrum efficiency.	
DSB+C (AM)	Easier to generate than DSB-SC, especially at high-power levels. Inexpensive receivers using envelope detection.	Poor power efficiency. Poor Spectrum efficiency. Poor low-frequency response. Exhibits threshold effect in noise.	Used in commercial AM.
SSB-SC	Excellent spectrum efficiency.	Complex transmitter design. Complex receiver design (same as DSB-SC). Poor low-frequency response.	Used in military communication systems, and to multiplex multiple phone calls onto long-haul microwave links.
SSB+C	Good spectrum efficiency. Low receiver complexity.	Poor power efficiency. Complex transmitters. Poor low-frequency response. Poor noise performance.	
VSB-SC	Good spectrum efficiency. Excellent low-frequency response. Transmitter easier to build than for SSB.	Complex receivers (same as DSB-SC).	
VSB+C	Good spectrum efficiency. Good low-frequency response. Inexpensive receivers using envelope detection.	Poor power efficiency. Poor performance in noise.	Used in commercial TV
QAM	Good low-frequency response. Good spectrum efficiency.	Complex receivers. Sensitive to frequency and phase errors.	Two SSB signals may be preferable.

unwanted signal is called an *image* and must be removed at the receiver’s front end for acceptable receiver performance.

Superheterodyning is also used in TV, FM, and other receiver designs where the use of an intermediate frequency permits effective IF filtering strategies. The relative merits of the modulation schemes discussed in this Section are summarized in Table 12.5.

Defining Terms

Amplitude modulation: Linear modulation schemes that imprint the message signal onto the amplitude component of a carrier. In contrast, *angle modulation* methods operate by modulating the phase of the carrier. Amplitude modulation schemes include DSB-SC, DSB+C, SSB-SC, SSB+C, VSB-C, VSB+C, and QAM, as well as numerous digital communications methods.

Carrier: A sinusoidal signal of frequency f_c (the *carrier frequency*). It is mixed with a *message* signal to produce a modulated transmitter output signal centered at f_c . In *suppressed carrier* systems, no carrier component is present in the spectrum, whereas in added-carrier systems, such as broadcast AM, the carrier contains a significant amount of power

Detection: The process of converting the transmitted passband signal back into a baseband message signal. *Envelope detection* operates by extracting the envelope of the received signal to reconstruct the message signal, whereas *product* or *coherent detection* uses a local oscillator in phase with the transmitter oscillator along with a mixing circuit. Also known as *demodulation*.

Double sideband (DSB): An amplitude modulation transmission scheme where both sidebands are transmitted.

- Message signal:** The input audio signal or program that is desired to be transmitted. This can be speech, music, or a digital signal.
- Modulation:** The process of multiplying, or *mixing*, a message signal with a carrier signal. This causes the message spectrum to be translated out to the positive and negative carrier frequencies. In other words, it transforms a *baseband* signal (the message) into a *passband* signal (the transmitter output).
- Quadrature:** The condition when two signals having the same carrier frequency exhibit a 90° phase difference.
- Sideband:** A component of an amplitude modulated waveform. A modulated signal has a spectrum that is symmetric about frequency f_c , such that the upper-half is a mirror image of the lower-half. These are termed the *upper sideband* and *lower sideband*; each sideband contains an entire copy of the program information.
- Single sideband (SSB):** A transmission scheme using only one sideband to convey information.
- Superheterodyne:** A receiver design that mixes the input signal with a carrier tuned to f_{IF} Hz above the desired station. This translates it to an *intermediate frequency* f_{IF} , where efficient fixed frequency filters can be utilized. *Image stations* located at $f_c + 2f_{IF}$ must be removed by the RF section to prevent interference.
- Vestigial sideband (VSB):** A transmission scheme using one sideband plus a carefully controlled portion of the other sideband. This system provides excellent fidelity at all frequencies and are still spectrally efficient.

12.3 Frequency Modulation

Ken Seymour

12.3.1 Introduction

Frequency modulation (FM) is one of the most widely used modes of modulation. From applications in commercial broadcasting, television audio, cordless phones, to cellular and mobile communications, FM is indeed both a reliable and important form of modulation. The brainchild of Edwin H. Armstrong, FM was first demonstrated in December 1933 (Lewis, 1991, p. 256) as a solution to eliminate the static and noise problems that plagued AM communications.

In amplitude modulation (AM), interference, such as static, lightning, and manmade noise, cause the amplitude of an RF signal to vary widely. This is because these noises are predominately amplitude modulated signals in composition. The noise is added and superimposed on the transmitted AM signal carrying the desired intelligence. This increases the overall amplitude of the signal as shown in Fig. 12.31. These added variations are then demodulated at the receiver, and the noise is passed onto the audio section, where they are reproduced as clicks, pops, and various other objectionable noises. The problems associated with amplitude modulation are overcome in frequency modulation. FM receivers are designed to reduce the amplitude variations of an incoming signal. This is done without effecting the frequency modulated waveform that contains the desired intelligence.

12.3.2 The Modulated FM Carrier

The composition of the unmodulated AM carrier and FM carrier are identical. That is, the RF carrier is a sinusoidal waveform operating at a specific period or frequency. As the frequency is increased, the period of the waveform decreases as more cycles are completed per second. When an AM carrier is modulated, the amplitude of the carrier is effected. When the FM carrier is modulated, the frequency of the carrier varies by an amount that is proportional to amplitude of the modulating waveform; this occurs at a rate that is determined by the modulation frequency.

To better understand how the modulating signal affects a carrier that is being frequency modulated, it is best to use illustrative examples. Figure 12.32 graphically illustrates what happens when a carrier is frequency modulated. Figure 12.32(a) shows one period of an audio signal that will be used to frequency modulate a carrier. The AC signal is positive for 180° and swings negative for the remaining 180° to complete one 360° cycle.

Figure 12.32(b) illustrates the effect of how the audio signal (a) affects the carrier. At time $t = <0$, we see the RF carrier operating at a specific frequency. This is sometimes referred to as *center* or *resting* frequency. At time $t = 0$, the modulating signal (a) is applied to the RF carrier. As the amplitude of signal

FIGURE 12.31 Typical AM signal with induced noise.

FIGURE 12.32 Frequency modulating an RF carrier.

(a) swings positive, the frequency of the RF carrier also begins to change. At time $t = 1$, the frequency of the modulated RF carrier has increased proportionally, resulting in a greater number of cycles occurring in a given interval of time. At time $t = 2$, the amplitude of the modulating signal (a) reaches its maximum. At the same time, the RF carrier has increased to its maximum frequency. At time $t = 3$, the modulating waveform (a) begins to decrease in amplitude and the carrier frequency (b) also begins to decrease. At time $t = 4$, the modulating frequency returns to zero and the carrier frequency returns to the resting frequency.

For the last 180° portion of the modulation cycle, the amplitude of the modulating signal goes negative. At time $t = 6$, the modulating signal (a) has decreased to its maximum negative value and the frequency of the modulated carrier (b) also reaches its minimum. In fact, it has decreased to a frequency below that of the unmodulated carrier. At time $t = 7$, the modulation amplitude begins its return journey back to zero. Then, at $t = 8$, the carrier frequency returns to the resting frequency. Figure 12.32(c) shows waveforms (a) and (b) superimposed on each other to better illustrate the waveform relationships.

When an FM signal is received, it is the amount of frequency shift that is produced in the modulated waveform that determines the audio intensity or volume that is heard on the speaker of the receiver. To summarize, the frequency modulated carrier observes these following characteristics:

- The higher the modulating amplitude, the greater is the amount of frequency shift away from the resting frequency. This form of FM is also referred to as **direct FM**.
- As the amplitude of the modulating source increases, the frequency of the carrier increases.
- As the amplitude of the modulating source increases, the frequency of the carrier increases.
- As the amplitude of the modulating source decreases, the frequency of the carrier decreases.
- The amplitude of the FM modulated carrier remains constant as the amplitude of the modulating source varies.

Table 12.6 illustrates how a modulating signal affects an FM and AM modulated waveform. For example, as the amplitude of the modulating signal increases, the overall frequency swing on FM increases. With AM, the amplitude of the carrier increases.

TABLE 12.6 Summary of Modulation Effects on AM vs. FM

	Modulating Amplitude	
	Increases	Decreases
FM	Frequency swing increases	Frequency swing decreases
AM	Carrier level increases	Carrier level decreases

12.3.3 Frequency Deviation

As we saw in the previous section, the amplitude of the modulating signal plays an important part in the overall characteristic of the carrier frequency. The peak difference between the modulated carrier and the frequency of the carrier is known as the **frequency deviation** (Code, 1993). The peak difference between the minimum and maximum frequency values is known as the *frequency (or carrier) swing* (Code, 1993). This can be defined as

$$\Delta f = f_{pc} - f_c$$

where

Δf = frequency deviation

f_{pc} = peak frequency of the modulated carrier (minimum or maximum)

f_c = frequency of the carrier (unmodulated)

Example 12.1

A commercial FM broadcast station operates on a frequency of 97.1 MHz. On a modulation peak, the frequency increases to 97.13 MHz. Determine the (1) frequency deviation and (2) the frequency swing. The solution is as follows:

1. Applying the deviation equation: $f_{pc} = 97.13$ and $f_c = 97.10$. Substituting terms: $\Delta f = 97.13 - 97.10$. This results in a frequency deviation of +30 kHz.
2. The frequency swing would be the peak difference of the minimum and maximum frequency deviation or $(2)(\Delta f) = (2)(30\text{ kHz}) = 60$ kHz.

It is important to remember, that there are two cases of frequency deviation. In the preceding example, the frequency was increased as a result of the modulating signal. Likewise in FM, when a carrier is modulated, the carrier frequency also goes negative. Therefore, the swing is defined as $(2)(\Delta f)$. The FCC places limits on the amount of deviation that a frequency can swing. With commercial FM stations, the frequency deviation is ± 75 kHz or 150 kHz total frequency swing. Depending on the FM communication service, the FCC imposes different frequency deviation requirements.

12.3.4 Percent of Modulation in FM

In amplitude modulation, 100% modulation is defined as the point where the amplitude of the RF carrier rises to twice the normal amplitude at its maximum, and drops to zero at its minimum. Anything greater than 100% modulation, in AM, causes distortion to the modulated wave.

With FM, it is the amount of frequency deviation that determines the degree of modulation. The frequency deviation that corresponds to 100% modulation is an arbitrary value defined by the FCC or other appropriate licensing authority as related to the FM service in use. For commercial FM broadcasting, 100% modulation is reached when the carrier frequency deviation reaches 75 kHz. In television, 100% modulation is set at a frequency deviation of ± 25 kHz by the FCC.

If the carrier is modulated above 100%, distortion and spurious sidebands are not produced as in AM. To avoid interference between adjacent stations, the FCC has set the channel spacing for commercial FM at 200 kHz. This gives ample guard band for stations operating at 100% modulation, which accounts for a ± 75 kHz frequency deviation or a total frequency swing of 150 kHz.

12.3.5 Modulation Index

In FM, the **modulation index** is often used more frequently than **percentage of modulation**. Modulation index is defined as the ratio of the frequency deviation to the frequency of the modulating signal (National, 1985, p. 3.3–65). The term has no units and is expressed as a decimal. For a constant frequency deviation, the modulation index drops as the frequency of the modulating signal increases. During the transmission of an FM signal, the modulation index varies as the modulation frequency varies. As we shall see later, this relationship is important for determining the bandwidth requirements of an FM signal

$$mf = \Delta f / f_s$$

where

mf = modulation index

Δf = frequency deviation

f_s = frequency of the modulating signal

Example 12.2

A 97.1-MHz carrier frequency is modulated by a 10-kHz audio signal source. This produces a frequency deviation of ± 40 kHz. Determine the modulation index. The solution is

$$\begin{aligned} mf &= 40/10 \\ &= 4 \end{aligned}$$

12.3.6 Bandwidth and Sidebands Produced by FM

Frequency modulation differs from amplitude modulation in that the modulated wave consists of the carrier frequency and numerous sideband components that are generated for each modulating frequency. Recall that AM consists of a carrier and a upper and lower sideband. The bandwidth of an AM signal is determined by the highest frequency of the modulating signal. For example, a carrier is modulated by a audio signal which contains frequencies up to 4000 Hz. The AM bandwidth would therefore be: $(2)(4000) = 8000$ Hz.

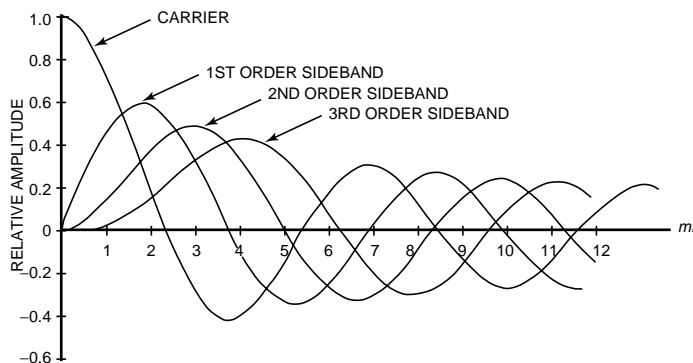

FIGURE 12.33 Relationship of carrier and sideband amplitudes to modulation index mf (Bessel functions).

TABLE 12.7 Bessel Functions: Values of Carrier and Sideband Amplitudes

Modul. Index, mf	Carrier, A f_c	Amplitude of Sidebands											
		f_1	f_2	f_3	f_4	f_5	f_6	f_7	f_8	f_9	f_{10}	f_{11}	f_{12}

5.00	-0.18	-0.33	0.05	0.36	0.39	0.26	0.13	0.05	0.02	0.01	—		
6.00	0.15	-0.28	-0.24	0.11	0.36	0.36	0.25	0.13	0.06	0.02	0.01	—	
7.00	0.30	0.00	-0.30	-0.17	0.16	0.35	0.34	0.23	0.13	0.06	0.02	0.01	—
8.00	0.17	0.23	-0.11	-0.29	-0.10	0.19	0.34	0.32	0.22	0.13	0.06	0.03	0.01

In FM, the amplitude of modulating signal is the primary factor in determining the amount of bandwidth. This was illustrated in Fig. 12.32 where the difference in the amplitude of the audio modulating signal produced a difference frequency change, or deviation. This deviation could shift the frequency of the carrier by 75 kHz or more, depending on the amplitude of the modulating signal.

The sidebands generated in FM are spaced on both sides of the carrier at frequency intervals equal to the modulating frequency and its multiples. To better understand all of the components of FM sidebands, we will analyze a FM modulated carrier using *Bessel functions* and *spectral diagrams*. Figure 12.33 illustrates the mathematical relationship of the Bessel function, the FM waveform theoretically contains an infinite number of side frequencies on both sides of the carrier. The side frequencies are spaced at intervals that correspond to the modulating frequency, which can be represented as

$$f_c +/ -fs +/ -2fs +/ -3fs +/ -4fs \dots \infty$$

Notice that the Bessel functions illustrated in Fig. 12.33 resemble damped sine waves. The Bessel curves enable us to understand the component of the FM sidebands. The number of sidebands depends totally on the modulation index (mf). Table 12.7 is a tabular representation of the Bessel curve illustrated in Fig. 12.33. It shows the amplitudes of the sidebands for audio modulating harmonics where they decrease to a value close to the amplitude of the unmodulated carrier. The following example illustrates how to determine FM side bands using the Bessel tables.

Example 12.3

Analyze and draw a spectral diagram of: (1) an AM carrier modulated 100% by a 12.5-kHz audio source and (2) an FM carrier modulated by an 12.5-kHz audio source. Assume a frequency deviation of ± 75 kHz. The solution is as follows:

FIGURE 12.34 Example 12.3(1) AM spectral diagram.

1. The spectral diagram is easy to illustrate as shown in Fig. 12.34. Notice that there are two significant sidebands, upper and lower. The total bandwidth is 25 kHz.
2. Next, we need to determine the modulation index. This is defined as

$$mf = \Delta f / fs$$

Substituting terms, $mf = 75,000 / 12,500 = 6$.

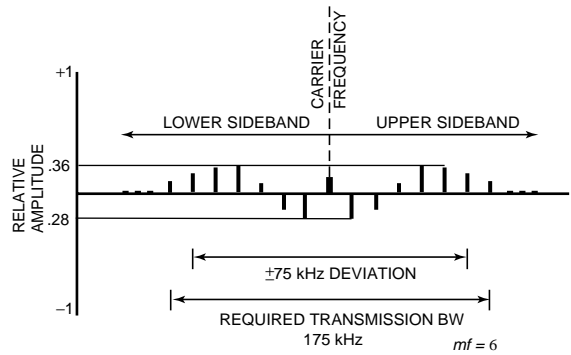

FIGURE 12.35 Example 12.3(2) FM spectral diagram.

Referring to Table 12.7, with a modulation index of 6, we see that there are 10 harmonics plus the carrier. The amplitudes of the sideband harmonics are taken from the table and are illustrated in the spectral diagram shown in Fig. 12.35.

There also may be upper and lower sideband frequencies that extend beyond the allowable deviation in an FM signal, in this example beyond the ± 75 -kHz limit. The total number of sideband frequencies that are produced is different for each different value of modulation index. The greater the modulation index is, the greater the number of sideband components.

12.3.7 Narrow-Band versus Wide-Band FM

The *narrow-band* (NBFM) and *wide-band* (WBFM) terms refer to the amount of frequency deviation (Δf) that is present for a specific transmitted FM signal. This directly correlates to the amount of spectral bandwidth that the transmission occupies. NBFM is typically used for communications services that occupy less spectral bandwidth. This service is used for two-way voice communications, amateurs, and by governmental agencies. The FCC limits the frequency deviation to less than ± 15 kHz for these services. WBFM on the other hand, typically uses a frequency deviation greater than ± 15 kHz.

12.3.8 Phase Modulation

So far, we have seen how FM can be produced by shifting the frequency of the carrier above and below a resting frequency as determined by the amplitude of the modulation signal. Frequency modulation can also be produced by shifting the phase of the carrier relative to an arbitrary reference point. This is known as **phase modulation (PM)**. When a carrier is phase modulated, the input signal is designed to alter the phase of the carrier. When the amplitude of the modulating signal swings positive, the greater is the phase shift of the carrier results as it advances or leads in phase. This results in a greater frequency swing. As the amplitude of the modulating signal goes negative, the carrier will lag in phase. This method of frequency modulation is often referred to as *indirect FM*.

12.3.9 FM Transmission Principles

The basic transmission principles used today for frequency modulation falls into two categories. One type, *direct FM*, is the modulation process where the frequency of the transmitter oscillator varies in accordance with the amplitude of the modulating signal. The other type, *indirect FM*, obtains a frequency modulated waveform by phase modulating the carrier.

The method of modulating an FM transmitter vs modulating an AM transmitter differs significantly. With AM, modulation generally takes place in a higher level stage of the transmitter at the final RF power amplifier stages. With FM, modulation takes place in a much lower stage of the transmitter, usually the

FIGURE 12.36 Simplified reactance modulator.

master oscillator itself. The lower level modulation of FM is generally performed before any frequency multiplication occurs to minimize increasing phase shift and frequency deviation.

To frequency modulate a carrier directly, an active device is used in conjunction with the input signal to produce a variable reactance (capacitive or inductive) across its output. If the variable reactance is placed across a tuned tank circuit, the effective capacitance or inductance of the tank will change. This, in turn, will change the resonant frequency of the circuit. This methodology was primarily used to generate FM in the early days of FM broadcast service. Today, *voltage controlled oscillators* are commonly used, and circuits built around variactor diodes are found.

Direct FM Modulators

Over the years, many types of circuits have been used to produce direct FM. In each case, a reactance device is used to shunt capacitive or inductive reactance across an oscillator. The value of capacitive or inductive reactance is made to vary as the amplitude of the modulating signal varies. Since the reactive load is placed across an oscillator tuned circuit, the frequency of the oscillator will therefore shift by a predetermined amount, thereby creating an FM signal. A Typical example of a reactance modulator is shown in Fig. 12.36. The circuit uses a field effect transistor (FET) where the modulating signal is applies to the modulator through C_1 . The actual components that effect the overall reactance consist of R_1 and C_2 . Typically, the value of C_2 is small as this is the input capacitance to the FET. This may only be a few picofarads. However, this capacitance will generally be much larger by a significant amount due to the *Miller effect*. Capacitor C_3 has no significant effect on the reactance of the modulator. It is strictly a blocking capacitor, which keeps DC from effecting the gate bias of the FET.

To further understand the performance of the reactance modulator, an equivalent circuit of Fig. 12.36 is represented in Fig. 12.37. The FET is represented as a current source $g_m V_g$, with the internal drain resistance r_d . The impedances Z_1 and Z_2 are a combination of resistance and capacitive reactance, which are designed to provide a 90° , phase shift. This will be evident as the analysis of the reactance FET proceeds.

FIGURE 12.37 Equivalent circuit of the reactance modulator.

In an FET, the internal drain resistance r_d is typically very high. Therefore, we can neglect it in our analysis. Looking into the model, the impedance between points A and B is designated Z_{AB} and the voltage across A and B is V_{AB} . We are interested in Z_{AB} , because the value of this impedance will indicate the value of added reactance to the master frequency oscillator. Looking at Z_{AB} , it appears that the output impedance is the series combination of Z_1 and Z_2 (neglecting r_d). This is not exactly true, because one of the components (Z_1 or Z_2) is reactive and is a variable factor that depends on the drain current flowing through the FET and the operating frequency. Since the drain current depends upon the transconductance g_m of the FET, the impedance injected also depends upon the g_m . This is shown as follows.

The impedance is defined as

$$Z_{AB} = V_{AB}/I_{AB} \quad (12.39)$$

By definition, we also know that the circuit current is (r_d is neglected)

$$I_{AB} = g_m V_g \quad (12.40)$$

Substituting terms, Eq. (12.40) into Eq. (12.39)

$$Z_{AB} = V_{AB}/g_m V_g \quad (12.41)$$

Referring to Fig. 12.37, V_g is derived using the voltage divider principle

$$V_g = V_{AB}(Z_2/(Z_1 + Z_2)) \quad (12.42)$$

Substituting terms, Eq. (12.42) into Eq. (12.41)

$$Z_{AB} = \frac{V_{AB}}{g_m V_{AB}(Z_2/(Z_1 + Z_2))} \quad (12.43)$$

$$Z_{AB} = ((Z_1 + Z_2)/Z_2)/(g_m) \quad (12.44)$$

$$Z_{AB} = (1/g_m)((Z_1 + Z_2)/Z_2) \quad (12.45)$$

$$Z_{AB} = (1/g_m)(1 + Z_1/Z_2) \quad (12.46)$$

$$Z_{AB} = (1/g_m) + (1/g_m)(Z_1/Z_2) \quad (12.47)$$

Equation (12.47) represents the impedance seen when looking into the reactive FET circuit, at points A and B. Since the unit for transconductance is given in mho, the term $1/g_m$ will therefore be resistive in ohms. The equation then states that the impedance across points A and B consists of a *resistance in series with a reactance*. In this case, the reactance Z_1 is R_1 (purely resistive) and Z_2 is C_2 . As Eq. (12.47) also illustrates, the transconductance value of the FET is a key term and plays an important role in determining the overall added reactance. Since the transconductance of the FET is dependent on the gate voltage,² it is apparent that when a modulating signal is applied to C_1 , the g_m of the FET will vary as the audio voltage varies. This, in turn, varies the reactance applied to the master oscillator tank circuit.

Using vector diagrams, we can also analyze the phase relationship of the reactance modulator. Referring back to Fig. 12.36 and Fig. 12.37, the resistance of R_1 is typically very high compared to the capacitive reactance of C_2 . The $R_1 C_2$ circuit is then resistive. Since this circuit is resistive, the current I_{AB} that flows through it is in phase with the voltage V_{AB} . Voltage V_{AB} is also across $R_1 C_2$ (or $Z_1 Z_2$ in Fig. 12.37). This is true

² $g_m = \left(\frac{\partial I_d}{\partial V_{gs}} \right) \Big|_{V_{DS}}$

because current and voltage tends to be in phase in a resistive network. However, voltage V_{C_2} , which is across C_2 , is out of phase with I_{AB} . This is because the voltage that is across a capacitor lags behind its current by 90° . This is illustrated in the vector diagram of Fig. 12.38.

By design, we also see that V_{C_2} is also the voltage applied to the gate of the FET, V_g . Since the drain current variations in the FET are a direct result of variations in gate voltage, the drain current I_d is in phase with the gate voltage V_g . This is shown in Fig. 12.38 with I_d next to V_{C_2} . As previously shown, we can put V_{AB} next to I_{AB} since they are in phase. The vector diagram shows that I_d , the drain current of the FET, is 90° behind V_{AB} . Notice that V_{AB} is also across the oscillator tuned circuit. Thus, we now have a circuit where the drain current lags the voltage across the oscillator tank by 90° . AC analysis has proven that the current through an inductance lags behind the voltage across the inductor by 90° . The voltage, V_{AB} therefore behaves the same as inductance. Again, as this inductance varies, so to will the total impedance of the oscillator tank circuit, which in turn results in FM.

FIGURE 12.38 Vector diagram of reactance modulator producing FM. Note: $V_g = V_{C_2}$

FIGURE 12.39 Voltage controlled direct-FM modulator.

**Voltage Controlled Oscillator (VCO)
Direct-FM Modulators**

Another one of the more common direct-FM modulation techniques in use today uses an analog voltage controlled oscillator (VCO) in a phase locked loop (PLL) arrangement. This is shown in Fig. 12.39. In this configuration, a VCO produces a desired carrier frequency, which is in turn modulated by applying the audio signal to the VCO input via a variator diode. A variator diode is generally used to vary the capacitance of an circuit. Therefore, oscillator tank the variator behaves as a variable capacitor whose capacitance varies as the input voltage across it varies. As the input capacitance of the VCO is changed by the variator, the output frequency of the VCO is shifted, which produces a direct-FM modulated signal.

Indirect-FM Modulators

Thus far we have only discussed the direct method of producing FM and just briefly mentioned the indirect method. Historically, the indirect method, or phase modulation, was originally developed by Armstrong in the early 1930s and results published in 1936 (Armstrong, 1936). His was the first method to provide a practical system for producing an FM signal as many of the early FM transmitters used his method of modulation.

Simply stated, in phase modulation, the phase of the carrier signal deviates away from its resting position as modulation is applied. This is accomplished by passing a fixed RF carrier through a time-delay network, which makes the carrier change in phase. If the time-delay network is made to vary in accordance with the amplitude of an input signal, the delay network will change the phase of the carrier in accordance with the applied audio. The resultant output from the time-delay network will then be a phase modulated signal. The center frequency of the carrier is typically produced by using a stable oscillator circuit, such as a crystal, that is resonate at some frequency lower than that of the final desired output frequency. For this reason, there are typically many stages of frequency multiplication that are used following the phase modulator.

FIGURE 12.40 Phase modulator principle and vector diagram.

The basic principle of phase modulation can easily be illustrated in the following example. Figure 12.40 shows a simple phase modulated circuit consisting of a crystal oscillator (providing a center frequency) and a series RC network. The output of this circuit is taken across the variable resistor R whose resistance varies according to the applied audio signal. The vector diagram illustrates the impedance of the RC circuit for three different values of resistance. With the resistance variable, the resultant phase of the oscillator frequency will be variable and the modulated output voltage V_{AB} varies in phase. Resistance R_2 represents the circuit resistance with no modulation present. Resistance R_1 represents the circuit resistance when the amplitude of the modulating signal swings positive, and resistance R_3 represents the circuit resistance as the amplitude of the modulating signal swings negative. The component $-X_C$ is the capacitive reactance of C .

When the modulating signal is applied to the circuit, it alternately causes the resistance to decrease R_1 and to increase R_3 . The phase of the current through the RC circuit varies as long as the phase angle of the impedance varies. As we have shown, as R varies, the resultant phase angle θ varies from θ_1 to θ_3 . The output voltage V_{AB} also follows the phase change in the current and impedance, and the result is a phase modulated signal.

In a real application, the variable resistance R in the example can be replaced with an active device such as an FET. For an FET to function properly, it must act like a variable resistance. This happens in the FET, for example, as the dynamic drain resistance is placed in parallel with the load resistor R_4 as illustrated in Fig. 12.41. The capacitive reactance of C_2 determines the amount of phase shift that occurs with the overall variable resistance of the FET. This example is one of the most simple types of phase modulators.

FIGURE 12.41 Simple FET phase modulator.

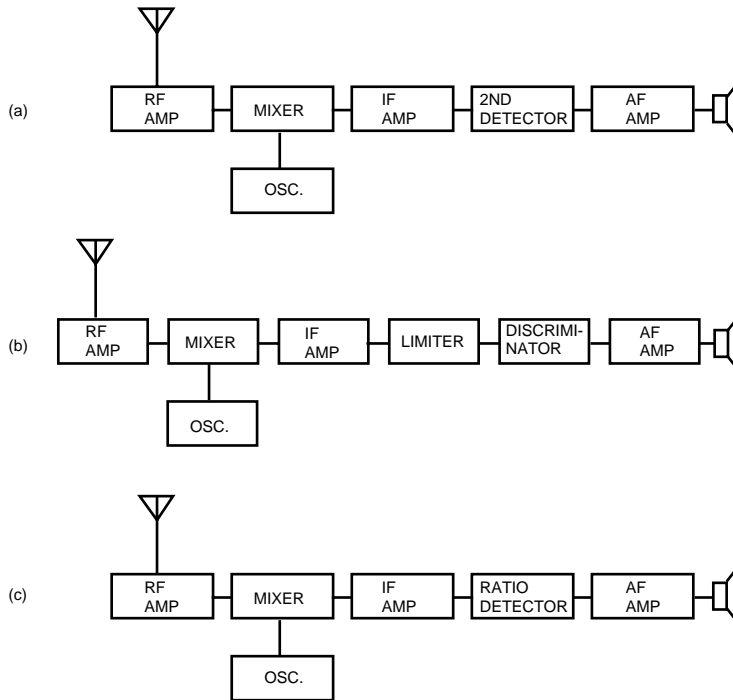

FIGURE 12.42 Functional block diagrams of typical AM and FM receivers: (a) AM receiver, (b) FM receiver using a Foster–Seeley discriminator and limiter, (c) FM receiver using a ratio detector.

12.3.10 FM Reception Principles

Regardless of frequency, the receivers for FM communications are similar to those for AM. The functional layout for both types of receivers are similar in that a superheterodyne circuit is used. Both receiver types contain RF amplification, mixing, a local oscillator, IF amplification, detection, and amplification. There are, however, a few important design differences. Retrieval of the intelligence of an FM signal requires a slightly different detector circuit and some form of signal limiting. FM requires a detector that is designed to discriminate between a positive and negative frequency deviation. In addition, any variation in the amplitude of the carrier represents undesirable noise. This is removed by a **limiter** stage before demodulation occurs. A functional comparison between an AM receiver and two types of FM receivers is illustrated in Fig. 12.42.

As is apparent in the illustration, the major circuit differences between the AM and FM receiver consist of the **limiter**, **discriminator**, and **ratio-detector** stages. There are other minor differences, but these will not be discussed in detail since they are not unique to FM receiver design. These include differences in the receiver tuning and RF amplification stages and final amplification. The tuning range and RF amplification stages are different only in the design of the received frequency.

Limiters

The limiter stage of an FM receiver is basically an IF amplifier that is designed to saturate and clip off undesired AM and noise components from a signal prior to FM detection. With proper design, the output of the limiter will have a constant amplitude as the output signal is applied to the following detector stages. [Figure 12.43](#) shows a limiter circuit designed with an FET.

When the noise levels on the positive peaks exceed a specified design level, limiting action is produced by driving the FET out of the active region into saturation. To help ensure saturation, the supply voltage is

FIGURE 12.43 Typical FET limiter.

reduced to a level that still enables a small input signal to drive the FET into saturation. Lowering the drain voltage also reduces the overall gain of the limiter. For this reason, the majority of FM receivers typically have more IF stages than their AM counterparts. As the input signal swings negative, the extreme negative peaks are removed by driving the FET into cutoff. Notice the flattening of the upper portion of the output waveform shown in Fig. 12.44. This is caused by driving the FET into saturation. As the figure shows, an input signal is the voltage applied to the gate of the FET and the output current is the current through the drain.

Operation of the limiter is very straightforward. The input signal to the FET is coupled to the gate through C_2 via the tuned input tank circuit. Gate leak bias is used, which stabilizes the output signal and improves the limiter response time. The time constant of the bias network ($C_2 R_1$) is typically in the range of 1–15 μs . For the limiter to operate properly, the input signal must have sufficient amplitude to drive the gate positive. As the gate signal goes positive, the gate current flows and charges C_2 to a value almost equal to the peak amplitude of the input signal. This causes the drain current to flow, and the FET acts like a normal RF amplifier. If the signal is strong, the FET will be driven into saturation and the drain current reaches its peak level. As the signal drops, the capacitor discharges through R_1 and produces a negative voltage, which reduces the drain current. The drain voltage is reduced to a level below that of other stages in the receiver by R_2 and zener D_1 .

FIGURE 12.44 Dynamic transfer characteristics of an FM limiter (I_d vs. V_g).

FIGURE 12.45 A simplified Foster-Seeley discriminator.

FM Detectors

The two most popular classic detector circuits for FM are the Foster-Seeley discriminator and the ratio detector. Other types of FM detection used today include phase-locked loop circuitry. The basic function of the discriminator is to convert the frequency swings in the FM signal back into amplitude variations for further audio processing. The discriminator is, therefore, susceptible to both amplitude and frequency variations. For this reason, the Foster-Seeley detector is always preceded by a limiter stage. The ratio detector on the other hand, acts like a limiter, and so there is no need for the use of a separate limiter stage.

Discriminators and Ratio Detectors

Perhaps the most frequently used FM detector is the Foster-Seeley discriminator. The design is simple and its operational characteristics are less critical than other types. A typical Foster-Seeley discriminator circuit is illustrated in Fig. 12.45. The tuned circuit L_1C_1 is tuned to the center resting frequency of the IF stage. With no modulation present, the voltage developed across the center tap of L_1 (L_2 and L_3) is out of phase with the voltage across L_1 . When this occurs, the current through D_1 and D_2 are equal, and the voltage developed across R_1 and R_2 will be equal and opposite in polarity. The output voltage from the circuit will, therefore, be zero.

When modulation occurs, the frequency varies above and below the carrier resting frequency. The tuned tank circuit, L_1C_1 , becomes inductive or capacitive, depending on which way the signal shifts from the resting frequency. As the tuned circuit turns reactive, the phase angle changes between voltage and current. The resulting current flow is different flowing through D_1 from that flowing through D_2 . As a rectified voltage is developed across R_1 and R_2 , the difference between these two voltages will no longer be zero. This is, then, the reproduced output voltage that is produced as the modulation frequency varies.

The ratio detector is another commonly used FM detector. Notice that there are some close similarities between this and the Foster-Seeley discriminator. The major difference, as illustrated in Fig. 12.46, is that

FIGURE 12.46 A simplified ratio detector.

one of the diodes is reversed, there is a capacitor (C_4) across the other two capacitors, and the output voltage is taken between the junction of R_1 and R_2 and the taped junction of capacitors C_2 and C_3 at terminals A and B.

The basic operation of the ratio detector is similar to that of the Foster–Seeley discriminator. The input is coupled to the tuned circuit consisting of L_1 and C_1 . At the resting frequency, diodes D_1 and D_2 conduct equally. As the frequency of the input signal swings above and below the resting frequency, either diode D_1 or D_2 will conduct more heavily. Since one of the diodes is reversed, current also flows through the entire circuit path of D_2 through the time constant of $C_4 R_1 R_2$, through D_1 and back into the top of L_1 . After several RF cycles, C_4 charges to the peak value of the voltage across L_2 . Variations in amplitude of the incoming signal have little effect on the charging of C_4 , and the voltage across the capacitor remains fairly constant (due to a long time constant). This results in a practically constant voltage across $R_1 + R_2$ and $C_2 + C_3$. This, then, results in a constant output voltage. Since the output voltage was not effected by amplitude variations, the need for limiting is reduced.

With no modulation applied to the circuit, both diodes conduct equally and C_4 charges up. This results in a constant output voltage of zero at terminals AB. When the frequency changes as a result of modulation on the carrier, diode D_1 or D_2 will conduct more heavily. This makes the voltage ratio charged on C_2 and C_3 unequal, which gives the name ratio detector. The voltage at terminals AB is, therefore, the output signal of the demodulated FM signal.

Defining Terms

Direct FM: Frequency modulation produced by changing the frequency of a carrier as a result of applying a modulating signal.

Discriminator: A detector used in an FM receiver to demodulate the FM signal.

Frequency deviation: The peak difference between modulated wave and the carrier frequency.

Frequency modulation: A system of modulation where the instantaneous radio frequency varies in proportion to the instantaneous amplitude of the modulating signal and the instantaneous radio frequency is independent of the frequency of the modulating signal.

Limiting: A stage of an FM receive that is designed to saturate and clip off undesired AM and noise components from a signal prior to FM detection.

Modulation index: The ratio of the frequency deviation to the frequency of the modulating signal.

Percentage modulation: The ratio of the actual frequency deviation to the frequency deviation defined as 100% modulation, expressed in percentage. For FM broadcast stations, a frequency deviation of ± 75 kHz is defined as 100% modulation.

Phase modulation: Frequency modulation produced by shifting the phase of the carrier relative to an arbitrary reference point. This method of frequency modulation is often referred to as indirect FM.

Ratio detector: A detector used in an FM receiver to demodulate the FM signal.

12.4 Pulse Modulation

Rodger E. Ziemer

12.4.1 Introduction

Pulse modulation is important for many applications including telephone call transmission, compact disks for music, airline passenger communication systems, and digital control systems, among others. The reasons for the use of pulse modulation even in cases where the information is analog in form are many. For example, in telephone call transmission, the overloading of cable trays by copper wire in the late 1960s in part led to the development of the T carrier system, which employs **time-division multiplexing** (TDM). Thus, several separate telephone calls can be carried by the same transmission line. Airline passenger communication systems were similarly developed based on TDM to save in weight of the transmission lines required to address several functions at each passenger's seat, including the attendant calling function and several channels of entertainment media. In the late 1980s compact disks and the associated recording and playback technology were developed to provide high-fidelity music with little danger of degradation due to damage of the medium (i.e., the compact disk). Control systems in aircraft, particularly high-performance military aircraft, rely on the servomechanism commands and responses being conveyed by transmission lines to the various control points with these commands being represented in digital format. Spacecraft similarly utilize baseband digital pulse modulation to distribute commands and acquire data from the various sensors and systems on board.

12.4.2 The Sampling Theorem

The basis for pulse modulation applications is representing analog signals as properly spaced samples. The theoretical justification for this is Shannon's **sampling theorem** (Ziemer and Tranter, 2002), which may be stated succinctly as follows:

Lowpass Uniform Sampling Theorem: A signal with no frequency components above W Hz can be uniquely represented by uniformly spaced samples taken at intervals spaced no greater than $1/2W$ sec apart.

Various forms of this sampling theorem are often used, including a bandpass uniform sampling version and quadrature sampling for bandpass signals.

The proof of the low-pass uniform sampling theorem (hereafter referred to simply as the sampling theorem) is based on the following Fourier transform theorems (Ziemer and Tranter, 2002):

Multiplication Theorem: Given two signals, $x(t)$ and $y(t)$, with Fourier transforms $X(f)$ and $Y(f)$, where f is the frequency in Hz, the Fourier transform of their product is the convolution of their Fourier transforms:

$$x(t)y(t) \leftrightarrow X(f) * Y(f) = \int_{-\infty}^{\infty} X(\lambda)Y(f - \lambda) d\lambda \quad (12.48)$$

where the double-headed arrow denotes a Fourier transform pair.

Fourier Transform of the Ideal Sampling Waveform: The Fourier transform of a doubly infinite train of uniformly spaced impulses is itself a doubly-infinite train of uniformly spaced impulses, or

$$\sum_{n=-\infty}^{\infty} \delta(t - nT_s) \leftrightarrow f_s \sum_{n=-\infty}^{\infty} \delta(f - nf_s), \quad f_s = \frac{1}{T_s} \quad (12.49)$$

Consider a low-pass signal $x(t)$ with Fourier transform $X(f)$ bandlimited so that none of its spectral components lie above W Hz. Ideal impulse sampling of $x(t)$ gives

$$x_\delta(t) = x(t) \sum_{n=-\infty}^{\infty} \delta(t - nT_s) = \sum_{n=-\infty}^{\infty} x(nT_s)\delta(t - nT_s) \tag{12.50}$$

Use of Eq. (12.48) and Eq. (12.49) to obtain the Fourier transform of $x_\delta(t)$ gives

$$X_\delta(f) = X(f) * f_s \sum_{n=-\infty}^{\infty} \delta(f - nf_s) = f_s \sum_{n=-\infty}^{\infty} X(f - nf_s) \tag{12.51}$$

where $\delta(f - nf_s) * X(f) = X(f - nf_s)$ has been used and the asterisk denotes convolution. Equation (12.51) is sketched in Fig. 12.47(b) for an assumed $X(f)$ shown in Fig. 12.47(a). It is seen that if the sampling frequency f_s is greater than $2W$, then the baseband portion of the sampled signal spectrum can be separated from the translated spectra centered around nonzero multiples of f_s , and the result is an undistorted version of the original signal spectrum $X(f)$. If the signal to be sampled, $x(t)$, is bandlimited but $f_s < 2W$, the translates of $X(f)$ centered at $f = \pm f_s$ will overlap with the component centered at $f = 0$. The resulting error is referred to as **aliasing**. If the signal to be sampled, $x(t)$, is not strictly bandlimited, then the sampling frequency cannot be chosen large enough to prevent overlap of the translates making up the sampled signal spectrum. Perfect distortionless recovery is impossible and

FIGURE 12.47 Spectra for sampling of a strictly bandlimited signal: (a) spectrum of signal to be sampled, (b) sampled signal spectrum for $f_s > 2W$, (c) sampled signal spectrum for $f_s = 2W$ (d) sampled signal spectrum for $f_s < 2W$. (All maximum spectral levels scaled to unity.)

FIGURE 12.48 Spectra for sampling a signal with nonbandlimited spectrum: (a) spectrum of signal to be sampled, (b) sampled signal spectrum for very large f_s (minimal aliasing), (c) sampled signal spectrum for f_s moderately large (some aliasing), (d) sampled signal spectrum for f_s too small (significant aliasing).

distortion results due to the filtering operation used for signal recovery, as does aliasing. The aliasing due to a nonbandlimited signal spectrum is illustrated in Fig. 12.48.

Clearly, sampling by means of impulses is impossible from a practical standpoint. A more practical waveform is the train of square pulses illustrated in Fig. 12.49(a). The sampling operation can be done in two ways with such a pulse train. The first, referred to as **natural sampling**, consists of multiplication of the signal to be sampled, $x(t)$ as shown in Fig. 12.49(b), by a pulse train, such as that shown in Fig. 12.49(a), as illustrated in Fig. 12.49(c). The second, called **flat top sampling**, is accomplished by sampling the waveform $x(t)$ at the instants nT_s and holding that value for the duration of the pulses making up the pulse train as illustrated in Fig. 12.49(d). For the former, the difference in the spectrum from ideal sampling is provided by the transform pair

$$p_\tau(t) = \begin{cases} 1, & 0 \leq t \leq \tau \\ 0, & \text{otherwise} \end{cases} \leftrightarrow \tau \text{sinc}(\tau f) e^{-j\pi\tau f} \tag{12.52}$$

where τ is the pulse width and $\text{sinc}(u) = \sin(\pi u)/(\pi u)$. The ideal sampling waveform (Eq. (12.49)) can be converted to the natural sampling waveform, shown in Fig. 12.49(a), by convolving $p_\tau(t)$ with Eq. (12.49). The Fourier transform of the natural sampled waveform is, therefore, the product of the transform in Eq. (12.49) and the transform in Eq. (12.52), and the overall effect on the spectrum is to multiply each term of Eq. (12.51) by $\tau \text{sinc}(n\tau f_s) e^{-jn\pi\tau f_s}$. Thus, the spectrum is not distorted, but each term in the spectrum is multiplied by the weighting function $\tau \text{sinc}(n\tau f_s)$. On the other hand, flat top sampling can

FIGURE 12.49 illustration of practical sampling of a signal and pulse modulation techniques: (a) pulse sampling function, (b) signal to be sampled, (c) natural sampling, (d) flat top sampling or pulse-amplitude modulation, (e) pulse-width modulation, (f) pulse-position modulation.

be represented as

$$\begin{aligned}
 x_{\text{flat}}(t) &= \sum_{n=-\infty}^{\infty} x(nT_s) p_{\tau}(t - nT_s) \\
 &= p_{\tau}(t) * \sum_{n=-\infty}^{\infty} x(nT_s) \delta(t - nT_s) \\
 &= p_{\tau}(t) * x_{\delta}(t)
 \end{aligned}
 \tag{12.53}$$

In analogy to Eq. (12.48), the Fourier transform of the convolution of two signals is the product of their respective Fourier transforms. Thus, the spectrum of Eq. (12.53) is

$$X_{\text{flat}}(f) = \tau f_s \text{sinc}(\tau f) \sum_{n=-\infty}^{\infty} X(f - nf_s)
 \tag{12.54}$$

It is seen that in the case of flat top sampling, the sampled signal spectrum is a distorted version of $X(f)$ because of the factor $\tau f_s \text{sinc}(\tau f)$. If $\tau \ll T_s$, this distortion is small and the original signal can be recovered almost exactly. If not, the factor $\tau f_s \text{sinc}(\tau f)$ must be compensated for by an inverse filter having a frequency response of the form $[\text{sinc}(\tau f)]^{-1}$ before recovery of $x(t)$ takes place.

Some additional remarks with respect to Fig. 12.49 relate to other ways of representing a sampled signal as shown in Fig. 12.49(e) Fig. 12.49(f). In Fig. 12.49(e), the samples are represented as pulses the width of which

vary in proportion to the sample values, while in Fig. 12.49(f) they are represented in terms of pulse delays from the points of initial sampling in proportion to the sample values. The former is called pulse width modulation (PWM) and the latter is called pulse position modulation (PPM). Pulse width modulation is often used to control the speed of DC motors used in various variable-speed drive applications.

12.4.3 Analog-to-Digital Conversion

Although analog samples can be transmitted from the source to destination, and historically this was done, it is now more usual to digitize the samples of an analog signal and transmit them in digital form. To do so, the additional steps of quantization and encoding are required first. This process is called **analog-to-digital (A/D) conversion**. This quantization is usually accomplished in terms of a binary code for each sample. Two methods for such representation will be discussed here. First, the base two representation for any set of positive integers is of the form

$$x(nT_s) = b_{m-1} \times 2^{m-1} + \dots + b_2 \times 2^2 + b_1 \times 2^1 + b_0 \times 2^0 \tag{12.55}$$

where m is the number of bits b_i in the representation, also called the **wordlength**. As an example, consider the sample values of Fig. 12.49, which are given in Table 12.8, where the sample values are rounded to the nearest integer value. A disadvantage of the binary code is that several bits can change for a one-unit change in the sample value. For example, the **binary representation** of 15_{10} is 01111 whereas the binary representation of 16_{10} is 10000. An alternative representation, where a one decimal-unit change in sample magnitude results in a single digit change in the binary representation, is the **Gray code**, which can be found from the binary code by means of the following algorithm:

$$\begin{aligned} g_0 &= b_0 \\ g_i &= b_i \oplus b_{i-1}, \quad i > 0 \end{aligned} \tag{12.56}$$

The Gray code representation of the samples shown in Fig. 12.47 is given in the fourth column of Table 12.8.
